Figure 70-10. Anatomy of the superior and inferior hypogastric plexuses and subsidiary plexuses. See text for details.

At its lower border the plexus divides into right and left hypogastric nerves, often called the *middle hypogastric plexuses*, which descend to contribute to the inferior hypogastric (pelvic) plexuses. The superior hypogastric plexus gives off branches to the ureteric and testicular (or ovarian) plexuses and to those on the common iliac arteries. As emphasized in Chapter 66, the plexus contains sensory fibers that transmit nociceptive impulses from the body of the uterus and cervix that pass cephalad through the lower lumbar splanchnic nerves. In addition to the sympathetic fibers, which descend to form the superior hypogastric plexus, it contains parasympathetic fibers derived from the pelvic splanchnic nerves, which ascend from the inferior hypogastric plexus. Usually, these parasympathetic fibers pass cephalad to the left of the superior hypogastric plexus, across the sigmoid vessels and branches of the left colic vessels, to become distributed partly along the branches of the inferior mesenteric artery. Parasympathetic fibers also arise directly from the pelvic splanchnic nerves and pass as independent retroperitoneal nerves to supply a short portion of the distal left part of the transverse colon, left colic (splenic) flexure, descending colon, and sigmoid colon (Fig. 70-11). The parasympathetic supply to the distal colon is largely through these direct branches of the pelvic splanchnic nerves and not through the hypogastric and inferior mesenteric plexuses (6,7,8,9 and 10).

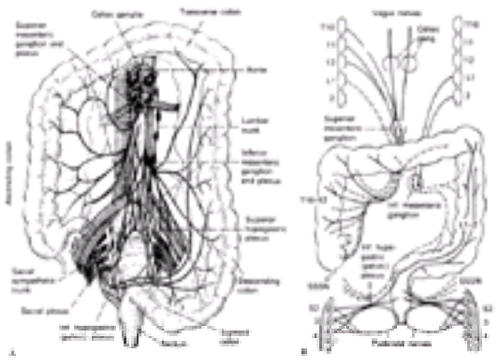

Figure 70-11. Innervation of the large intestine. **A:** Anatomic relationship of the nerves supplying various parts of the colon and rectum. **B:** Schematic depiction of the innervation of the vagus, sympathetic, and sensory fibers. The right and transverse colon up to the splenic flexure is supplied by the preganglionic parasympathetic fibers of the vagus nerves, which synapse in the wall of the viscus with short postganglionic fibers. The sympathetic supply is through preganglionic fibers derived from T-10 to T-12 (*solid lines*), which synapse with postganglionic fibers (*dashed lines*) in the superior mesenteric ganglion. This portion of the gut also receives postganglionic fibers from the L-1 ganglion. This part of the colon is supplied by sensory (nociceptive) fibers that accompany the sympathetic nerves and enter the spinal cord at T-10 and L-1 inclusively. The descending colon receives preganglionic sympathetic fibers from L-1 to L-2, which synapse in the inferior mesenteric ganglion with the postganglionic fibers that supply the viscus as far as the sigmoid colon. Postganglionic sympathetic fibers to the rest of the colon from the rectosigmoid junction and rectum are derived from sacral sympathetic splanchnic nerves (SSSN), which are derived from the sacral portion of the sympathetic chain. The descending colon is supplied with parasympathetic preganglionic fibers, which originate in spinal cord segments S-2, S-3, and S-4 and pass through the inferior hypogastric (pelvic plexus) and from there to the colon and rectum, where they end in the wall of the viscus and synapse with short postganglionic fibers. The sensory fibers that conduct nociceptive impulses accompany the parasympathetic nerves and enter the spinal cord in the S-2, S-3, and S-4 segments. Sensory supply to the rectum is through the pudendal nerve. (See Chapter 65 for a more detailed description of the origin and course of these nerve pathways.) (Modified from Netter FH. Innervation of the small intestine. In: *The CIBA collection of medical illustrations.* Vol 3, Digestive system, lower digestive tract. Summit, NJ: CIBA Pharmaceutical, 1979:76–79; and Bonica JJ. *The management of pain*. Philadelphia: Lea & Febiger, 1953:395–397.)

Hypogastric Nerves (Middle Hypogastric Plexus)

The superior hypogastric plexus divides below into right and left hypogastric *nerves*, each of which runs down in the extraperitoneal connective tissue into the pelvis medial to each internal iliac artery and its branches to contribute to the formation of the inferior hypogastric (pelvic) plexus. Each nerve can be single or can form an elongated narrow plexus that consists of two or three longitudinal nerves connected by anastomosing filaments. Each nerve or plexus can be joined near its beginning by the lowest lumbar splanchnic nerve. From each hypogastric nerve branches pass to the testicular or ovarian plexus, ureteric plexus, the plexus on the internal iliac artery, and sigmoid colon.

Inferior Hypogastric (Pelvic) Plexus

Each of the two inferior hypogastric plexuses is formed by fibers contributed by (a) the hypogastric nerves, which contain mostly sympathetic efferent and afferent fibers; (b) postganglionic sympathetic fibers from the sacral splanchnic nerves; and (c) parasympathetic fibers derived from the pelvic splanchnic nerves (nervi erigentes) that have their cell bodies in the S-2, S-3, and S- 4 segments of the spinal cord (Fig. 70-12; see Fig. 70-10).

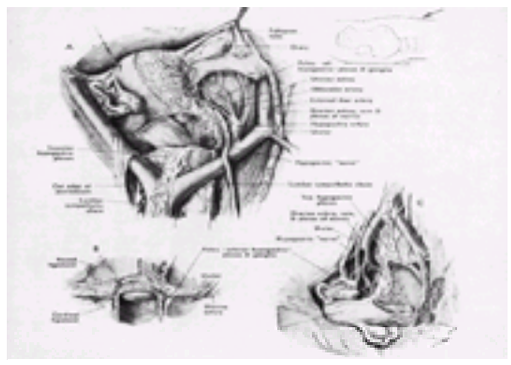

Figure 70-12. Nerve supply of uterus. **A:** Superior view of pelvis (inset: *arrow*). The peritoneum has been removed to show the distribution of the lower portion of the aortic plexus, superior hypogastric plexus, and pelvic (inferior hypogastric) plexus. Note the relation of the nerve supply to the uterus. **B:** Coronal section of cervix and vagina showing distribution of the pelvic plexus in the paracervical region. Note the relation of the plexus to the uterine artery and ureter. **C:** Sagittal section of pelvis with view of its right lateral wall showing course and relation of some of the nerves to the uterus. (From Bonica JJ, McDonald JS. *Principles and practice of obstetric analgesia and anesthesia*, 2nd ed. Baltimore: Williams & Wilkins, 1995:520.)

Each of the two hypogastric plexuses lies in the extraperitoneal connective tissue. In the man each plexus is situated on the rectum, seminal vesicle, prostate, and posterior part of the urinary bladder. In the woman each plexus is placed on the side of the rectum, uterine cervix, vaginal fornix, and posterior part of the urinary bladder and extends into the base of the broad ligaments of the uterus. Lateral to the plexus are the internal iliac vessels and their branches and tributaries and the levator ani, coccygeus, and obturator internus muscles. Behind are the sacral and coccygeal plexuses and above are the superior vesical and obliterated umbilical arteries. The plexus contains numerous small ganglia.

The cell bodies of preganglionic efferent sympathetic fibers originate in the lower three thoracic and upper two lumbar segments of the spinal cord. Some of these lie in the ganglia in the lumbar and sacral parts of the paravertebral sympathetic trunk, while others synapse with cell bodies of postganglionic sympathetic neurons in the lower part of the aortic plexus and in the inferior and superior hypogastric plexuses. The sympathetic afferents follow the course of the sympathetic pathways in a reverse direction, with their cell bodies located in the posterior ganglia and their proximal axons passing into the spinal cord to contact cells of the superficial dorsal horn.

The preganglionic parasympathetic fibers originate in the S-2, S-3, and S-4 sacral segments of the spinal cord, reach the plexus in the pelvic splanchnic nerves, and synapse with cell bodies of postganglionic parasympathetic neurons located in the plexus or, more frequently, in the walls of the viscera supplied by the inferior hypogastric plexus. From the inferior hypogastric plexus many branches are distributed to the pelvic (and some abdominal) viscera directly by accompanying the branches of the internal iliac artery (10). As mentioned previously, parasympathetic fibers pass upward into the superior hypogastric plexus (or as separate filaments accompanying it) to reach the inferior mesenteric plexus through the medium of the aortic plexus and supply the splenic flexure and descending and sigmoid parts of the colon. Afferent fibers associated with parasympathetic fibers convey sensations for reflex action but also convey nociceptive impulses.

Subsidiary Plexuses

The subsidiaries of the inferior hypogastric plexus are the middle rectal plexus, vesical plexus, prostatic plexus, and uterovaginal plexus.

Middle Rectal Plexus. The middle rectal plexus arises from the upper part of the inferior hypogastric plexus, with the fibers passing to the rectum either directly or along the middle rectal artery. The plexus communicates above with branches of the superior rectal plexus (derived from the inferior mesenteric plexus) and extends inferiorly as far as the internal anal sphincter. The nerve supply of the rectum and anal canal is derived from the superior rectal plexus, middle rectal plexus, and inferior rectal (hemorrhoidal) nerves, which are branches of the pudendal nerves. Parasympathetic preganglionic fibers from the superior and middle sacral plexuses

synapse with postganglionic neurons in the myenteric plexus, which is well developed in the wall of the sigmoid colon, rectum, and anal canal (see Fig. 70-11).

The sympathetic afferents and efferents pass through the plexus uninterrupted. The efferent sympathetic fibers in the rectal plexus are concerned with inhibition of expulsive musculature and contraction of the sphincter. Afferent fibers that transmit nociceptive impulses pass along both the sympathetic and parasympathetic nerves, but the parasympathetic afferent and efferent fibers are more active in controlling the defecation process. The inferior rectal nerves supply motor fibers to the external anal sphincter and sensory somatic fibers to the lower (ectodermal) part of the anal canal.

Vesical Plexus. The vesical plexus arises from the anterior part of the inferior hypogastric plexus. It is composed of many nerves that accompany the vesical arteries to the bladder. Branches from the plexus pass to the seminal vesicles and vas deferens. Many small collections of nerve cells are present among the nerve fibers in the muscular wall of the bladder. The sympathetic preganglionic efferent fibers in the plexus have their cell bodies in the lower two thoracic and the upper two lumbar segments of the spinal cord. Their axons pass through the inferior thoracic splanchnic nerve and the upper two lumbar splanchnic nerves, eventually ending to synapse with cell bodies of postganglionic fibers that are scattered in the superior and inferior hypogastric plexuses and in the wall of the bladder (Fig. 70-13).

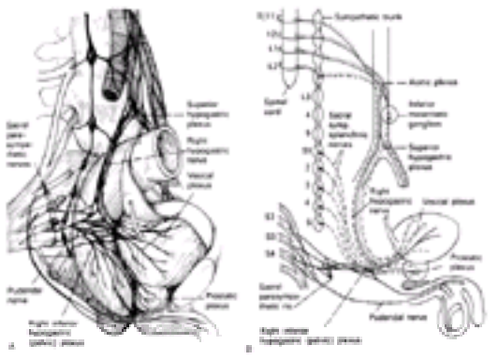

Figure 70-13. **A:** Nerve supply of the urinary bladder and prostate showing the relationship of the various nerve structures to the large intestine and their distribution in the bladder and prostate. **B:** Schematic illustration showing the segmental nerve supply to the bladder, penis, and scrotum. (*Solid lines*, preganglionic fibers; *dashed lines*, postganglionic fibers; *dotted lines*, sensory fibers.)

The parasympathetic preganglionic efferent fibers arise from the S-2, S-3, and S-4 segments of the spinal cord and synapse with cells near to or in the walls of the bladder. These nerves convey motor fibers to the muscular coats of the bladder and inhibitory fibers to the sphincter. The efferent sympathetic nerves convey motor fibers to the sphincter and inhibitory fibers to the muscular coats. Some authorities maintain that the sympathetic fibers are mainly vasomotor in function, and that filling and emptying of the bladder are normally controlled exclusively by the parasympathetic nerves (1) (a further description of the nerve supply to the bladder is given in Chapter 73).

Prostatic Plexus. The prostatic plexus arises from the lower part of the inferior hypogastric plexus and is composed of relatively large nerves that enter the base and sides of the prostate and contain collections of nerve cells. The nerves are distributed to the prostate, seminal vesicles, prostatic urethra, ejaculatory ducts, corpora cavernosa, corpus spongiosum, membranous and penile parts of the urethra, and bulbourethral glands. The nerves that supply the corpora cavernosa form two sets, the lesser and greater cavernous nerves of the penis. These nerves arise from the anterior part of the prostatic plexus and join with branches from the pudendal nerve to pass anteriorly below the pubic arch. Filaments of the lesser cavernous nerves pierce the fibrous covering of the penis near its root and supply the erectile tissue of the corpus spongiosum and penile urethra. The greater cavernous nerves run anteriorly on the dorsum of the penis, communicate with the dorsal nerve of the penis, and are distributed to the erectile tissue. Some of the filaments pass to the erectile tissue of the corpus spongiosum. The sympathetic nerves that supply the male genital organs produce vasoconstriction, while parasympathetic nerves produce vasodilation (6).

The seminal vesicles are supplied by nerves derived from the vesical plexus, prostatic plexus, and lower part of the inferior hypogastric plexus. Nerve filaments pass from these structures to the ejaculatory ducts and vas deferens. It is generally believed that constriction of the seminal vesicles and seminal ejaculation are brought about by the sympathetic nerves (6,8). These nerves also produce inhibition of the bladder musculature and contraction of the sphincter during ejaculation, thus preventing reflux of the seminal fluid into the bladder (a more detailed description of the nerve supply to the prostate is given in Chapter 73).

Uterovaginal Plexus. The uterovaginal plexus arises from the inferior hypogastric plexus, predominantly from that part of the plexus lying in the base of the broad ligament (see Fig. 70-12). Some nerves pass caudad from the plexus down with the vaginal arteries, others pass directly to the cervix uteri, and still others pass cephalad with or near the uterine arteries in the broad ligament. The nerves passing to the cervix form a plexus in which small paracervical ganglia are found. One ganglion is sometimes large and is called the *uterine cervical ganglion*. The uterine nerves pass cephalad, with the uterine artery supplying branches to the body of the uterus. In the upper part of the broad ligament they supply branches to the uterine tube and communicate with the tubal nerves from the inferior hypogastric plexus and with the nerves of the ovarian plexus. Branches of the uterine nerves ramify in the myometrium and endometrium by accompanying blood vessels.

The efferent preganglionic sympathetic fibers supplying the uterus are derived from cell bodies located in the T-10, T-11, T-12 (and sometimes T-5 to T-9), and L-1 (and sometimes L-2) segments of the cord, while the axons pass peripherally and synapse in various ganglia (8). The preganglionic parasympathetic fibers arise from the S-2, S-3, and S-4 sacral segments of the cord and are relayed in the paracervical ganglia. The sympathetic nerves can produce uterine contractions and vasoconstriction and the parasympathetic nerves can produce uterine inhibition and vasodilation. The results of the activity of these two systems are complicated, however, by the pronounced hormonal control of uterine function (4,8).

The vaginal plexus arises from the lower part of the pelvic and uterovaginal plexuses and follows the vaginal arteries and their branches to be distributed to the walls of the vagina, erectile tissue of the vestibular bulbs and clitoris (cavernous nerves of the clitoris), urethra, and greater vestibular glands. These nerves contain numerous parasympathetic fibers, which have a vasodilatory effect on the erectile tissue. (A more detailed description and illustrations of the nerve supply to the pelvic viscera are contained in Chapter 71 and Chapter 73.)

Neurology of the Perineum

The perineum derives its nerve supply primarily from various branches of the pudendal nerve. It also receives some fibers from the anterior labial or scrotal branches of the ilioinguinal, genital branch of the genitofemoral, perforating cutaneous, and muscular branches of the S-2, S-3, and S-4, and anococcygeal nerves. The perineal branches of the ilioinguinal and genitofemoral nerves are discussed in Chapter 75 in connection with the nerve supply to the lower limbs. The anatomy of the pudendal plexus and then the anatomy and distribution of the pudendal nerve are presented first.

Pudendal Plexus

The pudendal plexus is formed by the union of the anterior divisions of the S-2 and S-3 nerves and of the entire S-4 nerve (Fig. 70-14). It lies in the lower part of the posterior wall of the pelvic cavity and the anterior surface of the piriformis muscle, where it divides into the pudendal nerve, perforating cutaneous nerve, and visceral and muscular branches. The visceral branches make up the pelvic nerve, which leaves the pudendal plexus and proceeds anteriorly to join the pelvic plexuses to contribute parasympathetic fibers.

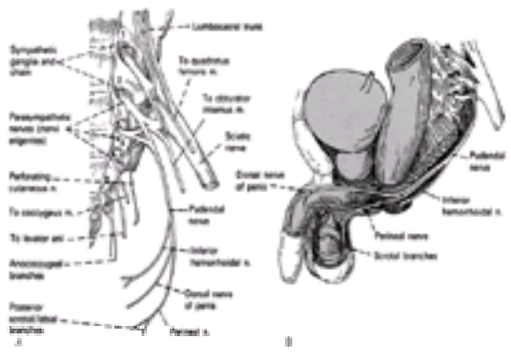

Figure 70-14. **A:** Anatomy of the pudendal plexus and its branches. See text for details. **B:** Parasagittal view depicting the course and branches of the left pudendal nerve in the male subject. (**A** modified from Bonica JJ. *Principles and practice of obstetric analgesia and anesthesia*. Vol 1. Philadelphia: Davis, 1967:490; **B** modified from Netter FH. *The CIBA collection of medical illustrations*. Vol 2, Reproductive system. Summit, NJ: CIBA Pharmaceuticals, 1979:19.)

The muscular branches of the pudendal plexus are provided mainly by the S-4 nerve to supply the levator ani, coccygeus, and sphincter ani externus muscles. The nerves to the levator ani and coccygeus muscles enter these structures on their pelvic surface. The nerve to the sphincter ani externus, generally known as the *perineal branch* of the S-4 nerve, pierces the sacrotuberous ligament and coccygeus muscle and enters the ischiorectal fossa to supply muscular branches to the sphincter and cutaneous branches to the skin between the anus and coccyx.

The perforating cutaneous branches of the S-2 and S-3 nerves descend in front of the coccygeus muscle and pass through it, perforate the sacrotuberous ligament, and turn around at the inferior border of the gluteus maximus to supply the skin of the buttocks. Some of the fibers, however, run anteriorly to the perineum. The anococcygeal nerve, derived from the S-4 and S-5 and coccygeal nerves, also penetrates the sacrotuberous ligaments to supply the skin behind the anus in the anococcygeal area.

Anatomy of the Pudendal Nerve

The anatomy of the pudendal nerve is shown in Figure 70-15 and Figure 70-16. The somatic fibers are derived from the anterior primary division of the S-2, S-3, and S-4 nerves, while the sympathetic fibers are contributed by the sacral portion of the sympathetic chain. All these fibers combine to form a single trunk approximately 1 cm proximal (posterior) to the ischial spine. The formed nerve is directed anteriorly and inferiorly and leaves the pelvic cavity by passing through the greater sciatic foramen inferior to the piriformis muscle, between it and the coccygeal muscle. It then reenters the pelvic cavity through the lesser sciatic foramen and proceeds anteriorly through Alcock's (pudendal) canal.

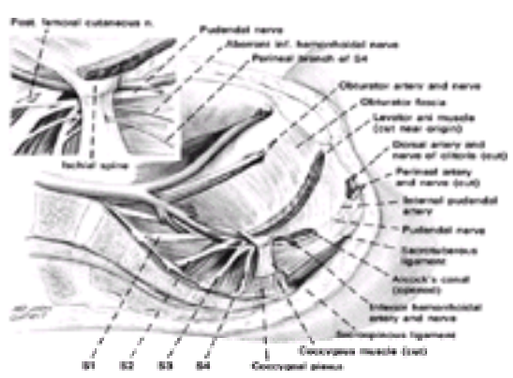

Figure 70-15. Sagittal section of the perineum showing the origin and course of the pudendal nerve. The pudendal nerve passes posterior to the junction of the ischial spine and the sacrospinous ligament and then reenters the pelvis to pass through Alcock's canal. Inset: Aberrant hemorrhoidal nerve (which occurs in 50% of individuals) and perineal branch of S-4. See text for details. (Modified from Bonica JJ. *Principles and practice of obstetric analgesia and anesthesia*. Vol 1 Philadelphia: FA Davis, 1967:490.)

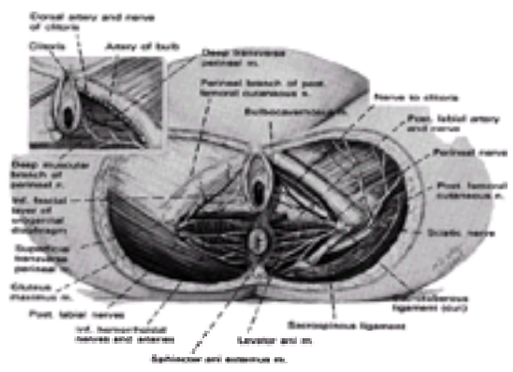

Figure 70-16. Nerve supply of the perineum of a gravida showing the principal branches of the pudendal nerve as well as the posterior femoral cutaneous nerve and other nerves that supply sensory fibers to the skin, subcutaneous tissue, external genitalia, and muscular fibers to the various muscles. The superficial transverse perineal muscles have been cut to show the course of the perineal nerve. Inset: Deeper dissection after inferior (superficial) fascia of the urogenital diaphragm has been removed shows the course of the dorsal nerve of the clitoris. The posterior two-thirds of the nerve passes through the thickness of the muscle. (Modified from Bonica JJ. *Principles and practice of obstetric analgesia and anesthesia*. Vol 1. Philadelphia: Davis, 1967:491.)

The nerve passes posterior to the junction between the ischial spine and sacrospinous ligament and anterior to the sacrotuberous ligament. Except when the ischial spine is long and prominent, the nerve does not pass behind the spine but rather passes diagonally across the posterior surface of the sacrospinous ligament just as it attaches to the spine (11). Here, it is medial to the internal pudendal vessels that separated from the nerve to the obturator internus muscle. The posterior femoral cutaneous nerve lies lateral and posterior to the pudendal nerve, while the sciatic nerve is much more lateral and some distance away from the pudendal nerve.

The pudendal nerve trunk divides into three main branches, the inferior hemorrhoidal, perineal, and dorsal nerve to the clitoris (or to the penis). Each of these makes an important contribution to the nerve supply of the perineum.

Inferior Hemorrhoidal Nerve

In approximately 50% of individuals, the inferior hemorrhoidal nerve arises directly from the S-3 and S-4 nerves, while in the other 50% it arises from the pudendal nerve (11,12). In the latter instance it branches off from the parent nerve just distal to the sacrospinous ligament and then accompanies the pudendal nerve within the posterior part of Alcock's canal. The inferior hemorrhoidal nerve pierces the medial wall of Alcock's canal, crosses the ischiorectal fossa, and proceeds medially and anteriorly across the ischiorectal fossa accompanied by the inferior hemorrhoidal vessels to reach the perianal region. Midway in its course to the anus it divides into muscular branches for the sphincter ani externus, cutaneous filaments that supply the skin around the anus, and branches that communicate with other nerves of the

perineum. When the inferior hemorrhoidal nerve arises separately, it does not pass through Alcock's canal but proceeds anteriorly from its origin, lying significantly more medially than the pudendal nerve.

Perineal Nerve

The perineal nerve is the largest of the three branches of the pudendal nerve. It arises near the base of the urogenital diaphragm, approximately 3 cm above the inferior border of the ischial tuberosity, and divides almost immediately into the superficial cutaneous and deep muscular branches. The superficial part of the perineal nerve is purely cutaneous and consists of two nerves, medial posterior and lateral posterior labial (or scrotal) nerves. These supply the skin of the perineum and the major portion of the ipsilateral labia majora and minora (or the scrotum) (Fig. 70-17). They also communicate with the inferior hemorrhoidal nerves and with the perineal branch of the posterior femoral cutaneous nerve.

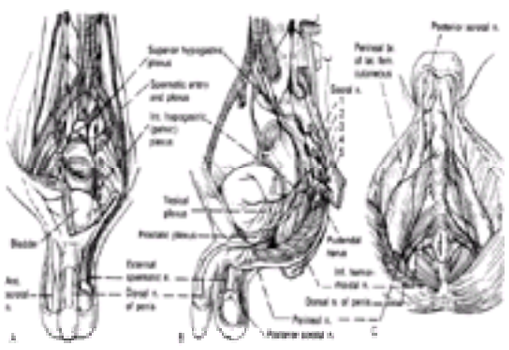

Figure 70-17. Nerve supply of the male genitalia. **A:** Anterior view. **B:** Sagittal view. **C:** Perineal view.

The deep branch of the perineal nerve arises at the anterior end of the ischiorectal fossa and proceeds anteriorly by passing between the superior and inferior layers of the urogenital diaphragm to reach the urethra. Its branches supply the following muscles: transversus perinei superficialis, bulbocavernosus, ischiocavernosus, transversus perinei profundus, sphincter urethrae, and anterior part of the levator ani and sphincter ani externus. It also supplies sensory fibers to the fascia of these muscles. The deep branch of the perineal nerve terminates in the urethra and supplies the erectile tissue of the bulb of the vestibule, urethra, and mucous membrane of the urethra with vasomotor nerves.

Dorsal Nerve of the Clitoris (or Penis)

The third branch of the pudendal nerve, the dorsal nerve of the clitoris in the woman or of the penis in the man, emerges from the anterior end of Alcock's canal, passes through the urogenital diaphragm, and proceeds anteriorly, lying between the two layers of the fascia of the diaphragm. Near the apex of the urogenital diaphragm, it pierces the superficial fascial layer and proceeds anteriorly on the side of the dorsal artery of the clitoris or penis to reach the dorsum of the structure it supplies. This nerve also supplies a small branch to the corpus cavernosum muscle and carries sympathetic fibers that supply the erectile tissue (see Fig. 70-14B).

Physiology of the Pelvis and Perineum

Pelvic pain does not come from cutting, crushing, or burning a visceral structure: Pain, in fact, from visceral structures comes from distension and stretching. Chronic pelvic pain is likely due to the classic visceral stimuli such as stretch, distension, or hypoxia or inflammatory stimuli. Simple examples of this are the distension of the cervix during the first stage of labor that causes the majority of pain during that time period; another is the hypoxia associated with a uterine fibroid that undergoes infarction. Another may be the pain associated with a hemorrhagic corpus luteum cyst as its capsule distends to three to five times its size. Pain transmission from visceral organs (bowel, bladder, rectum, uterus, ovaries, and fallopian tubes) is distinct from somatic structures (skin, ligaments, muscles). Visceral pain is characteristic of deep pain that is difficult to localize and stimulates autonomic reflexes such as nausea, vomiting, and diaphoresis (13). Viscerosomatic convergence characterizes the visceral input to the dorsal horn. This explains the frequent “referred visceral pain to cutaneous areas” phenomena. This and the poorly localizable quality of visceral pelvic pain are due primarily to the fact that there are no second-order neurons receiving only visceral input. Furthermore, there are many more somatic second- order neurons than there are viscerosomatic neurons (14). Somatic structures have nociceptors that are special types of receptors sensitive to tissue damage. Pain from the pelvic reproductive organs may emanate from high-level activity in nonspecific wide dynamic range receptors (15,16).

Visceral pain may be responsible for referred pain. Commonly, referred pain is more or less localized in the same dermatome supplied by the spinal cord segment receiving the visceral stimulus. Examples of gynecologic pains associated with referred pain in certain specified dermatomes are the T-10 to L-2 spinal segments with referral to the anterior abdominal wall and anterior thighs, and the L-1 to L-2 spinal segments with referral to the lower back (17,18 and 19). One animal model of referred pain included uterine inflammation that caused plasma extravasation in skin of the abdomen and groin areas of referral (17).

Etiology and Epidemiology of the Pelvis and Perineum

It is truly difficult to point to a single cause for pain. This section outlines some of the basic underlying mechanisms that set the stage for the development of the final common pathways for recognition of pain. Because etiology and epidemiology are so close in definition we simultaneously consider both of these. Epidemiology is defined as the various factors that determine frequency and distribution of disease and its consideration, as noted, is in conjunction with etiology in this section.

We have organized this section on etiology and epidemiology into categories for the purpose of discussion and logical order (Table 70-1). This order has nothing to do with frequency or severity of the disorders. A detailed description of many of the disorders is found in Chapter 72.

TABLE 70-1. General causes of chronic pelvic pain

Gynecologic Disorders

Ovarian Disorders. The pain associated with this category is largely due to stretch of tissues due to hemorrhage or lost blood supply due to twisted pedicles. Some of the common abnormalities are presented here.

Corpus Luteum Cyst. Corpus luteum cyst consists of a hemorrhagic episode with onset of pain when distension occurs to the point of excessive stretch of the peritoneal covering surrounding the cyst. Diagnosis is made with ultrasound. Laparoscopy can allow for confirmation and a definitive surgical correction; however, pain medication and observation usually suffice unless hemoperitoneum ensues, due to rupture of the cyst. The cyst resolves over 4 to 8 weeks.

Twisted Ovarian Cyst. Some ovarian cysts can twist to the point that local vascular supply is embarrassed and this can elicit pain of varying degrees. This type of pain usually develops rapidly and presents with sharp definition and radiation to the iliac fossa, often with nausea and localized peritoneal signs. Diagnosis here is by laparoscopy, where definitive therapy can be put into place with either aspiration followed by excision or total excision of the entire cyst or ovary without aspiration if there is concern about the possibility of any malignant potential. If the ovary is necrotic, reducing the torsion is inadequate therapy, and oophorectomy is necessary.

Cyclic Pelvic Pain. Cyclic pelvic pain implies pain associated with menstrual cycling. Cyclic pain can include both primary and secondary dysmenorrhea. Atypical cyclic pain is a variation of secondary dysmenorrhea. The diagnosis of cyclic pain is simple and depends on accurate history taking and a review of daily pain with a detailed menstrual record. Up to 50% of menstruating women are said to suffer from primary dysmenorrhea (20). *Primary dysmenorrhea* is defined as menstrual pain without pelvic pathology. Often primary dysmenorrhea appears early on, in the first or second year after menarche. Pain is in the suprapubic area with referral to both thighs or the lumbosacral area. Typical of visceral pain there may be associated nausea, vomiting, and diarrhea. Onset is just prior to or just after the first day of menstruation and lasts for 48 to 72 hours. Dysmenorrhea pain is transmitted via the thoracolumbar spinal segments and pelvic afferents.

The stimulus relevant during the development of such pain is thought to include some of the following components:

- Myometrial contractions leading to intense intrauterine pressure and uterine hypoxia
- Prostaglandins and leukotriene production that sensitizes afferent pelvic nerves
- Altered central receptivity of the afferent input from the pelvis (21)

Secondary dysmenorrhea is menstrual pain associated with pelvic pathology. It may occur years after the beginning of menstruation. The most common causes of secondary dysmenorrhea are endometriosis and adenomyosis. Other causes pathology associated with the uterus, tubes, and ovaries must be considered, such as subacute salpingo-oophoritis. To rule out secondary dysmenorrhea a full gynecologic workup must be carried out including pelvic examination, ultrasound, and magnetic resonance imaging (MRI) if deemed necessary, laboratory studies to rule out specific offending agents such as gonorrhea and chlamydia, and laparoscopy if indicated.

Medical and surgical therapy must be outlined for the benefit of the patient so she can understand her options for obtaining relief from pain. Medical therapy is primarily focused on use of nonsteroidal antiinflammatory drugs, oral contraceptive pills, and other more potent analgesics if necessary. The goal is to restore function. Some have used acupuncture as a treatment adjunct. Surgical approaches to dysmenorrhea are chiefly laparoscopic in nature, with certain ablative neural procedures offered in selected cases of secondary dysmenorrhea; occasionally, there may even be an indication for hysterectomy depending on the level and type of pathology (22). Long-term studies and certainly any controlled studies of neurectomy procedures are grossly lacking.

Ovarian Remnant Syndrome. This syndrome can be associated with a previous total abdominal hysterectomy and bilateral salpingo-oophorectomy. It is thought that a small amount of ovarian tissue is left behind and the resultant ovarian remnants become responsible for the symptoms of pain (23,24). The incidence of small amounts of ovarian remnants left after hysterectomy is really unknown. This diagnosis is considered after a history and an abnormal hormonal evaluation in a patient with pelvic pain are noted, especially if the pain is cyclic (23,25). A pelvic examination may result in the finding of a tender mass in the lateral region of the pelvis. Hormonal levels may not be confirmatory because, occasionally, follicle-stimulating hormone may not be elevated depending on the hormonal activity inherent in the ovarian tissue *in situ*. Often an ultrasound after ovarian stimulation with clomiphene can confirm a mass in the correct location. If the diagnosis is confirmed, a laparotomy and removal of residual ovarian tissue is the usual treatment (26). Surgical management via laparoscopy has been associated with complications including hemorrhage and ureteral, bladder, and bowel injury. Recurrent remnants occur in 15% of cases. An alternative to surgical management is treatment with gonadotropin-releasing hormone agonists and estrogen with progestin supplement (23,27).

Uterine Disorders

Endometriosis. Another major and distressing cause of chronic pelvic pain and secondary dysmenorrhea is endometriosis. Endometriosis is second only to primary dysmenorrhea as a leading cause of pain in women. The incidence is estimated to be 1% to 2% in the general female population, but as high as 15% in infertile women. There is an apparent increase in incidence of endometriosis in the past decade that may reflect better diagnosis and more liberal use of laparoscopy in early diagnosis. One remarkable statistic is that endometriosis is diagnosed in 28% to 74% of the patients who have laparoscopic examination for chronic pelvic pain (28,29,30,31 and 32). The strict definition is the presence of endometrial glands and stroma located outside the uterine cavity. The favored theory of etiology is retrograde menses. The diagnosis is suggested by the presence of dysmenorrhea, dyspareunia, dysfunctional uterine bleeding, and infertility. Confirmation is by laparotomy or laparoscopy. The lesions may be seen on the surface of the pelvic viscera adjacent to the uterus. Nonpigmented lesions progress in time to become pigmented. Removal of these lesions usually causes great improvement of the symptoms. Endometriosis, by itself, is one of the major causes of pelvic pain, and perhaps one of the most confounding problems because this disease can present with widely varying symptoms and signs. It is often confusing because it can mimic many other disease states. Endometrial implants may affect many different abdominal organs and the visceral and parietal peritoneum. Typically, they can be dark red or brown, or they may be colorless. The diagnosis is made on the basis of the history and confirmed by laparoscopy and biopsy. Treatment is surgical, with destruction of many of the implants by laser or electrosurgery. Other effective treatment methods are medical, with suppression of both estrogen and progesterone by use of pituitary inhibitory hormones such as the newly developed gonadotropin-releasing hormone agonist drugs such as Synarel, Lupron, or Zoladex. Surgical exploration via laparoscopy with ablative treatment of the identified endometrial implants and, sometimes, surgical severance of either the uterocervical plexus (LUNA procedure) or the superior hypogastric plexus (presacral neurectomy) may give permanent relief of pain (28). Danazol, a synthetic androgen, and high-dose progesterone (medroxyprogesterone acetate, 100 mg per day) are equally effective for pain.

The most common symptoms of endometriosis include infertility, dysmenorrhea, dyspareunia, and abnormal bleeding. Pelvic pain in women with endometriosis may occur at any time in the menstrual cycle. The pain is varyingly described. There may be pain with intercourse, urination, defecation, or it can be constant. Many patients have surgical removal of all reproductive organs, only to have continued pain that is often discovered to be from other causes. Therefore, a complete workup and the elimination of other causes are prudent.

Adenomyosis. The first description was by Rokitansky in 1860: endometrial glands embedded within hyperplastic uterine muscle tissue. He did not coin the term *adenomyosis*, however; this was done by Cullen, who reported the first series of cases in 1896. The incidence has varied from a low of 5% to a high of nearly 70% from routine hysterectomies. Typical signs and symptoms include heavy menstrual bleeding, dysmenorrhea, and an enlarged, tender, and painful uterus.

Fallopian Tube Disorders

Ectopic Pregnancy. Hemorrhage is the primary problem in this disease process. Pain may be due to peritoneal stretch or irritation due to hemoperitoneum. Ultrasound can now rapidly diagnose ectopic pregnancy; laparoscopy confirms the diagnosis and can be therapeutic at the same time. In earlier days there was no concern about tubal sacrifice, but today tubal conservation via salpingotomy with removal of ectopic gestation is the procedure of choice if this can be accomplished with adequate hemostasis (29).

Salpingo-oophoritis. Salpingo-oophoritis can cause chronic pelvic pain, although patients usually present with symptoms and signs of acute or subacute infection before the pain becomes chronic. In the past, frequent recurrent acute infections were typical; however, with the advent of potent broad-spectrum aerobic and anaerobic antibiotic regimens, this is less of a problem. Sweet and Gibbs proposed criteria for making the clinical diagnosis of acute salpingitis (33). Two of the three must be present: lower abdominal pain as well as lower abdominal tenderness (with or without rebound); cervical motion tenderness; and adnexal tenderness. In addition, one of the following minor criteria must be met: temperature greater than 38°C, leukocytosis (greater than 10,500 white blood cells per mm ^{3}), culdocentesis fluid containing white cells or bacteria on Gram's stain, presence of an inflammatory mass, elevated erythrocyte sedimentation rate, a Gram's stain from the endocervix revealing gram-negative intracellular diplococci, or a monoclonal smear from the endocervical secretions revealing chlamydia or gonorrhea.

Patients may present with a history of having had numerous episodes of pain associated with fever and may have been given the diagnosis of pelvic inflammatory disease. However, the patient may not have salpingitis at all. Clinical diagnosis leads to error in 50% of the cases (33). Laparoscopy with visualization of pelvic organs and peritoneal fluid cultures is diagnostic. Intravenous aerobic and anaerobic antibiotic therapy is the standard treatment for salpingo-oophoritis. Only rarely

are hysterectomy and salpingo-oophorectomy required, generally for tuboovarian abscesses.

Miscellaneous Disorders

Pelvic Congestion. Many believe the primary disorder lies in congestion of the arteries and veins in both the right and left pedicles just under the ovaries and fallopian tubes. Clinically, the syndrome includes abdominal and low back pain, dysmenorrhea, dyspareunia, and menorrhagia. The pain is usually bilateral and lower pelvic in distribution and exacerbated by the menstrual period. Anxiety, chronic fatigue, breast tenderness, symptoms of irritable bowel, and premenstrual syndrome are associated complaints. On examination, there is tenderness over the uterus, broad ligaments, and especially the uterosacral ligaments, and often polycystic ovaries are present (34,35).

The diagnosis of pelvic congestion used to be a clinical diagnosis. Now with use of radiology studies and rapid series pelvic venograms, the diagnosis can be more accurately made. Beard and colleagues have published studies in which the diagnosis was made via transuterine venogram. However, this test was technically not feasible or unreadable in 21% of Beard's sample (35). There are a few small studies concerning the utility of pelvic ultrasound with Doppler or MRI for the diagnosis of pelvic congestion (36). Some advocate standing venograms only to make the diagnosis of pelvic congestion.

Vaginal Disorders

Vaginismus. Causes of vaginismus include congenital, infectious, traumatic, or psychological factors. Because the primary cause by far is psychological, it is important to consult a psychologist early on in the diagnosis of this malady. Some of the underlying issues may stem from childhood problems such as sexual abuse. The treatment regimen is complex and demands intensive therapy targeted at several positive forces that knowledgeable psychologists can institute (18).

Tension Myalgia. Tension myalgia is a loose category of diagnoses that should be treated first by identification of the involved muscles that could involve the levator, the piriformis, or the coccygeus muscle groups. These are best treated by attempts to relieve the spasm by heat and massage or local anesthetic injection of the involved muscles directly. Follow-up with specific oriented muscle stretching and exercises greatly helps this painful condition and assists with recovery and prevention of repeated episodes.

Hymeneal Syndrome. Hymeneal syndrome produces an interesting group of patients. Note that the perineum is richly innervated from nerves from different spinal cord segments so that there is some overlap protection in regard to innervation. Patients are often so distraught and histrionic that the initial practitioner may entirely miss the diagnosis due to preoccupation with the reaction the patient displays during physical and gynecologic examination. The patient may complain so vigorously that a pelvic examination is not even possible (i.e., the examiner cannot get past the introitus). In other instances, the examiner does get past the introitus only to find there is no evidence of pain on examination of the vagina, cervix, uterus, and fallopian tubes and ovaries. The past history of these patients may reveal an infection with *Candida albicans*. It would appear that repeated infections by this agent can cause irritation of the superficial nerves in and around the area of the hymeneal ring (3). Patients usually have a history of normal, healthy sexual patterns before the onset of their vaginal pain, but develop significant dysfunction sexually secondary to their disease process. The patient workup must include at least three successful hymeneal blocks that can be performed prior to consideration for surgery. In our series of patients all had repeated hymeneal local anesthetic blocks with demonstrated complete relief of symptoms. The association of the infectious process and specifically the offending fungal agent is too consistent to be coincidence.

Perineal Disorders

Bartholinitis. Infection is the chief problem involving Bartholin glands. This often requires surgical incision and drainage to reverse the effects of inflammation and sequestration of purulent matter. Complete disruption of all communicating and infected sacs should be carried out along with administration of antibiotics (37).

Skene's Urethritis. This set of glands lying along the urethral orifice can also become infected. Usually, heat and gentle pressure can empty the infected material, but rarely, patients may require incision and drainage and antibiotics, similar to those described in bartholinitis (38).

Herpes. The chief pain problems initially include dysuria, dyspareunia, vesicular eruptions, and groin pain. These can be treated with bella donna and opium suppositories, avoidance of sex, acyclovir cream, acyclovir oral medication, and systemic analgesics. Long-term pain can be due to actual neuropathic changes. These are treated by identification of the involved nerve or nerves and local anesthetic blocks for pain relief trials spaced over several weeks. Some patients who are refractory to these may be considered for other methods of nerve treatment, such as cryotherapy or thermolysis. *Focal vulvitis* is a general term that has been used in the past to describe a syndrome of general vulvar pain without evident cause (39).

Condyloma. In early stages, colposcopy helps make the diagnosis. Treatment is by 5-fluorouracil until all wart activity appears neutralized. The skin recovers over a short period of time and develops normal texture again. In some cases, larger lesions may have to be removed by use of cryotherapy, fulguration, or surgical excision. One of the important differentials is human papilloma virus disease (39).

Gastrointestinal Disorders

It is understandable that some patients referred to gynecologists with chronic pelvic pain may well suffer from gastrointestinal pathology (40,41). The cervix, uterus, adnexa, and the lowest portion of the ileum, sigmoid colon, and rectum have the same visceral innervation. This innervation is via sympathetic nerves to spinal cord segments T-10 to L-1 (42).

Irritable Bowel Syndrome. A common cause of pain in the lower abdomen that can be misinterpreted as pelvic pain is irritable bowel syndrome. It can be responsible for a large number of referrals received by general gynecologists. Prime complaints center about a diffuse tightening pain that is intermittent in nature. Periodic episodes of diarrhea may also be experienced. It has a proclivity for the left inferior aspect of the abdomen (42). Diagnosis is made on history and exclusion of other conditions, such as diverticulitis.

Appendicitis. Appendicitis is included in the differential diagnosis, even though it rarely is confused with pelvic pain. The location and the historic aspects of appendicitis are giveaways most of the time, although there can be instances in which the appendix is atypically located and leads to confusion in the diagnosis. Often a gynecologic condition, such as ectopic pregnancy, may further confuse the issue from the diagnostic viewpoint. Finally, another condition termed *chronic appendicitis* may confound the doctor in an attempt to establish a chronic pelvic pain diagnosis (43).

Diverticulitis. As mentioned previously, a common cause of chronic bowel pain that can be confused with pelvic pain is diverticulitis. Diverticulosis can occur in upward of 40% of the asymptomatic population; fortunately, only a small percentage of patients go on to develop the painful and destructive disease of chronic diverticulitis. Diverticulitis can cause left lower quadrant pain also and it can present as a very severe, even *surgical*, appearance. The diagnosis is made on examination and radiology studies (44).

Tumors. Colon tumors can be a cause of chronic lower abdominal pain in women that can also be confused with pelvic pain. History is important here in noting any changes in bowel habits, signs of bleeding, or weight loss, which may suggest neoplasm. Naturally, the diagnosis can be made on digital or endoscopic examination of the patient with the suspicious history.

Hernia. Hernias located at the round ligament are another important consideration in the differential diagnosis of pelvic pain. Although there is a low incidence of inguinal hernia in women, they can occur (45). Spigelian hernias can also confuse the diagnostic picture. These cause lower abdominal pain located in the lower quadrants and they occur between the transversalis and rectus muscles. The actual protrusion is due to a defect in the transversalis fascia. The successful treatment is surgical repair.

Genitourinary Disorders

Another frequent group of disorders that often are confused as being pelvic pain are the pains of urologic origin. Anatomically, sympathetic and parasympathetic nerve complexes are shared closely and may also be involved in other poorly clarified pathways. Developmentally speaking, the urethra-bladder-vagina and vestibule area are all derived from the embryologic urogenital sinus. Some of the confusing diagnoses include urethral diverticula; interstitial cystitis; bladder tumors; upper and

lower excretory tract etiologies of pain, such as stones in the ureters or urethra; and endometriosis (40,46).

Urethral Syndrome. This lower tract disease process is of an irritative nature. Chief signs and symptoms include dysuria, urinary frequency, and often dyspareunia (46,47). A negative urinalysis, negative or a low colony count (e.g., less than 10^4 colonies per mL) on urine culture, and negative chlamydia study help steer attention away from the urologic system and begin to focus on the pelvis. On the other hand, a negative pelvic workup and normal evaluation for vulvovaginitis steer attention toward the possibility of a urethral syndrome. Etiology of the syndrome is unclear for the most part; yet some suggest that there may be an underlying chronic inflammation of the periurethral glands and periurethral muscular fatigue. Treatment consists of pelvic floor muscle biofeedback and chronic suppression with 3 months of a broad-spectrum antibiotic (46). In this syndrome, one should consider the use of vaginal estrogen for postmenopausal women (47). Last, but not least, consideration should be given to pelvic muscle biofeedback and muscle relaxants.

Interstitial Cystitis. Urinary urgency, frequency, and nocturia that are associated with severe suprapubic pain mean consideration of interstitial cystitis as the prime differential diagnostic problem. There is no laboratory confirmation of bacterial, viral, or other infectious agents being involved in this syndrome (48). The consensus criteria for the diagnosis of interstitial cystitis include at least two of the following conditions:

- Pain on bladder filling relieved by emptying
- Pain in suprapubic, pelvic, urethral, vaginal, or perineal region
- Glomerulations on endoscopy or decreased compliance on cystometrogram

If these criteria are not met, the diagnosis of interstitial cystitis should not be made (48). This disease process is thought of as an inflammatory condition or possibly an autoimmune disease. Pathophysiologically, a deficiency of bladder mucosa glycosaminoglycan and an overactive bladder sensory neuropeptide system are considered (49). Several different therapy considerations have surfaced; some of these are a special bladder diet, hydrodistension of the bladder, dimethylsulfoxide bladder treatments, glycosaminoglycan treatments, and transcutaneous electrical nerve stimulation. Other additional therapies include physical therapy, pelvic floor muscle biofeedback, and a series of local anesthetic nerve blocks. Other medical treatments include anticholinergic, antispasmodic, nonsteroidal, or antiinflammatory oral agents. Tricyclic antidepressants and narcotics are also used in medical therapy.

Musculoskeletal Disorders

Pelvic pain can be associated with pain complaints in the nearby low back area, the lower abdomen, and even radiation to the upper thighs. Low back pain can be caused by vascular, neurologic, muscular, skeletal, or gynecologic pathology (50,51). Even though muscular and skeletal problems may not be the chief cause of a given chronic pelvic pain, they can certainly increase its severity (51). A physical therapist who can evaluate posture, muscle length and strength, and joint range of motion should always improve the general efficacy of the treatment regimen (51).

Myofascial pain can be a cause of pelvic pain and, if not the primary cause, can be a significant contributor to fuel the pain overall. Various practitioners have found varying numbers of patients in whom myofascial pain is a significant factor. Reiter and Gambone (39) found 15% with myofascial pain, whereas Slocumb (18,51) found 89%.

Muscles that receive their innervation from the T-12 to L-4 spinal nerves can elicit visceral referral pain to the lower abdomen and muscles such as the rectus, iliopsoas, quadratus lumborum, piriformis, and obturators. Similarly, the reproductive organs such as the tubes, ovaries, and uterus that are innervated from T-10 to L-2 can refer pain to the abdominal wall, low back, thighs, and pelvic floor (51). Myofascial pain is increased by activity emanating from the deep visceral structures that share similar dermatomal innervation (19,52,53). Pain can be increased dramatically by a head lift maneuver during a pelvic examination where one finger is on the abdomen and the other finger is in the vagina. This is a method by which one can elucidate the primary origin of pain (i.e., suprafascial or subfascial).

Osseous Disorders

Osteitis Pubis. Active women in competitive sports who present with pubic pain and adductor pain should be considered for osteitis pubis as a cause. In one study of 59 patients, recovery was slow, taking up to 7 months in women. There was also an associated finding of pelvic malalignment or sacroiliac dysfunction in these patients (54).

Adductor Tendonitis. Adductor tendonitis is usually associated with marathon walkers or runners who suffer from acute injury to the adductor muscle of the anterior thigh that attaches directly to the pubic ramus. The patient complains of pain in the pubic ramus itself and is convinced the pain is of bony origin. It is often misdiagnosed as pelvic pain due to the complaint by the patient of diffuse ache that radiates into the involved pelvic area laterally. Diagnosis is made by running the examining finger along the medial margin of the adductor muscle up to the point of insertion on the pubic ramus. At this point the patient suffers exquisite pain and pinpoints the pain as being located exactly at the point of insertion. A local anesthetic injection completely eradicates the pain within minutes of injection. It may be necessary to repeat such a treatment a few times for complete eradication of the pain.

Osteoporotic Sacral Fractures. Osteoporotic sacral fractures were found to be associated with pelvic pain complaints in which other pathologic causes had been excluded (55).

Neuropathic Disorders

Exploratory laparotomy or laparoscopy may stretch, avulse, or otherwise damage either the ilioinguinal or iliohypogastric nerves or both nerves. A neuropathy may result and develop after variable intervals. The pain may begin days, weeks, or even months after the injury. It is common that there is a gradual escalation of pain over time. This type of neuropathic pain is usually reported as burning or stabbing. It may develop to a degree that incapacitates the patient. Often the well-meaning doctor misses the diagnosis altogether and does not even examine this area or consider it as part of a differential diagnosis. Yet, abdominal cutaneous nerve entrapment or injury should be considered in the differential diagnosis of chronic lower abdominal pain that follows surgical exploration. Such an injury can also follow trauma, automobile accidents, or exercise. Other commonly involved nerves other than the ilioinguinal (T-12 and L-1) and iliohypogastric (T-12 and L-1) are the genitofemoral (L-1, L-2) and obturator (L-2, L-3, L-4). Nerve entrapment pain is typified by exacerbation by exercise and relieved by inactivity (56,57). Other descriptives include stabbing, crampy, burning, or aching pain. There may or may not be pain radiating to upper thigh, labia, or scrotum.

Examination includes the direct palpation of the local area with the blunt end on a pencil or pen with pressure distributed directly vertically downward. In this manner, the affected nerve or nerves can be identified and marked for later local anesthetic injection if the patient so desires (58). A useful maneuver to differentiate pain coming from affected nerves above the fascia as opposed to pain coming from nerves below the fascia is to instruct the patient to lift her head as if performing a *crunch*. This immediately exacerbates the pain above the fascia in the area where pressure is exerted downward. An examining finger in the vagina will quickly determine the pain is not coming from the intraabdominal compartment (59). The diagnosis is further established by a local anesthetic nerve block with only 2 to 3 mL or 0.025% bupivacaine (60). Immediate relief is the usual reaction. It is important to continue this therapy for several weeks to defeat the already established pain pattern at the spinal cord level. Those patients who do not respond may be candidates for cryoneurolysis; this type of therapy can result in long pain-free intervals. Generally good response results have been reported in as high as 70% of patients (60). Concomitant therapy includes use of medications such as low-dose tricyclic antidepressants and anticonvulsants. Physical therapy, psychology referral, and even some life- style changes may be necessary for optimal long-term results.

Ilioinguinal and Iliohypogastric Nerve Disturbances. Patients with these diagnoses have histories that often include surgical or other types of trauma in the area of the lower abdominal wall. The genesis of the pain is not known, but suspect is the retraction placed on nerves located around the incision line that may result in overstretch and avulsive-type neural injuries. The onset of pain after the initial trauma is variable due to the intensity of the injury and perhaps the fiber size. Many gynecologic patients have exposure to the Pfannenstiel-type incision that cross cuts both the ilioinguinal and iliohypogastric nerves. In addition, the injury may be from retraction in the lower corners of the incision where the nerves are located. Interesting enough, many of the patients in this group of patients have histories of repeated abdominal exploration of one type or another because their original physician was convinced the initial problem of intraabdominal pathology had not been solved or perhaps that recurrent pain might be due to abdominal adhesions or other yet defined “organ-related pathology.” This is becoming less common due to the widespread use of laparoscopy, but the latter procedure in itself may cause abdominal neuropathy due to placement of the scope, obturator, or one or more ancillary percutaneous sites. In this case the patient was seen with initially eight tender points identified. These cases are best managed by repeated local anesthetic nerve blocks spaced over time to take advantage of the maximal signal depression, but not so frequently as to set up a new pain from mechanical stimulation. Most patients fall into the responding category by 4 to 6 weeks. Those who do not can benefit from abdominal catheter placement and continuous local anesthetic irrigation of the nerves between the transversalis and oblique muscle groups (61). Those who do not respond to that therapy can be treated with cryotherapy for destruction of those

few refractory nerves still causing problems (62). For ultimate failures in instances where multiple nests of neuromas may still be active and have been refractory to all the previously mentioned modalities, one can consider surgical intervention and extirpation of the nerves to try to correct the problem (63).

Genitofemoral Nerve Disorders. Genitofemoral nerve disorders are also labeled *genitofemoral neuropathies*. Patients report variable stories of low abdominal pain or even back pain that has migrated to the front of the body and now descends into the scrotal or labial area. The pain may be incapacitating. Nerve blocks and tender point injections usually provide pain relief. It is hoped that patients will exhibit gradual reductions in pain scores over time and that they will have an increase in their function. Sometimes the reasons for failure must be viewed as an invitation to explore further the possibility of an overlooked pathologic condition that may have been missed. For example, one patient we managed had been refractory to repeated therapy over time, and on surgical exploration it was discovered that a suture was found around the genital branch of the genitofemoral nerve just at the site of a former hernia repair. Because the distal portion of the nerve was notably atrophic, it was resected above the area of involvement and the patient follow-up has been gratifying in that the patient is now pain free.

Psychological Disorders

The psychological interview is best performed at the time of the first visit, often prior to the physical examination. This is important because it sets up the framework for recognition by the patient that this is a vital aspect of health and well-being. A psychologist working in concert with a physician with established goals provides a productive working relationship. Ideally, it would be beneficial to have the psychologist be schooled or experienced in the area of sexual function and the problems inherent in this very specialized care continuum. The literature is replete with articles relating association of childhood abuse and later sexual and psychological dysfunction, and many minor and major gynecologic pain problems have also been blamed on such disturbances (63). These problems are often hidden and not immediately apparent in early physician relationships because the patient is waiting for some signs of comfort and trust to appear or because the patient has suppressed the past history to the extent that it is not available for recall until an expert uses his or her skill to extract it later on.

Significant psychological impairment can have devastating effects on the success of a planned program for a patient's recovery, especially when it is not even suspected as being a problem. Hypnosis, biofeedback, and group therapy have all been demonstrated to be useful treatment strategies for women with pelvic pain.

Women with chronic pelvic pain can have a high level of psychological disturbance. One survey of 40 women with pelvic pain revealed the typical Minnesota Multiphasic Personality Inventory profile labeled “conversion V” (64). In another study, Minnesota Multiphasic Personality Inventory profiles of women with chronic pain without obvious pathology were compared with those of women with pain arising from endometriosis and a control group (65). The two pain groups differed from controls but not from each other.

Various studies have attempted to define better and better relational aspects of pelvic pain, depression, and sexual abuse. Some of these are very specific and look at the interaction of depression and pain only (66,67). Others have revealed interesting affective disorder problems in women with pelvic pain without a definite diagnosis of pathology versus women with a diagnosis of pathology (67). Women with pelvic pain who had no definite diagnoses were also found to have a higher prevalence of sexual abuse and major depression with associated dysthymic, panic, and somatization disorders (66,67,68,69 and 70).

A study by Rapkin et al. investigated the relational aspect between physical abuse and sexual abuse (69). Abuse of any sort was a predictor that the patient would go on to suffer “chronic pain” later. The conclusions reached were that abuse increased vulnerability and promoted a sense of helplessness (71) (Table 70-2).

TABLE 70-2. Sexual and physical abuse data

One of the problems in the diagnosis of those patients whose pain is labeled as *psychogenic* or *nonorganic* is that many may have neuropathy of various types that many physicians in practice today are not capable of diagnosing or treating. Most gynecologists, urologists, and surgeons are taught to think in terms of organ pathology, not in terms of nerve pathology. It is only recently that medical schools even are beginning to offer classes and approaches to considering neuropathic causes of pain. Unfortunately, many physicians tell patients that they cannot find a reason for the patient's pain and therefore the patient's pain is most likely in the head. Many patients who have been told this can be found to have a specific pudendal, obturator, or genital branch of the genitofemoral nerve neuropathy. Furthermore, most of these were amenable to simple local anesthetic nerve blockade with excellent results. This treatment was often repeated four to five times until the patient had prolonged or even permanent pain relief.

CLINICAL CONSIDERATIONS

History

All chronic pain patients have had their histories taken multiple times. It may be frustrating for them to repeat the details of their pain history, but it is important to get their attention and to establish a caring, concerned rapport with the patient from the outset. During the history it is important to ascertain the chronologic order of the physicians who have been consulted, the diagnostic tests they instituted, the procedures they used in either diagnosis or therapy, and the medications they prescribed. It is also important to get some idea as to the impact the pain has had on the function of the patient. This part of the pain history is vital because it not only illustrates the degree of difficulty the patient has had in the past, but it can also be used as a reference point for future improvement. In this day of long-term follow-up and outcomes orientation, it is especially important for the pain practitioner to carefully follow patients to be certain of outcome.

Physical Examination

The physical examination should be focused primarily on the area of the patient's complaint and must be detailed in regard to sensory and motor findings and structural changes that are noticeable. One of the important characteristics that differentiates the pain examination from other medical examinations is the hands-on examination by the physician. During this process, the areas of pain and the types of stimulation that reproduce the pain are assessed. An example of the physical examination may be illustrated by assuming a patient has pain in her right pelvic area. In such a case the physical examination should begin with the abdomen and include the lower extremities and, of course, a pelvic examination. In the process of examining these areas, the physician must attempt to elicit pain by superficial and deep pressure exerted by either the examining finger or an elongated cotton-tipped swab in the vagina or by a blunt probe, such as the blunt end of a pen or pencil on the abdomen.

In the past, there was a tendency to encourage pain specialists to perform a complete physical examination on every patient because of the fear of overlooking something that may have been previously missed in a prior workup. In cases where a patient comes to the office as a self-referral and does not have a family physician and has not had a routine physical examination then, of course, a complete physical examination is the best course. However, when the patient is referred by her own physician who requests from you a consultation for a specialized area, such as pelvic pain, then it is expensive, time consuming, and probably unnecessary to repeat a complete examination.

Pelvic Examination

An important step in differentiating an abdominal versus a pelvic origin of pain is the pelvic examination. Individual maximum tender points are identified, and then a comparison of the abdominal versus pelvic digital pressures can be made. With this maneuver it becomes clear which is the primary location of pain. This can be amplified with instructions to the patient to raise her head and contract the abdominus rectus muscles. This latter maneuver results in maximal pain above the rectus sheath and localizes the pain to the abdomen, not pelvis. One of the important skills in identification of pain is how to correctly use the examining hands and fingers during the physical examination. There is a skill that must be learned in regard to discovery of these maximum tender points. Percussion and palpation are the key skills that are required. The use of the hands-on experience to determine painful areas in and around the area of primary pain complaint is a skill that is very important and one that is often not taught in clinical training. Nevertheless, it is this very skill that must be learned and learned well if one is determined to work in the area of pain management. Pelvic pain diagnosis can be a problem for those who are not gynecologically trained. This is a problem that demands an extensive and experienced knowledge of the pelvic area and its anatomy and physiology. It literally takes years to be able to learn to perform a good pelvic examination and to be able to sensitively detect subtle abnormalities that may exist in the pelvis. Furthermore, the patients who are referred with pelvic pain are ones already examined by their gynecologists over and over again. The pelvic examination itself must be modified so as to not stimulate great degrees of pain during the examination, yet the operator must still be able to detect abnormalities. Pelvic pain is an area where pain specialists cannot expect to be effective unless they have had extensive training and subsequent experience in the area of pelvic examination. The pelvic examination is made up of the following parts: observation of the external genitalia, Bartholin's glands, hymen, vagina, cervix; and palpation of the cervix, uterus, vulva and ovaries, and rectal/vaginal septum.

Diagnosis

There are several procedures that must be considered basic diagnostic tools in the practitioner's approach to pelvic pain. These include the following tools as a minimum:

- A careful and considerate pelvic examination is directed to the sites of pelvic pain, not the usual pelvic bimanual examination.
- A pelvic ultrasound examination helps identify difficult to detect abnormalities that are hidden due to a patient's not allowing deep palpation due to pain.
- Pelvic MRI is the ultimate tool for detection of hidden tumors, masses, or even totally obscured endometriomas that may lead to occult neural involvement.
- Abdominal MRI is used to rule out possible pathology in the abdomen that cannot be appreciated or cannot be detected on physical examination.
- Computed tomographic (CT) scan is the ultimate examination tool for problems that interface osseous and soft tissue planes. It may be indicated at times even in the face of a normal MRI if historic and laboratory findings point toward abnormalities along this interface.
- Bone scan is important in picking up fractures and other bony pathology that may involve nerve distributions that are not visible on plain roentgenography.
- CA 125 values may be helpful in certain situations to help confirm a diagnosis that is already highly suspicious because of strong history and physical findings. One example might be a suspicion of endometriosis, for example.

It is important to record and assess all previous studies such as those mentioned previously and to take detailed notes on dates and findings. These can help one to understand the past thought processes of physicians who have cared for the patient. Furthermore, tests should not be unnecessarily repeated.

Differential Diagnosis

The physician confronted with a pelvic pain patient who has already been seen by several other doctors must make a very important decision for the benefit of that patient. This decision is to undertake the workup and treatment or to refer the patient to a known specialist in the area of pelvic pain. The evaluation of all the different gynecologic processes that could be responsible for the patient's pain is difficult. An example of the confusion in diagnosis in this area is typified by one study from 1989 that showed that patients suffering from irritable bowel syndrome had over a 20% incidence of hysterectomy. This reveals the confusion in differentiating abdominal pain and pelvic pain (72). Some of the problems confounding the practitioner who attempts to sort out the cause and treatment of the chronic pain patient with pelvic and abdominal pain are the facts that the etiology can be quite variable, the target organs affected quite disparate, and the intensity of the pain quite different. This can lead to early frustrations from invoking diagnostic tests that repeatedly turn up negative. Patients want to believe in their physicians and thus the pressure is intense on physicians to devise some treatment that may be beneficial. To complicate matters, some of the health care team members, such as the gynecologist, internist, neurologist, or family practitioner, are not trained in the application of various diagnostic and therapeutic local anesthetic blocks, while other members of the health care team, such as the anesthesiologist, neurologist, or internist, are not versed in and have had little experience in pelvic examinations. Both of these skills are important in the workup, diagnosis, and management of pelvic pain patients.

An important aspect of the differentiation is the pelvic examination, in which various tissues and sensitive locations are thoroughly examined with care and sensitivity. It is at this time that maximum tender points often are located and appreciated by the appropriately trained and experienced clinician. With physicians not trained to understand the importance of the neuropathic aspect of pain etiology, there is a tendency to blame pelvic organs that are readily apparent or adhesions that are remnants of past surgeries. The latter, however, are rarely the cause of pelvic pain and should not be just a default excuse when no other etiology for the pain is evident. It is also at this time that the clinician needs to do various diagnostic blocks to rule out neuropathies that may well be the culprit. These must be done with a full understanding and appreciation for the innervation pathways for the pelvis. This can only be accomplished after many years of study of the anatomy and relationships of the muscles, ligaments, bony pelvis, and neuroanatomy. Such a topic cannot be summarized in a chapter, and it is not something that can be taught in one or two or even several sessions during a *learning* visit. In instances in which the initial physician has completed a workup that reveals no obvious organic abnormalities and the patient still complains of pain, the physician in charge should consider referring the patient to someone who specializes in pelvic pain. Furthermore, our experience in a well-based diagnosis and management practice of chronic pelvic pain helps us to develop a successful outcome result profile. Table 70-3 serves as an excellent primary differential diagnosis guide.

TABLE 70-3. Pelvic and perineal pain: summary of etiology and differential diagnoses

Other Examinations

There are several laboratory studies to be completed during a workup for pelvic pain. Some of these include complete blood count; erythrocyte sedimentation rate; urinalysis and culture with sensitivities; cervical and urethral cultures (gonorrhea and chlamydia); wet mount of vaginal secretions; Papanicolaou smear; stool guaiac; and, if diarrhea is present, a stool culture. If the pelvic or abdominal examination is suggestive of a mass, an ultrasound or MRI evaluation is indicated. If symptoms and signs are suggestive of other system involvement, fiberoptic or other appropriate endoscopic imaging studies of other organ systems should be considered.

Psychological assessment is very important in nearly all pelvic pain patients because of the special intimate relational aspects of this type of pain. It really does occupy a special role in regard to complexity. All patients should be evaluated by a psychologist familiar with the special management problems posed by those suffering from chronic pelvic pain. Assessment in the context of chronic pain involves a broad range of measures, reflecting biological, social, and psychological influences and sequelae. As noted previously, pelvic pain may well affect sexual functioning, and therefore may well have additional repercussions on mood, health, and well-being of a relationship, and finally, self esteem. The important area of either physical abuse or sexual abuse must be brought up and evaluated. The impact of the pain and the effect on the patient's daily functioning must be explored. Psychological testing should be used at the outset to determine if affective disturbance is

present and to establish a baseline by which later improvements may be gauged.

Special Studies

There are many special studies that can be used to aid in the diagnosis of the patient who has pelvic pain of obscure origin. MRI is most valuable. This examination is noninvasive; cross-sectional high-resolution images of the body are full of anatomic information. The advantage of using MRI for the evaluation of the pelvis is that the contrasting images of the tissues are superior to the CT scan and ultrasound–so much so as to distinguish normal and abnormal tissues not possible with other methods.

Ultrasound is the best image method currently available for early examination of the pelvis. Its advantage is its lower relative cost and the availability of the technique. It works by reflection of high-frequency sound waves off of anatomic structures; the picture formed is the result of the various acoustic densities presented to the waves. Ultrasound is useful as a determinant of whether pelvic organs are normal or not and whether there is displacement due to other pathologic entities.

The CT scan is also valuable as a diagnostic tool in determining pelvic abnormality, especially in relation to bony anatomy. Because the CT scan does use x-rays, the picture is excellent in regard to the bony relationships and thus serves as an excellent medium for evaluation of pelvic problems associated with tumor growth, tumor invasion, and distortion of pelvic anatomy.

Laparoscopy or peritoneoscopy is the spinoff of the older culdoscopy surgical technique (73,74). Its advantage is considerable compared with that older method, however, in that the positioning of the patient is more reasonable and both diagnostic and considerable therapeutic procedures can be performed via the laparoscopic technique. It is the most widely applied diagnostic technique used today in gynecology, and its application avoids many exploratory operative procedures that would have been done in the past. Its use does require significant experience and expertise. It is a valuable tool in both diagnostic and operative procedures.

There are several procedures that must be considered beyond the basic workup tools in a practitioner's approach to pelvic pain. These include the special studies listed in Table 70-4 that form the foundation in an exhaustive approach to the diagnosis of the patient with pelvic pain.

Special study	Benefit
Pelvic examination	Pelvic pain identification
Pelvic ultrasound	Identification of hidden masses
Pelvic magnetic resonance imaging	Detection of hidden tumors
Abdominal magnetic resonance imaging	Rule out abdominal abnormalities
Computed tomographic scan	Ultimate osseous/tissue plane diagnosis
Bone scan	Hidden fractures not visible by x-ray
CA 125 values	Confirm highly suspicious neoplastic diagnoses

TABLE 70-4. Special studies in the diagnosis of the patient with pelvic pain

The workup of a patient with pelvic pain must be taken as a serious responsibility. It must be realized that these patients have gone to numerous physicians only to be told the etiology of their pain cannot be diagnosed. It is important to the patient to note and consider the previous workups and their findings. Some of these studies may need to be repeated, while others should not be repeated.

Treatment by Surgical Therapy

Management of pelvic pain by surgical means is the most common modality of treatment by the gynecologist. The problem with this most common treatment of pelvic pain is there are no studies that prove its worthiness in spite of thousands upon thousands of hysterectomies being performed for pelvic pain. Rarely has there been a randomized controlled study of this modality of treatment. Another problem with such surgical therapy is that it is often deemed *curative* because of a single postoperative follow- up at 6 weeks. Many times the patients begin to have pain again 4 to 6 months after the conclusion of the surgical treatment.

Laparoscopy

The mainstay of diagnosis is laparoscopy. This has become a first-round standard procedure in the evaluation of patients with intractable pelvic pain. Laparoscopy is very useful on the diagnostic side in regard to pelvic pain. It has also become important in the management of pelvic pain. Studies have revealed that a wide variation of patients (from 14% to 77%) did not have pathology; and furthermore, two-thirds had only findings of adhesions that may not cause pain (32,75). Finally, nonsurgical management of chronic pelvic pain has been rated successful in 65% to 90% of patients regardless of presence of *pathology* (76,77,78 and 79). One of these studies had two randomized groups: one with laparoscopic approach routinely performed (n = 49) and one with medical treatment with attention to somatic, psychological, dietary, and physiotherapeutic factors (n = 57) (79). Of the 49 patients in the standard group, 65% had no abnormality, 5% endometriosis, 18% had adhesions, and the remainder myomata, ovarian cysts, or pelvic varices. The 57 patients in the medical group had more effective reduction of pelvic pain (75% versus 41%; p <.01) (79). It would appear that laparoscopy's primary role is to provide reassurance by direct visualization and in the surgical management of adhesions and laser therapy of endometriosis (32,80).

Hysterectomy

Nearly 20% of all hysterectomies performed in this country are for chronic pelvic pain (2). Upward of 30% of patients who arrive at pelvic pain clinics have previously had hysterectomy without relief of pain (3). One center experienced a remarkable reduction in the performance of hysterectomy for chronic pain once a multidisciplinary approach to chronic pelvic pain was initiated (78). Two completely different types of patients with pelvic pain are excellent candidates for hysterectomy, especially if they have relief of pain with hormonal suppression. These are pelvic pain patients with cyclic pain and pelvic pain patients with associated dysfunctional uterine bleeding. One prospective hysterectomy study revealed 18% of the patients had undergone hysterectomy for pelvic pain. Significant improvement in pain and associated symptoms occurred in 95% of these women (81,82). Another study of hysterectomy was a retrospective one that involved 99 women with chronic pelvic pain said to be of uterine origin. Relief occurred in 77% of these patients, but 25% of the patients went on to experience persistent or worsening of their pain at a 1-year follow-up (83). Another hysterectomy study by Hillis and colleagues noted a 74% good response rate after removal (84). Follow- up of these patients revealed that persistent pain was associated with multiparity, prior history of pelvic inflammatory disease, lack of pathology, and Medicare payer status. Hysterectomy continues to remain an option for appropriately selected patients with pain centrally located and where pain can be traced to uterine origin (84). It certainly is not indicated in cases where clear-cut neuropathic pain is a predominant factor.

Presacral Neurectomy

Cotte first described the procedure called *presacral neurectomy* in 1925. Presacral neurectomy was recommended for the pain of dysmenorrhea (85). The presacral nerve is really made up of a plexus of nerves referred to as the superior hypogastric plexus. This plexus receives major afferent input supply from the cervix, uterus, and fallopian tubes. Afferents traveling with the sympathetic nerve supply from the bladder and rectum also pass through the superior hypogastric plexus. The acts of micturition and defecation are dependent on an intact sacral autonomic nerve supply, yet they are relatively unaffected by resection of the superior hypogastric plexus. Afferents from the lateral abdominal cavity that include the adnexal structures travel with sympathetic fibers that enter the spinal cord much higher at the T-9 to T-10 levels. Thus, lateralizing pain of visceral origin is not relieved by presacral neurectomy.

The use of the presacral neurectomy procedure has also not been studied in a controlled fashion. It has been described, however, for the management of central pelvic pain in the setting of both cyclic (dysmenorrhea) and noncyclic pain (86,87,88 and 89). It is often used in conjunction with other treatments for endometriosis. In one study, laparoscopic laser resection of endometriomas resulted in relief of pain in 26% of the women; additional presacral neurectomy increased the pain relief to

75% of patients (87). The surgery is technically difficult to perform via laparoscopy (90). Complications of hemorrhage and ureteral injury are not uncommon. Resection of the right and left side of the sympathetic complex that sweep upward and centrally from the broad ligaments is similar to the presacral neurectomy procedure. This procedure is referred to as the *LUNA procedure*. Again, there is little objective evidence of its efficacy; it has been subjected to only one randomized controlled trial (91). In that study, 81% of the patients had relief with the LUNA procedure, but continued relief at 1-year follow-up was only 45% of the 10 subjects (91).

Multidisciplinary Pain Management

Multidisciplinary pain management was introduced by Dr. John J. Bonica. It was his dream and conviction that a group of health care givers could solve pain problems better than those who would continue on as individual pain practitioners. A multidisciplinary pelvic pain team usually includes an anesthesiologist or pain medicine physician; a gynecologist; a neurologist; a psychologist; a pharmacologist; a physical therapist; and, many times, a dietitian. Medical therapy is built around a solid design that is individualized for the patient. Therapy may include medications, such as nonsteroidal antiinflammatory medications, narcotics, tricyclic antidepressants and g-aminobutyric acid–(GABA)ergics, local anesthetic nerve blocks, psychological therapy, and physical therapy regimens, as well as alternative medicine approaches.

In the final analysis, many patients relate their frustrations in regard to multiple single physician visits, laboratory studies, diagnostic studies, and surgical explorations. Most frustrating, above all, is that these attempts are made without a definitive diagnosis and without a substantial reduction in pain. Most patients confess they were at the end of their mental and physical tolerances; the last straw was the physician who told them “the pain is in your head.”

Support for such teams come from programs using cognitive behavioral therapy, acupuncture, and tricyclic antidepressants that were successful in pain reduction by 50% in up to 85% of the subjects (77,92). Other studies have suggested that similar results may be obtained with a multidisciplinary team (78,79,93,94 and 95). A prospective, randomized, controlled study that used the multidisciplinary approach in combination with traditional gynecologic treatment, psychological, dietary, and physical therapy input was found to be more effective than traditional gynecologic (medical and surgical) management (79).

CHAPTER 71

Pain of Childbirth

John S. McDonald

Childbirth pain management is one of the most valued aspects of the entire specialty of anesthesiology. It is most appreciated by the mother who, through the ages, has suffered from hours of painful, torturous labor only to be subjected to the final challenge of a painful delivery. Likewise, it is appreciated by the obstetric nurse staff, the obstetricians, and the neonatologists. The strong pain control movement in labor and delivery in this country has been an outstanding marker for the rest of the world and set an important *human caring* standard. There has been much to overcome in regard to false beliefs associated with the childbirth experience. For example, one false belief promoted by the *natural childbirth* proponents was that labor and vaginal delivery can and should be painless. Now, of course, it is known that labor and delivery are actually painful events for the majority of women. Another false belief in some societies is that labor pain itself has an important biological function and should not be relieved. More common is the false belief that any pharmacologic method of modern pain relief has deleterious effects on the mother and fetus because of depression of the brain and breathing.

Pain does have the important biological function of indicating the initiation of labor. This does not mean, however, that it should go on unbridled once it has served this function. In fact, persistent severe pain can have harmful effects on the mother as well as the fetus. It is true that improperly administered analgesia and anesthesia can cause serious complications. But modern research and training have been increasingly responsible for showing that properly administered anesthesia does not contribute to maternal and perinatal mortality and morbidity. The modern expectant parturient in this country now expects and demands high levels of obstetric anesthesiology that help her through the rigors of labor and delivery with both adequate pain relief and safety.

This chapter reviews modern methods of obstetric anesthesiology. The material is presented in two major sections. The first, Basic Considerations, includes a brief historic review and discusses the magnitude of parturition pain and the physiologic and psychological alterations produced by pregnancy and labor. It also discusses how all these are affected by pain and pain relief methods. The second, Clinical Considerations, includes a review of the basic principles of current pain management for controlling childbirth pain.

BASIC CONSIDERATIONS

Historic Notes

Childbirth and childbirth pain management have always been high-priority items for the lay public and medical specialists. Some authorities (1,2 and 3) have suggested that primitive women, like animals, experience no pain in labor or delivery. Contrary to this, all evidence points to the fact that women have suffered pain in childbirth for as long as humans have existed (4,5,6,7 and 8). It is unlikely that the process of labor and the pain associated with it have changed appreciably from even prehistoric times (9).

The earliest attempts to control pain in childbirth consisted of psychological, physical, and even pharmacologic methods, either by themselves or in combination. Unbelievably crude physical methods in the form of brute force were used. The tribal strongman or heavyweight sometimes resorted to jumping on the abdomen of the pregnant woman to hasten the delivery of the child (7). Other physical measures included having the parturient tied to or suspended from a tree, with her arms tied over her head or with ropes under her armpits (7,8). Our aboriginal forebears also used autosuggestion. Incantations, spells, and words of power were used by the woman in labor to put the pain demons to flight. These methods entailed the use of suggestion, distraction, and other psychological forms of relief. The Egyptians and Chinese used the concentrated form of suggestion, which today we call hypnosis. Ellis (10) suggested that possibly the first recorded instance of hypnotism occurred with the protoobstetric case found in Genesis 2:21: “And the Lord God caused a deep sleep to fall upon Adam, and he slept; and he took one of his ribs, and closed up the flesh instead thereof.”

After many centuries, peoples' idea of the cause of labor pain underwent a change. What had once been a sport of evil spirits became a punishment inflicted by an offended deity. This perhaps explained the prophetic curse in Genesis 3:16: “Unto the woman, I will multiply thy sorrow and thy conception; in sorrow thou shalt bring forth children.” When Christianity fully developed, pain became important as a means of obtaining grace, and the woman in labor was expected to accept pain voluntarily. The same affirmation of physical pain became embraced by Oriental cultures, as well as by the various Western religions.

Despite these teachings, attempts to find methods to relieve childbirth pain continued. Pharmacologic agents, in addition to psychological analgesia, began to be used. Herbal concoctions and extracts of poppy, mandrake, hemp, and henbane plants formed the mainstay of these agents (11,12). Alcohol in many different forms was also used as an analgesic in childbirth. In the Persian literature, wine is mentioned as the agent used for the abdominal delivery of Rustan, a semimythical hero (13). In the Middle Ages, wine, beer, brandy, and other alcoholic beverages were kept by the maternity bed for self-administration (14). These methods continued to be used until the advent of modern anesthesia, which was the famous first public demonstration of ether anesthesia for a surgical operation by William T. G. Morton on October 16, 1846 (15).

The Scottish obstetrician, Sir James Y. Simpson, is credited for the introduction of modern analgesia in obstetrics. He used ether for childbirth on January 19, 1847, and chloroform for childbirth on November 8, 1847 (16). The use of analgesia for childbirth aroused violent opposition from some physicians, the public, and particularly the clergy, who labeled Simpson a heretic, a blasphemer, and an agent of the devil. For support they cited the Biblical admonition, “In sorrow thou shalt bring forth children” (Genesis 3:16). In rebuttal, Simpson, who himself was an astute student of the Bible, cited the passage quoted previously (Genesis 2:21). Simpson further added “What God, Himself, did cannot be sinful” (16).

In 1853, the successful administration of chloroform analgesia to Queen Victoria for the birth of her eighth child, Prince Leopold, was a remarkable event. Her positive expression of pleasure with its effect is considered to be one of the most important milestones in the history of obstetric anesthesia. The analgesia was administered by Dr. John Snow, whose precocious concepts, painstaking research, and perspicuous writings did so much for the forward development of the field of anesthesia. He gave Queen Victoria 15- minim doses intermittently on a handkerchief and thus established the method of *chloroforme à la reine*. This event was not published in *The Lancet* until April 18, 1857, because of the opposition of Thomas Wakley, editor of *The Lancet* (17). It was published in the form of a report that Snow had safely administered chloroform to Queen Victoria for the delivery of a new princess, Beatrice. This announcement, late as it was, signaled a moral, medical, and even religious sanction for the alleviation of childbirth pain.

Despite this auspicious beginning, obstetric analgesia and anesthesia remained a field neglected by medicine and medical practitioners for the ensuing 12 decades. Fortunately, during the 1940s and 1950s, a few pioneers in anesthesia became interested in the issue and made Herculean efforts to promote development of this subspecialty. This came about as a result of these efforts and the following factors:

- The increasing number of in-hospital births
- The appreciation by obstetricians of obstetric anesthesia
- The increasing interest among women in obtaining labor pain relief

- The sanctioning of pain relief during childbirth by religious leaders

Fortunately, at the beginning of the twenty-first century many anesthesiologists are interested and involved in research and the teaching of obstetric anesthesia. It is fair to state that in the understanding and usage of the principles of safe obstetric analgesia and anesthesia, more has been accomplished in the past 30 years than in the previous 100 years.

Magnitude of the Problem

The perpetration of the false information about childbirth helped to set back and repress advances in obstetric anesthesiology for decades. This has been and continues to be a result of inadequate dissemination of information to the public about advances in knowledge and current therapeutic procedures. In the past, many proponents of natural childbirth compounded the problem by insisting that pain need not occur during normal labor and that when it occurs it is the product of modern cultural and environmental factors. The origin of this notion is not known, but Behan (18) was among the first to mention it, stating in 1914 that “like menstruation, childbirth naturally should be a painless process. It is only as culture advances that the labor becomes painful, for in women of primitive races pain is absent. Savages of a low degree of civilization are generally little troubled by parturiency.” Nineteen years later the same argument was put forth by Dick-Read (1), who for the next 25 years, traveled worldwide espousing this thesis, strongly condemning pharmacologic analgesia and encouraging the use of his method of natural childbirth (2). In 1950, in the former Union of Soviet Socialist Republics, Velvovski and associates (3) began to use the technique of *psychoprophylaxis*, which was a modification of the Dick-Read method. Prophylaxis was subsequently embraced by Lamaze (19) of France, who did much to popularize it in Europe and the western hemisphere.

The claim by these clinicians and their followers that childbirth among primitive peoples is painless has been disputed. Ford (4), who studied this and other problems of reproduction in 64 primitive societies, wrote that “the popular impression of childbirth in primitive society as painless and easy is definitely contradicted by our cases. As a matter of fact, it is often prolonged and painful.” After studying 80 primitive groups, Freedman and Ferguson (5) reported that the pain response in these groups during childbirth was similar to that observed in American and European parturients. Similar views have been expressed by others who studied the problem of labor pain in primitive societies (6,7). Bonica (*unpublished data*, 1965) observed more than 24 parturients from primitive societies in Australia and Africa, most of whom manifested severe pain behavior. Finally, mention of the prevalence of pain during childbirth and its importance is found in the writings of the ancient Babylonians, Egyptians, Chinese, Hebrews, Greeks, and in the writings of many subsequent cultures and civilizations (20).

Incidence and Intensity of Labor Pain

Although it is a common observation in obstetrics that parturients vary in the amount of suffering associated with labor and vaginal delivery, few well-designed studies on the prevalence, intensity, and quality of labor pain have been performed.

Lundh (21) published a survey of several Swedish investigations, which included both primiparas and multiparas; these revealed that the incidence of intolerable severe pain ranged from 35% to 58%, with the remainder having moderate pain. Bundsen (22) found that 77% of primiparas reported that their pain during childbirth was severe or intolerable. Nettelbladt and colleagues (23) found that 35% reported intolerable pain, 37% had severe pain, and 28% had moderate pain during labor and delivery. Records on 2,700 parturients observed (and many interviewed) by Bonica while visiting or working (demonstrating obstetric anesthetic techniques) in 121 obstetric centers (with some having 100 to 150 deliveries daily) in 35 countries on six continents indicated that the frequency and intensity of labor pain were as follows: 15% had little or no pain, 35% had moderate pain, 30% had severe pain, and 20% had extremely severe pain. The data are similar to those noted among over 8,000 American parturients to whom Bonica administered or supervised anesthetic care during the past 40 years (Bonica, *unpublished data*, 1969) (24,25).

Obviously, the drawbacks of these surveys and observations were that they were based on simple numeric or verbal descriptions of pain and thus lack quantification. One of the first attempts to quantify the intensity of labor pain was made by Javert and Hardy (26), who used the Hardy-Wolff-Goodell dolorimeter to induce experimental pain and asked the parturients to compare it to the pain of their labor. The method entails the application of thermal heat, measured in millicalories (mc), to 3.5 cm^2 of skin for 3 seconds. The stimulus is increased in intensity stepwise until perceptible pain (pain threshold) and eventually the greatest perceivable pain (ceiling or maximum pain) are induced. They used a pain scale that ranged from 1 dol (pain unit), assigned to pain threshold, to 12.5 dol, denoting maximum pain, which was produced by a stimulus of sufficient intensity to produce a third-degree burn. Javert and Hardy (26) studied 26 primiparas and 6 multiparas during the course of normal labor and delivery and found (a) the intensity of pain in the early part (latent phase) of the first stage was 2 to 3 dol; (b) an increase to 3 to 4 dol at approximately 4-cm cervical dilatation; (c) an increase to 5 to 7 dol at 6 to 8 cm; (d) an increase to 8 to 9 dol at full dilatation; and (e) an increase to 9.0 to 10.5 dol as the head dilated and stretched the perineum.

Melzack and associates (27,28) used the McGill Pain Questionnaire to measure pain during labor and delivery in 87 primiparas and 54 multiparas. They found that the mean total pain rating index (PRI) was 34 for primiparas and 30 for multiparas, thus confirming the widely held view that labor is significantly more painful for the first birth than for later births. Significant differences were also found between primiparas and multiparas for each of the four classes of words describing their pain. The sensory qualities of the pain were described as sharp, cramping, aching, throbbing, stabbing, hot, shooting, or heavy; the affective qualities were described as tiring by half and exhausting by more than a third. Subsequently, Melzack (27) compared the mean total PRI scores for several pain syndromes obtained in an earlier study (28) with those of labor and noted that the scores for labor pain were some 8 to 10 points higher than those associated with back pain, cancer pain, phantom limb pain, or postherpetic neuralgia (Fig. 71-1A). As might be expected, although the average intensity of labor pain was extremely high, a wide range in pain scores was observed, which Melzack (27) divided into six groups within the range of the PRI scores recorded (ranging from 2 to 62) (Fig. 71-1B).

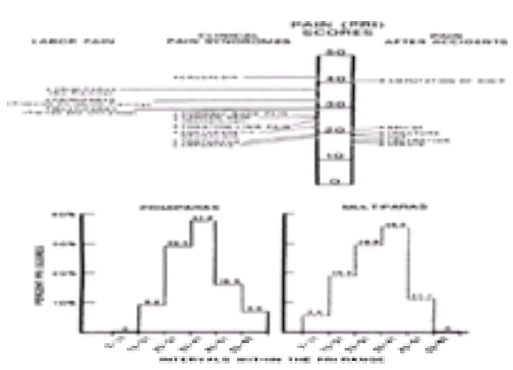

Figure 71-1. **A:** Comparison of pain scores using the McGill Pain Questionnaire obtained from women during labor and from patients in general hospital clinics and an emergency department. The pain rating index (PRI) represents the sum of the rank values for all words chosen from 20 sets of pain descriptions. **B:** Distribution of PRI scores for primiparas and multiparas in six intervals of the total PRI range. [Reprinted from Melzack R. The myth of painless childbirth (the John J. Bonica Lecture). *Pain* 1984;191:321–337, with permission.]

Assigning verbal descriptors of pain intensity to these data suggests that approximately 10% of primiparas and approximately 24% of multiparas experienced mild to moderate pain, approximately 30% of both groups rated their pain as severe, approximately 38% of primiparas and 35% of multiparas felt very severe pain, and 23% of primiparas and 11% of multiparas experienced horrible or excruciating pain. The mean PRI score of 61 primiparas who received prepared childbirth training was 33; and, for the 26 primiparas who received no training, the mean PRI score was 37. On the other hand, no significant difference was noted in any of the PRI measures of the 30 multiparas who had received training and 24 who received no training. Of the 28 parturients who were given successful epidural analgesia, the PRI score decreased from a mean of 28 before the block to a mean of 8.0 and 7.6 at 30 and 60 minutes, respectively, after induction of analgesia. These scores were based on the use of such words as numbness, pressing, and tingling.

Physiologic Alterations during Pregnancy and Labor

To provide optimal pain relief to the parturient using current techniques, it is essential for the anesthesiologist to have (a) a thorough understanding of the maternal physiologic alterations produced by pregnancy, labor, and parturition; (b) a thorough understanding of the physiology and pharmacology of the fetal-placental complex; (c) a thorough understanding of the forces of labor; and (d) a thorough understanding of how these are altered by the administration of analgesics and

anesthetics.

From the viewpoint of anesthetic care, the changes in the mother involving circulation; respiration; acid–base and electrolyte balance; and gastrointestinal, renal, and hepatic functions are the most important. These changes, produced by placental hormones, by the mechanical effects of the growing uterus, or by both, occur because of the increasing metabolic needs of the maternal-fetal- placental complex (9). They also prepare the gravida for the stresses of parturition and for the subsequent occlusion of the placental circulation.

Circulatory Alterations

Antepartum Hematologic Changes. Beginning at 6 to 8 weeks of pregnancy, the total blood, plasma, and red cell volumes progressively increase, reaching a maximum at 28 to 32 weeks and thereafter remaining constant until parturition (Fig. 71-2). This hypervolemia of pregnancy is accommodated by enlargement of the uterus and breasts and by increased blood flow to the kidneys, skeletal muscles, and skin and parallels the increased cardiac output and ventilation. These changes facilitate the maternal-fetal exchange of blood gases, nutrients, and metabolites and enable the gravida to tolerate blood loss during parturition, which is 300 to 500 mL with vaginal delivery and 600 to 1,000 mL with cesarean section (20,29). The increase in plasma volume (50%) is greater than the increase in red cell mass (30%), resulting in hemodilution and a consequent decrease in red cell count, hemoglobin, and hematocrit, the so-called physiologic anemia of pregnancy.

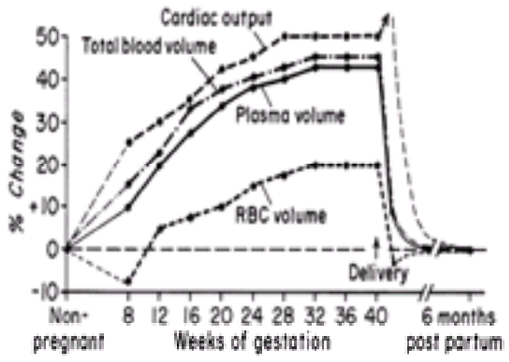

Figure 71-2. Changes in blood volume, plasma volume, red cell volume, and cardiac output during pregnancy and in the puerperium. The curves were constructed from data in the literature and illustrate trends in terms of percentage change rather than in absolute values. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:2, with permission.)

Antepartum Hemodynamic Changes. Figure 71-3 depicts the changes in heart rate and stroke volume and consequently in cardiac output. These three variables differ markedly in the lateral and supine positions, especially during the last trimester, when the enlarged uterus compresses the inferior vena cava and other veins at the pelvic brim. This vein-compressing effect is greatest in the supine position, significantly less in the lateral position, and least in the knee-chest position. Figure 71-4 depicts the effect of the compression by the gravid uterus on the inferior vena cava and the aorta in the supine and lateral positions.

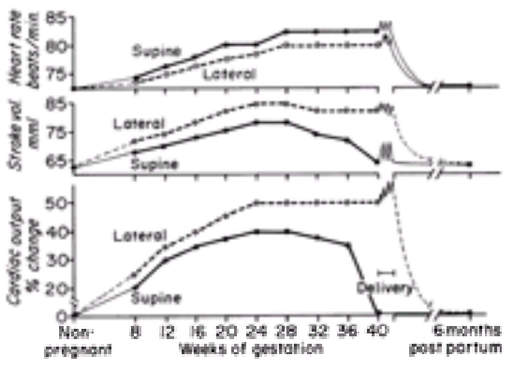

Figure 71-3. Changes in heart rate, stroke volume, and cardiac output during pregnancy and in the puerperium. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:5, with permission.)

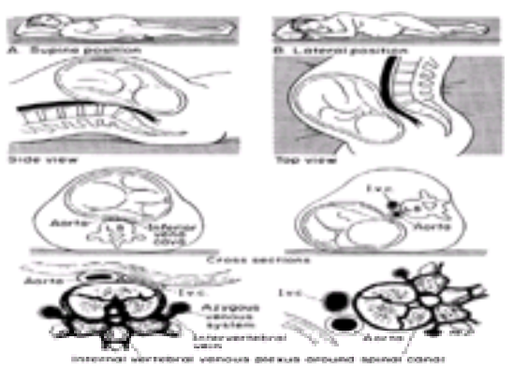

Figure 71-4. Effects of the pregnant uterus on the inferior vena cava and the aorta in the supine position (*left*) and lateral position (*right*) The marked aortocaval compression in the supine position causes venous blood to be diverted to and through vertebral venous plexus, which becomes engorged and thus reduces the size of the epidural and subarachnoid spaces. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:8, with permission.)

The obstruction of the inferior vena cava reduces the venous return to the heart and thus reduces cardiac output. This effect is offset by two compensatory mechanisms: (a) an increase in sympathetic tone with generalized vasoconstriction, and an increase in total peripheral resistance and heart rate; and (b) diversion of some of the blood coming back to the heart from the lower one-half of the body by a detour through the internal vertebral venous plexus. Consequently, in 90% of gravidas, these compensatory mechanisms are sufficiently effective to maintain arterial blood pressure at near normal levels. However, in the remaining 10% the obstruction is so great and the amount of blood returned to the heart and the consequent cardiac output are so low that, despite the intense vasoconstriction and tachycardia, blood pressure falls sufficiently to cause supine hypotensive syndrome (30,31).

Figure 71-5 depicts the changes in arterial blood pressure, venous pressure, and total peripheral resistance during pregnancy. The latter is reduced some 20% (32,33).

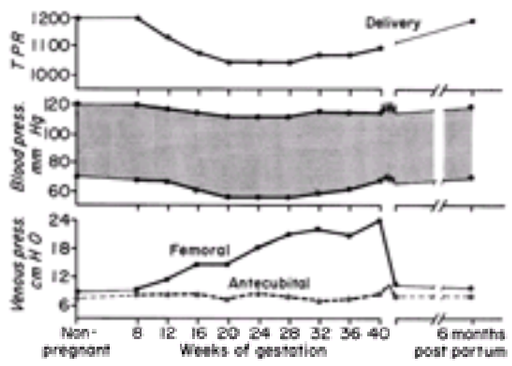

Figure 71-5. Changes in total peripheral resistance (TPR) (*top*), systolic and diastolic blood pressures (*middle*), and venous pressure (*bottom*). Pressure in the antecubital vein remains normal but pressure in the femoral vein steadily increases because of the progressive compression of the inferior vena cava by the gravid uterus. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:5, with permission.)

Parturition Hemodynamic Changes

Cardiac Output. During labor cardiac output increases above prelabor levels (Fig. 71-6). Between contractions, cardiac output during the early first stage is approximately 15% above that of prelabor, during the late first stage it is approximately 30%, during the second stage approximately 45%, immediately after delivery approximately 65%, and 1 hour after delivery it is 30% to 50% above prelabor levels (31,32 and 33). With each uterine contraction the uterus is raised by action of the uterine ligaments, and 250 to 300 mL of blood is also squeezed out of the uterus into the central circulation. Moreover, increased venous return from the pelvis and lower limbs is made possible by a decrease in the degree of obstruction as the uterus is lifted away from the spinal column (34). Consequently, stroke volume, cardiac output, and left ventricular work increase (34,35 and 36). Each contraction consistently increases cardiac output 15% to 25% above that between the contractions.

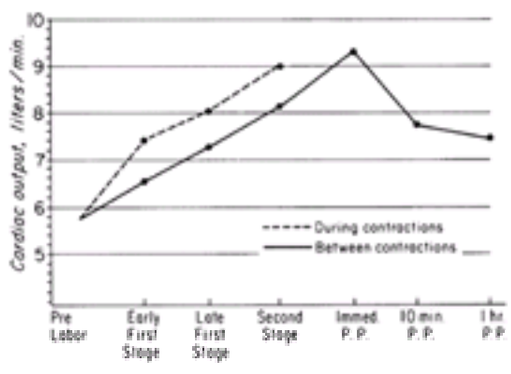

Figure 71-6. Cardiac output during various phases of labor, between contractions, and during contractions. The cardiac output progressively increases between contractions and increases 15% to 20% more during contractions. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:6, with permission.)

Blood Pressure. Figure 71-7 depicts the changes in arterial blood pressure caused by uterine contractions. The magnitude of these changes varies and depends on the intensity of the contraction and the position of the parturient, with these parameters being greater in the supine than in the lateral position. As emphasized later, pain, anxiety, and apprehension produce a significant further increase because of the release of catecholamines. During the second stage the bearing-down efforts often alter blood pressure in a way similar to that produced by the Valsalva's maneuver (34). The changes in venous pressure are rapidly transmitted to the internal vertebral venous plexus and thus cause a transient rise in the epidural and cerebrospinal fluid pressures, which have some influence on the spread of local anesthetic injection into these spaces (37).

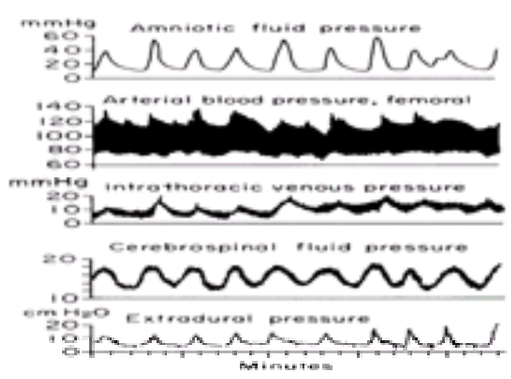

Figure 71-7. Hemodynamic effects of uterine contractions. The increases in arterial blood pressure and central venous pressure are reflected in cerebrospinal fluid and epidural pressures. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:7, with permission.)

During labor, the compression of the large veins is exaggerated by uterine contractions. As the uterus tenses and hardens and increases its pressure on the major veins and arteries across the pelvic brim, often the mother's circulation apparently improves, but with a hidden deterioration of the placental blood pressure. Each contraction tips the uterus around a fulcrum formed by the lumbosacral vertebral prominence, and aortic compression is increased, leading to a hyperdynamic circulation above the compression but a further deterioration below it. Consequently, the maternal cardiac output increases sharply, accompanied by a hypertensive rise of blood pressure above the obstruction but a marked decrease below it.

Clinical Implications. These changes in blood volume and hemodynamics produced by pregnancy, parturition, and puerperium are of significant relevance to anesthetic care. Whereas the increase in cardiac workload is tolerated by healthy gravidas, the increase in the work of the heart in those with heart disease and consequent low myocardial reserve can constitute too great a strain and can precipitate pulmonary congestion. In such patients it is especially important to obviate any further increase in the work of the heart caused by pain during labor by providing effective analgesia, preferably with regional techniques. Moreover, the engorgement of the epidural space reduces its size and therefore less local anesthetic is needed to achieve epidural analgesia. Fluctuations in the cerebrospinal fluid pressure can also influence the extent of subarachnoid block. Finally, and most important, postural hemodynamic changes make it mandatory for gravidas to avoid the supine position during the latter phases of pregnancy and during labor. Because the induction of spinal or epidural anesthesia or other procedures that entail vasomotor blockade deprive gravidas of a compensatory vasoconstriction, they are likely to incur much greater decreases in arterial blood pressure than nonpregnant women. Unless prophylactic measures are carried out, such severe hypotension can develop that the lives of the mother and fetus are threatened (38,39 and 40).

Changes in Respiration

Pregnancy produces impressive anatomic and physiologic changes involving the airway, lung volumes, ventilation, and dynamics of breathing. In most gravidas, capillary engorgement takes place throughout the respiratory tract and the growing uterus causes the diaphragm to rise 4 cm. This rise is counterbalanced by an

increase of 2 cm in the anteroposterior and transverse diameters of the thoracic cage and flaring of the ribs, producing a 5- to 7-cm increase in the circumference of the thoracic cage.

Lung Volumes. Lung volumes begin to change during the fifth month of gestation, with a consequent progressive decrease in expiratory reserve volume (ERV), residual volume (RV), and functional residual capacity (41) (Fig. 71-8). The reduction in functional residual capacity is sufficient to cause some degree of airway closure in 50% of parturients at term during normal tidal ventilation (42). Obesity, recumbency, and the lithotomy position aggravate this effect further. This can result in lowered ventilation- perfusion ratios in the dependent portions of the lung and might account for the lowered arterial oxygen pressure seen in some parturients at term.

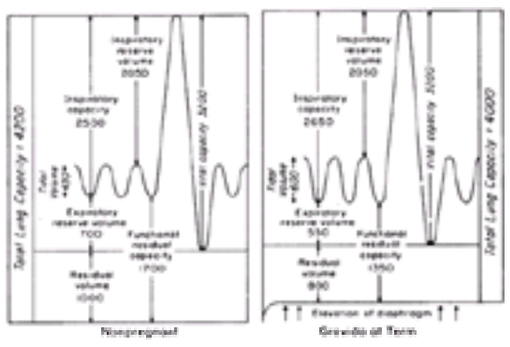

Figure 71-8. Pulmonary volumes and capacity in the nonpregnant state **(A)** and in the gravida at term **(B)**. The changes in the functional residual capacity, expiratory reserve volume, and residual volume begin after the fifth month of pregnancy and increase progressively until term. (Reprinted from Bonica JJ. *Principles and practice of obstetric analgesia and anesthesia*. Vol 1. Philadelphia: FA Davis, 1967:24, with permission.)

Ventilation

Antepartum Changes. Ventilation increases significantly during pregnancy (Fig. 71-9). The changes in lung volumes and ventilation lead to a reduction of arterial and alveolar carbon dioxide pressure, which averages 32 mm Hg at term, and an increase in the oxygen tension to approximately 105 mm Hg. These are accompanied by a decrease in arterial oxygen pressure and by changes in other acid–base parameters (see Acid–Base Balance, later in this chapter).

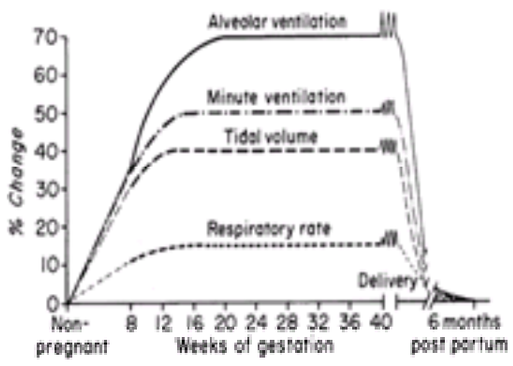

Figure 71-9. Changes in ventilatory parameters during pregnancy. Almost maximum hyperventilation occurs as early as the second or third month of gestation. Because the respiratory rate increases to a much lesser extent than tidal volume and dead space remains normal, the percentage increase in alveolar ventilation is greater than the percentage increase in minute ventilation. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:17, with permission.)

Parturition Changes. Ventilation is further increased by the pain of labor, anxiety, and apprehension or voluntarily in patients trained in natural childbirth. The magnitude of hyperventilation varies greatly, with respiratory rates as high as 60 to 70 per minute and tidal volumes of up to 2,250 mL, and maximum peak inspiratory flow rates of up to 340 L per minute have been reported (43,44). The effects of labor pain on ventilation as well as on circulation are discussed in more detail later in this chapter.

Clinical Implications. These changes in ventilation also have important clinical implications. The anatomic changes are conducive to respiratory obstruction of the nasal passages, to an increased hazard of tracheal intubation, and to misinterpretation of physical findings. Changes in lung volumes and ventilation increase the efficiency of gaseous transfer between maternal blood and the alveolar air so that the carbon dioxide tension is decreased and that of oxygen is increased. Such changes, in turn, enhance the transfer of these gases between the mother and the fetus. On the other hand, these changes make gravidas more susceptible to the effects of more rapid changes in respiratory blood gas levels during respiratory complications than nonpregnant women. Hypoventilation, breath holding, or respiratory obstruction produces hypoxia, hypercapnia, and respiratory acidosis more readily in the gravidas than in nonpregnant women. Conversely, moderate to severe hyperventilation achieved spontaneously by awake gravidas or produced by the anesthesiologist with excessive positive pressure ventilation during general anesthesia can quickly lead to severe respiratory alkalosis. The respiratory alkalosis is associated with a decrease in cerebral blood flow, and possible decreased uterine blood flow, and a shift of the maternal oxygen dissociation curve to the left. Prolonged acute hypocarbia also results in diminished bicarbonate and buffer base levels that contribute to the development of metabolic acidosis during painful labor (45,46).

Other Physiologic Changes

Acid–Base Balance. The acid–base balance changes during pregnancy and labor. The total base level decreases from the normal nonpregnant level of approximately 155 to approximately 148 mEq per L, with a corresponding decrease in potassium, calcium, and magnesium concentrations. The plasma bicarbonate level decreases from an average of 25 to 21 mEq per L (Fig. 71-10). The plasma buffer base concentration, which refers to the total buffer available and includes bicarbonate, protein, and hemoglobin, decreases from a normal adult mean level of 47 to 42 mEq per L and base excess decreases to 3.0 mEq per L. In normal gravidas the pH of the blood remains at 7.4, suggesting that normal pregnant women have a compensatory alkali deficit.

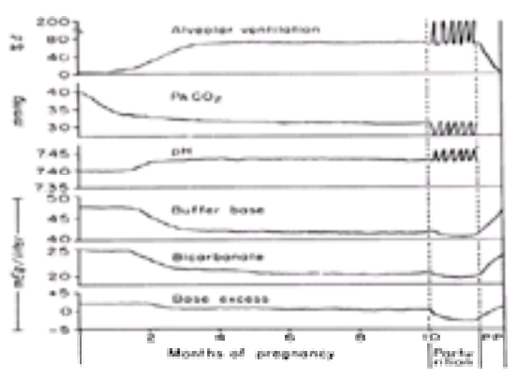

Figure 71-10. Changes in alveolar ventilation, arterial carbon dioxide pressure, pH, and acid–base concentrations during pregnancy, parturition, and postpartum. With

the nearly 80% increase in alveolar ventilation the Paco $_2$ decreases to levels of 32 mm Hg at term, with concomitant changes in the acid–base balance. During parturition further changes occur, especially during uterine contractions, which increase ventilation and decrease the Paco $_2$. All these variables return to normal 1 to 3 weeks after delivery. (Reprinted from Bonica JJ. Maternal respiratory changes during pregnancy and parturition. In: Marx GF, ed. *Parturition and perinatology*. Clinical anesthesia series. Vol 10, No. 2. Philadelphia: FA Davis, 1973:9, with permission.)

Gastrointestinal Function. During pregnancy the stomach and intestines are progressively displaced cephalad by the enlarging uterus, with consequent increases in intraabdominal and intragastric pressures. Together with a decreased gastric emptying time and increased gastric acidity, the tendency to esophageal reflux is increased (20).

Renal and Hepatic Function. During pregnancy the muscular tone and rhythmicity of the urinary tract decrease. This results in an increase in urinary tract dead space and a progressive increase in the glomerular filtration rate that affects the renal plasma flow, filtration fraction, and tubular reabsorption. These changes cause a decrease in the urea nitrogen concentration. Several liver function tests show abnormal values during normal pregnancy, but nonetheless the liver functions without difficulty.

Metabolic Rate and Oxygen Consumption. During pregnancy the basal metabolic rate and oxygen consumption progressively increase; at term their values are 20% above normal. In addition, water, protein, and minerals are retained and stored, along with retention of salts and the acquisition of fat. During parturition the metabolism and oxygen consumption increase further to satisfy the increased requirements of the uterus and, during the second stage of labor, to meet additional needs consequent to the bearing- down efforts. Parturients who have inadequate pain relief have greater oxygen consumption than those who have complete pain relief. Most of the former develop a progressive metabolic acidosis and a steady rise in the free fatty acid level, as well as showing other endocrine responses to pain.

Effects of the Pain of Childbirth

Labor and vaginal delivery produce tissue damage and, like tissue injury from other causes, result in pain and local segmental, suprasegmental, and cortical responses (see Chapter 9). These responses include marked stimulation of respiration, circulation, hypothalamic autonomic centers of neuroendocrine function, limbic structures, and psychodynamic mechanisms of anxiety and apprehension, resulting in what has come to be known as the *stress response* to injury. As a result, the parturient incurs marked increases in respiration, circulation, and metabolism, and other body functions are altered (Fig. 71-11,Fig. 71-12 and Fig. 71-13). These maternal changes can have a deleterious impact on the fetus and newborn. Pain and reflex responses have a predominant role in these alterations of maternal function, because blockade of the nociceptive pathways by regional analgesia with a local anesthetic greatly diminishes or eliminates them. We now summarize the impact of the pain of childbirth on the mother, uterus, and fetus and newborn, and then present data on the effects of analgesia and sedation on these changes.

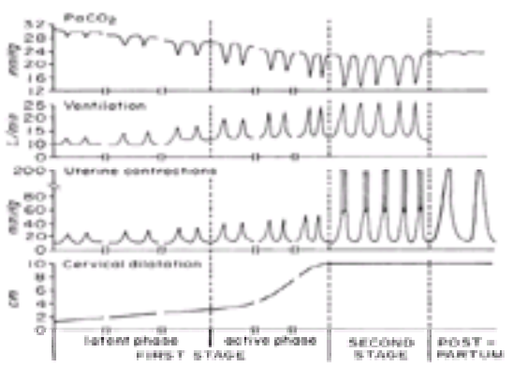

Figure 71-11. Schematic representation of ventilatory changes during labor in an unpremedicated gravida. Note the correlation of the stages of labor as reflected by the Friedman's curve (*bottom tracing*), the frequency and intensity of uterine contractions, minute ventilation, and arterial carbon dioxide tension (*top tracing*). Early in labor uterine contractions are slight and are associated with mild pain, causing only small increases in minute ventilation and decreases in the Paco $_2$. As labor progresses, however, the greater intensity of contractions causes greater changes in ventilation and Paco $_2$. During the active phase, contractions with an increased intrauterine pressure of 40 to 60 mm Hg cause severe pain, which acts as an intense stimulus to ventilation with a consequent reduction of the Paco $_2$ to 18 to 20 mm Hg. During the second stage the reflex bearing-down efforts further increase intrauterine pressure and distend the perineum, producing consequent additional pain that prompts the parturient to ventilate at a rate almost twice that of early labor and causing a commensurate reduction in the Paco $_2$. (Modified from Bonica JJ. Maternal respiratory changes during pregnancy and parturition. In: Marx GF, ed. *Parturition and perinatology*. Clinical anesthesia series. Vol 10, No. 2. Philadelphia: FA Davis, 1973.)

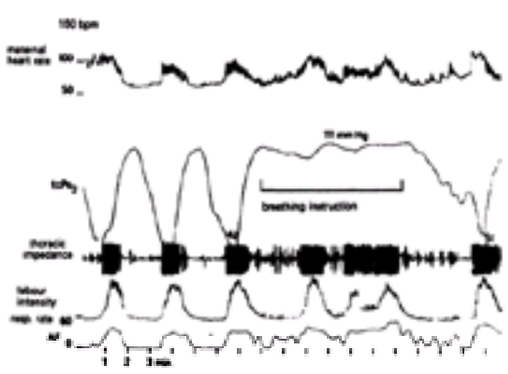

Figure 71-12. Continuous recording of maternal heart rate, transcutaneous (tc)Po $_2$ thoracic impedance, uterine pressure (labor intensity), and respiratory rate after the parturient was given 100 mg of meperidine intramuscularly. With each uterine contraction marked hyperventilation caused the tcPo $_2$ to increase to 110 mm Hg but then to fall to low levels as a result of the marked respiratory alkalosis and of the respiratory depressant effect of the meperidine. The large decreases in tcPo $_2$ were avoided by giving the parturient breathing instructions during the relaxation period. (Reprinted from Peabody JL. Transcutaneous oxygen measurement to evaluate drug effect. *Clin Perinatol* 1979;6:109–121, with permission.)

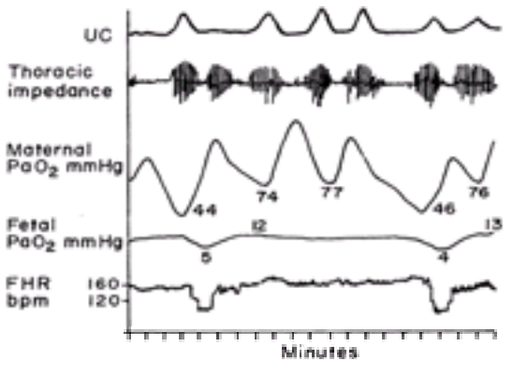

Figure 71-13. Continuous recording of uterine contractions (UC), maternal thoracic impedance, maternal transcutaneous oxygen tension (Pao $_2$), fetal oxygen tension,

and fetal heart rate (FHR) in a primipara 120 minutes before spontaneous delivery of an infant with an Apgar of 7. Marked hyperventilation during uterine contractions was followed by hypoventilation or apnea between contractions. With the parturient breathing air during and after the first and fourth periods of hyperventilation, the maternal Pao_2 fell to 44 and 46 mm Hg, with a consequent decrease in fetal Pao_2 and variable decelerations, which reflected fetal hypoxia. [Modified from Huch A, Huch R, Schneider H, Rooth G. Continuous transcutaneous monitoring of foetal oxygen tension during labour. *Br J Obstet Gynecol* 1977;84(Suppl 1):1–39.]

Changes in Ventilation. The pain of childbirth is a powerful respiratory stimulus, causing marked increases in tidal volume and minute ventilation. In a study by Bonica and Caldeyro-Barcia of a group of unpremedicated, unprepared primiparas, the minute ventilation increased from a normal mean of approximately 10 L per minute between contractions to a mean of 23 L per minute to 35 L per minute during contractions (44). Consequent to the hyperventilation was a fall of the arterial carbon dioxide pressure ($Paco_2$) from a normal pregnant level of 32 mm Hg to a value of 16 to 20 mm Hg, with some as low as 10 to 15 mm Hg, and a concomitant increase in pH to 7.55 to 7.60 (see Fig. 71-11). Hyperventilation consequent to the pain of uterine contraction has also been reported by Brownridge (47), Peabody (41), and Roemer and Vogel (48).

Endocrine Effects. Animal studies have shown that acute pain caused by noxious stimulation produces a significant (20% to 40%) increase in catecholamine levels, particularly norepinephrine (NE), with a consequent 35% to 70% decrease in uterine blood flow (49,50) (Fig. 71-14). Human studies have shown that severe pain and anxiety during active labor cause a 300% to 600% increase in the epinephrine level, a 200% to 400% increase in the NE level, a 200% to 300% increase in the cortisol level, and significant increases in corticosteroid and adrenocorticotropic hormone levels during the course of labor; these reach peak values at or after delivery (51,52,53 and 54). Lederman and associates (52,53) noted that, during the period of active labor, the epinephrine level increased by nearly 300%, the NE level by 150%, and the cortisol level by 200%. They noted that the higher epinephrine levels were significantly associated with uterine contractile activity at the onset of active labor (3-cm cervical dilatation) and with longer labor during the active phase (3- to 10-cm cervical dilatation). Increased epinephrine and cortisol levels were correlated significantly with anxiety and pain.

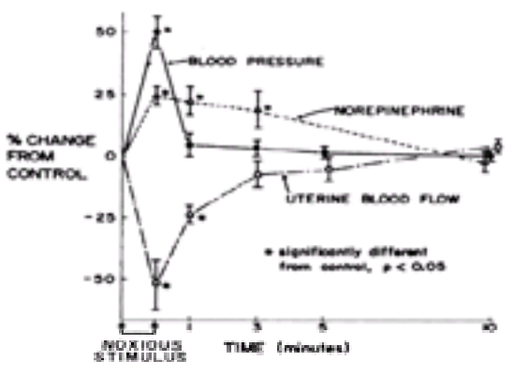

Figure 71-14. Effects of noxious stimulus on maternal arterial blood pressure, norepinephrine blood level, and uterine blood flow. The stress was induced by application of an electric current onto the skin of an ewe at term. The increase in arterial pressure is transient but the decay in norepinephrine level is more protracted and is reflected by a mirror image decrease in uterine blood flow. (Reprinted from Shnider SM, Wright RG, Levinson G, et al. Uterine blood flow and plasma norepinephrine changes during maternal stress in the pregnant ewe. *Anesthesiology* 1979;50:524–527, with permission.)

In a later study, Ohno and associates (55) carried out a comprehensive study of catecholamines and cyclic nucleotides during labor and following delivery and noted a nearly twofold increase in the dopamine level, a threefold increase in the epinephrine level, and a twofold increase in the NE as well as a small increase in the cyclic adenosine monophosphate level. They noted a positive correlation between epinephrine on the one hand and heart rate and systolic blood pressure on the other, as well as a correlation between NE and cyclic adenosine monophosphate during labor. The greater increase in epinephrine than in NE was contrasted with the findings of a previous study, which showed that NE was much greater than epinephrine during physical exercise. This led to the conclusion that elevated sympathoadrenal activity during labor is a result of pain and anxiety rather than of physical effort. Other data, however, show that although pain is a major factor in the elevation of catecholamine levels, physical effort during the second stage does contribute to the increase in catecholamine levels.

Other studies have demonstrated a progressive increase in plasma b-endorphin, b-lipotropin, and adrenocorticotropic hormone levels, all of which are derived from a common precursor (56,57,58,59,60 and 61). These values have been found to peak at delivery or in the immediate postpartum period at 4 to 10 times the prelabor and nonpregnant values. These findings have led to the speculation that plasma b-endorphin might have an intrinsic analgesic role during parturition (62). Against this is the fact that plasma b-endorphin levels that are considerably higher than those observed in these studies do not appear to cross the blood–brain barrier or have analgesic effects in humans (63). In addition, no change in pain threshold has been demonstrated in parturients (64).

Cardiovascular Changes. During labor, the progressive increase in cardiac output is 40% to 50% higher than the prelabor value during the late first and second stages. Some parturients have an increase of nearly 100% with a further increase of 20% to 30% during each painful uterine contraction. Available data suggest that 40% to 50% of the increase during the contraction is caused by the extrusion of 250 to 300 mL of blood from the uterus and by increased venous return from the pelvis and lower limbs into the maternal central circulation. The rest is caused by an increase in sympathetic activity provoked by pain, anxiety, apprehension, and the physical effort of labor, which contribute to the progressive rise in cardiac output as labor advances (34,35). Uterine contractions in the absence of analgesia also cause increases of 20 to 30 mm Hg in the systolic and diastolic blood pressures. The increases in cardiac output and systolic blood pressure lead to a significant increase in left ventricular work that is tolerated by healthy parturients, but can prove deleterious if the parturients have heart disease, pregnancy-induced hypertension (preeclampsia), essential hypertension, pulmonary hypertension, or severe anemia.

Metabolic and Other Effects. During the first and second stages of labor-free fatty acids and lactate levels increase significantly, apparently as a result of the pain-induced release of catecholamines and the consequent sympathetic-induced lipolytic metabolism (65). This assumption is based on the fact that, with complete blockade of nociceptive (afferent) and efferent pathways achieved with epidural or other forms of regional analgesia, only slight increases in maternal free fatty acid and lactate levels and acidosis are seen. During the second stage of labor maternal acidosis is a result of the pain and physical exertion inherent in the active bearing-down (pushing) effort during contractions.

Increased sympathetic activity caused by labor pain and anxiety also increases metabolism and oxygen consumption and decreases gastrointestinal and urinary bladder motility. The increased oxygen consumption, plus that inherent in the work of labor, together with the loss of bicarbonate from the kidney as compensation for the pain-induced respiratory alkalosis and often reduced carbohydrate intake, produce a progressive metabolic acidosis that is transferred to the fetus. The maternal pyruvate level increases, along with an even greater increase in the lactate level and a progressive accumulation of excess lactate, which is reflected by a progressive increase in base excess (45,46,66).

The pain of labor also affects the function of the gastrointestinal tract. Gastrin release is stimulated during painful labor and results in an increase in gastric acid secretion (67). Moreover, the pain and associated anxiety and emotional stress produce segmental and suprasegmental reflex inhibition of gastrointestinal motility and function, and consequently a significant delay in gastric emptying. These reflex effects of nociception are aggravated by the recumbent position and by the use of opioids and other depressant drugs (9,20,68,69). The combined effect of pain and depressant drugs can cause food and fluids other than water to be retained for as long as 36 hours or more. During this period of time swallowed air and gastric juices accumulate progressively, with the pH of the stomach contents decreasing below the critical value of 2.5 in most parturients. These two events, plus the delayed gastric emptying of acidic gastric contents, increases the risk of regurgitation and pulmonary aspiration during the induction of general anesthesia.

Psychological Effects. Severe labor pain can produce serious long-term emotional disturbances that might impair the parturient's mental health, negatively influence her relationship with her baby during the first few crucial days, and cause fears of future pregnancies that could affect her sexual relationship with her husband (23,24,70,71,72 and 73). Kartchner (70), Rogers (71), Melzack (27), and others (72,73) reported a significant number of women who had participated in natural childbirth developed or had aggravation of prelabor depression and other deleterious emotional reactions in the postpartum period, consequent to the pain

experienced during their childbirth without analgesia. Cheetham and Rzadkowolski (72) reported that nearly two-thirds of parturients experienced some type of emotional upset characterized predominantly by a decrease in mental acuity and in social interests, and an increase in their feelings of dysphoria, depression, and anxiety. They pointed out that psychological aspects of labor are accentuated by the well-cited triad of fear, tension, and pain, which might in turn decrease uterine activity and thus prolong labor. In addition, Melzack (27) noted that some women might experience an added burden of guilt, anger, and failure when they anticipate natural, painless childbirth and are then confronted with such severe pain that they require epidural analgesia. Stewart (73) reported that some women who failed to achieve painless childbirth and experienced such severe pain as to require epidural analgesia subsequently became miserable, depressed, and even suicidal, and lost interest in sex. In some cases, the husbands of women who anticipated natural childbirth had to undergo psychotherapy for serious reactions after seeing their wives experience such severe pain that they developed feelings of guilt and subsequent impotence and phobias.

Effects on Uterine Activity and Labor. Through increased secretion of catecholamines and cortisol, pain and emotional stress can either increase or decrease uterine contractility and thus influence the duration of labor. NE increases uterine activity, whereas epinephrine and cortisol decrease it (9,53). Morishima and colleagues (49,74) reported that, in pregnant baboons and Rhesus monkeys, nociceptive stimulation increased uterine activity about 60% to 65% and was associated with a decrease in fetal heart rate and oxygenation. In contrast, severe pain and anxiety in some parturients caused such an increase in epinephrine and cortisol levels that uterine activity was consequently decreased and labor was prolonged (52,53). In a small number of parturients, pain and anxiety produce *incoordinate uterine contractions* manifested by a decrease in intensity coupled with an increase in frequency and uterine tonus (75).

Effects on the Fetus. During labor the intermittent reduction of intervillous blood flow during the peak of a contraction leads to a temporary decrease in placental gas exchange. This impairment is often further increased by pain-induced severe hyperventilation, which causes severe respiratory alkalosis and results in the following: (a) a shift (to the left) in the maternal oxygen dissociation curve, which diminishes the transfer of oxygen from mother to fetus; (b) maternal hypoxemia during uterine relaxation; (c) umbilical vasoconstriction with a consequent decrease in umbilical blood flow (76); and (d) a reduction in uterine blood flow, which is provoked by an increase in NE and cortisol release (see Fig. 71-14).

These deleterious effects on the fetus have been demonstrated in several species of animals and in humans (49,53,74,75). Figure 71-13 depicts the deleterious effects on fetal heart rate that are caused by marked hyperventilation during a contraction and by hypoventilation between contractions. Lederman (53) also noted that parturients who were anxious and had pain had a higher incidence of abnormal fetal heart rate patterns, and that their infants had lower 1- and 5-minute Apgar scores.

Under the conditions of normal labor, such series of transient and intermittent impairments of blood gas exchange are tolerated by the normal fetus because oxygen is stored in the fetal circulation and intervillous space and is sufficient to maintain adequate fetal oxygenation during the brief period of placental hypoperfusion. Moreover, the fetus can compensate by increasing the proportion of cardiac output that is distributed to the myocardium and brain (77,78). If the previously mentioned factors are combined with an excessive increase in uterine activity, however, fetal hypoxia, hypercapnia, and acidosis develop that might still be tolerated by the normal fetus, although its ability to withstand oxygen deprivation is limited. If the fetus is already at risk because of obstetric or maternal complications (e.g., preeclampsia, heart disease, diabetes), the pain-induced reductions of oxygen and carbon dioxide transfer can be the critical factors that produce perinatal morbidity and could even contribute to mortality (9,20,49,74). The maternal metabolic acidosis is transferred to the fetus, making it more vulnerable to the effects of intrauterine asphyxia caused by cord compression, prolapse, or other obstetric complications (9,77,79).

Effects of Sedation and Analgesia

There are many clinical studies, backed up by laboratory studies, that have shown that relief of pain can decrease or virtually eliminate most of the untoward maternal and fetal alterations that were just summarized. We summarize some of these in the next few paragraphs.

Ventilation. Partial relief of pain with opioids decreases hyperventilation to the point that the Paco $_2$ is in the 22 to 25 mm Hg range and oxygenation improves (44,45,46 and 47). Complete pain relief achieved with epidural analgesia prevents the transient period of hyperventilation during a contraction and prevents hypoventilation during relaxation, so that the Paco$_2$ remains normal in the range of 28 to 32 mm Hg and the Pao$_2$ increases to approximately 100 mm Hg (Fig. 71-15 and Fig. 71-16).

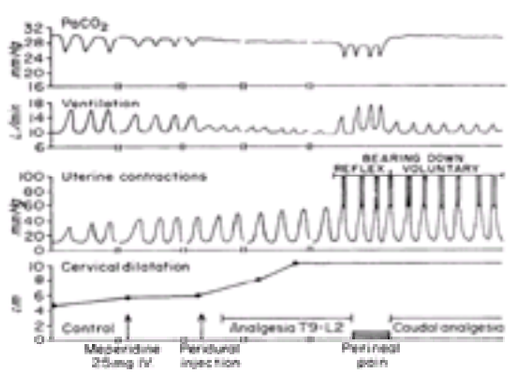

Figure 71-15. Schematic representation of the effects of analgesia on ventilation based on measurements in a primipara. At 5-cm cervical dilatation 25 mg of meperidine intravenously resulted in partial relief of pain and consequently produced smaller changes in ventilation and Paco $_2$. Subsequent induction of segmental epidural analgesia produced complete pain relief, which eliminated maternal hyperventilation and Paco $_2$ changes without affecting uterine contractions. During the second stage the onset of perineal pain and initiation of reflex bearing-down efforts caused a concomitant increase in ventilation and a slight decrease in the Paco $_2$ which were eliminated with the induction of low caudal (S-1 to S-5) analgesia. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:114, with permission.)

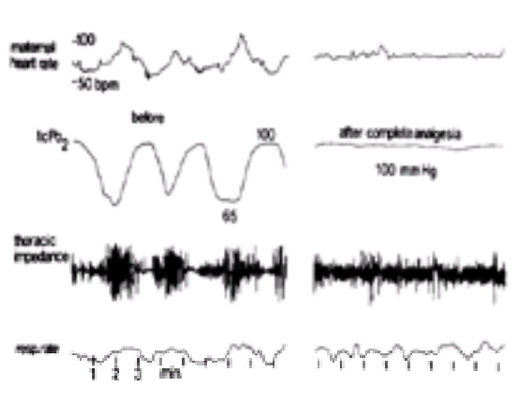

Figure 71-16. Polygraph recording of maternal heart rate, transcutaneous oxygen tension (tcPo $_2$), thoracic impedance, and respiratory rate during labor. Before the induction of epidural analgesia the pain of uterine contractions caused marked hyperventilation and a consequent increase in tcPo $_2$ to 100 mm Hg, which fell to 65 to 70 mm Hg between contractions. After complete epidural analgesia all curves were more regular, and the tcPo $_2$ was maintained at a stable 100 mm Hg. (Reprinted from Peabody JL. Transcutaneous oxygen measurement to evaluate drug effect. *Clin Perinatol* 1979;6:109–121, with permission.)

Neuroendocrine Effects. Studies have provided impressive evidence that epidural analgesia, by blocking nociceptive input and sympathetic efferents, reduces the release of catecholamines, b-endorphins, adrenocorticotropic hormone, and cortisol (51,58,59,65,80,81,82 and 83). This neuroendocrine-lowering effect is primarily the result of the relief of pain during labor (84). This study revealed that spinal anesthesia at the T-4 dermatomal level decreased catecholamine levels in women in labor, but did not do so in women who were not in labor. These results suggest that the mechanism by which catecholamine release is decreased is relief of maternal

pain.

Epidural analgesia during labor and delivery does not decrease catecholamine and b-endorphin release in the fetus and newborn (59,61,81,82,83 and 84). This response indicates that, even during uncomplicated deliveries with adequate maternal analgesia, the newborn can be distressed by the process of birth by vaginal delivery. One study (84) suggested catecholamines have important roles in regard to neonatal adaptation including surfactant synthesis and release, lung liquid resorption, nonshivering thermogenesis, glucose homeostasis, cardiovascular changes, and water metabolism.

Cardiovascular Effects. By decreasing the pain-induced sympathetic hyperactivity and neuroendocrine response, epidural analgesia eliminates that portion of the increase in cardiac output and blood pressure caused by pain. Figure 71-17 and Figure 71-18 show that epidural analgesia decreases the progressive increase in cardiac output and its further increase during uterine contractions to approximately 50% of that before analgesia. A similar decrease in periodic increase in blood pressure is depicted in Figure 71-19. Several studies have proven the value of epidural analgesia in lessening the increase in cardiac output, cardiac work, and blood pressure in laboring parturients. These become important with heart disease, pregnancy-induced hypertension (preeclampsia), and pulmonary hypertension, provided of course that maternal hypotension is avoided (85,86).

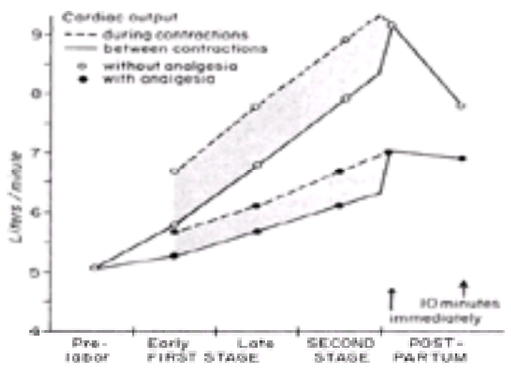

Figure 71-17. Cardiac output during various phases of labor between contractions and during contractions. In a group of patients laboring without analgesia, the progressive increases between contractions and the further increases during each contraction were much greater than corresponding changes in a group of patients who received continuous epidural analgesia. (Data from Bonica JJ. *Principles and practice of obstetric analgesia and anesthesia*. Vol 1. Philadelphia: FA Davis, 1967.)

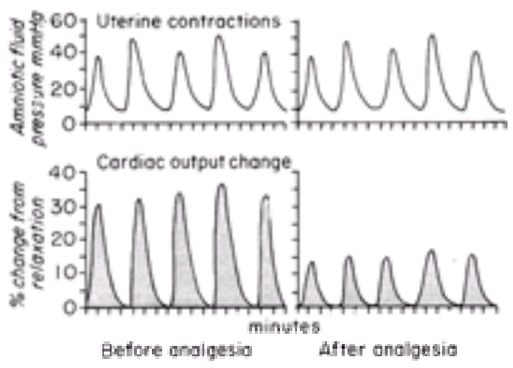

Figure 71-18. Increases in cardiac output during each uterine contraction before and after induction of continuous epidural analgesia in a primipara. With pain relief the increases in cardiac output during contractions were approximately 50% of those before induction of analgesia. (Reprinted from Bonica JJ. Labour pain. In: Wall PD, Melzack R, eds. *Textbook of pain*, 2nd ed. Edinburgh, UK: Churchill Livingstone, 1989:491, with permission.)

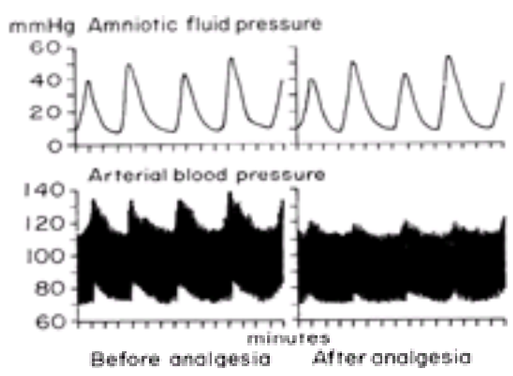

Figure 71-19. Fluctuations in blood pressure produced by uterine contractions before and after induction of continuous epidural analgesia. Like the cardiac output changes (see Fig. 71-18), complete relief of pain resulted in decreasing the contraction-induced fluctuations to nearly 60% of the values measured before analgesia. (Reprinted from Bonica JJ. Labour pain. In: Wall PD, Melzack R, eds. *Textbook of pain*, 2nd ed. Edinburgh, UK: Churchill Livingstone, 1989:491, with permission.)

Metabolic Effects. The relief of pain and associated anxiety with continuous epidural analgesia decreases the total work of labor, maternal metabolism, and oxygen consumption. Buchan (65) showed that during labor, epidural analgesia reduced internal stress by abolishing pain, thus eliminating the progressive increase in the 11-hydroxycorticosteroid levels normally seen throughout labor. Consequently, epidural analgesia significantly reduces maternal and fetal metabolic acidosis. The superiority of epidural analgesia over systemic opioids and other systemic drugs in decreasing maternal work, oxygen consumption, and maternal and fetal metabolic acidosis has been impressively demonstrated by a number of investigators (45,46,51,87,88,89,90 and 91) (Fig. 71-20). Because active pushing during the second stage of labor contributes to metabolic acidosis, epidural analgesia does not completely eliminate metabolic and fetal acidosis. Figure 71-20 demonstrates that epidural analgesia and elimination of the bearing-down effort (pushing) during the second stage almost eliminate maternal metabolic acidosis. Moreover, under these conditions it decreases but does not eliminate the degree of fetal acidosis; the latter may well be a result of the physical stress on the fetus during the process of birth.

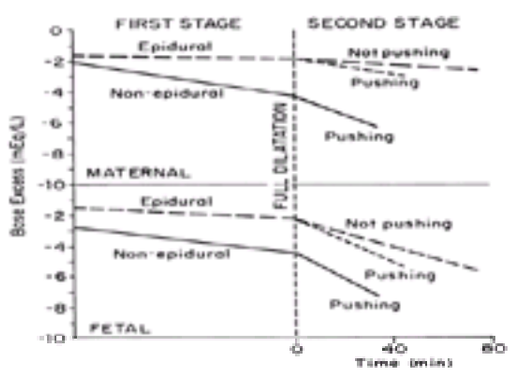

Figure 71-20. Mean changes in extent of maternal (*above*) and fetal (*below*) metabolic acidosis during the first and second stages of labor in a group of parturients

managed without lumbar epidural analgesia and in two similar groups managed with epidural analgesia, one of which retained the bearing-down reflex and the other did not. The parturients were delivered by outlet forceps. Significant metabolic acidosis was experienced by those in the nonepidural group of parturients whereas those given epidural analgesia experienced few or no changes in their acid–base status. Fetuses born of mothers managed without epidural also developed metabolic acidosis during the first stage, and to an even greater degree during the second stage. In contrast, fetuses of mothers given epidural had no change in acid–base status during the first stage but showed a time-dependent increase in metabolic acidosis during the second stage. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:115, with permission.)

Effects on Uterine Activity. By decreasing the sympathetic-induced hyperactivity, sedation and complete analgesia can reduce or eliminate uterine hyperactivity or remedy hypoactivity, and it can convert incoordinate uterine contractions to normal contractions (9,75,91) (Fig. 71-21). Equally important is the efficacy of analgesia in reducing placental hypoperfusion and any existing deterioration in uterine blood flow. Such treatment can thus decrease or even eliminate impairment of blood gas transfer that might be a result of increased catecholamines or uterine hyperactivity (9).

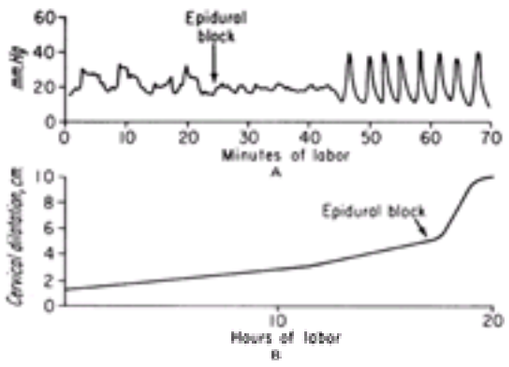

Figure 71-21. Effect of epidural block on incoordinate uterine contractile pattern. **A:** Intrauterine pressure tracings. Note the temporary decrease in uterine contractions and the subsequent normalization of the previously irregular contractions. **B:** Cervimetric curve showing the rapid cervical dilation that followed start of the epidural block. (Reprinted from Bonica JJ, McDonald JS. *Principles and practice of obstetric analgesia and anesthesia*, 2nd ed. Baltimore: Williams & Wilkins, 1995:381, with permission.)

Effects on the Fetus. These benefits of pain relief, best achieved with regional analgesia, are likely to be of value in general for most infants, but they are especially important for the fetus at risk. Regional techniques have been found to be the best method of analgesia for breech delivery and for multiple pregnancies (9,92,93). It has been shown that epidural analgesia, through its vasomotor-blocking effect, increases intervillous blood flow in parturients with severe preeclampsia and probably also in those with hypertension, diabetes, and other conditions that decrease placental blood flow and function (9,92,93,94 and 95). Janisch and coworkers (96) found that continuous epidural analgesia administered to preeclamptic patients during their last few weeks of gestation produced a 100% increase in placental blood flow. Jouppila and colleagues (97) studied the influence of lumbar epidural analgesia that was limited to a few segments and the effect of a more extensive type of lumbar epidural block on parturients with severe preeclampsia. They found that the limited block increased intervillous blood flow by 34%, whereas the more extensive block increased it by a mean of 77%. They attributed this effect to the relief of severe vasoconstriction by the vasomotor block. However, maternal hypotension associated with the epidural must be strictly avoided by appropriate prophylactic measures such as intravenous infusion of fluids and lateral displacement of the uterus to maintain maternal systemic pressure.

Mechanisms, Pathways, and Characteristics of the Pain of Parturition

To provide optimal pain relief with regional analgesia, it is essential for the obstetric team to understand the peripheral mechanisms and pathways of the pain of parturition and the factors that influence its intensity, duration, and quality. Most of these factors vary during the different phases and stages of labor and are therapeutically significant, so they are considered separately over the next few paragraphs.

Pain of the First Stage of Labor

Intrinsic Mechanisms. During the first stage, labor pain initially is entirely in the uterus and its adnexa during contractions. Recall that labor pain may be caused by the following conditions:

- Pressure on nerve endings between the muscle fibers of the body and fundus of the uterus (98)
- Contraction of the ischemic myometrium and cervix consequent to expulsion of blood from the uterus during the contraction (99) or as a result of vasoconstriction consequent to sympathetic hyperactivity (2)
- Inflammatory changes of uterine muscles (98)
- Contraction of the cervix and lower uterine segment consequent to fear-induced hyperactivity of the sympathetic nervous system (2)
- Dilatation of the cervix and lower uterine segment (24,99)

Most data support the concept that the pain of the first stage of labor is predominantly a result of dilatation of the cervix and lower uterine segment and of the consequent distension, stretching, and tearing of these structures during progressive contractions. Contractions of the uterus under isometric conditions (i.e., against the obstruction presented by the cervix and perineum) also probably contribute to the pain of uterine contractions.

These hypotheses are based on the following considerations:

- Stretching of smooth muscle of a hollow viscus is an adequate stimulus for visceral pain (100).
- The degree of cervical and lower uterine segment dilatation is correlated with the rapidity with which it occurs on the one hand and with the intensity of the pain on the other (20).
- The time of onset of uterine contractions is related to the time of onset of the pain. This lag, which is longest in the early stages of labor and lessens as labor progresses, occurs because uterine contractions need time to increase the amniotic fluid pressure to 15 mm Hg above tonus. This has been determined to be the minimum pressure required to initiate distension of the cervix and lower uterine segment (101).
- In the parturient undergoing cesarean section with abdominal field block, the exposed but unanesthetized uterus can be incised and gently palpated without discomfort to the conscious parturient (24,99). On the other hand, forceful palpation and stretching of the cervix and lower uterine segment produced pain similar in quality and location to that experienced during labor (24,99).
- When the cervix is suddenly and widely dilated in parturients or in gynecologic patients, they feel pain similar in quality, distribution, and intensity to that experienced during uterine contractions (24,99,102).

The evidence that contractions of the body of the uterus contribute to the pain of labor is, to some degree, puzzling. Braxton-Hicks contractions of prelabor are frequently painless, even though they can attain the intensity of labor contractions. During the immediate postpartum period, the intensity of uterine contractions of the empty uterus might be two to three times stronger than the contractions of active labor; yet, they are associated either with much less intense pain or with no pain at all. On the other hand, strong contractions are associated with severe pain in most parturients with mechanical distortion caused by abnormal fetal positions and in those in whom the cervix dilates slowly.

Peripheral Pathways. Based on studies of the segments of hyperalgesia associated with various uterine disorders, as well as of hyperalgesia during the second stage of labor, Head (103) concluded the sensory nerve supply of the uterus involved the T-11, T-12, and frequently T-10 and L-1 to L-2 segments. The cervix was supplied by the S-2, S-3, and S-4 segments. Some 40 years later, based on animal experiments and studies of parturients, Cleland (104) concluded that in humans the

sensory supply of the uterus was by T-11 and T- 12, and pain caused by stretch of the birth canal was transmitted through undetermined sacral segments. This latter finding was interpreted to mean that the cervix and vagina are supplied by the sacral segments. As a result of these two studies it became widely taught that nociceptive impulses from the body of the uterus are transmitted through the T-11 and T-12 nerves, and that pain from the cervix and lower uterine segment is transmitted through the pelvic nerve to the S-2, S-3, and S-4 spinal segments.

Bonica's observations were at variance with this concept; he and associates carried out a study that involved 240 parturients and 35 gynecologic patients investigated over a period of 22 years (105). That study entailed the use of discrete blocks of various nociceptive pathways by paravertebral block, segmental epidural block, caudal block, and transsacral block of various segments (105). This extensive study demonstrated conclusively that the upper part of the cervix and the lower uterine segment are not supplied by sensory fibers that accompany the pelvic nerves (nervi erigentes), as stated in almost every modern anatomy and obstetric textbook (106,107,108 and 109). Rather, these structures are supplied by afferents that accompany the sympathetic nerves in the following sequence: the uterine and cervical plexus; the pelvic (inferior hypogastric) plexus; the middle hypogastric plexus or nerve; and the superior hypogastric and aortic plexuses.

The nociceptive afferents then pass to the lumbar sympathetic chain and course cephalad through the lower thoracic sympathetic chain via the rami communicantes of the T-10, T-11, T-12, and L-1 spinal segments. Finally, they pass through the posterior roots of these nerves to make synaptic contact with interneurons in the dorsal horn (Fig. 71-22 and Fig. 71-23).

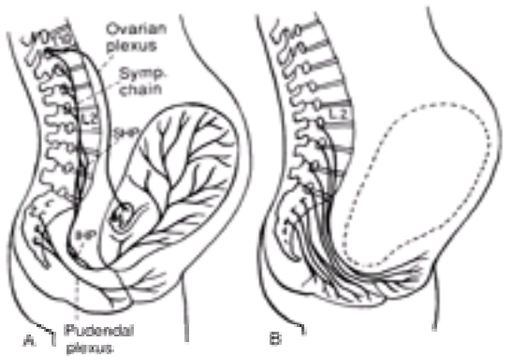

Figure 71-22. Schematic depiction of the peripheral nociceptive pathways involved in the pain of childbirth. **A:** The uterus, including the cervix and lower uterine segments, is supplied by afferents that pass from the uterus to the spinal cord by accompanying sympathetic nerves through the inferior hypogastric plexus (IHP), the hypogastric nerve, the superior hypogastric plexus (SHP), the lumbar and lower thoracic sympathetic chain, and the nerves at T-10, T-11, T-12, and L-1. **B:** The nerves involved in transmission of nociceptive impulses are provoked by noxious stimulation of pelvic structures. See text for details.

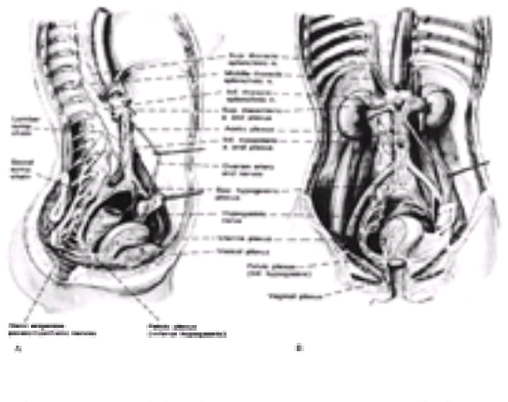

Figure 71-23. Gross anatomy of the nerve supply to the uterus. **A:** Lateral view. **B:** Anterior view. The uterus is shown in the nonpregnant state to permit the various nerves that supply it to be depicted. Note that the uterine and cervical plexuses are derived from the pelvic plexus, which contains parasympathetic and sympathetic efferents. The parasympathetic efferents have their cell bodies in the middle three sacral segments, and the parasympathetic afferents pass through these segments and progress cephalad through the neuraxis. The sympathetic efferents and afferents pass through the hypogastric nerve, which in turn is a continuation of the superior hypogastric and aortic plexuses. Note that fibers from the latter two plexuses pass on to the lumbar sympathetic chain, the afferents of which mediate nociceptive impulses and accompany the sympathetic fibers through these structures. From the lumbar and lower thoracic sympathetic chain the nociceptive afferents pass to the T-10, T-11, T-12, and L-1 spinal nerves and reach the spinal cord via their posterior roots and rootlets. (Modified from Bonica JJ. *Principles and practice of obstetric analgesia and anesthesia*. Philadelphia: FA Davis, 1967:110–111.)

Typical of the pain arising from viscera, the pain of the first stage of labor is referred to the dermatomes supplied by the same spinal cord segments that receive input from the uterus and cervix. During the early phase of the first stage the pain is felt as an ache and is limited to the T-11 and T-12 dermatomes (Fig. 71-24A). As labor progresses to the active phase of the first stage, 3- to 4-cm cervical dilatation, the pain in the T-11 and T-12 dermatomes becomes more severe and is described as sharp and cramping and spreads to the two adjacent (T-10 and L-1) dermatomes (Fig. 71-24B).

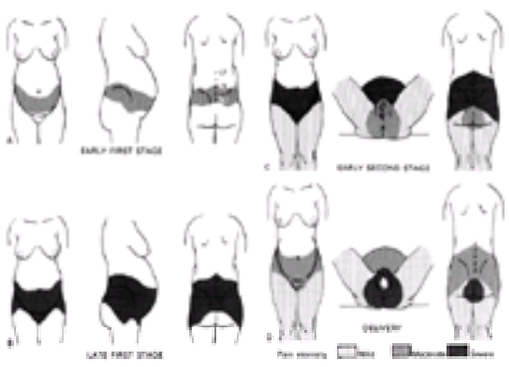

Figure 71-24. The intensity and distribution of parturition pain during the various phases of labor and delivery. **A:** In the early first stage the pain is referred to the T-11 and T-12 dermatomes. **B:** In the late first stage, however, the severe pain is also referred to the T-10 to L-1 dermatomes. **C:** In the early second stage uterine contractions remain intense and produce severe pain in the T-10 to L-1 dermatomes. At the same time the presenting part exerts pressure on pelvic structures and thus causes moderate pain in the very low back and perineum and often produces mild pain in the thighs and legs. **D:** Intensity and distribution of pain during the latter phase of the second stage and during actual delivery. The perineal component is the primary cause of pain whereas uterine contractions produce moderate pain. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:46–47, with permission.)

The distribution of the T-10, T-11, T-12, and L-1 dermatomes in the back overlies the lower three lumbar vertebrae and the upper half of the sacrum (see Fig. 71-9). Often, the pain is not referred to the entire dermatome but can be more severe in one or more patches of varying sizes within the territory of one or more of the individual dermatomes (20,26,27).

Second and Third Stages of Labor

Once the cervix is fully dilated, the amount of nociceptive stimulation arising in this structure decreases, but the contractions of the body of the uterus and distension of the lower uterine segment continue to cause pain in the same areas of reference as in the first stage of labor. In addition, the progressively greater pressure of the presenting part on pain-sensitive structures in the pelvis and distension of the outlet and perineum become new sources of pain. Progressively greater distension causes intense stretching and actual tearing of fascia and subcutaneous tissues and pressure on the skeletal muscles of the perineum. Like other pain caused by stimulation of superficial somatic structures, the perineal pain is sharp and well localized, predominantly to the regions supplied by the pudendal nerves, and can be eliminated by block of these nerves (9,110) (Fig. 71-25A and Fig. 71-25C).

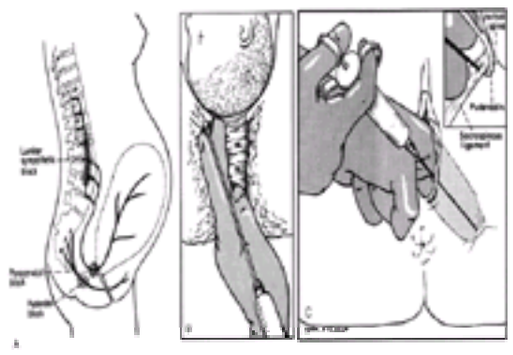

Figure 71-25. **A:** Sites of three regional techniques for obstetric analgesia. Lumbar sympathetic block is rarely used but is highly effective in relieving pain of the first stage and can be preferable to the use of paracervical block, especially in high-risk pregnancies. **B:** Technique of paracervical block. The coronal section of the vagina and the lower part of the uterus containing the fetal head are shown. The 22-gauge needle is contained within a guide, with its point protruding only 5 to 7 mm beyond the end of the guide. This prevents the needle being inserted more than 5 to 7 mm beyond the surface of the mucosa. After negative aspiration an injection of 8 to 10 mL of 0.25% bupivacaine at 4 and 8 o'clock of the cervical fornix produces relief of uterine pain for several hours. **C:** Transvaginal technique of blocking the pudendal nerve. The two fingers of the left hand are inserted into the vagina to guide the needle point into the sacrospinous ligament. As long as the bevel of the needle is in the ligament there is some resistance to the injection of local anesthetic, but as soon as the bevel passes through the ligament there is a sudden lack of resistance, indicating that the needle point is next to the nerve. (Modified from Bonica JJ. *Principles and practice of obstetric analgesia and anesthesia*. Vol 1. Philadelphia: FA Davis, 1967:493, 514–515.)

In the late part of the first stage and during the second stage, a number of parturients develop aching, burning, or cramping discomfort in the thigh and, less frequently, in the legs (Fig. 71-24C and Fig. 71-24D). This is a result of stimulation of pain-sensitive structures within the pelvic cavity, including traction on pelvic parietal peritoneum and the uterine ligaments; stretching and tension of the bladder, urethra, and rectum; stretching and tension of ligaments, fascia, and muscles in the pelvic cavity; and undue pressure on one or more roots of the lumbosacral plexus.

These factors usually produce mild pain referred to the lower lumbar and sacral segments (see Fig. 71-22B), but if the fetus is in an abnormal position, with undue pressure by the presenting part, the referred pain can become moderate or severe (see Fig. 71-24C and Fig. 71-24D).

The transmission of the nociceptive information that arises from these various structures to the dorsal horn and then to other parts of the spinal cord and to the ascending systems to the brain is presumably similar to that of other types of acute pain. The pain is provoked by tissue damage in the cervix and perineum and is thought to be passed to the dorsal horn through A-d and C nociceptive fibers.

Factors That Affect the Pain of Childbirth

In addition to the role played by such intrinsic factors as the intensity, duration, and pattern of contractions and related physiologic and biochemical mechanisms, the amount or degree of pain and suffering associated with childbirth is influenced by physical, psychological, emotional, and motivational factors (9,24,27,94,98,108,109).

Physical Factors. Physical factors that influence the incidence, severity, and duration of the pain of childbirth include the age, parity, and condition of the parturient, the condition of the cervix at the onset of labor, and the relationship of the size of the infant to the size of the birth canal. Many of these factors are interrelated. Generally, an older primipara experiences a longer and more painful labor than a younger primipara. The cervix of the multipara begins to soften even before the onset of labor and is less sensitive than that of the primipara. The intensity of uterine contractions in early labor tends to be higher in primiparas than in multiparas, whereas in the latter phase of labor the reverse is true. In the presence of dystocia caused by a contracted pelvis, a large baby, or abnormal presentation, the parturient experiences more pain than under normal conditions. Melzack and associates (27,28) found that high pain levels were associated with a history of menstrual difficulties. Fatigue, loss of sleep, and general debility influence a parturient's tolerance of the painful experience and increase the pain behavior. This is particularly significant in parturients with prolonged labor.

Psychological Factors. Psychological factors that can and frequently do affect the incidence and intensity of parturition pain include the mentation, attitude, and mood of the parturient at the time of labor, as well as other emotional factors. Fear, apprehension, and anxiety probably enhance pain perception and pain behavior (9,20,23). One of the most frequent causes of fear and anxiety is ignorance of or misinformation about the processes of pregnancy and parturition, and what the onset of labor signifies. An uninformed parturient, especially a primipara, can be disturbed by fear of the unknown, death, suffering, mutilation, possible complications, and concern for her condition or that of her fetus (20). Parturients who have had an unplanned or illegitimate pregnancy or have an ambivalent or negative reaction to gestation report more pain than those who do not (20,23,111). In contrast, other emotional factors, such as intense motivation and cultural influences, can affect modulation of sensory transmissions and certainly can influence the affective and behavioral dimensions of pain. Moreover, cognitive intervention such as giving the parturient preparatory information about labor, thus reducing uncertainty while focusing attention or producing distraction and dissociation from pain (all parts of an *educated* childbirth program), reduces pain behavior.

The influence of education and psychological conditioning inherent in psychoprophylaxis and natural childbirth in modifying pain behavior without significantly affecting pain sensation is now widely appreciated. During 5- to 10-day visits to obstetric centers that practiced psychoprophylaxis or natural childbirth in the Soviet Union, France, Germany, Italy, the Netherlands, Sweden, and the United States, made over a 5-month period in 1959, Bonica observed approximately 700 parturients (and interviewed many) who had received training in one of these methods, and more than 85% of them manifested little or no pain behavior during labor and delivery. When questioned the next day, however, most of them indicated that the process had been painful but many quickly added that they were pleased to cooperate with their instructor and obstetric team (9). Especially impressive was the marked change in behavior of Italian parturients in a large obstetric center in Turin noted during two visits made 5 years apart. During the first visit, in 1954, the labor ward was a scene of cacophony caused by the screaming, pleading, and praying of the nearly 50 laboring women in the same ward. In contrast, 5 years later, one heard only an occasional moan from a similar number of parturients who had undergone an intensive course of psychoprophylaxis. Most went through the entire labor and delivery with minimal pain behavior but later stated that they had had moderate to severe pain.

Summary

It is obvious that the pain-associated responses to noxious stimulation provoked by uterine contractions and other tissue-damaging factors during labor and vaginal delivery are the net effects of highly complex interactions of various neural systems, modulating influences, and psychological factors. Through the interaction of the afferent system and neocortical processes, the parturient receives perceptual and discriminate information that is analyzed and that usually activates motivational cognitive processes. These, in turn, act on the motor system and initiate psychodynamic mechanisms of anxiety and apprehension that produce the complex physiologic, behavioral, and affective responses that characterize acute pain.

CLINICAL CONSIDERATIONS: MANAGEMENT OF THE PAIN OF CHILDBIRTH

The pain as previously described in detail for the first and second stages of labor and that associated with actual delivery not only produces suffering and emotional disturbances, but also induces segmental and suprasegmental reflex responses that further magnify the pain experience. It is the challenge and task of the obstetric team to provide optimal relief of pain to parturients with the resources available.

Many drugs and techniques are currently available for providing analgesia during childbirth. The methods vary according to geographic region or country and depend on the culture, medical personnel, facilities, and other sociologic and professional factors. To be used properly, each drug and technique must be evaluated from four interrelated viewpoints: (a) analgesic potency and other therapeutic efficacy; (b) side effects on the mother; (c) effects on the fetus and newborn; and (d) effects on the forces of labor.

Table 71-1 contains a critical evaluation of the various drugs and techniques in current use from these perspectives. The effects on the mother, fetus, and newborn, and the forces of labor discussed in the table are based on the use of optimal doses and routes of administration of systemic drugs and on the use of optimal concentrations and volumes of local and regional anesthetics.

TABLE 71-1. Pharmacology and applications of obstetric analgesia and anesthesia

General Considerations

Basic Principles

To obtain the most effective results with obstetric analgesia and anesthesia, those on the obstetric team must adhere to certain basic principles. The objective is to provide optimal relief of pain to the mother with little or no risk to her and her infant. The type of analgesia or anesthesia must be tailored to the needs of each mother and infant within the framework of the personnel and resources available. Each member of the obstetric team must be fully informed of the plans and possible problems of other members, with excellent communication, coordination, and cooperation among those on the team. The anesthetist must have a thorough understanding of the physiologic and pathophysiologic alterations caused by pregnancy and labor, and how these are affected by each type of analgesia.

Antepartal and Preanesthetic Care. The proper preparation of the gravida and her spouse during the antepartum period is one of the most important responsibilities of the obstetric team (94). She and her husband should be informed about the physiology and psychology of pregnancy and labor and about the psychological and emotional effects these might produce. Understanding the changes in her circulation, respiration, endocrine function, and other systems helps the gravida to understand and accept the inconveniences, discomforts, and awkwardness of the lopsided silhouette she develops during pregnancy (20,94). Similarly, a discussion of the physiology and clinical course of labor provides her with useful information and helps her to cooperate and participate actively during labor as well as in the many other aspects of educated childbirth. During one of the antepartum visits the obstetrician should bring up the matter of analgesia and anesthesia and, if the gravida indicates that she is interested, the advantages, disadvantages, and limitations of each technique should be clearly explained by a responsible member of the anesthesiology team. If the gravida delivers in the hospital, it is essential that everyone who comes in contact with the patient (from the admission clerk to members of the house staff) thoroughly appreciate the importance of a friendly and reassuring attitude.

Those gravidas who indicate a desire for some form of pain relief should be seen by an anesthesiologist either prior to or soon after admission to the hospital. Proper preanesthetic care requires a thorough evaluation of the parturient, including a medical and anesthesia history, physical examination, assessment of the physiologic and emotional status of the parturient, and discussion of the various forms of analgesia and anesthesia available. Selection of the method of analgesia to be used is made in consultation with the parturient and obstetrician.

Intrapartal and Intraanesthetic Care. During labor, the uterine contractions, cervical dilatation, and advance of the presenting part should be monitored. The cervicographic method of following the progress of labor is recommended. During a home or hospital delivery in which modern equipment is not available, the fetal heart rate is monitored by auscultation. The limitations of this method and of palpating uterine contractions are generally recognized and emphasize the need for the clinical use of more sophisticated techniques, especially in monitoring the labor of women with high-risk pregnancies. Currently, a number of systems permit the continuous and simultaneous measurements of fetal heart rate and myometrial activity; these are simple to operate, easy to maintain, and of reasonable cost. During labor the parturient is made to lie on her side and should only assume the supine position for brief periods (seconds), during which left lateral tilt or left uterine displacement is used. The induction and maintenance of regional analgesia are also carried out with the parturient on her side.

Current Methods of Obstetric Analgesia and Anesthesia

All the drugs and techniques that are currently available to provide pain relief during childbirth can be arbitrarily classified into four categories: (a) nonpharmacologic analgesia, primarily in the form of psychological and physiologic techniques; (b) simple methods of pharmacologic analgesia; (c) inhalation analgesia and anesthesia; and (d) regional analgesia. Detailed consideration of these methods is precluded here, but the pharmacologic methods are summarized in Table 71-1.

Nonpharmacologic Techniques

The past 40 years have seen a progressive increase in the application of several methods that do not entail the use of pharmacologic agents to relieve the pain of childbirth. These include the following methods: (a) natural childbirth, originally proposed and practiced by the late Dick-Read (1,2); (b) the method of psychoprophylaxis originated by Velvovski and associates in the Soviet Union (3) in the late 1940s and practiced thereafter and advocated by Lamaze (19) in Paris and worldwide since then; (c) hypnosis, which has been used sporadically in a few obstetric clinics; and (d) acupuncture and transcutaneous electrical nerve stimulation, both of which have been given clinical trials during the past 15 years.

Psychological Analgesia. The term *psychological analgesia* applies to both educated (natural) childbirth and psychoprophylaxis because, despite claims to the contrary by the proponents of each method, these have similar physiotherapeutic and psychophysiologic bases (9,20). Early proponents of these techniques claimed that most patients can achieve *painless* childbirth, but most current workers in the field acknowledge the fact that pain is not completely eliminated in most parturients but can be somewhat ameliorated. The major benefits of these methods are a decrease in anxiety and apprehension and enhancement of the parturient's ability to cope with the entire process and to control her behavior. In addition, the patients experience a personal sense of achievement and enhancement of the early bonding process by immediate visual, auditory, and tactile contact between the mother and her newborn.

Analysis of published data and observations in various countries suggests that, if psychoprophylactic or natural childbirth methods are properly used by both primiparas and multiparas, the following results can be expected: (a) little or no pain is experienced by 15% to 20%, and no analgesia or anesthesia is required during the entire process; (b) the pain is decreased in an additional 15% to 20% to a moderate degree, and parturients require less pharmacologic analgesia and anesthesia; and (c) the pain is not affected in the remainder of patients but fear and anxiety are less, and parturients manifest less pain behavior (9,94).

One report (112) indicates that women who are trained in prepared childbirth methods have shorter labor, fewer operative deliveries, fewer intrapartum and

postpartum complications, less blood loss, and better and happier babies than those given drug- induced analgesia or anesthesia. Other studies with proper controls indicate no significant differences regarding these variables between those in prepared and unprepared (analgesia) groups (25,26 and 27,113,114). Observations by Bonica that were made in hospitals in the Soviet Union, eastern and western Europe, and North and South America help to explain these discrepancies. He believed the differences in opinion were the result of differences in motivation, attitude, and personality of parturients and their instructors, the practices of the obstetrician, and the skill with which analgesia and anesthesia were given. These observations and extensive obstetric anesthesia experience lead to the conclusion that the logical approach to pain control during the birth process is best when prepared childbirth training is combined with regional analgesia. This viewpoint is supported by Melzack's work in this field (27).

Hypnosis. Most practitioners of hypnosis for pregnant women begin with early preparation at approximately the fifth or sixth month of pregnancy and subsequently thereafter every 2 to 4 weeks. Various techniques have been used. The word *hypnosis* is not used; rather, the term *medical relaxation* is used instead to suggest to parturients what is expected of them during preparatory sessions and at delivery. Although most women derive some benefit, only a small percentage (15% to 20%) of parturients are sufficiently susceptible to hypnotic suggestion to be able to obtain complete pain relief.

Acupuncture and Transcutaneous Electric Nerve Stimulation. Despite the great interest in China in the use of acupuncture analgesia for surgery, the use of this method in obstetrics has been limited to cesarean section (115,116 and 117). The Chinese have not used it for vaginal delivery because of their cultural premise that parturition is a physiologic function and does not require analgesia. This technique has been tried in Europe, North America, and other parts of Asia, with conflicting results. Several obstetric anesthesiologists have given acupuncture an adequate trial but did not obtain satisfactory results and discontinued its use (118,119,120 and 121).

Transcutaneous electric nerve stimulation is another nonpharmacologic technique that has been given a limited clinical trial. The first pair of electrodes is usually applied to the skin overlying the T-10 to L-1 vertebrae, with one electrode just lateral of the midline, while the second pair is applied bilaterally on the skin overlying the S-2 to S-4 vertebrae. Low-intensity high-frequency (60- to 80-Hz) stimulation is applied continuously through the upper electrodes and, as soon as more intense pain caused by the onset of uterine contractions is felt, parturients themselves increase the stimulation until tingling sensations are felt. Uncontrolled clinical trials suggest that 40% to 60% of parturients obtain good or partial relief of pain during the first stage, but two-thirds of these require regional analgesia during the second stage and for delivery.

Simple Techniques of Pharmacologic Analgesia

In many parts of the world in which anesthetists are not available, the midwife or obstetrician must rely on the use of prepared childbirth and on simple methods of drug analgesia. In this context, it must be recalled that mild pain during the early first stage can be relieved by using suggestion combined with sedatives and tranquilizers. With the onset of moderate pain during the active phase of labor, however, opioids are usually required, and these are given either intramuscularly or intravenously in small increments. Properly administered opioids produce adequate but not complete relief of moderate pain in 70% to 80% of parturients and relief of severe pain in 35% to 60% of parturients (9,20,94). Opioids do not produce significant maternal respiratory depression in optimal doses, but can produce neonatal depression that can be minimized. Inhalation analgesia, bilateral pudendal block, or infiltration of the perineum is used for the actual pain of delivery.

Inhalation Analgesia and Anesthesia

Inhalation *analgesia* is a widely used method of relieving childbirth pain because it produces moderately effective pain relief without causing loss of consciousness or significant maternal or neonatal depression. The agents most commonly used are 40% to 50% nitrous oxide in oxygen. This agent can be administered intermittently during uterine contractions, by the parturient, or administered by a midwife or anesthetist. In some parts of the world, one can still obtain premixed cylinders of 50% nitrous oxide and 50% oxygen that are termed Entonox. For optimal results, inhalation of the drug should begin some 10 to 15 seconds before the painful period of each contraction. Properly used, inhalation analgesia produces good pain relief in approximately 60% and partial relief in another 30% of parturients (9,20,92,93,94 and 95).

Inhalation anesthesia in analgesic concentrations only is still used for vaginal delivery because it affords maximum control of depth and duration of action and is rapidly eliminated at the end of the procedure. On the other hand, deep general anesthesia carries the risk of provoking regurgitation or vomiting and consequent pulmonary aspiration (92,95). General anesthesia should therefore only be given by a properly trained specialist who has secured the airway by tracheal intubation (Table 71-2).

Intubation hazards
Visualization impaired due to edema
Increased bleeding caused by trauma
Nasotracheal route contraindicated due to bleeding potential
Desaturation time decreased due to diminished functional residual capacity
Oxygenation hazards
Desaturation time decreased due to diminished functional residual capacity
Increased tidal volume and minute ventilation
Metabolic rate changes and oxygen extraction problems
Cardiovascular hazards
Increased blood volume
Increased cardiac output
Increased cardiac size and position change
Reduced peripheral vascular resistance
Instability due to uterine compression

[See references 106–108.]

TABLE 71-2. Impact of physiologic changes of pregnancy on general anesthesia [a]

Regional Analgesia and Anesthesia

The use of regional analgesia and anesthesia during labor and for delivery has increased dramatically over the past 30 years in the United States and Great Britain; and, more recently, it has increased significantly in many European countries in which the use of pharmacologic obstetric anesthesia has been limited. The most common techniques are continuous lumbar epidural block, subarachnoid (saddle) block, bilateral paracervical or bilateral pudendal block, or both, continuous caudal block, and double-catheter epidural block, which consists of combining segmental epidural and low caudal blocks (Table 71-3).

Technique	Comparison
Needle puncture L-3 to L-4	Less drug required
Test dose for safety	Continuous analgesia
Bolus 5 mL of drug	Maternal movement possible
Begin infusion at 10 mL/hr	Maternal sensation intact
Peripheral analgesia by site of dosage of 8 mL of 5% ropivacaine	Less blood pressure fluctuation

TABLE 71-3. Continuous lumbar epidural infusion technique

Advantages, Disadvantages, and Contraindications. The popularity of regional analgesia and anesthesia is that it provides the following advantages over other

methods:

- In contrast to narcotics and inhalation analgesia, regional analgesia and anesthesia produce complete relief of pain in most parturients.
- The hazard of pulmonary aspiration of gastric contents inherent in general anesthesia is greatly reduced or eliminated.
- By blocking all nociceptive and efferent pathways, it obviates the pain-induced deleterious reflex responses noted in the previous section.
- With most techniques, the use of a dilute solution of local anesthetic produces block of nociceptive (A-d and C) fibers, with minimal or no effect on the larger somatomotor and tactile fibers.
- Provided it is properly administered and complications are avoided, regional analgesia and anesthesia cause no maternal or neonatal depression.
- Administered properly, regional analgesia and anesthesia have no clinically significant effect on the progress of labor.
- *Continuous* epidural analgesia can be extended for delivery and can even be modified for cesarean section, if necessary.
- Regional analgesia permits the mother to remain awake and alert during labor and delivery so that she can experience the pleasure of actively participating in the birth process (by bearing down voluntarily) and of promptly bonding with her child.

On the other hand, the various techniques have certain disadvantages:

- The use of regional analgesia and anesthesia requires greater knowledge of anatomy and greater technical skill for administration than the use of systemic drugs, inhalation agents, or general anesthesia.
- Technical failures occur, although the incidence is small in experienced hands.
- The vasomotor block inherent in spinal, epidural, and caudal block can cause significant maternal hypotension if prophylactic measures are not carried out.
- Techniques that produce premature perineal muscle relaxation can interfere with the mechanism of internal rotation and might increase the incidence of occipitoposterior or occipitotransverse positions.
- Techniques that produce perineal analgesia cause loss of the afferent limb of the reflex urge to bear down and, unless the parturient is instructed how to bear down effectively, it can prolong the second stage, require the use of outlet forceps, or both.
- Spinal, caudal, or lumbar epidural and double-catheter techniques are relatively contraindicated in parturients with coagulopathy because of the risk of hemorrhage within the spinal canal.
- Regional analgesia and anesthesia procedures can only be carried out in a hospital.

In addition to the relative contraindications of the use of regional analgesia and anesthesia in parturients with coagulation defects, other contraindications to this procedure have been noted:

- The use of regional analgesia and anesthesia is contraindicated if the anesthesiologist lacks skill and experience in the technique, lacks knowledge of obstetric physiology and pathophysiology, or lacks knowledge about the prevention and treatment of complications.
- Infection of the puncture site, preexisting coagulation defects, or hemorrhagic hypovolemia or shock are contraindications, especially for subarachnoid and epidural techniques.
- The parturient's refusal or intense fear of regional anesthesia is a contraindication.
- A lack of experience or appreciation by the obstetrician of how regional analgesia and anesthesia influence the management of labor negates the use of these techniques.

To achieve the stated objectives of obstetric analgesia (i.e., good maternal pain relief with little or no risk to the parturient or her infant), it is essential for the anesthesiologist to fulfill the following criteria:

- The anesthesiologist must have a thorough understanding of parturition pain pathways and the pharmacology of local anesthetics, must have acquired sufficient skill and experience with the various techniques, and must know how to manage the parturient during and after regional analgesia has been administered.
- The anesthesiologist must know the possible complications, their prevention, and prompt treatment.
- The anesthesiologist must ensure that none of the regional procedures be started without an *intravenous infusion running and without having equipment for treatment of complications and for resuscitation available for immediate use*.
- The anesthesiologist should avoid using a regional technique if it is contraindicated.
- Except in circumstances in which the use of regional analgesia is particularly indicated and has significant advantages over other methods, it should not be used against the wishes of the parturient.
- Regional analgesia should not be started until the contractions are strong, last 35 to 40 seconds or more, and occur at intervals of 3 minutes or less (9,94). The only exceptions to this rule are the parturients who experience extreme pain during the latent phase of labor and those in whom labor has been induced and maintained with oxytocin.
- The parturient should be continuously monitored during and after administration of the analgesia and her blood pressure, pulse, and respiration measured every 30 seconds during the first 15 minutes and every 5 minutes thereafter.
- Frequently, it is necessary to complement regional analgesia with psychological support and, if necessary, a sedative and small doses of a narcotic.
- Nursing personnel who are skilled and willing to supervise the parturient properly must be available.

Prevention of Complications. Care must be exercised to avoid three serious, life-threatening complications:

- Maternal hypotension can be avoided or minimized by infusing 1 L of fluid 10 minutes before inducing spinal, epidural, or caudal block to compensate for the increased vasodilation consequent to the vasomotor blockade. It is also essential to have the parturient labor on her side to avoid aortocaval compression inherent in the supine position.
- Systemic toxic reactions must be prevented by avoiding excessive doses or accidental intravenous injection of therapeutic doses.
- High or total spinal anesthesia may result from accidental subarachnoid injection of a local anesthetic dose intended for epidural block.

The latter two complications can almost always be prevented by attempting to aspirate blood or cerebrospinal fluid and by injecting a test dose of 2 to 3 mL of a solution containing 5 to 7.5 mg of bupivacaine and 15 mg of epinephrine. If the injection is accidentally subarachnoid, the parturient develops a low T-10 to S-5 spinal anesthesia, which can be used instead of the epidural block. If the injection is intravenous, the epinephrine should produce moderate tachycardia and hypertension within 20 to 30 seconds of the injection that lasts for 30 to 60 seconds. This, of course, means the patient's heart rate must be monitored during the phase of the test dose. A large therapeutic dose should be injected only when neither occurs.

Paracervical and Pudendal Block. The techniques of paracervical block (PCB) combined with pudendal block are shown in Figure 71-25. These procedures can be performed by the obstetrician or the physician managing the parturient. They offer advantages and certain disadvantages.

The primary advantages from their use include (a) the procedures are especially useful in cases in which anesthetists are not available; (b) both procedures can be done easily, provided the physician knows the anatomy well; and (c) PCB provides good relief of uterine pain during the first and second stages of labor, while pudendal block provides good relief of perineal pain during the second stage and delivery.

The primary disadvantages from their usage include (a) PCB produces transient fetal bradycardia in 5% to 20% of cases; (b) pudendal block can impair the bearing-down reflex; (c) both PCB and pudendal block entail the risk of systemic toxicity from overdose or accidental intravenous injection; and (d) the degree of pain relief is less than with other regional techniques.

Subarachnoid Block. Subarachnoid block, also frequently referred to as *spinal anesthesia* and *modified saddle block*, usually produces analgesia and anesthesia extending from the T-10 to the S-5 spinal segments.

The following are advantages of the use of subarachnoid block:

- It is relatively simple to perform and is rapid and certain in its action.
- It entails the use of small amounts of local anesthetic (e.g., 5 mg of bupivacaine), thus eliminating the risk of systemic toxicity.
- It can be initiated in the first stage of labor and carried out until delivery.

- It produces the most profound perineal relaxation, thus facilitating the use of forceps or other maneuvers that require perineal relaxation.

The following are the disadvantages of the use of subarachnoid block:

- It produces a higher incidence and degree of hypotension than epidural block, although these could be reduced with the infusion of fluids prior to induction of the procedure.
- It produces premature perineal paralysis and thus interferes with flexion and internal rotation of the presenting part.
- It eliminates the bearing-down reflex although the parturient can voluntarily bear down effectively, provided the abdominal muscles are not paralyzed.
- It produces not only numbness but also paralysis of the lower limbs, making it impossible for the parturient to move them.
- It carries the risk of postpuncture headache, the incidence of which depends on the size of the needle used and on the number of punctures done. The incidence of headache should be between 1% and 5% if a 25-gauge spinal needle is used (9,92,94,95) (Table 71-4).

Technique	Comparison
Needle puncture L-3 to L-4	Advantage of pure opioid analgesia in SAS for early labor
Single puncture through needle technique	No effect on blood pressure or motor system
Use of opioid early in labor in SAS, use of lumbar epidural later in first and second stage	Decreased risk to fetus due to reduced amount of drug used

SAS, subarachnoid space.

TABLE 71-4. Combined spinal-lumbar epidural technique

Continuous Caudal Analgesia and Anesthesia. Continuous caudal analgesia and anesthesia is a form of epidural blockade that provides good pain relief during labor and produces anesthesia for vaginal delivery (Fig. 71-26).

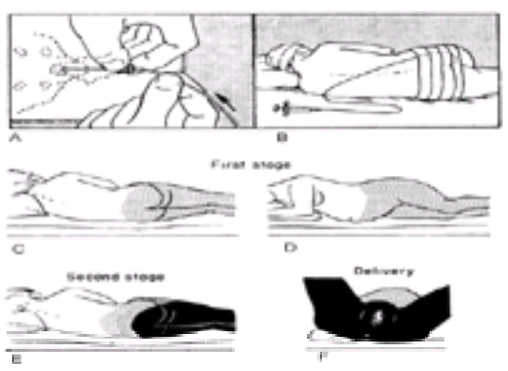

Figure 71-26. Technique of continuous caudal analgesia. **A:** A special 18-gauge, thin-walled, 7-cm needle is inserted and advanced 2 cm and its shaft turned 180 degrees so that its bevel faces the roof of the sacral canal. **B:** A plastic epidural catheter is introduced and advanced 8 to 10 cm to place its tip at the level of the S-1 to L-5 vertebrae. **C,D:** For the first stage and early second stage low concentrations of anesthetics are used to produce only analgesia (*light stippling*). **E,F:** After internal rotation of the presenting part, a higher concentration is injected to achieve motor block and perineal relaxation (*black*) and differential block of the T-10 to T-12 segments (*light stippling*) and of the lumbar segments (*heavy stippling*). (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:110, with permission.)

The advantages of the use of continuous caudal analgesia and anesthesia include that (a) it has a slower onset of vasomotor blockade than subarachnoid block and consequently produces less hypotension; (b) by using an analgesic concentration of local anesthetic (e.g., 0.25% bupivacaine) it produces less perineal and lower limb paralysis than subarachnoid block; and (c) it has no risk of postpuncture headache.

The disadvantages of the use of continuous caudal analgesia and anesthesia include the following: (a) it requires larger amounts of local anesthetic than other regional techniques; (b) more anatomic anomalies occur in the sacrum than in the lumbar region and consequently it is more difficult to execute this procedure, thus entailing a greater risk of failure; and (c) if the procedure is carried out by inexperienced personnel during late labor there is a risk of puncturing the rectum and fetal head.

Continuous Epidural Block. In medical centers in the United States, Great Britain, and other countries that have specialized obstetric anesthesia services, epidural blockade is the procedure of choice for most parturients because it provides effective pain relief in 85% to 95% of women in labor (9,20,92,94,95,122) (Fig. 71-27). Inadequate perineal analgesia for delivery is a frequent occurrence, but this can be avoided by administering a large dose of local anesthetic when delivery is imminent or by having parturients receive a top-up dose (reinjection of local anesthetic) in the sitting position 10 to 15 minutes before delivery.

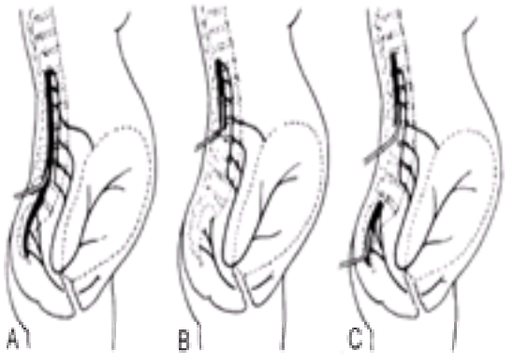

Figure 71-27. Technique of continuous spinal epidural block. **A:** Standard technique for vaginal delivery (analgesia of T-1 to S-5). **B:** Segmental (T- 1 to L-1) block for analgesia during first stage of labor. **C:** Double-catheter technique. White tube, level of catheter; black area in spinal canal, diffusion of local anesthetic. (Reprinted from Bonica JJ. *Principles and practice of obstetric analgesia and anesthesia*. Vol 1. Philadelphia: FA Davis, 1967:614, with permission.)

It is now generally accepted that epidural analgesia does not prolong, and might even shorten, the duration of the first stage of labor (9,92,94,95,116). Although a transitory decrease in uterine activity has been described, this is of little clinical importance. The most recent literature debate on this issue was begun by a well-meaning obstetrician. During a study of epidurals and their effects, the study had to be discontinued due to a flagrant increase in the cesarean section rate. Unless the technique is carried out precisely and the parturient is coached to bear down effectively, the duration of the second stage of labor might be prolonged and instruments might be needed for delivery. Figure 71-28 and Table 71-3 summarize the technique of standard epidural analgesia and its advantages and

disadvantages as compared with other forms of epidural blockade. Figure 71-29 and Table 71-4 summarize the technique of segmental epidural analgesia for the first stage of labor and the extension of this procedure to involve the perineum for the second stage of labor.

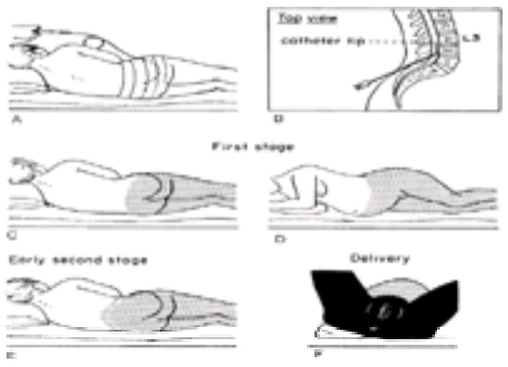

Figure 71-28. The technique of standard continuous lumbar epidural block. A preload infusion of fluid is started. **A,B:** A continuous catheter is then inserted through a needle placed in the L-4 interlaminar space and advanced until its tip is at the L-3 vertebra. **C:** With the onset of moderate pain a test dose is injected and, if negative, 10 to 12 mL of analgesic concentrations of local anesthetic (e.g., 0.25 bupivacaine) are injected to produce analgesia extending from T-10 to S-5. **C–E:** The patient is then made to lie on her side and given oxygen and frequent monitoring, top-up analgesia doses are injected as soon as pain returns to produce continuous pain relief. **F:** After flexion and internal rotation of the presenting part has occurred, a higher concentration of local anesthetic (0.5% bupivacaine) is injected with the patient in the semirecumbent position to produce perineal relaxation and anesthesia (*black*). A wedge is placed under the right buttock for delivery to displace the uterus toward the left, away from the inferior vena cava. (Table 71-5 summarizes the techniques, advantages, and disadvantages of the procedure.) (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:105, with permission.)

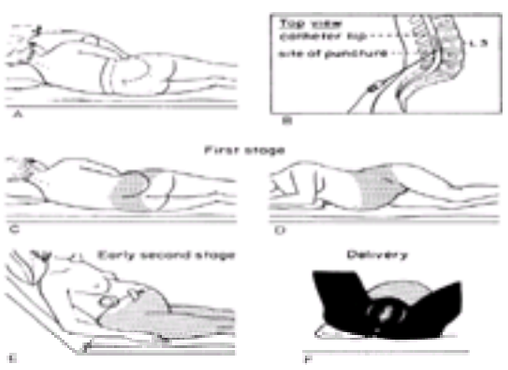

Figure 71-29. Technique of continuous segmental epidural analgesia and anesthesia. After a preload infusion of fluid is started, a continuous catheter is inserted through a needle placed in the L-3 interspace and advanced so that its tip is at L-2. **A,B:** With the onset of moderate pain a test dose is injected and, if negative, 4 to 6 mL of local analgesic solution is injected to produce segmental analgesia **(C,D)**. **E:** For the second stage the analgesia is extended to the sacral segments by injecting a larger volume of the same concentration of local anesthetic, with the patient in the semirecumbent position. **F:** After internal rotation an injection is made of a higher concentration of local anesthetic to produce motor block of the sacral segments and thus achieve perineal relaxation and anesthesia (*black*). The wedge under the right buttock causes the uterus to displace to the left. (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:107, with permission.)

Double-Catheter Technique. The double-catheter technique involves the insertion of one catheter into the lumbar epidural space, with its tip at the level of the T-12 vertebra, and another catheter placed into the sacral canal, with its tip at the level of the S-3 vertebra (Fig. 71-30 and Table 71-5). This technique was first used and advocated by the late John Cleland (123), whose monumental studies of the pathways of uterine pain have already been mentioned. Having had extensive experience with this technique, Dr. Bonica also believed it to be the ultimate in analgesia and anesthesia for labor and vaginal delivery because it provided all the advantages of regional block with few of its disadvantages. The technique permits exquisitely specific analgesia for the first and second stages of labor and produces anesthesia for the delivery. This author has used this technique for delivery of several obstetric patients with valvular heart disease during vaginal delivery. In every case, the patient's blood pressure was maintained within the normal range even during delivery of the baby's head with forceps. The reason for this was activation of the caudal catheter with a small amount of local anesthetic that selectively blocks S-2 to S-4 while the upper T-10 to T-12 analgesia was wearing off. This effectively reduced the spread of the sympathetic blockade to the point that there was just no negative physiologic impact on blood pressure.

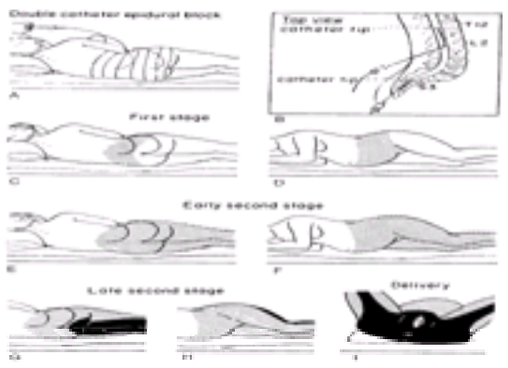

Figure 71-30. Double-catheter technique for epidural analgesia and anesthesia. **A,B:** The two catheters are inserted: The upper catheter is inserted through the L-2 interspace and advanced so that its tip is at T-12; the second catheter is inserted into the sacral canal and advanced so that its tip is at S- 3. **C,D:** As soon as contractions produce moderate pain, small volumes (4 to 5 mL) of analgesic concentrations of local anesthetic are injected through the upper catheter to relieve the pain. Similar injections are repeated throughout labor. **E,F:** When the presenting part exerts pressure on the pelvic structures and perineum, causing pain in the lower lumbar and sacral segments, 5- to 7-mL volumes of analgesic concentrations of local anesthetic are injected through the lower catheter. **G–I:** After flexion and internal rotation are completed a high concentration of the local anesthetic is injected through the lower catheter to produce perineal muscle relaxation and anesthesia of the sacral segments (*black*). (Reprinted from Bonica JJ. *Obstetric analgesia and anesthesia*, 2nd ed. Seattle: University of Washington Press, 1980:113, with permission.)

Technique	Comparison
Needle puncture at L-2 to L-3; catheter advanced 3 cm (T-12)	Requires less drug than standard or single-catheter techniques
Needle puncture in sacrum at S-4; advance catheter to S-3	Most specific technique for labor and delivery
Aspiration test and injection of test dose	Least effect on mother and fetus
If negative at 5 minutes, inject 4 mL of analgesic solution of 0.25%	No effects on newborn
Bupivacaine in upper catheter: analgesia T-10 to L-1	No premature numbness or weakness of limbs
Continuous pump delivery	No premature perineal relaxation; no interference with flexion and internal rotation
With onset of pain in limbs and perineum, inject 5 to 7 mL of 3% rapivacaine	
Continue analgesia until after internal rotation; 5 to 7 mL 0.5% rapivacaine through the lower catheter	Two catheters are required; greater risk of complication and failure

TABLE 71-5. Double-catheter epidural block

The double-catheter technique accomplishes analgesia with smaller individual doses with the following advantages (see Table 71-5):

- Hypotension and other side effects and the risk of systemic toxic reactions in the mother are minimized.
- It causes little or no effect on uterine contractions (because of the smaller doses of local anesthetic).
- It permits the voluntary use of the abdominal muscles because the analgesic concentrations do not produce motor blockade.
- Although the caudal analgesia interrupts the afferent limb of the reflex urge to bear down, the parturient can voluntarily exert as much increase in intraabdominal pressure as she does reflexively and, indeed, in some instances, she can bear down more effectively because she has pain relief.
- The fetus receives less local anesthetic than with any other epidural technique, and therefore incurs no drug-induced cardiovascular or central nervous system depression. With this or any other epidural technique it is best to insert the catheters once it has been decided that active labor has been established, but before the parturient has experienced severe pain, so that she obtains the full benefits of the analgesia.

Intraspinal Opioids for Labor Pain

Both intrathecal and epidural opioids have been used during the first stage of labor to relieve the pain of uterine contractions. The logic of the use of opioids dates back to the original work of Yaksh, who in 1979 published the first article on the use of opioids in the central nervous system (124,125). Most of these studies began in the mid- to late 1980s. Fortunately, now, the use of opioids is firmly established and has paved the way for better and even safer methods of pain relief for obstetric anesthesiology.

Intrathecal Opioids. Morphine in doses ranging from 0.5 to 2.0 mg injected intrathecally has apparently provided fairly good relief from uterine contraction pain, lasting for several hours (126). The onset of analgesia was slow, however, and analgesia during the delivery was poor, requiring supplementary pain relief. The serious disadvantages of the use of intrathecal morphine in labor is the high incidence of adverse side effects, including pruritus, nausea, urinary retention, and rarely, but potentially tragic, respiratory depression.

Epidural Opioids. Epidural morphine has been used in doses ranging from 2 to 10 mg (127,128). Most reports suggest that analgesia was poor, even in the high-dose range, and in many cases, was ineffective in relieving the pain of uterine contractions (129). Like intrathecal morphine, the onset of analgesia was slow, and supplementary analgesia was needed during delivery. Moreover, side effects similar to those seen with intrathecal morphine have been encountered.

Epidural meperidine has been found to produce analgesia within 10 minutes and has been more consistent and reliable than morphine. Both the efficacy and duration of analgesia are dose dependent: With an injection of 25 mg, analgesia was less reliable than that produced by 0.125% bupivacaine (130) and lasted less than 1 hour (131). Increasing the dose to 50 or 100 mg provided analgesia that was almost equivalent to that obtained with 0.25% bupivacaine for approximately 2 hours, but these higher doses were associated with a higher incidence of side effects (132).

Epidural fentanyl in doses ranging from 0.15 to 0.20 mg also provided effective analgesia for the pain caused by uterine contractions within 10 minutes, and lasted for 90 to 130 minutes during labor (112). Perineal analgesia was poor and side effects also occurred. The addition of 0.8 mg of fentanyl to a test dose of bupivacaine provided a more rapid and complete onset of analgesia and significantly prolonged the duration of the effect of the local anesthetic (112).

Epidural Local Anesthetic and Opioid Combinations. A number of obstetric anesthesiologists have used a combination of opioids and dilute solutions of local anesthetics (e.g., 0.125% bupivacaine) with significant success. There are advantages and limitations to all drugs. It is interesting to note that the limitation of opioids is ineffective second-stage analgesia and the advantage of local anesthetics is effective second-stage analgesia. It is similarly interesting to note that the limitation of local anesthetics is selective visceral analgesia and the advantage of opioids is intense visceral analgesia. Thus, we can see the advantage of combining these two for a potent effect on labor pain.

Several opioids have been combined with popular local anesthetics, such as bupivacaine and lidocaine. These have been fentanyl, sufentanil, meperidine, alfentanil, and butorphanol. By far the most frequently used opioid combined with local anesthetic for labor and delivery is fentanyl (133). Sufentanil may well prove to be the preferred opioid of choice because of its advantageous chemical properties. It is twice as lipid soluble as its closest competitor, fentanyl. Furthermore, it has high affinity for the mu receptors themselves. And, finally, there is no evidence of neonatal depression (134).

The main advantage of using such an opioid is to reduce the total amount of local anesthetic and thus enjoy a decreased risk of the untoward effects of these agents (135,136). These, of course, include nuisance complications such as minor hypotension, inability to move the lower extremities, a reduction in the force of uterine contractions, and a slowing of the labor process. They also include major catastrophic complications, such as full-blown central nervous system convulsions and cardiac arrest and death. Thus, the stage is set for more frequent use of such agents if only to avoid these complications.

A newcomer to the local anesthetic stable is ropivacaine. Ropivacaine is the newest member of the amide local anesthetics. Its pharmacologic properties are between mepivacaine and bupivacaine. This local anesthetic stands out among others because of its high potency and low toxicity. Another clinical advantage appears to be some vasoconstriction, thus making it appealing for local anesthetic nerve blocks and field blocks (137). This latter attribute does not carry over to vasoconstriction of the placental circulation, so its usefulness in obstetrics is not impaired (138).

The use of such combinations in dilute dosages mandates the use of a pump and a continuous delivery of the agents on a minute- to-minute basis. There are many different pump systems now available that reliably deliver preset dosages of these combinations. In instances in which adequate analgesia is not obtained with the more dilute solutions, bolus injections of regular strength medications can be administered to push past areas of skipped analgesia; this is particularly applicable in the late second stage and near delivery. The continuous infusion method has been used and reported by several investigators over the past decade; this work substantiates the fact that this method of delivery is safe and effective and indeed the preferable method for delivery of analgesia to the mother in labor (139,140).

The mechanism of action of the opioids is still questionable. Whether they act on the spinal cord itself or act via a circuitous route by systemic uptake is not known. Similarly, it has not been shown whether they act in an additive fashion or a synergistic fashion (141,142).

Episiotomy Pain

Many obstetricians and midwives perform an episiotomy to facilitate delivery, especially in primiparas, although it is also frequently performed in multiparas. Prophylactic episiotomy is done to decrease the duration of the second stage of labor, to protect against tears, and to facilitate the introduction of forceps if their use becomes necessary. The pain caused by this procedure is also transmitted by branches of the pudendal nerve and can be obviated with local infiltration or pudendal block or with other types of regional anesthesia.

In a comprehensive review, Thacker and Banta (143) discussed the benefits and risks of episiotomy in labor and delivery as recorded in the English language literature (350 books and articles published between 1860 and 1980). They cited the fact that, in 1979, an episiotomy was performed in nearly 63% of vaginal deliveries in the United States. It was determined, however, that episiotomy did not offer a clear benefit to women in terms of decreased number of lacerations. Moreover, in reviewing the extensive literature, it was noted that the role of episiotomy in preventing serious pelvic relaxation has not been adequately studied. In fact, women who did not have an episiotomy had little risk of pelvic relaxation. In regard to the issue of doing an episiotomy to protect the brain of infants, it was noted that it is beneficial in extreme cases, such as when the fetus is large and labor is prolonged (143). The probable benefit, however, does not necessarily mean that most routine episiotomies can be justified.

The risks of episiotomy include extension of the episiotomy by tear of tissues, unsatisfactory anatomic results, blood loss, pain, edema, and infection (143).

It was concluded that risks of episiotomy are more severe than many obstetricians appreciate. Although rarely associated with a life-threatening problem,

complications of this procedure can be a source of serious morbidity to young mothers, who already have major personal and social adjustments to undergo.

One study in Great Britain by Kitzinger and Walters (144) revealed that, among 717 women who had had an episiotomy, 45% stated that the perineum was moderately uncomfortable at the end of the first week, 19% thought it was painful, and 9% thought it was very painful. The figures among 341 women who had had perineal tears (no episiotomy) were 39%, 11%, and 4%, respectively. Moreover, in 17% of those who had had an episiotomy the pain often distracted them when breast-feeding and 22% could not sit comfortably when holding the baby. Many of the women who had had an episiotomy experienced pain during sexual intercourse that persisted for more than 3 months in some. It was also concluded (144) that, although episiotomy might be necessary in special cases (e.g., when it is necessary to hasten delivery), it is not necessary in most women and, when done, causes unnecessary pain for varying periods following delivery.

In one report it was suggested that local infiltration with saline solution before the episiotomy repair decreases the severity of postepisiotomy pain (145). It was postulated that the pain is a result of tight enclosure caused by the edema and inflammation that can be accommodated under less pressure if slack is created by prior distension of the tissues. Postepisiotomy pain is treated with cold or hot sitz baths. In women who have moderate to severe pain, nonopioid analgesics, given alone or combined with weak opioids, can be used, but care must be exercised in prescribing these or any other drugs in women who are breast-feeding their infants.

CHAPTER 72

Gynecologic Pain Syndromes

John S. McDonald and Mark L. Elliott

Pain that emanates from the structures that form the pelvis and pelvic cavity is one of the major catastrophic threats to the health and well-being of both female and male patients. This chapter highlights many of the different gynecologic pain syndromes mentioned in Chapter 70. It is hoped that awareness of these will help the practitioner to think in more global terms and to help develop a rich differential diagnosis when confronted with the patient who has pelvic pain. The material is presented in two discrete sections: one devoted to medical or clinical considerations and a second devoted to psychological considerations. It is fitting that psychology play a major role in this chapter, because it is very rare that women who suffer from chronic pelvic pain do not have either primary or secondary psychological involvement.

The medical section of this chapter is organized into basic considerations, with an introductory discussion of etiology and epidemiology, and clinical considerations, with discussions on physical examination, differential diagnosis, diagnosis, and, finally, treatment. The psychology section of this chapter deals wholly with the psychology of gynecologic pain syndromes. Psychology is the most pivotal and closely related science to pain and the suffering caused by pain.

MEDICAL SECTION

Basic Considerations

Etiology and Epidemiology

Pelvic pain has long confused the physician and patient alike. It is without a doubt one of the most difficult diagnostic and management challenges in medicine. Patients with pelvic pain are often seen by family physicians, internists, gynecologists, urologists, neurologists, and general pain specialists. Gynecologists manage the largest fraction of pelvic pain patients. The confusing and confounding aspects of pelvic pain diagnosis and management come from physicians being locked into the myth that most all pelvic pain is due to organopathologic causes or the complex relational aspect of sexual abuse.

If a health care system can be improved, one aspect of that improvement will be some method of early referral of pelvic pain patients to knowledgeable practitioners such as chronic pain specialists so as to avoid two very important mistakes: (a) the languishing of patients in a diagnostic limbo by family doctors, internists, neurologists, gynecologists, and surgeons and (b) a reduction in the unnecessary surgical procedures performed on the basis of “pelvic pain symptomatology.” One of the goals of this chapter is a modification of referral practice so that patients will not suffer from either of these problems. A new, fresh approach must then also include at the outset the very important and often overlooked psychological aspects of pelvic disease processes and the problems created by them. Psychology now serves as a pivotal focus for understanding the management plans that will or will not make sense with regard to helping the patient get well. The incredible sea of experience in sexual abuse and the manner in which that can make or break a carefully conceived plan of treatment is indispensable. The last section of this chapter is entirely dedicated to psychology and its overall impact with regard to pelvic pain.

Acute Gynecologic Pain Syndromes

Ectopic Pregnancy. One important cause of pain in early pregnancy is abnormal or ectopic pregnancy. In ectopic pregnancy, the conceptus implants itself outside the uterine cavity—for example, in the uterine cornu, along the uterine tube, on the ovary, or on various portions of the abdominal and pelvic peritoneum. In 98% of cases, the ectopic pregnancy is an actual “tubal pregnancy” and occurs whenever the migration of the fertilized ovum toward the uterine cavity is unduly delayed by tubal factors. The incidence is near 1 in 200 pregnancies, but frequency may be influenced by an increasing incidence of acute salpingitis (1).

Ectopic pregnancy presents with two classic clinical scenarios: (a) the threat of massive hemorrhage and (b) severe pain driven by peritoneal distension and stretch. Later, pain may be caused by extrusion of the ectopic pregnancy and by further hemorrhage that causes accumulation of peritoneal blood. As a result, when an ectopic pregnancy causes severe pain in the first trimester, it often indicates an acute abdomen and anemia, which may necessitate surgery. Laparoscopy will confirm an ectopic pregnancy with implantation outside the uterine cavity.

Symptoms and Signs. Pelvic pain is the most common symptom of ectopic pregnancy (2). Pain is limited to the site of implantation and probably represents stretching of the visceral peritoneum over the organ involved. If hemorrhage occurs and is contained within the ectopic site, pain increases. Once the trophoblast breaks through the fallopian tube, massive hemorrhage may occur into the peritoneal cavity. The accompanying pain is initially localized deep in the pelvis as blood collects in the cul-de-sac. In the supine position, blood runs upward along the lateral border of the peritoneal cavity, with resultant diaphragm irritation and shoulder pain. The patient may feel faint, and physical examination may reveal that the patient is pale and has other signs of hypovolemia. Evidence of abdominal distension and tenderness on palpation is also found, especially over the iliac fossa, where the pain starts. Pelvic examination is difficult because of the tenderness of the abdomen. Often, a bulging cul-de-sac can be appreciated on careful palpation.

Diagnosis. Early recognition of ectopic pregnancy is imperative because it is a significant cause of maternal mortality (3). The diagnosis is not difficult and is made on the basis of history, physical examination, and laboratory studies. Aspiration of a bulging posterior cul-de-sac through a large needle yields nonclotting blood—that is, blood that has already clotted and lysed. Decreased and increased human chorionic gonadotropin levels suggest an abnormal gestation, such as ectopic pregnancy. Ultrasonography in the hands of an experienced sonographer can provide helpful information about ectopic pregnancy.

Because pain in early pregnancy can be caused by either a normal or abnormal gestation, the clinician should attempt to make this distinction based on history, physical findings, and appropriate laboratory findings. Signs of shock can occur and may be manifest in public places far removed from hospitals. Such an episode naturally indicates significant intraperitoneal or vaginal blood loss that must be attended to immediately.

Treatment. Treatment of ectopic pregnancy pain involves a correct diagnosis and a surgical procedure appropriate to the individual patient and the operative findings. Current conservative surgical therapy includes opening the tube and removing the conceptus or simply excising the conceptus and rejoining the tube to retain the reproductive abilities of the patient (1). The surgeon must be fully aware of the patient's desires regarding this matter before operating because, even in a patient with a ruptured uterine tube, some portion of the organ might be salvageable. Removal of the conceptus, regardless of its location, usually eliminates the pain. Postoperative pain can be controlled with administration of narcotics (e.g., intermittent injection, patient-controlled anesthesia, or lumbar epidural opioid analgesia).

Abortion. Spontaneous abortion is associated with pain caused by uterine muscle contractions and by attempts to expel the conceptus from the endometrial cavity.

Symptoms and Signs. Spontaneous abortion usually produces intermittent menstrual-like cramping pain that is mild initially but gradually increases in intensity. Later, vaginal bleeding, which can be profuse, and passage of placental tissue from the vagina accompany the cramps.

In septic abortion, signs of infection are also present, such as fever, occasional chills, a purulent discharge, and tenderness of the uterus. When the infection spreads to the adnexa and pelvic peritoneum, signs of peritoneal inflammation appear, including nausea, constipation, reflex muscle spasm, and even signs of septicemia.

Diagnosis. Diagnosis is made by the history and physical findings. A patient with septic abortion reveals laboratory signs of infection. Ultrasonography can be used to reveal a fragmental gestational sac, a low implantation of the sac, and absence of fetal heart movements. Radioimmunoassay for human chorionic gonadotropin is positive, denoting the presence of functional placental tissue.

Treatment. A patient with a threatened abortion, a closed os, no passage of tissue, and vaginal bleeding needs close observation but no immediate intervention. Pain usually stops once the threat of abortion passes, the abortus is passed, or pregnancy is terminated surgically (usually by dilatation and curettage). In the instance of a threatened abortion, the patient's pain and bleeding increase until she completely passes all tissue, which terminates the gestation, or until dilatation and curettage. The pain subsides once this process is complete, although uterine cramps can persist if an oxytocic agent is administered after the procedure to keep the uterus well contracted.

Fibroid Degeneration. During pregnancy, estrogen secretion by the placenta causes uterine myomata, or “fibroids,” to enlarge, often without a concomitant increase in blood supply. Consequently an aseptic degeneration within the tumor can occur.

Symptoms and Signs. Aseptic degeneration of a myoma causes pain that is localized at the site of the tumor. Initially the discomfort is a dull, constant ache, but it usually progresses to an intense unremitting pain that prevents the patient from all activity, including sleep. The location of the pain depends on the location of the fibroid. The tumor is usually tender on palpation, possibly accompanied by slight fever and a moderate leukocytosis.

Diagnosis and Treatment. The diagnosis is usually made through careful evaluation of the pain and its location and by physical examination. Because the pain is usually unremitting until degeneration is complete, administration of narcotics such as morphine might be necessary to relieve the pain. Analgesia and bed rest are continued until the pain ceases.

Endometritis

Etiology and Pathophysiology. Acute endometritis is distinguished from pelvic inflammatory disease (PID) because the former involves only the uterus. Endometritis (infection of the uterus) results when bacteria invade the uterus and multiply. The pain of acute endometritis is caused by multiplication of infecting organisms and accumulation of the products of infection.

Ordinarily, the cervix presents an impenetrable barrier to invasive organisms. When the cervix has been breached by surgical instrumentation (e.g., as in dilatation and curettage) or the passage of a pregnancy (spontaneous abortion or a term pregnancy), however, the uterus is open to colonization by organisms. The offending organism can be one of the normal vaginal flora or can be a more virulent organism introduced by sexual activity, such as *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, or *Bacteroides*. A pregnant uterus most often becomes infected after attempted evacuation of a failed pregnancy.

Symptoms and Signs. The initial symptoms are lower abdominal pain centrally located over the pubic symphysis. The pain can become crampy in nature, accompanied by foul-smelling vaginal discharge or vaginal bleeding. Urinary frequency can occur as the bladder becomes irritated, and a low-grade fever might be present.

In endometritis, pain occurs on manipulation of the uterus during the vaginal examination and is confined to the uterus; the adnexal areas are relatively free of pain.

Diagnosis. A recent pregnancy or uterine instrumentation combined with the appropriate symptoms and signs is the basis for the diagnosis of endometritis. Visualization of the cervix with culture of the exudate, particularly for organisms causing sexually transmitted diseases, should be performed.

Endometritis must be differentiated from uterine cramping without infection and from cystitis. The patient experiencing uterine pain without infection usually is afebrile, and the white blood cell count is elevated only slightly. Such elevation can be confusing, however, because pregnancy itself causes a leukocytosis. In endometritis, however, the purulent and foul-smelling cervical discharge can show growth when culture and sensitivity tests are performed or can reveal organisms with Gram's stain.

Cystitis is distinguished by the presence of red and white blood cells and bacteria in the urine. These organisms can usually be cultured.

Treatment. Mild endometritis is usually treated on an outpatient basis with oral medication to eliminate the organisms typically found in gynecologic infections. Such medication generally includes an immediate dose of penicillin or cephalosporin followed by doxycycline or tetracycline for 10 days (see the treatment section in Acute Pelvic Inflammatory Disease). Septic abortion requires hospitalization and parenteral antibiotics along with appropriate support if gram-negative sepsis develops.

Pelvic Inflammatory Disease. Acute PID involves infection of the intraabdominal pelvic organs and nearby structures. PID poses a serious threat to the health and welfare of women because an estimated 1 million cases occur annually in the United States and are a major cause of ectopic pregnancies and infertility (4).

Etiology and Pathophysiology. Aerobic or anaerobic bacteria can be the responsible infectious agents that are normally found in the cervical or vaginal flora. Lower genital tract cultures reveal the organisms *N. gonorrhoeae* and *C. trachomatis*. Recently, *Haemophilus influenzae* has been increasingly associated with salpingitis (5). Other microbes include both aerobes—for example, *Escherichia coli* and group B streptococci—and anaerobes—for example, *Bacteroides bivius* and *Bacteroides* species (6,7). These organisms ascend to the upper genital tract through the cervix by cervical instrumentation or through loss of the cervical mucous plug during menstruation.

Sexual activity is the most common denominator for women who have PID (8). In fact, women who have multiple sex partners are more likely to have PID than those who have one partner. A previous episode of PID also predisposes a person to a subsequent episode (4). In the 1960s and 1970s, the use of an intrauterine device called the Dalkon shield was associated with a large risk of PID. Other intrauterine devices have produced an increased risk of subsequent PID; interestingly enough, the incidence is greater in nulliparous women than in multiparous women (9). One published survey showed only a slight risk of infection in the first 4 months after insertion of an intrauterine device (IUD) (10). The use of oral contraceptive tablets instead of an IUD seems to decrease the incidence of PID. This decrease in incidence may be because of changes in the cervical mucus (11). The most common factor in causation of PID is sexual contact with a partner who has gonorrhea (12). Another common cause is surgical instrumentation of the uterus for either diagnostic purposes or termination of pregnancy. This invasive action can spread an infection of the lower genital tract upward.

The pain of PID is caused by multiplication of the infecting agent within the pelvic organs. This causes tissue destruction and accumulation of products of infection that irritate peritoneal surfaces. The edema occurring in response to infection causes further tissue damage and distortion. Some believe patients have pain from adhesions that develop secondarily between damaged intraabdominal organs or between these organs and the abdominal wall. Adhesions often occur in the lower abdomen and pelvic cavity, and perihepatic lesions have been reported, as in the Fitz-Hugh-Curtis syndrome. This is a perihepatitis that occurs as a complication of gonorrhea in some women. It is postulated that when movement occurs between tissues fixed by these adhesions, pain may result. These adhesions are more friable in acute infection and increase with the severity and number of infections. As mentioned, there are those who believe that adhesions can be responsible for pain. On the other hand, there are those whose work have demonstrated no clear relationship between adhesions and pain (13).

Symptoms and Signs. Typical pain in patients with acute PID usually occurs in the abdominal and pelvic areas and is manifest by tenderness of the adnexa, general abdominal rebound tenderness, and extreme discomfort on any movement of the cervix. Some patients with severe cases can have very severe abdominal pain, compounded by intractable nausea and diarrhea.

A gonorrheal infection usually produces severe pain soon after the first menses. In contrast, chlamydial infection usually produces no symptoms at all; sometimes mild pain lasts several weeks. Patients with mixed flora, particularly an anaerobic infection, are often febrile and appear seriously ill as well as in pain. Dysuria and dyspareunia are also common in patients with PID. Among the possible complications of acute PID are the following:

Abscess in the pouch of Douglas
Tuboovarian abscess
Recurrent episodes of PID
Infertility
Ectopic pregnancy
hronic lower abdominal pain

Diagnosis. The diagnosis of PID depends on by far the most common symptom: the presence of abdominal pain. Closely associated are rebound abdominal tenderness, discomfort on motion of the cervix, and tenderness of the adnexa. Diagnosis is aided also by the presence of at least one of the following laboratory findings:

Gram-negative intracellular diplococci found on culture of cervical discharge

Bacteria and white blood cells found in the fluid obtained by culdocentesis

A pelvic or adnexal mass or leukocytosis (white blood cell count >10,500 per µL)

Fever of 38°C (100.4°F)

An erythrocyte sedimentation rate higher than 15 mm per hour.

PID must be differentiated from several other conditions that can cause pelvic pain and/or masses. These include early pregnancy, endometriosis, ovarian neoplasia, appendicitis, diverticulitis, bowel disease, cystitis, and pyelonephritis.

Some delineation of these may be aided by use of ultrasound and pregnancy tests to rule out ectopic pregnancy. Naturally, if culdocentesis produces blood instead of purulent material, an accident of pregnancy or a ruptured ovarian cyst must be suspected as the primary cause. A significant history of prior severe dysmenorrhea, tenesmus, and dyspareunia suggests the possibility of endometriosis. Nongynecologic disease such as appendicitis can present with signs and symptoms that closely resemble those of PID. However, the pain of appendicitis is usually unilateral, and periumbilical and gastrointestinal symptoms such as nausea and vomiting often occur early in the course of the disease. Another bowel disease process—regional ileitis, or Crohn's disease—is a chronic disease process, and thus patients with pain from this disease entity often have a clear history that helps point toward that diagnosis.

Other nongynecologic disease processes involve the urinary system. Infections, particularly acute cystitis and severe pyelonephritis, can often be confused with PID. The discovery of significant amounts of bacteria, white and red blood cells, or casts, or a combination of these in an aseptically collected urine specimen, strongly suggests the presence of a urinary tract infection. In addition, the pain of cystitis is located in a low and central position on the lower abdomen, whereas the pain of severe pyelonephritis can be bilateral and low in the groin and costovertebral angles. The point to make here is that the urogenital system should always be considered and a centrifuged urine sample analyzed to rule out urinary tract disorders when confronted with generalized abdominal pain. When the diagnosis of PID is uncertain, further diagnostic study, such as laparoscopy, is necessary.

Treatment. The current treatment of PID concentrates on coverage of the major bacterial pathogens. The chief antibiotic regimens are noted in Table 72-1. These medications are as noted from the Centers for Disease Control guidelines. After adequate treatment time the pain will begin to subside. Treatment usually needs to be carried out for upwards of 48 to 72 hours. The pain can be managed with a nonsteroidal antiinflammatory drug (NSAID) or a potent opioid, if necessary. Many patients can be treated on an outpatient basis, such as those with a first episode of PID who have a temperature lower than 38°C. These patients must be able to walk and eat and must have no pelvic mass suggestive of abscess.

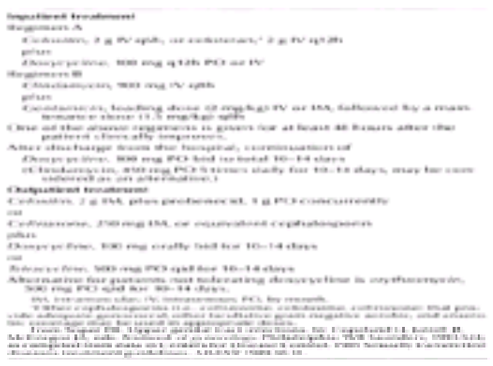

TABLE 72-1. 1989 Centers for Disease Control treatment guidelines for pelvic inflammatory disease

If a patient has any of the following conditions, she should be admitted to a hospital for parenteral antibiotic therapy:

Failure to respond to oral medication

Inability to take oral medication or walk because of severe infection

A greatly elevated temperature

Upper abdominal signs

A suspected or diagnosed abscess

Pregnancy

Ongoing use of an IUD

Most patients improve within 48 hours with parenteral antibiotic therapy. Some patients, however, require surgical intervention because they are seriously ill and have failed to respond to antibiotics or because they have become even more ill in spite of 48 hours of antibiotic therapy. Surgery is almost always indicated for patients who are admitted with a pelvic mass that has disappeared or who are moribund on admission; both conditions suggest a ruptured pelvic abscess. Other patients might require exploratory surgery to establish a diagnosis of PID if the pelvic examination shows no abnormalities and if pain fails to resolve after antibiotic therapy.

Surgery for PID should be tailored to the patient's condition and the patient's desire for conservation of reproductive capability. The use of new and more potent antibiotics has decreased the incidence of life-threatening ruptured abscesses. The advent of more advanced techniques for treating infertility, such as tubal microsurgery and *in vitro* fertilization, has decreased the number of surgical procedures that remove all pelvic organs if a conservative approach is requested by the patient (14,15).

Adnexal Torsion

Etiology and Pathophysiology. Adnexal structures are made up of the uterine tubes, the ovaries, the peritoneum, and the accompanying blood vessels. These structures are anchored proximally at the isthmus of the tubes; the distal ends of the tubes adjacent to the ovaries are free and suspended in the pelvic cavity. Thus, it is easy to see that enlargement of an ovary by an ovarian tumor could rotate the entire fallopian tube and cause ischemia in all of the aforementioned structures. This could lead to necrosis, and severe pain is the end result.

Torsion by itself can also produce intermittent pain if the tube rotates to and fro, or acute progressive pain can result if necrosis occurs. It needs to be stressed that normal adnexal organs only very rarely undergo torsion.

Symptoms and Signs. Adnexal torsion often elicits a dull ache on the involved side that has a sinusoidal pain pattern. Nausea and fever can accompany the pain.

Diagnosis. The diagnosis is made during pelvic examination by noting the presence of an extremely tender mass usually on one side. This certainly suggests that the diagnosis of torsion of the adnexa be considered. Ultrasonic imaging of the pelvis can be useful when tenderness makes delineation of a mass during pelvic examination difficult or impossible. The diagnosis of adnexal torsion is more likely if there is a finding of mild elevation of the white blood cell count in the presence of fever and nausea. The differential diagnosis must include ectopic pregnancy, functional ovarian cysts, endometriomas, ovarian neoplasia, and pelvic inflammation.

Treatment. Once torsion has been diagnosed, surgical confirmation and treatment should be undertaken with laparoscopy as quickly as possible. In the presence of a discrete, painful adnexal mass sufficiently large to warrant operation, laparoscopy is now clearly the choice over laparotomy.

If the adnexa have twisted and the structures involved are gangrenous, the mass should be excised completely without untwisting it. This practice prevents clots from being squeezed from the venous complex involved into the general circulation. When operating on a woman's pelvic organs, the nature and extent of the surgical process must be in accordance with the patient's wishes for future pregnancy.

Bleeding of Functional Ovarian Cysts

Etiology and Pathophysiology. A functioning ovary produces two cysts per month: a follicle cyst and a corpus luteum cyst. The follicle cyst ruptures and releases an egg, while the remaining cells unite and convert to a corpus luteum. With development of pregnancy, the corpus luteum remains and grows; without pregnancy, the corpus luteum withers away usually within 14 days.

Symptoms and Signs. When ovulation occurs, the patient can experience acute unilateral pelvic pain. This has been referred to as *mittelschmerz*, which refers to ovulation pain (16). The pain is often sharp in quality with no radiation. The pain may subside gradually until it disappears, or it may decrease in intensity but convert to a generalized lower abdominal pain. It is not unusual to have pain in the shoulder. Initially, the pain may be due to follicle rupture, whereas subsequent pain may arise from blood collecting in the pelvis. The etiology of the shoulder pain is the diaphragm, which becomes irritated by blood collecting under it. If bleeding continues, a hemoperitoneum can develop and the patient can experience syncope.

Diagnosis. The suspicion of a leaking ovarian cyst must be considered when symptomatology occurs late in the menstrual cycle in conjunction with an adnexal mass. A rupture of such an ovarian cyst should be suspected when a subsequent examination of an adnexal mass reported to be present “disappears.” The presence of intraperitoneal fluid can be detected by ultrasonic imaging. If signs of hypovolemia are present, a hemoperitoneum should be suspected and an immediate peritoneal puncture, culdocentesis, or laparoscopy should be carried out. If blood is obtained on aspiration, however, the source of the bleeding must be located by direct visualization. Although laparoscopy can be used, the presence of a significant amount of blood can make visualization of pelvic organs difficult. Under these circumstances laparotomy may be substituted. Bleeding ovarian cysts may be difficult to distinguish from other causes of intraperitoneal bleeding, adnexal masses, and pain due to pregnancy and endometriosis. Although endometriosis is a possible cause, pain from this condition usually occurs closer to the onset of menses.

Treatment. A ruptured cyst accompanied by severe pain may subside without evidence of a progressive hemoperitoneum. This scenario needs no further treatment except pain control. If recurring monthly pain of this nature is severe enough to warrant suppression of ovulation, then ovulation may be suspended by use of birth control medication. Hemoperitoneum, on the other hand, requires evacuation, drainage, and surgical removal or repair at the site of bleeding.

Dysmenorrhea. Dysmenorrhea is pelvic or low abdominal pain that causes misery and dysfunctional lifestyles for millions of women. It is cyclic pain directly related to menstrual periods. Dysmenorrhea is a common disorder, affecting as many as 5 million young women in this country. The majority of sufferers have severe pain; up to 10% are unable to function normally for some time each month (17). The pain associated with menses can begin a few hours or days before the onset of the menstrual period and last a few days or even throughout the entire period. The pain is often relegated to an unimportant status or “something that will quickly go away.” Thus, often it is not treated adequately and the patients have to find over-the-counter medications for most of their pain relief.

Primary Dysmenorrhea

ETIOLOGY AND PATHOPHYSIOLOGY. Primary dysmenorrhea is pain located in the lower abdomen that has no obvious cause such as endometriosis or other common pathology. The pain of dysmenorrhea is not associated with pelvic structural abnormalities, and the exact cause of the pain is not yet determined for certain. There is evidence that such pain can be caused by relative uterine ischemia from hypercontractility of the myometrium (18,19). Such a hypercontractile state can be the result of excess prostaglandins or vasopressin; the prostaglandin's action could increase uterine contractility and then sensitize nerve endings to the pain-producing effects of other compounds, such as bradykinins. This theory has received support in the laboratory experimentation and because use of prostaglandin inhibitors does result in significant pain relief in dysmenorrhea (20).

SYMPTOMS AND SIGNS. The pain of dysmenorrhea often begins just before menstruation and increases in severity as flow begins. It is cramping in nature and localized in the midportion of the lower abdomen. The pain can involve the lower back and, on rare occasion, the upper thighs. Prodromal symptoms, characteristic of the prostaglandin effect seen commonly with other systems, include the following

Diarrhea
Nausea
Headache
Light-headedness
Palpitations, diaphoresis, and tremulousness
Anxiety

DIAGNOSIS. Patients who fit the picture of menstrual pain beginning shortly after menarche and who report subsequent dysmenorrhea with the symptoms as described may be diagnosed as having primary dysmenorrhea. The pelvic examination is normal, and there are no suspicions of any pathologic problems, but some conditions that cause secondary dysmenorrhea such as uterine polyps and endometriosis can be present despite a normal pelvic examination. It is only after time and exhaustive tests that these conditions may be discovered.

TREATMENT. The pain of dysmenorrhea incriminates uterine ischemia and sensitization of uterine pain fibers resulting from excessive myometrial contractility due to prostaglandin stimulation. Therefore, it is logical that prostaglandin synthetase inhibitors (NSAIDs) that block enzymes of the arachidonic acid pathway are effective therapy for primary dysmenorrhea (21). Some of the commonly used current drugs in the treatment of primary dysmenorrhea are shown in Table 72-2. The action of these agents is somewhat similar except for mefenamic acid, which, in addition to inhibiting prostaglandin synthetase, aids in the breakdown of prostaglandins. All these drugs can cause gastrointestinal irritation as a side effect. Although aspirin inhibits prostaglandin synthetase, it acts primarily as a prostaglandin synthesizer in platelets and is not particularly effective in the uterus (22).

Drug (brand name)	Dose
Carbamazepine (Tegretol)	100 mg bid
Celecoxib (Celebrex)	100 mg bid
Diclofenac (Arthrotec)	50 mg bid
Gabapentin (Neurontin)	300–2,700 mg qd
Ibuprofen (Motrin)	300 or 600 mg tid PO, tailored to individual symptoms and response
Mefenamic acid (Ponstel)	Initial dose of two 250 mg tablets PO, followed by 250 mg q6h (for not more than 1 wk)
Naproxen sodium (Anaprox)	Initial dose 2 tablets 250 mg PO, then one tablet q6–8h
Naproxen (Naprosyn)	250 mg PO bid
Phenylbutazone (Lartical)	100–1,800 mg qd
Propionic acid (Actron)	12.5–25 mg q6h
Orudis	25–50 mg q8h
Tramadol (Ultram)	50 mg tid
Zafirlukast (Accolate)	20 mg bid

PO, by mouth.

TABLE 72-2. Nonopioid analgesics for primary dysmenorrhea

Oral contraceptives sometimes relieve dysmenorrhea through a decrease in the amount of prostaglandin F_2 stored in the endometrium and released into the menstrual blood (23). Oral contraceptives also make the myometrium less sensitive to prostaglandins, as shown by one study that demonstrated decreased motility in response to exogenously administered prostaglandins (24). Although suppression of ovulation can be beneficial in relieving dysmenorrhea, the patient must be willing to accept the risks, however minimal, of oral contraceptives.

Inhalation of terbutaline has also been used for alleviation of the pain of dysmenorrhea. In one double-blind crossover study, significant pain relief was experienced in the 14 women tested (25). One study, which used meclofenamate therapy and found it to be effective, differentiated patient response to placebo versus drug by using a discriminatory test for pain relief as opposed to objective uterine activity (26). Table 72-3 and Figure 72-1 list treatment regimens that may be considered for dysmenorrhea.

1. Nonsteroidal antiinflammatory drugs
2. Oral contraceptives
3. Antidiuretics therapy
4. Gonadotropin-releasing hormone agonist[a]
5. Presacral neurectomy
6. Ovariectomy

[a]Plus add back of estrogen to prevent hypoestrogenism.

TABLE 72-3. Treatment regimen for dysmenorrhea

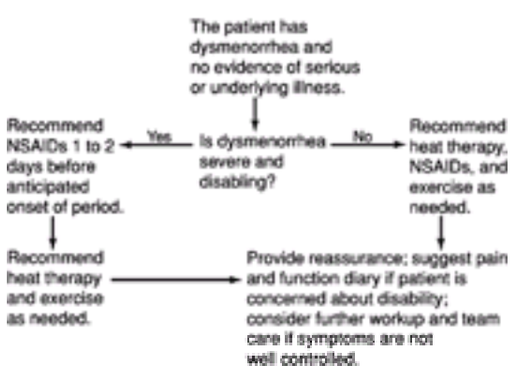

Figure 72-1. Treatment regimen for dysmenorrhea. (NSAIDs, nonsteroidal antiinflammatory drugs.) (From *Paradigm, a practical guide: applying the principles of pain management to common problems*; as adapted from Loeser JD, ed. *Common pain problems: guide to practical management*. Darien, CT: Health Communications Inc., 1998:17, with permission.)

Secondary Dysmenorrhea

ETIOLOGY AND PATHOPHYSIOLOGY. Secondary dysmenorrhea is related to organic pelvic pathology. Pain can be intrauterine in origin, such as that occurring with submucosal fibroids, polyps of the endometrium, or use of an intrauterine device. In these cases pain is thought to be caused by contractions generated by the uterus trying to expel its contents. Although narrowing of the cervical canal was once thought to be a significant factor, studies of canal width in dysmenorrheic and normal women showed no difference (27). Relative stenosis can occur, however, if the endometrial lining sloughs off in large chunks, a condition called “membranous dysmenorrhea.” Other pathologic intrauterine possibilities for acute abdominal pain include deterioration of a myoma that is either subserosal or intramuscular. Such an infarction can cause significant distress and even simulate an acute abdomen as a result of the intensity of pain. Other differential diagnoses must be entertained, however, because infarction of other intraabdominal organs can also simulate uterine fibroid infarction (28).

Secondary dysmenorrhea can also be related to adenomyosis, the presence of endometrial glands deep within the myometrial tissue. When menstruation occurs, menstrual blood is released directly into myometrial tissue, thereby increasing cramping and irritation of the fibers themselves.

Endometriosis, the presence of endometrial tissue in abnormal locations in the pelvis, is a common cause of secondary dysmenorrhea. The mechanism of pain in this condition is not well understood but probably includes a combination of excess prostaglandin production, increased peritoneal sensitivity, chemical irritation of the peritoneum, and bleeding in sites of endometriosis, such as the rectovaginal septum or ovary.

SYMPTOMS AND SIGNS. In some cases secondary dysmenorrhea resembles primary dysmenorrhea and is accompanied by symptoms and signs suggestive of prostaglandin excess. In other cases, the pain of endometriosis can be considered because the pain begins several days before menstrual flow. The pain can be located in the low back and rectum and tends to be more dull and constant rather than cramping in nature. Pain can also occur with intercourse or on urination or defecation. This pain can last longer than the menstrual period, and the pain level can progressively increase over time.

DIAGNOSIS. Pelvic examination often reveals abnormalities that indicate the cause of secondary dysmenorrhea. An enlarged and irregular uterus suggests the presence of fibroids, whereas a visible string from the cervical os corroborates the presence of an intrauterine device. A large, boggy, tender uterus suggests adenomyosis, whereas a fixed retroverted uterus, nodules in the cul-de- sac or on the uterosacral ligaments, and tender masses in the adnexa indicate endometriosis. A study of endometriosis, which used the cell surface antigen CA-125 as measured by serum radioimmunoassay, revealed a most remarkable correlation to women with mild (13.6 U per mL), moderate (22.8 U per mL), severe (27 U per mL), and very severe (50 U per mL) (29). In comparison, women with normal laparoscopic examinations had CA-125 levels of only 7.8 U per mL. It appears that this might be a valuable assay for the diagnosis and management of endometriosis.

Special studies examining the uterine cavity, such as hysterosalpingography, direct visualization with the hysteroscope, or cervical dilatation and uterine curettage, all

help to delineate pathologic conditions such as submucosal fibroids or endometrial polyps. Laparoscopy is a most valuable tool needed to visualize the pelvis and to determine if endometriosis is present.

TREATMENT. Treatment of secondary dysmenorrhea centers around discovery of the cause of the problem causing the pathologic pelvic condition and then elimination of the cause, if possible. Intrauterine devices, fibroids, and polyps can all be removed. Endometriosis requires special treatment. Although adenomyosis can be managed by making the endometrial tissue quiescent in the same ways as those described for endometriosis, definitive management requires hysterectomy.

Chronic Gynecologic Pain Syndromes

Chronic Endometriosis. Endometriosis is defined as functioning endometrial tissue located at extrinsic sites outside the uterus. Most common of such sites are the ovaries, the cul-de-sac, the uterine tubes, the supporting ligaments of the uterus, the pelvic peritoneum, the rectovaginal septum, the cervix, and the surface of the bowel (30). Several theories have been proposed for the etiology of endometriosis. The most likely theory is that of retrograde menstruation, with implantation of endometrial tissue onto peritoneal surfaces (31). Spread of endometrial implants by the lymphatic system has been postulated and reported (32). Hematogenous spread of viable endometrial tissue has also been hypothesized (33).

Endometriosis itself is one of the major causes of pelvic pain and perhaps one of the most confounding problems because this disease can present clinically almost as anything. It can mimic many other disease states. Endometrial implants may attach to many different abdominal organs and tissues. They can be in the typical form of a dark red or brown color, or they may be even colorless. The diagnosis is made on the basis of the history and definitively by laparoscopy. Some of the most popular treatment methods today consist of medical treatment with suppression of both estrogen and progesterone by use of pituitary inhibitory hormones such as the newly developed gonadotropin-releasing hormone inhibitor drugs. Surgical exploration via laparoscopy with laser treatment of the identified endometrial implants and sometimes surgical severance of either the uterocervical plexus (lateral uterosacral nerve ablation procedure) or the superior hypogastric plexus (presacral neurectomy) may give relief of pain (34). Other surgical treatment includes the previously discussed plus the addition of immune therapy management that involves identifying certain immune responsive elements that are treated to elicit a favorable patient response.

The pain of endometriosis can occur at any time and can mimic any known pelvic pathology. The pain can occur with menses or sexual intercourse or can always be present. The mechanisms causing pain are not well established but probably involve release of prostaglandins into the peritoneal fluid from the ectopic endometrium. In addition, chemical irritation of the peritoneal surfaces by the products of menstruation or swelling and stretching of the tissue invaded by an endometrioma could lead to pain. Scarring can also occur at the site of or around the endometrial implants.

Symptoms and Signs. The patient with endometriosis can have dysmenorrhea, dyspareunia, chronic pelvic pain, or all three. In addition, she can be infertile. Other symptoms include hematuria, hematochezia, bowel obstruction, or bleeding from unusual sites such as the pleural cavity or an abdominal scar; all are related to the location of the lesions.

Diagnosis. Occurrence of the pain symptoms described, coupled with infertility, should suggest the possibility of endometriosis. Definitive diagnosis of endometriosis is made by visualization of the lesions. Histologic confirmation is not necessary and is often difficult to obtain because the endometriotic implants might not contain active glandular tissue. Although implants can be present on the cervix and visible on vaginal examination, they more commonly occur on the ovary and peritoneal surface and thus require an operative procedure for diagnosis.

To confirm diagnosis, endometriotic implants—and not just adhesions, which can be caused by pelvic inflammatory disease or previous surgery—must be seen. The classification system described by the American Fertility Society should be used to determine the stage of the disease (Fig. 72-2).

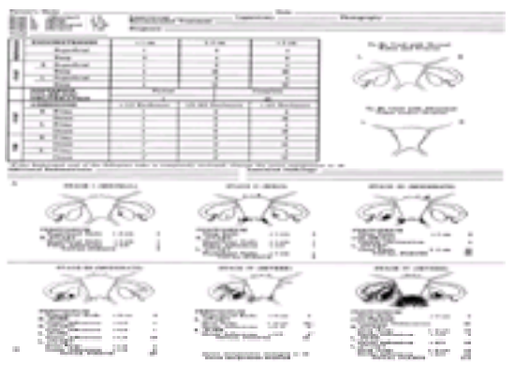

Figure 72-2. Classification of endometriosis. **A:** Suggested questionnaire and sketches of pelvic organs to aid in determination of stage of endometriosis. **B:** Examples and guidelines for use of point system. Determination of the stage or degree of endometrial involvement is based on a weighted point system. Distribution of points has been arbitrarily determined and may require further revision or refinement as knowledge of the disease increases. To ensure complete evaluation, inspection of the pelvis in a clockwise or counterclockwise fashion is encouraged. Number, size, and location of endometrial implants, plaques, endometriomas, and/or adhesions are noted. For example, five separate 0.5-cm superficial implants on the peritoneum (2.5 cm total) would be assigned 2 points. (The surface of the uterus should be considered peritoneum.) The severity of the endometriosis of adhesions should be assigned only the highest score for peritoneum, ovary, tube, or cul-de-sac. For example, a 4-cm superficial and a 2-cm deep implant of the peritoneum should be given a score of 6 (not 7). A 4-cm-deep endometrioma of the ovary associated with more than 3 cm of superficial disease should be scored 20 (not 24). In patients with only one adnexum, points applied to disease of the remaining tube and ovary should be multiplied by 2 (**). Points assigned may be circled and totaled. Aggregation of points indicates stage of disease (minimal, mild, moderate, or severe). The presence of endometriosis of the bowel, urinary tract, fallopian tube, vagina, cervix, skin, and so forth should be documented under “additional endometriosis.” Other pathology, such as tubal occlusion, leiomyomata, uterine anomaly, and so forth should be documented under “associated pathology.” All pathology should be depicted as specifically as possible on the sketch of pelvic organs, and means of observation should be noted. (Modified from The American Fertility Society. Revised American Fertility Society classification of endometriosis. *Fertil Steril* 1985:43:351.)

Treatment. Therapy must be highly individualized and depends on the extent of the disease and on the patient's desire to have children. If avoiding infertility is the prime consideration, measures should be undertaken to preserve and enhance the ability to conceive. If childbearing is to be delayed and relief of pain is the main concern, medical measures are appropriate for mild and moderate stages of the disease.

The object of medical treatment is to render the endometrial tissue quiescent. Early on, the mainstay of current therapy was danazol, a mildly androgenic compound that stops menstruation by inhibiting ovulation. Danazol is given orally in doses of 200 mg qid for 6 to 12 months. The major side effects are some increase in acne and weight, nausea, and irregular vaginal bleeding. A less common side effect is an increase in androgenic effects such as hirsutism, increase in libido, and decrease in breast size. Menstruation usually returns spontaneously within 1 or 2 months of cessation of therapy. Pregnancy rates after danazol therapy are reported to be higher than after other medical regimens for management of endometriosis. One disadvantage is that the drug is expensive. Danazol has largely been replaced now with leuprolide acetate (Lupron) therapy. Lupron is a gonadotropin-releasing hormone inhibitor that effectively switches off both estrogen and progesterone endogenous production. Lupron plus an add-back therapy that contains estrogen is now used to prevent the signs and symptoms of inadequate estrogen.

Another method of treating endometriosis is keeping the patient on a continuous regimen of oral contraceptives of the combination type—that is, a synthetic estrogen and a synthetic progestogen. This treatment suppresses ovulation and endogenous estrogen production and decidualizes the endometrium. The patient on oral contraceptives might experience nausea, fluid retention, and an initial increase in pelvic pain; these conditions subside after the first 2 months of treatment. Although the use of progestogens alone had been recommended, this practice was found to be associated with a higher rate of irregular vaginal bleeding, sometimes necessitating treatment with estrogen. Administration of androgens alone, once a recommended treatment, is no longer popular because of the significant incidence of adverse side effects and the effectiveness of newer regimens. The treatment regimen selected usually continues for 9 to 10 months. Pregnancy rates are somewhat lower after therapy with oral contraceptives than after therapy with danazol.

Surgical removal of implants is usually indicated for moderate endometriosis. This process is generally accomplished using laparoscopy or laparotomy, and the

patient can be placed on danazol postoperatively if she does not wish to conceive. Presacral neurectomy produces variable results and should only be considered in the young woman with disabling dysmenorrhea who has not responded to other measures (35). More severe degrees of endometriosis need more aggressive surgical treatment. In some patients pain relief can be achieved only by total abdominal hysterectomy and bilateral salpingo-oophorectomy to eliminate the cyclic production of ovarian hormones. One fresh approach to endometriosis is the combined surgical and immune therapy method. The latter uses skin testing and then desensitization. This method is being touted as a method to significantly reduce the symptoms of endometriosis, but there are no peer review journal reports yet available for examination. Unfortunately, some women even with hysterectomy still have pain because their pain was of a neuropathic origin. This is why it is absolutely imperative to work with a specialist in pelvic pain who can identify and treat this other major cause of pelvic pain. It makes good sense to have these patients evaluated first by such a pelvic pain specialist, then decide after a regimen of therapy is outlined whether hysterectomy is also indicated.

Chronic Pelvic Inflammatory Disease

Etiology and Pathophysiology. Scarring, tissue damage, and adhesions due to chronic PID can also cause chronic pelvic pain. The nerves to the intraabdominal pelvic organs and contiguous structures can be damaged, or the structures can adhere in such a way that painful stretching is produced by activities such as exercise, sexual intercourse, or passage of digested food along the bowel. Even if there is no damage evident on any diagnostic modality that we currently have, there may well be ischemia to nerves that set up pain patterns that develop a signal to the dorsal root ganglia that evokes pain.

Symptoms and Signs. Patients with damage from chronic pelvic infections can have pain with intercourse or increased physical activity. The pain may also be related to food consumption, bowel functions, or both. During an acute exacerbation they have classic signs and symptoms of an acute infection, such as fever, chills, elevated white cell count, and abdominal pain.

Diagnosis. The diagnosis of chronic PID is based on a documented history of prior episodes of the disease and sometimes by visualization of current damage sufficient to account for the pain. In many instances, however, the actual pathology may be invisible—that is, nerve damage is usually invisible to the examining eye.

Treatment. Major structural damage secondary to infection, such as hydrosalpinx, dense adhesions of the adnexa to the cul- de-sac and posterior aspect of the uterus, or adhesions of bowel and bladder to grossly abnormal adnexal structures, requires surgical treatment. Although the damage is surgically removable or at least partially correctable, all healing involves some scar tissue and any intraabdominal manipulation can lead to further damage. Moreover, no direct correlation between visible pathology and pain has been found. Therefore great care should be exercised not to promise complete pain relief from any surgical procedure. In other words, the general anatomy can be restored to a normal state, but the function is still impaired and the pain persists. It is questionable whether filmy adhesions in the pelvis even require surgery for treatment. Again, pain relief is not guaranteed. If the pelvic organs are visibly normal, surgery is not indicated for pain relief.

Uterine Prolapse

Etiology and Pathophysiology. Past literature supports the testimonial that tearing or stretching of the ligaments supporting the uterus can allow this organ to become displaced and result in pain. The Allen-Masters syndrome was one such literature reference. In addition, tension on nerves and blood vessels in these stretched or torn ligaments is thought to produce pain, but hard evidence is lacking, and it is entirely possible that disruptions of the uterine supports may not contribute significantly to pelvic pain. What this author has been impressed with is the instances in which pelvic support surgery has antedated the onset of pelvic pain. The question arises as to whether there was reduction in blood supply during dissection or actual suture placement in areas that restrict blood supply to nearby nerves.

Symptoms and Signs. Uterine prolapse can occur without symptoms, but symptoms can include a sensation of pressure or a sensation of “something falling.” Severe pain is rare, even in lieu of complete descensus or when the uterus is outside the vaginal introitus. A dull ache and feeling of pelvic heaviness is not atypical.

Diagnosis. In some instances the prolapsed uterus can be replaced by a pessary that can relieve symptoms. If the symptoms are significantly changed by this maneuver, permanent relief by surgery can be considered.

Treatment. Uterine prolapse is usually treated by hysterectomy if patients have finished bearing children. Suspension from above might be considered if the patients have many symptoms and signs and wish to retain their childbearing potential. In earlier days elevation of the uterus with obliteration of the vagina below was promoted by LaForte (36) in elderly patients who did not need a functional vagina and who had total uterine prolapse.

Chronic Pain of External Genital Organs: Vulvodynia

Etiology and Pathophysiology. Vulvovaginal pain can have a variety of etiologies. Some of the causes are obvious; however, a great number of cases of vulvodynia will be labeled unknown because the etiology is just not clear. Some of the most severe vulvodynia sufferers are victims of misdirected medical therapy and others the result of laser or chemical damage. These patients are very difficult to treat. It is important to reduce pain and suffering so that the pain scale does not continue to ascend week by week and month by month. Maceration of the fragile and damaged perineal tissues by improper garments or use of over-the-counter medications should be avoided. Loss of the epithelium can expose nerve endings to chronic stimulation by clothing; this stimulation can be compounded by scratching, which releases irritating algogenic agents such as bradykinin and histamine.

The role of allergy is unclear, but the suspicion is that certain foods, such as coffee, tea, cola, chocolate, citrus fruit, tomatoes, alcohol, and milk, produce perirectal and perineal sensitization with resultant itching in susceptible individuals. Pinworm infestation can also be a cause of perianal itching, particularly at night. Spasms of the levator muscle can cause perirectal and vulvar pain. Hidradenitis, a suppurative, purulent infection of the apocrine glands, can eventually result in chronic abscess, sinus tract formation, and chronic pain.

Symptoms and Signs. The patient with chronic vulvar pain might complain that clothing irritates her or that the vulva is always excessively sensitive. The pain can be localized to one area or generalized to the entire vulva. Draining sinuses or painful abscesses can be present on examination.

Diagnosis. The essential diagnostic element is visualization of the external genitalia and determination of whether a discrete lesion is present. In some cases the diagnosis will be readily apparent, such as a yeast infection. Infectious agents such as ringworm produce a classic red lesion with a serpiginous border of flaking skin. These flakes of skin can be examined for fungus by suspending them in a drop of potassium hydroxide or by examining the skin directly under a Wood's light; fluorescence indicates infection. The most common vulvovaginal fungus, *Candida albicans*, can also be seen on a potassium hydroxide preparation. Generalized maceration can be seen on visual inspection of the vulva. Bacterial cultures should be taken if a purulent exudate is present or if abscesses are noted. A history of pruritus ani suggests that a stool sample be examined for ova and parasites to detect pinworm.

Treatment. Specific infections should be treated with appropriate antibiotics or antifungal agents. General vulvar maceration requires mild cleansing with oil and less frequent immersion of tissues in water. Use of loose absorbent clothing is encouraged, as is dusting the area with cornstarch to absorb moisture. Products containing scents or deodorants should be avoided.

A thorough history of dietary habits should be obtained and offending items omitted in an attempt to reduce pruritus. It might be necessary to eliminate all questionable items and then add them gradually one by one to determine which, if any, are causing the problem. If this is not effective, one should consider skin testing with identification of any obvious allergens. There may be times when chronic abscess of the apocrine glands requires surgical drainage and administration of systemic antibiotics.

Chronic Pelvic Pain Due to Neuropathy. We believe that the majority of patients who present with chronic pelvic pain have neuropathy as the chief cause and not organ disorders. In a significant number of patients who present with pelvic pain with characteristics of pain of gynecologic origin, no obvious organic pathology can be found, even with comprehensive clinical and laboratory examination. When this occurs, the family physician or gynecologist should consider the possibility of a neuropathy that is difficult to diagnose and refer the patient to a chronic pelvic pain specialist. This will be appreciated by the patient who is in search of pain diagnosis and relief, and it certainly is preferable to the physician saying “I cannot find the origin of your pain, and I am afraid the pain may be in your head.” The latter statement should never be made to a patient under any circumstances.

In the late 1940s and early 1950s, several authorities proposed hypotheses to explain pelvic pain without obvious pathology. Taylor (37), one of the most prominent, suggested dysfunction of the autonomic and sensory nervous systems. He studied 10 patients who presented with the syndrome; blood flow probes were placed in the vagina, and an increased blood flow was noted during emotionally stressful situations. Although significant psychopathology was seen, the pain was attributed to

two types of pelvic autonomic disorders— one that Taylor called “vascular dysfunction of pelvic congestion” and the other “sensory change,” otherwise known as hypogastric plexalgia (38). In the former, the mechanism of pain was thought to be a combination of venous distension with interstitial edema, followed possibly by fibrosis of the uterus. In the latter type, the patient could have ultrasensitivity of the pelvic organs and tissues on a hereditary basis.

Theobald (39) called this syndrome “the pelvic sympathetic syndrome,” suggesting that abnormal sympathetic dysfunction might produce ischemia, dilatation of the hollow viscus, chemical irritation in the pelvis, or a combination of these, which in themselves cause pain. Others have suggested that nerve endings from previously damaged structures that were removed can still produce nociceptive impulses, and “phantom organ sensation” and “phantom pain” might ensue (40).

Allen and Masters (41) suggested that the syndrome is caused by small traumatic lacerations of the sacral uterine ligament or of a posterior leaf of the broad ligament. Subsequently, DeBrux and associates (42) examined 25 patients with chronic pelvic pain without obvious pathology in whom large biopsies were taken from the broad ligament, the uterosacral ligaments, and the peritoneum of the pouch of Douglas. They found microscopic lesions indicative of recurrent pelvic peritonitis in several patients. Microscopic findings of endometriosis were found in half of these patients, a hemangioma in two, and a neuroma in one. Renaer et al. (43,44,45 and 46) disputed this hypothesis because real tears in the supporting structure of the uterus are rare; when they do occur their role in chronic pain without pelvic pathology syndrome is negligible.

Ample evidence now exists that the pain of most patients with chronic pelvic pain is due to a neuropathy that has gone undetected by family physicians, gynecologists, urologists, internists, and neurologists. The neuropathology may be associated with the pelvis and include the pudendal nerves, the inferior hypogastric nerves, and the superior hypogastric nerve or even a combination of these. Other causes are also possible and are discussed below.

Symptoms and Signs. The most important symptom of this syndrome is lower abdominal pain and, less frequently, low back pain. Low abdominal pain can be felt either in the whole lower abdomen, in both iliac fossae, or unilaterally (Fig. 72-3). The pain is usually described as a vague discomfort that is continuously present at low levels, but exacerbation and remissions occur unrelated to anything the patient can identify. The pain can be brought on with intercourse or made worse by it (dyspareunia), but this does not prevent the patient from being sexually active. Various other gynecologic problems might be present such as dysmenorrhea, ovarian cysts, past infections, or infertility.

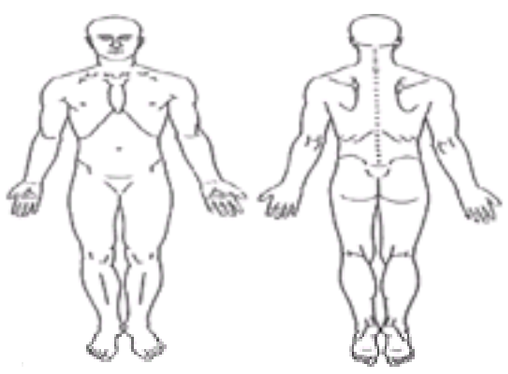

Figure 72-3. Unisex diagram of where a patient denotes painful areas front and back, used to direct the clinician to the chief areas of pain.

Patients can exhibit classic signs and symptoms of depression, such as loss of appetite, fatigue, insomnia, and loss of libido, or might only have a lack of ability to enjoy anything. Some patients can have a high energy level and poor impulse control, acting out anger in sociopathic ways, sometimes directed against the physician. Others can somatize all emotions, dealing with stress by denial and repression and presenting a bland, contented face to the world. As previously mentioned, a significant portion of these patients have experienced sexual abuse as children and as adults (47).

Some patients manifest abnormal illness behavior (48,49 and 50). They have a bodily preoccupation and conviction that they suffer from illness or disease, and they do not respond to reassurance by the physician. They maintain their symptoms—in this case, pain—to meet their psychological needs to be dependent yet in control of the situation. Although they seek cure, they continue to have their presenting complaint of pain in spite of all efforts to diagnose and treat it.

Some patients with chronic pelvic pain without obvious pathology have persistent pain as a result of positive or negative environmental factors (see Chapter 26). In our social system, physical illness elicits noncritical sympathy and support in which patients are cared for and absolved of all responsibility for their condition. In gynecologic patients (as in patients with other disease states), strong positive or negative reinforcing influences in the environment can cause the patient to develop “chronic pain behavior” or “learned pain,” which persists beyond the time of cure of the gynecologic disorder.

Diagnosis. Patients who present with chronic pelvic pain without obvious pathology are a diagnostic challenge. Because all chronic pain patients have significant behavioral components to their illness, these aspects of pain should be routinely evaluated. Serious psychopathology can be found equally in patients with and without organic pathology, so a psychological and behavioral evaluation should be done on all chronic pelvic pain patients by a clinical psychologist with experience and expertise in managing patients with chronic pain. Diagnostic measures to rule out all previously described organic problems should be used appropriately in selective fashion and concurrently with the psychologic and psychosocial evaluation. Because many patients consider the suggestion that psychological factors might be present as demeaning, criticizing, and threatening, it is important at the outset of the evaluation to make clear to patients that psychosocial evaluations are standard and routine in the evaluation of all patients. This often overlooked procedure, in addition to the psychological focusing during the evaluation process, helps to prepare the patient for biological, psychological, and social impressions of the pelvic pain.

The findings of physical and psychological evaluations should be presented by the gynecologist and a psychologist to the patient and the session should include the patient's husband or partner to make the problem of pelvic pain overtly a family problem or joint concern.

If the pelvic examination is normal, these findings should be presented to the patient, and the benefits and risks of visualizing the pelvic organs by laparoscopy should be discussed. Some authors have advocated not doing so (51), but others have shown that pathology can be present even when a comprehensive pelvic examination reveals no abnormality. Moreover, most patients are unwilling to accept the diagnosis that nothing serious is wrong with their pelvic organs unless a gynecologist has verified this by carefully visualizing the pelvis. This information is also useful to the multiple health care providers usually involved with these patients because it allows effective treatment programs to be proposed on a more rational basis.

It is difficult for gynecologists and other health care givers to be aware of the importance of neuropathic disease processes for the chief underlying cause of pelvic pain without evident pathology. In fact, this author believes that more than 60% of pelvic pain is really caused by injury to nerves and not to organs. In the next few paragraphs, various neuropathic causes of pelvic pain are outlined for the benefit of those who are unaware of this important category.

Pudendal Neuropathy. The pudendal nerve takes origin from sacral 2, 3, and 4 roots bilaterally. It winds around the sacral spinous process and then enters the pelvis via Alcock's canal as a single nerve. It divides into four distinct branches that include the clitoral, the superficial perineal, the deep perineal, and the posterior rectal branches. These nerves have a tenuous course that can be threatened by childbirth trauma, surgical trauma, and infectious episodes. The blood supply can also be compromised during various exploratory surgical procedures.

Inferior Hypogastric Neuropathy. The inferior hypogastric nerves are aligned on each side of the cervix and closely adjacent to the ureter. These nerves are the chief parasympathetic input to the pelvis. Bilateral denervation is as effective as a lumbar epidural with respect to sensory input from the uterus and cervix. Thus, they have a powerful sensory role to play in pelvic pain. Examination of this area is not easy, and local anesthetic nerve blocks are difficult to perform, extremely painful, and shadowed by the threat of central nervous system toxic complications due to the fact that the area is very vascular with both arterioles and venules that supply and drain the area (Fig. 72-4).

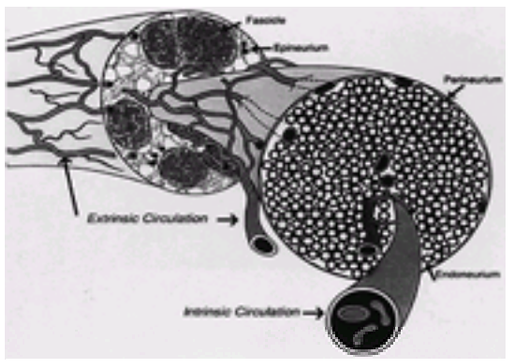

Figure 72-4. Circulation in peripheral nerve. The relationship between the extrinsic epineurial vessels and the intrinsic endoneurial vessels is emphasized. Numerous branching vessels form a rich anastomotic network on the surface of the fascicles. These vessels are connected to the intrinsic vasculature by transperineurial vessels, which are vulnerable to compressive forces acting from within or on the external surface of the nerve sheath. (From Myers RR, Heckman HM, Galbraith JA, et al. Subperineurial demyelination associated with reduced nerve blood flow and oxygen tension after epineurial vascular stripping. *Lab Invest* 1991:65:41–50, with permission.)

Ilioinguinal and Iliohypogastric Neuropathy. The patients with ilioinguinal and iliohypogastric neuropathy have past histories that often include surgical or other types of trauma in the area of the lower abdominal wall. Figure 72-7 shows the area involved in pain usually associated with these nerves. The genesis of the pain is not known, but suspect is the retraction placed on nerves located around the incision line that may result in stretch and avulsive-type neural injuries. The onset of pain after the initial trauma will be variable, due to the intensity of the injury and perhaps the fiber size. Many of the gynecologic patients have exposure to the Pfannenstiel-type incision, which cross-cuts both the ilioinguinal and iliohypogastric nerves. In addition, the injury may be from retraction in the lower corners of the incision, where the nerves are located. This can be seen in Figure 72-6. Interestingly enough, many of the patients in this group have histories of repeated abdominal exploration of one type or another because their original physician was convinced that the initial problem of intraabdominal pathology had not been solved or perhaps that recurrent pain might be due to abdominal adhesions or other yet defined “organ-related pathology.” This is becoming less so nowadays due to the widespread use of laparoscopy, but this procedure in itself may cause abdominal neuropathy due to placement of the scope, obturator, or one or more ancillary sites made percutaneously. A classic example of this patient type can be seen in Figure 72-7, in whom the obvious incisions can be seen and the maximal tender points are noted via the skin markers. In this case the patient was seen and eight tender points identified. These cases are managed by repeated local anesthetic nerve blocks spaced over time to take advantage of the effects of nerve blockade, but not so frequently as to set up a peripheral pain-generated signal from mechanical stimulation. Most patients will fall into the responding category by 4 to 6 weeks (52). Those who do not might benefit from abdominal catheter placement and continuous local anesthetic irrigation of the nerves between the transversalis and oblique muscle groups (53). Those who do not respond to prolonged block can be treated with cryotherapy for destruction of those nerves still causing problems (54). For ultimate failures in instances in which multiple nests of neuromas may still be active and have been refractory to all the modalities discussed previously, one can consider surgical intervention and extirpation of the local neuromata to try to correct the problem (55). This is often not a successful operation, however.

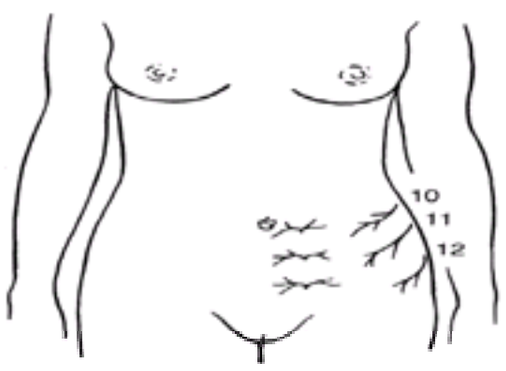

Figure 72-7. Distribution of pain in midabdominal area from T-10, T-11, and T-12. Treatment can be directed at local infiltration in skin area. (From McDonald JS. Associated pain management problems of parturition. In: Bonica JJ, McDonald JS, eds. *Principles and practice of obstetric analgesia and anesthesia*, 2nd ed. Baltimore: Williams & Wilkins, 1995:290, with permission.)

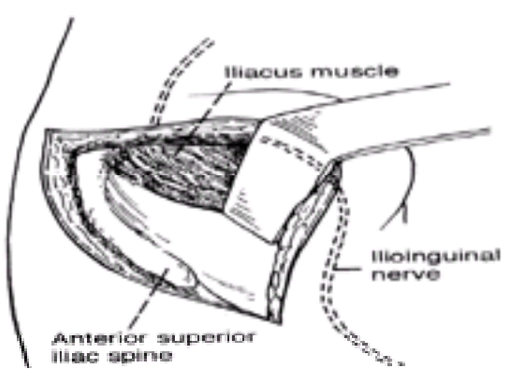

Figure 72-6. Demonstration of neuropathy generated by pressure exerted by the retractor on the ilioinguinal nerve. (From McDonald JS. Associated pain management problems of parturition. In: Bonica JJ, McDonald JS, eds. *Principles and practice of obstetric analgesia and anesthesia*, 2nd ed. Baltimore: Williams & Wilkins, 1995:290, with permission.)

Genitofemoral Neuropathy. Patients with genitofemoral neuropathy present with variable stories of low abdominal pain, or even back pain, that has migrated to the front of their body and now descends into the vulvar area. The pain is often incapacitating when it occurs in sharp, repeated attacks. There is a distinct message to be understood with regard to successes on an immediate basis. On the one hand, it is tremendously reassuring to note the significant reductions in pain after the individual nerve blocks and maximum tender point injections. Almost all patients will have pain reduction within minutes of office therapy. It is hoped that patients will exhibit gradual reductions in pain scores over time and that they will have an increase in their function at the same time. Some failures are to be expected in every type of pain management problem, and this disorder is no different. Sometimes the reasons for failure must be viewed as an open invitation to explore further the possibility of an overlooked pathologic condition. For example, one patient we managed had been refractory to repeated therapy over time, and on surgical exploration it was discovered that a suture was found around the genital branch of the genitofemoral nerve just at the site of a former hernia repair. Because the distal portion of the nerve was notably atrophic, it was resected above the area of involvement, and the patient is now pain free.

Hymenal Neuropathy. Patients with hymenal neuropathy are a most interesting group. Figure 72-8 shows the area of involvement with regard to this syndrome. Note that the perineum is richly innervated by nerves from different spinal cord segments so that there is some overlap protection with regard to innervation. Patients may be so distraught and histrionic that the initial practitioner may entirely miss the diagnosis due to preoccupation with the reaction the patient displays during physical and gynecologic examination. Often the patient complains so violently that a pelvic examination is not even possible— that is, the examiner cannot get past the introitus. In other instances, the examiner does get past the introitus, only to find there is no evidence of pain on examination of the vagina, cervix, uterus, fallopian tubes, and ovaries. The past history of such patients can often reveal a problem with *C. albicans* infection. It would appear that repeated infections to this agent can cause irritation of the superficial nerves in and around the area of the hymenal ring. Patients usually have a history of normal, healthy sexual patterns before the onset

of their vaginal pain but develop significant dysfunction sexually secondary to their disease process. This is usually manifest by symptoms of severe dyspareunia totally focused in the area of the vaginal outlet. In a group of patients we treated, four of five patients experienced complete relief of pain and a return to normal sexual function within 8 weeks of definitive therapy—surgical extirpation of the hymenal ring. In the one patient who did not have complete relief of pain, there was also a problem of significant psychological degree. This patient had a previous hysterectomy and oophorectomy and had problems adjusting to exogenous estrogen and thus had a thin vaginal mucosa with other associated problems.

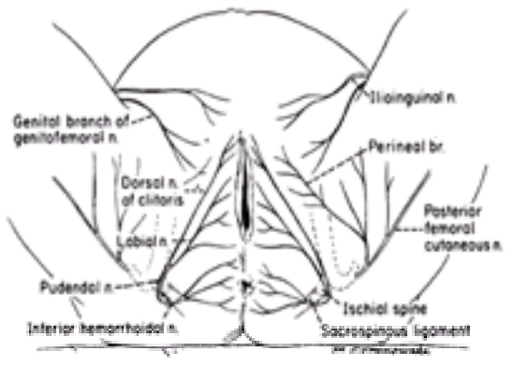

Figure 72-8. The cutaneous nerve supply of the perineum. The major supply is provided by branches of the pudendal nerve, including the inferior hemorrhoidal nerve, which supplies the posterior portion; the superficial branch of the perineal nerve, which divides into medial and lateral parts known as the posterior labial nerves; and the dorsal nerve of the clitoris. (From Bonica JJ, McDonald JS. Other regional analgesic/anesthetic techniques. In: Bonica JJ, McDonald JS, eds. *Principles and practice of obstetric analgesia and anesthesia*, 2nd ed. Baltimore: Williams & Wilkins, 1995:501, with permission.)

Figure 72-5. Pelvic pain assessment sheet. (CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CX, cervix; EXT GEN, external genitalia; GERD, gastroesophageal reflux disease; HTN, hypertension; IHN, inferior hypogastric neuropathy; LSD, lysergic acid diethylamide; MI, myocardial infarction; PCP, phencyclidine hydrochloride; PND, postural nocturnal dyspnea; PROM, promontory; RA, rheumatoid arthritis; TENS, transcutaneous electrical nerve stimulation; THC, tetrahydrocannabinol; TIA, transient ischemic attack; UTI, urinary tract infection.)

The patient workup should include at least two or three successful hymenal blocks performed before consideration for surgery. In our series of patients, all had repeated hymenal local anesthetic blocks, with demonstrated complete relief of symptoms. The association of the *Candida* infection is too consistent to be coincidence. As noted before, one might speculate that the fungus may gain deep mucous membrane penetrance and result in a damaging effect on the nerve endings, perhaps even causing neuromalike formation to occur.

Sympathetic Pelvic Neuropathy. Patients with sympathetic pelvic neuropathy have a historical vignette that is not typical from the standpoint of identification of any single source of causation. The area of innervation is shown in Figure 72-9 and includes the vagina and cervix, with innervation from the pudendal nerves with derivation from S-2 to S-4, and the uterus, tubes, and ovaries, with innervation from the sympathetic pelvic branches of T-10 to T-12. Many of the patients who complain of gynecologic pain have a deep pain in the pelvis not associated with physically detectable abdominal wall tenderness or myofascial disease of the abdominal musculature. This disease entity has been classified as a “sympathetic pelvis syndrome.” It must be recalled that visceral disease often results in pain transmitted to cutaneous areas—that is, referred pain—and often it may be interpreted as a primary disorder located in that specific area of the body. It is possible to have visceral etiology of cutaneous pain in such instances. Some patients will obtain relief from repeated local anesthetic nerve blocks if the physician is patient enough and if he or she is detailed enough to check the progress of improvement every time and note if it is specifically the same area of pain previously identified. In the remaining patients, who obtained relief of their pain for a short time, eventual surgical therapy may be necessary. It is often via a laparoscope, with which one of two nerve ablation techniques can be used—namely, uterosacral nerve ablation or superior hypogastric ganglion resection. Patients who were refractory to the local anesthetic block therapy are usually rendered pain free after the surgical resection; these patients will have a return to normal function and will be quite pleased with their therapy. It is difficult to instill in the reader the emotions felt by the patients who suffer from these pelvic pain disorders and who have been buffeted from physician to physician for years of management without success; their emotional state often is one of hopelessness and dejection due to loss of confidence that anything ever can be done to improve their status. Thus, when they begin to experience the small sense of pain relief and then the definitive procedure that relieves their pain so that they can begin to resume a relatively normal lifestyle, they are forever thankful and grateful.

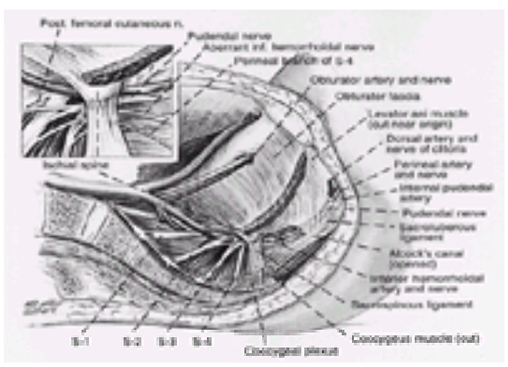

Figure 72-9. Sagittal section of the perineum showing the origin and course of the pudendal nerve. Its three roots derive from the second, third, and fourth sacral nerves, unite approximately 1 cm proximal (cephalad) to the ischial spine, then leave the pelvic cavity by passing through the greater sciatic foramen. The formed nerve then passes posterior to the junction between the ischial spine and the sacrospinous ligament, then reenters the pelvic cavity through the lesser sciatic foramen and proceeds anteriorly through Alcock's (pudendal) canal. (From Bonica JJ, McDonald JS. Other regional analgesic/anesthetic techniques. In: Bonica JJ, McDonald JS, eds. *Principles and practice of obstetric analgesia and anesthesia*, 2nd ed. Baltimore: Williams & Wilkins, 1995:503, with permission.)

Pelvic Joint Instability. Persistent pelvic pain and pelvic joint instability in some females have been associated with precocious puberty and use of oral contraceptives before reproduction. Thus, patients who complain of pelvic pain in which all diagnostic workups have been normal and who have histories of early onset of menarche associated with oral contraceptive use should be considered for possibilities of pelvic joint instability. Physical examination should establish this diagnosis (see Chapter 75).

Pyramidal Muscle Hematoma. Hematoma of the pyramidal muscle is a rare but possible complication that may cause impingement of the sciatic, inferior gluteal, and pudendal nerves. This may result from compression between the muscle and the iliac spine. In these cases a computed tomography (CT) scan should help to confirm the diagnosis (56).

Osteitis Pubis. In active females in competitive sports who present with pubic pain and adductor pain, osteitis pubis should be considered as a cause. In one study of 59 patients, recovery was slow, taking up to 7 months in women. There was also an associated finding of pelvic malalignment or sacroiliac dysfunction in these patients (57).

Adductor Tendinitis. Adductor tendinitis is usually associated with marathon walkers or runners who suffer from acute injury to the adductor muscle of the anterior thigh that attaches directly to the pubic ramus (57). It is often misdiagnosed as pelvic pain due to the complaint by the patient of diffuse ache that radiates into the involved pelvic area laterally. Diagnosis is made by running the examining finger along the medial margin of the adductor muscle up to the point of insertion on the pubic ramus. At this point, the patient will suffer exquisite pain and pinpoint the pain as being located exactly at the point of insertion. A local anesthetic injection will completely eradicate the pain within minutes of injection. It may be necessary to repeat such a treatment a few times for complete eradication of the pain.

Osteoporotic Sacral Fractures. Osteoporotic sacral fractures were found to be associated with pelvic pain complaints in which other pathologic causes had been excluded (57).

Focal Vulvitis. Focal vulvitis is a unique clinical syndrome of superficial dyspareunia and focal areas of inflammation and/or ulceration of the mucosa. This syndrome was described by Keetel in 1971 and later by Peckham in 1986 (58). Patients may disclose a history of many treatment failures. Typical symptoms are extreme pain with intercourse so severe as to cause abstinence. The characteristic signs are 3- to 10-mm areas of inflammation focused in the area of the vestibule that may or may not be detected as actual superficial ulcers. Most of the lesions are located in and around the Bartholin's ducts. Treatment successes include nonspecific therapy with various creams with or without antibiotics, cryotherapy to destroy the local ulcerative lesions, or surgery with actual extirpation of the hymenal ring with a surgical perineoplasty.

Clinical Considerations

Workup and Physical Examination

It is important to discuss some general steps to be invoked in approaching the patient who has acute or chronic pelvic pain problems. The first step, naturally, is careful and complete evaluation of the problem that the patient complains of in his or her first visit and in her own words. In-between steps involve development of a diagnostic pathway and organization of a management pathway. The last step is a follow-up evaluation of the improving patient who, it is hoped, is no longer in severe pain. This last step is one in which you must determine the effectiveness of your therapy plan and, in common terms, is the outcome of your treatment. It is very important in today's level of expectancy with regard to medical care. If therapy is a failure, referral must be considered without delay.

The essential steps in the initial evaluation of chronic pelvic pain patients include the following:

1. **Pain scale.** A pain scale must be established at the very first visit. We use a 0 to 10 scale, with 10 being the worst pain the patient has ever experienced. Some history is necessary to make sure the patient has indeed experienced a severe enough pain to be able to quantify it in a relative sense.
2. **History.** A careful history must be taken; it is important to listen to the patient explain the aspects of her problem herself. A thorough history should include the salient points the patient wants to bring out, yet a certain art form must be developed with regard to leading the patient and making sure the patient stays focused on the important facts and features of her pain. Salient features include circumstances that were operative at the time the pain began, the location and migration of the pain, the motion that makes the pain worse, and circumstances that make the pain worse or better.
3. **Physical examination.** A general physical examination is focused on the area of the patient's complaint. Often a referred patient may well have had recently a complete physical examination by her own local medical doctor. If so, the physical examination may be limited to the area of the pain. There are some instances in which “restricted area” examinations may result in missed diagnoses, but this can be kept to a minimum by making sure all potential diagnoses are considered.
4. **Diagnosis.** The diagnosis can only be reached by careful and detailed history and physical examinations that are repeated when indicated. Furthermore, differential diagnoses must be inclusive enough to include that which is most likely the cause of the problem.
5. **Identified goals.** Just after the development of the differential diagnosis list and even before definitive diagnosis, the physician may talk to the patient about goals in therapy. There are at least two immediate end point goals: improvement in personal and professional function and reduction in pain levels. Patients who are included in such goal-setting discussions will sense involvement in the decision-making loop and will sense that they are an important member of the team. Most important here is the empowerment given to the patient. All patients appreciate being given knowledge of their disease process and being empowered with the logical medical knowledge. Last, and very important, she will be empowered by the understanding that she has the attention of a concerned and sincerely interested physician. Further components of effective treatment include the following.
6. **Therapy.** An extensive treatment or therapy plan should be discussed with the patient, with treatment possibilities laid out so that the patient can see her options. This is valuable for the purpose of letting the patient know there are several therapeutic possibilities, not just a single one. This approach also enhances cooperation with the various therapy modalities.
7. **Follow-up.** Follow-up should begin just 1 week after the initial visit, either at the time of return to the clinic or at the time of a follow-up telephone call. This is an excellent time to review the treatment hierarchy in order to allay any disquietude the patient may have toward her treatment so far or even toward the eventual goals of therapy.
8. **Adjustment.** If progress is not being made, as evidenced by a repeat visit and examination, the physician must be prepared to invoke therapeutic adjustments to redirect effectiveness of medication.
9. **Long-term follow-up.** Times for follow-up can be scheduled on a predetermined basis and those times discussed during the setting of the goals or during the discussion of the therapy at the initial visit. A reasonable follow-up might be 1 week, 2 weeks, or even 4 weeks. By definition, 3 months separate acute pain from chronic pain; therefore, some of the supposed acute pain patients will be moved over to a chronic pain category as the length of time for pain increases and the therapy does not achieve its goal of pain relief and improved function within a 3-month window. Every time a patient is seen for follow-up in clinic or called for response to questions about her therapy, the physician should be made aware of untoward events, responses, or deterioration of patient wellness so that readjustments in therapy can be instituted immediately instead of waiting for a period of time when the patient can come back for a personal clinic appearance.
10. **Outcome.** Outcome is the “graduation” of the patient from the designed therapy regimen that was specifically developed for her. It is the gold standard for measurement of success or failure. It is the single most important focus from the patient's viewpoint because she originally comes to her physician with pain and a need to reduce that pain and improve her functional ability so that she can work and enjoy life again. It is suggested that outcome results be obtained and recorded in the patient's chart or a book of results the physician keeps personally.

Diagnostic Procedures

Several procedures must be considered basic diagnostic tools in a practitioner's approach to pelvic pain. These include as a minimum the following list that forms the basic foundation in the beginning approach to understanding the patient with pelvic pain:

1. **A careful and considerate pelvic examination directed to the sites of pelvic pain**, not the usual pelvic bimanual examination.
2. **Pelvic ultrasound examination** to help identify difficult-to-detect abnormalities that are “hidden” due to a patient's not allowing deep palpation because of pain.
3. **Pelvic magnetic resonance imaging (MRI)**, the ultimate examination for detection of hidden tumors, masses, or even totally obscured endometriomas that may include occult neural involvement.
4. **Abdominal MRI** to rule out possible pathology in the abdomen that cannot be appreciated or cannot be detected on physical examination.
5. **CT scan**, the ultimate examination for problems that interface the osseous and tissue planes (it may be indicated at times even in the face of a normal MRI if historical and laboratory findings point toward suspicion of abnormalities along this interface).
6. **Bone scan** to detect fractures that may involve nerve distributions and cause long-term pain and disability in instances when fractures are not visible on plain x-ray.
7. **CA-125 values**, which may be helpful in certain situations to help confirm a diagnosis that is already highly likely because of strong history and physical findings (e.g., for suspicion of endometriosis).

It is important to record and assess all previous studies such as those mentioned previously and to take detailed notes on dates and findings. These can help one to understand the past thought processes of physicians who have cared for the patient. They should not be repeated unnecessarily because of the delay in time, the added expense, and the implication for the patient that she harbors occult pathology.

Operative Procedures

Two operative procedures must be considered basic workup tools in the approach to pelvic pain:

1. **Laparoscopy** is perhaps the most frequently used gynecologic operative procedure. Its value is unquestioned; however, there may be situations in which strategically planned diagnostic pathways could make this procedure unnecessary.
2. **Laparotomy** is performed after laparoscopy indicates extensive disease and usually is performed for therapeutic reasons. Most of the time it is used in cases in which adhesions are so dense that laparoscopy is not possible. Other times, it may be used when a mass is located in an area difficult to observe.

Once again, it is important to carefully record all previous operative procedures, dates, and outcomes so that some sense can be made out of the complete history of the patient's pain and her therapy.

Initial Therapy

There are five cornerstones of therapy for pelvic pain: medical therapy, local anesthetic nerve block, psychological therapy, physical therapy, and alternative medicine. They can be viewed as a therapy hierarchy and can be used to reassure the patient that she and her pain are paramount in your mind and that her healing is your major goal.

Some type of therapy should begin at the first visit; usually it is a medication to rescue the patient from the severity and constancy of pain. Showing the patient that you are concerned about her welfare and are attempting to help with medication to improve her sleep and to help reduce some of the severity of the pain will go a long way in reassuring the patient she has met someone who has genuine concern about her well-being.

Patient Medical Log. The medical log records pain levels and medications on a daily basis. This is important because patients often are given medication, and very little, if any, feedback is determined. Thus, the patient remains on the same dosage, which may be too great, too little, or appropriate. A long-term goal is to reduce the dependency on medication regardless of the type of medication. This can be done only if the physician notes the progress that is being made on a return visit. Accurate data are required regarding drug dosage, when it was taken, and the effect.

The activity log is another important database that relates to patient function; it is a variation of the medical log and is really vital with regard to the progress that is being made. It can be kept along with the medical log or separately. It is best to begin the log with an activity notation about what the patient used to do or be capable of doing before the onset of the pain disorder. The log can be sheets of paper that the patient records on daily, or it can be regimented. This instrument can be the most valuable index of the functional status of the patient and a good indicator of the progress being made with various therapeutic trials. The activity log focuses the patient's attention on function rather than pain and serves as a key in the doctor-patient relationship.

Follow-Up Visits

Therapeutic Hierarchy

Medication. It is important to begin some therapy on the first visit. This can be by administration of various systemic medications or rest or exercise programs, but this should only be done after careful analysis of the currently used medications and after recording the successes and failures of the medications and therapies tried in the past. This is a time-consuming event, but it is really necessary to make a breakthrough in understanding the complete medical background of the patient. At this time it is also necessary to have an in-depth conversation with the patient about her sleep habits and to consider the addition of one of the low- dose antidepressant medications such as amitriptyline (10 to 25 mg taken at bedtime). The use of this regimen can aid in both decreasing the pain and in providing the patient with some badly needed sleep. Another approach to beginning therapy is emphasis on rapport by carefully outlining to the patient what the various problems are, what the possible etiologies may be, what the possible therapies might be, and how you and your staff will stand by the patient throughout the workup phase and be supportive into the therapy phase. Some may not look on this as therapy, but the concern and consideration of the physician, the eye contact, and the reaching out to touch the patient and display of sincere concern are not to be underestimated.

The basic foundation for treatment of noncancer pain patients of course begins with the use of over-the-counter, readily available drugs such as salicylates. The next step is usually NSAIDs, followed by tricyclic antidepressants. Next come anticonvulsant drugs, which have also been found to be effective in a variety of pain syndromes. Last is the use of the opioids. Yet, it is possible to have the patient continue for a short time on the opioid drugs he or she has been used to taking for pain relief by contacting the referral physician and establishing a good relationship with him or her. The message should be that you would appreciate the continuance of whatever medication the patient has been taking the past few months and that your aim will be to gradually reduce that over time and substitute other drugs such as the NSAIDs. This is done by having the referring physician continue to prescribe opioids for a short period of time that you identify with him or her. This can work out nicely if there is good communication between the two of you. There are some patients and some instances when use of opioid analgesics may have fewer side effects than tricyclic antidepressants and anticonvulsant drugs. There is also a wide difference in the incidence of side effects among opioids such as morphine sulfate, codeine, and pentazocine, which have side effects in the range of 20%, whereas oxycodone has a percentage one-half of that. The adverse effects usually associated with the opioids are pruritus, drowsiness, nausea, vomiting, dizziness, headache, euphoria, dry mouth, and swelling.

Neural Therapy. Early on the patient has had the treatment hierarchy explained so that by now she understands fully what is going on and has some grasp of the plan for her improvement. In this way she can become an informed patient who takes interest in herself and the therapy that is being offered. The following treatment modalities with respect to neural therapy are explained in detail and usually in the order listed so that the patient realizes there are, indeed, other pathways that can be explored if one of the types currently to be tried is a failure. Most important it is necessary to assure the patient that there are many different ways of approaching therapy and some methods work well in some patients and other methods work well in other patients.

One type of therapy is the local anesthetic nerve block. It is used early on for diagnostic purposes but it also serves as a beginning step of therapy. A dilute solution of some type of local anesthetic can be used to infiltrate the affected area with 3 to 5 mL of solution. It is best delivered with a 25-gauge needle or even a 27-gauge needle to minimize patient discomfort on repeated injections. These can be repeated at intervals to effect a decrease in the input signal to the central nervous system.

The transcutaneous electrical nerve stimulation unit is a battery-powered electrical stimulator that delivers intermittent shock waves to the skin (see Chapter 98). This stimulator can be used at the same time other therapies are used, such as local anesthetic nerve blocks. This parallel therapy can sometimes speed up the time for the patient to reach a comfortable level (59).

Another neural therapy is cryotherapy, which essentially consists of freezing of portions of the involved nerve so that it dies. The machines available for such treatments include sophisticated circuitry to provide for identification of involved nerves by electrical stimuli and then freeze therapy to effect destruction at a chosen local point immediately proximal to the involved nerve (60).

Another type of neural therapy is an insertion of a continuous abdominal catheter for the purpose of continuous irrigation of the involved nerves. This method should be considered only when patients are refractory to the local anesthetic block therapy mentioned previously. Its advantages are that it minimizes repeated painful injections, which are a necessary part of the repeat treatments, it reduces the visits necessary for repeated injections, and in some isolated cases it has given continuous pain relief instead of cyclic on and off pain relief (53).

The last method of neural therapy is mentioned here only for completeness and is not recommended by the authors for lasting pain relief. The method is surgical excision of a so-called neural bed in an area that has been repeatedly refractory to nerve block and other methods of pain relief. Surgical entry into the area where repeated therapeutic measures as mentioned previously have been ineffective has sometimes been carried out due to a neuroma persistence or due to ineffective or misdirected local anesthetic nerve blocks. It usually consists of opening of the incision and careful visualization of the incision line and wound bed to denote any

obvious pathology such as suture placement around a nerve or an obvious collection of neuromas due to old nerve damage (55).

Psychology. Psychological strategies are only briefly mentioned here, as they are the major topic of consideration in the next section of this chapter. The psychological interview is performed at the time of the first visit, often before the physical examination. This interview is important because it sets the framework for recognition by the patient that this is a vital aspect of her health and well- being and that its emphasis is noted because of its early inclusion. A psychologist who collaborates with the physician strengthens the message to the patient that there is indeed an intricate relationship between good general medical health and psychological well-being. Ideally, it would be beneficial to have the psychologist be schooled or experienced in the area of sexual function and the problems inherent in this very specialized aspect of health care. The literature is replete with articles relating association of childhood abuse and later sexual and psychological dysfunction; many minor and major gynecologic pain problems have also been blamed on such disturbances (61). These problems are often hidden and not immediately apparent in early physician relationships because the patient is waiting for some signs of comfort and trust to appear or because the patient has suppressed her past history to the extent that it is not readily available for recall.

Significant psychological impairment can have devastating effects on the success of a planned program for a patient's recovery, especially in instances in which it is not even suspected as being a problem. We have developed a “dyssexualis” history that helps us to identify those patients with significant sexual dysfunction early on in the workup (Fig. 72-10).

Figure 72-10. Dyssexualis questionnaire.

Psychological treatment strategies include not only individual psychotherapy but also hypnosis, biofeedback, and group psychotherapy.

Physical Therapy. After completion of the initial workup and consideration of the possible pathology, it is wise to go over the possibilities with the patient and to discuss how the pathology can be related to the anatomy. To facilitate this the physician may want to use anatomy book pictures to demonstrate that relationship. This aspect of the treatment regimen is often overlooked, but it is vital to good recovery and adds substantially to the overall therapy regimen that one needs to put together for the patient. In addition, the patient will realize from the outset that she will not be relying on one treatment method. The latter philosophy is commonly understood by patients, but we cannot emphasize too much how confidence in the physician is eroded when only one method of treatment is suggested and it begins to fail the patient once again. At such a point the patient may become demoralized and depressed because she has experienced such feeling before in her interaction with many prior physicians. The prime physical therapy methods include heat, electrical stimulation, deep ultrasound, and massage. It is important to work with a professional physical therapist so that he or she can devise treatments specifically designed for the patient. The physical therapist should examine the patient, design a special mode of therapy for the patient, and follow the patient over time, with feedback to you for follow-up purposes.

Alternative Medicine. Alternative medicine would not even have been considered 5 years ago during a discussion of pelvic pain. Today it is politically correct, widely used, and often funded by third-party payors. Alternative-care strategies also help to make the patient feel included in her healing process and help her to hold onto some of the “remedy”-oriented methods of treatment that many patients already use. Yoga, meditation, chiropractic, nutrient therapy, and acupuncture are common forms of alternative care.

Patient Goal Setting

It is possible to identify the mutually nonexclusive goals of improved function and decreased pain. Of course, any early discussions regarding pain treatment results must be guarded with respect to any promises of certain definite endpoints. It is unwise to tell a patient who presents with a pain score of 8 out of 10 that by the end of therapy she can expect a reduction to a 2 or 1 out of 10. It makes more sense to say that the general goal over time will be to reduce the beginning pain score from a severe range of 7 to 10 to a moderate pain score of 4 to 6 to a mild range of 1 to 3. In this way, one can avoid fixating on a numerical score. In addition, it is very important to stress function improvement by noting the patient's function percentage from the professional standpoint and the personal standpoint. With regard to the former, it is necessary to identify what the patient's level of professional function was at a full 100% and then identify what it is now at the pain score recorded. With regard to the latter, it is necessary to identify what the patient's level of personal function was at a full 100% and then, similarly, identify what it is now at the current pain level.

Treatment Trials Outcome: Criteria and Results

An attitude of futility develops after a period of time when treatment trial after trial fails to alleviate the pain. Because physical causes are much more socially acceptable than mental or psychological ones, both physician and patient continually seek to find organic pathology. The problem is that the physical causes of chronic pelvic pain are difficult to identify and prove. Special techniques of physical examination are called for, and the physician must have a high index of suspicion for neuropathic conditions such as nerve compression and neurapraxias, which result in problems such as hyperalgesia and allodynia, myofascial pain syndromes, pressure neuropathy of the pudendal nerve, obturator nerve, and the inferior hypogastric ganglion.

This is a time-consuming activity, but it is really necessary to make a breakthrough in understanding the complete medical background of the patient.

Enhancement of the Patient-Doctor Relationship

Enhancing the patient-doctor relationship is difficult to teach. In many ways, the adage “you either have it or not, you cannot develop it” has validity. However, it is possible for any physician to enhance his or her patient-doctor relationship. This is done by simply working on developing the philosophy of caring. Physicians do care; if they did not they would not have gone into medicine. A caring physician is the first requirement. Next, it is important to develop and work on listening skills. Patients have an important story to tell and they want to tell it. You want to listen. All that stands in the way is a busy or overloaded schedule and the physician's patience, which is not an easy item to work on and perfect. Certainly, all of us have harried schedules and often not enough time in a workday. Nevertheless, we can begin by listening to patients' stories without interrupting them over and over, guiding them, and distracting them from their natural “storybook” line. Finally, it is important to let the patient know you sincerely care about her, that you do want her to get better, and that she and her problem are priorities in your life. It is possible to transmit sincerity, but it must be done naturally and freely. This is not something you can “construct” for the moment. Patients will immediately discern whether you are being truly sincere or not.

Avoiding Adversarial Relationships. There will be instances when patients do not “heal” or “perform” as you would like them to or even as you both had agreed they would. This is not a time to be condescending because the patient is well aware of the fact that she has not complied with therapy. She is dreading the next visit, when you will discover she has not kept on track. The last thing she needs at a time like that is to be scolded or embarrassed or demeaned. She needs understanding, support, and to ventilate and explain why she acted in the manner she did. Use such instances as times to grow the patient-doctor relationship closer together, not farther apart.

The Interdisciplinary Pain Approach. The interdisciplinary management approach was championed by Dr. John J. Bonica in the middle 1950s, long before most even understood the concept of pain, pain diagnosis, pain management, or the difference between acute and chronic pain syndromes. He was dedicated to the belief that

patients could be best managed by groups of practitioners from different specialties working together to obtain the most positive results for pain patients. He also was cognizant of the fact that most pain patients have more than one problem at the root of their pain condition.

Interdisciplinary management of pelvic pain problems involve the interaction of several specialties. These include gynecology, anesthesiology, urology, orthopedics, neurology, neurosurgery, psychology, psychiatry, and general surgery. Pelvic pain, more than most pain syndromes, has eluded proper diagnosis and treatment time after time. Patients often become trapped in a web of endless physician shopping for someone who believes their pain is real and for someone who will stick with them until some reasonable relief is obtained. Most physicians resort to the first and most common therapy management tool—surgery. This results in removal of one or more organs in surgery after surgery until no pelvic organs remain; even the bladder is taken in some instances (63)! Because the treatment of chronic pelvic pain is quite controversial and far from being established as a routine or classic therapy model, it makes perfect sense that patients who do suffer from chronic pelvic pain be seen in some type of interdisciplinary complex. This can consist of a clinic where one, two, or even three pain practitioners interact and collectively work on common difficult-to-manage patient problems on a routine basis. Referrals to ancillary specialties can be organized and development of good collegial relationships established. A 1990 study of this model tested against a comparison group that did not use the interdisciplinary model revealed that the former group of patients had more success with pain reduction, anxiety reduction, and depression reduction and had an improved participation in daily psychosocial activities such as return to work, social activities, and sexual activity when compared with the traditionally managed group (64).

PSYCHOLOGICAL FACTORS IN GYNECOLOGIC PAIN SYNDROMES

The medical information presented in this chapter illuminates the spectrum of diagnostic and treatment conundrums that can confound the practitioner who works with chronic pelvic pain and significantly impair the woman's capacity to lead a productive life. Patients with chronic pelvic pain often experience progressively limited professional, social, and/or personal pursuits, if not pleasures. Providing treatment for these women is complicated by a plethora of etiologic factors and numerous diagnostic considerations that cross medical and psychological specialties. Furthermore, they often describe increasing frustration with being transferred between and within medical specialties. Multiple physician visits, multiple diagnostic tests, multiple drug trials, and multiple treatment regimens, including multiple surgeries, often produce little relief from their pain while significantly increasing stress and psychosocial symptoms, such as depression and sexual dysfunction. Unfortunately when medical treatment is not conclusive or successful, women with chronic pelvic pain, more than any other pain condition, are often labeled as “crazy” or told that the pain is “in their head.” Practitioners and partners frequently become quite nihilistic and often manage their frustration in ways that are psychologically detrimental to the patient. Practitioners need to be aware of the potent psychophysiologic impact of the patient's stress and psychosocial environment on medical efficacy and the patient's recovery.

Most studies (e.g., see references 61,65) find that the average woman with chronic pelvic pain is in her early 30s and has an average pain of 7 on a visual analog scale of 10. This pain has often lasted for 3 to 4 years and resulted in an average of three to four gynecologic surgeries before she is seen by a specialist or at a pelvic pain clinic. Frequent use of hysterectomy, much too often without relief of pain, is a further misfortune from which many of these women suffer (65).

It is our belief that psychological evaluation and treatment are critical components when working with a woman suffering from chronic pelvic pain. The complexity of this condition has prompted a more specific focus on the collaboration of medical and psychosocial professionals. We strongly encourage an interdisciplinary approach that includes at least mental health and medical professionals. The physician who is presented with chronic pelvic pain must have a broad-based understanding of the problem in order to facilitate effective triage and referral, if not treatment. This portion of our chapter makes it clear that psychological factors are critical to this process.

Historical Considerations

Psychological trauma, such as sexual and physical abuse, in the history of patients who develop chronic pelvic pain is important to understanding this complex problem (61,65,66,67 and 68). The impact of these historical factors in “causing” pelvic pain remains controversial; however, we believe that they may exacerbate a woman's experience of pain in the pelvis and consequently reduce medical efficacy.

Trauma

History of sexual and physical abuse has become a frequent topic of discussion and debate regarding the etiologic impact on patients with chronic pelvic pain (61,65,66 and 67,69,70). Most studies indicate that an average of 20% to 30% of women with pelvic pain have experienced childhood sexual trauma or abuse (61,65,66,69,71). When the pain is “nonsomatic” or “of unknown etiology,” the frequency of abuse is found to be much higher. For example, Harrop Griffiths et al. (67) found that of 25 women who had undergone a laparoscopy, 64% reported child sexual abuse (48% mild and 16% severe) as compared with 23.3% of women who received a laparoscopy for infertility (23.3% mild and 0% severe). Furthermore, 48% of those with chronic pain also reported adult sexual abuse (20% mild and 28% severe) compared with 13.3% of infertility controls (3.3% mild and 1% severe). Interestingly, when they compared the pelvic pain patients with positive and negative findings during laparoscopy, there was no significant difference in the frequency of sexual abuse.

Reiter et al. (65) found that 64% of patients with “nonsomatic” pain reported childhood sexual abuse. These authors also found that the sexual histories of these patients were different than those of the “organic” patients. The nonsomatic patients had sex at an earlier age and also had a greater number of sexual partners.

Physical abuse history has also been found to be an important diagnostic consideration for women with chronic pelvic pain. In fact, one group of researchers (72) found that childhood physical abuse, not childhood sexual abuse, was directly associated with the symptoms of depression, anxiety, and somatization found in this group of patients. These authors reported that childhood sexual abuse and childhood physical abuse are highly correlated. However, physical abuse has the strongest correlation with psychological symptoms associated with chronic pelvic pain and the greater probability of resulting in adult posttraumatic stress disorder (PTSD) symptoms. Another study in Scandinavia (73) found that women living in a physically abusive relationship were more likely to have experienced chronic pelvic pain. Of those in the abusive relationship, 15% reported pain at the time of the interview, compared with 2% of the control group. In addition, more of the abuse group reported a higher number of psychological problems (82%) compared with the controls (14%).

Toomey et al. (68) studied the differences between patients who had been physically or sexually abused and those who had not. These authors found that the two groups did not differ in their pain descriptions or the functional impact of their pain. However, the abused patients with chronic pelvic pain did differ in the following ways: (a) They had greater perceived “punishing responses” from those around them; (b) they reported less life control; (c) they had a greater somatic focus; and (d) they reported more generalized psychological distress.

Sexual, physical, and other types of traumas warrant special attention because they often result in PTSD (74). These traumas and consequent disorders can cause a variety of psychological and medical symptoms, many of which manifest themselves somatically. It is also interesting to speculate why there is a tendency for individuals to be affected by stress in different, but consistent, body parts (e.g., ulcers, headaches, back spasm). Therefore, stress characteristics and psychological factors may predicate which body parts may be more susceptible to pain by altering peripheral and central nervous system pain receptors. In fact, Bremer et al. (75) found that chronic stress in adulthood resulted in a significant volume change in the right hippocampus for Vietnam veterans in the study. The role of trauma/stress psychophysiology and neurochemistry (e.g., cortisol, prolactin) is becoming a more central area of investigation for understanding pain and interventional efficacy.

Seminal psychophysiologic research by Heim et al. (76) investigated whether stress markers in the hypothalamic-pituitary-adrenal (HPA) axis were altered in 16 women with chronic pelvic pain without organic pathology compared with 14 infertile controls. All subjects received a thorough gynecologic evaluation, including a laparoscopy. Sexual abuse (child or adult) was reported in 66.7% of the subjects with chronic pelvic pain without organic pathology (46.6% experienced “traumatic” abuse), compared with 21.4% of the infertile controls (7.1% “traumatic” abuse). It is important to note that 60% of women with chronic pelvic pain without organic pathology also reported a history of physical abuse, compared with 21.4% of controls. Therefore, it is not surprising that 40% of the chronic pelvic pain subjects met the DSM-IV diagnostic criteria for PTSD (74). Nevertheless, it was interesting that there was no significant difference between the two groups with regard to depression. The neuroendocrine results were equivocal when compared with other PTSD studies. However, the pattern of HPA dysregulation was very similar to findings for patients with chronic fatigue syndrome and fibromyalgia. Patients with chronic pelvic pain without organic pathology in this study were found to have decreased salivary cortisol levels (or adrenocortical hyporesponsiveness) in response to corticotropin-releasing hormone stimulation testing. It is hypothesized that hypercortisolism may be a significant etiological factor in the development of chronic pelvic pain because normal cortisol levels may be protective and low levels might cause an autoimmune insufficiency and therefore hypersusceptibility for a disease or illness process. The ultimate disinhibition of prostaglandin synthesis due to these neuroendocrine changes may also help explain the development and persistence of the pelvic pain. Furthermore, it is unclear how chronic stress might increase prolactin levels due to HPA axis disruption and therefore affect hormone sensitivities (e.g., estrogen, testosterone) and consequently disease or pain symptoms in the

pelvis.

Stress and trauma have also been found to have a serious impact on treatment efficacy for some pain conditions. For instance, Schofferman et al. (77) studied the impact of childhood trauma factors on surgical outcome for 86 post–lumbar surgery patients. The childhood trauma factors included (a) physical abuse, (b) sexual abuse, (c) alcohol/drug use in the primary caregiver, (d) “abandonment,” and (e) “emotional neglect.” The authors found that when patients reported 3 to 5 of these factors there was only a 27% chance of a successful surgical outcome, but a 95% chance of success occurred if none of these factors was endorsed.

The stress or trauma may include more than physical or sexual abuse. Pearce et al. (78) found that women with chronic pelvic pain without organic pathology reported significantly more stressful and traumatic life events (especially death and illness in family members/friends) compared with patients with identifiable pathology and non–chronic pelvic pain controls. Another study (76) found that patients with chronic pelvic pain without organic pathology also reported a significantly higher total number of major stressful life events compared with infertile women. Patients with chronic pelvic pain and traumatic or stressful histories also show a higher propensity for somatization disorders and hypochondriasis than controls (65,78,79). It was concluded that this exposure to illness and death causes a substantial increase in somatic awareness and possibly develops into a preoccupation.

This section on historical considerations is intended to imply neither a psychogenic origin to most chronic pelvic pain nor that psychological intervention is the primary solution. The sole purpose is to educate practitioners about the need for an appreciation of historical factors in the triage and referral process.

Common Psychological Problems

Global Psychological Symptoms

Women with chronic pelvic pain frequently develop a constellation of psychological symptoms, such as depression, anxiety disorders, substance abuse, and sexual dysfunction, that is directly related to the ineffective process of seeking help for their pain or the progression of their pain. A number of studies have found that women with chronic pelvic pain experience of a variety of psychological problems that can cross numerous diagnostic categories. For example, a small study found that of 20 women with pelvic pain, six met DSM-III criteria for major depressive disorder, six met criteria for generalized anxiety disorder, and one met criteria for panic disorder (80). More strikingly, Gross et al. (66) found that in a group of 25 patients with pelvic pain, nine were diagnosed with borderline personality disorders, nine with hysterical personality disorders, four with adolescent adjustment reactions, two with passive-aggressive character disorder, and one with narcissistic character disorder. Slocumb et al. (81) found that pelvic pain patients (n = 41) had higher levels of anxiety, depression, anger, and somatization compared with gynecologic controls (n = 41). The women with chronic pelvic pain were also less relaxed and content than controls, but showed no difference with regard to being friendly.

It is important to insert a qualifier while reading this section. It is very difficult, if not impossible, to differentiate the psychological sequelae associated with having a significant, psychosocially debilitating pain condition and any psychological psychiatric predisposition. In fact, Sternback and Timmermans (82) found that the abnormal Minnesota Multiphasic Personality Inventory (MMPI) profiles of patients with a pain condition (not chronic pelvic pain) returned to normal when the pain subsided.

Fry et al. (69) investigated the psychological symptoms in three groups: (a) normal subjects without pelvic pain or seeking psychiatric treatment, (b) women with chronic pelvic pain, and (c) patients in outpatient psychotherapy (Table 72-4).

Normal	Chronic pelvic pain patients	Outpatient psychiatric patients
Phobia	=	<
Obsessive	=	<
Hysterical	=	<
Anxiety	<	<
Depression	<	<
Somatic anxiety	<	<

=, same as; <, less than; >, more than normal controls.

TABLE 72-4. Psychological diagnosis in different types of patients

A common debate in the area of psychosocial etiology of chronic pelvic pain is whether patients with diagnosed organic etiology are different from those without a specific organic finding. A study using the MMPI (83) compared 25 women with organic pathology, 15 women without “obvious” pathology, and a pain-free control group. Chronic pelvic pain patients were found to have elevated scores on hypochondriasis, depression, and hysteria independent of organic pathology, but a similar elevation was not found for control group patients. Renaer et al. (84) also found no difference between the MMPI profiles of patients with chronic pelvic pain without organic etiology and those of patients with endometriosis.

Depression is common in a chronic pelvic pain patient population. Patients present with symptoms of dysphoria, anhedonia, sleep and appetite disturbances, pessimism, inertia, irritability, and despair. A small but significant number of patients describe increasing suicidal ideation if nothing can be done to alleviate their pain or help them return to a modicum of daily functioning. Harrop Griffiths et al. (67) found that women with chronic pelvic pain have a higher incidence of lifetime major depression and current major depression. Depression may significantly impede recovery, as Gil et al. (85) found that a negative cognitive style, common to depression, increases pain severity and psychological distress. Fry et al. (69) found that these patients also had a significantly higher level of hostility than gynecologic controls. It is very important to consider depression when the patient presents bitter, hostile symptoms.

The anxiety and fear described by chronic pelvic pain patients take on a ruminative, if not obsessive, style. Patients tend to catastrophize and develop superstitions regarding pain and certain behaviors. This cycle of superstition and disuse often exacerbates pain and perpetuates the problems. More often, however, the anxiety and fear of disuse cause them to overcompensate with excessive activities, especially when they are feeling better. Harrop Griffiths et al. (67) found that patients with chronic pelvic pain were more likely to have current phobias but not panic disorders. Some of our patients experience profound guilt and sometimes shame at not being able to do their perceived “wifely duties.” They may also experience shame and embarrassment because of the location of their pain or the symptoms of their pain. Low et al. (86) found that a positive laparoscopy group (n = 40) was significantly higher on extroversion, psychoticism, state anxiety, and trait anxiety than the group in whom endometriosis was not found (n = 41). The groups did not differ regarding levels of depression or of reported pain. The authors hypothesize that the endometriosis group may be predisposed to this disease by having an overanxious, perfectionistic personality style.

Somatization deserves special attention as an important version of rumination. Patients with chronic pelvic pain can become excessively focused on somatic symptoms and, with time, may have a tendency to overinterpret or misinterpret even the most benign symptoms. For instance, Kellner et al. (87) found that women with chronic pelvic pain had a much higher level of body preoccupation and disease conviction than did gynecologic controls. Also, 44% believed they had been misdiagnosed. Harrop Griffiths et al. (67) also found that these patients complained of significantly more somatic symptoms than infertility controls.

In our clinical experience, character disorders such as the borderline personality are less frequent than reported by some authors (e.g., see reference 88). Nevertheless, borderline patients with chronic pelvic pain warrant special attention in this chapter. These patients demand disproportionate clinical time and can become quite belligerent and act out when their attention needs are not “adequately” met. They may use rage and externalization of blame as manipulative tools to acquire prescriptions or specific, sometimes self-sabotaging, treatments. The physician must be critically aware of the potential for these patients to sexually misinterpret the physical examination. It is highly recommended that a chaperone be present during all physical examinations, especially gynecologic, when working with a borderline patient or a patient who presents with similar psychiatry symptoms.

Substance abuse can become a problem for patients with chronic pelvic pain when analgesics are the only perceived alternative to pain “management.” Harrop Griffiths et al. (67) found that patients had a higher lifetime drug abuse/dependence compared with controls, but no difference in alcohol abuse/dependence. The

problem of abuse is exacerbated when prescriptions for narcotics or anxiolytics are given to keep the “annoying” chronic pelvic pain patient “satisfied” and out of the office. Some of our patients use analgesics and/or alcohol as a psychotropic to numb not only the physical pain but also the emotional/psychological pain or symptoms common to their condition. Narcotics are an important part of the pain management regimen; however, patients should be consistently reevaluated for nonanalgesic use.

Psychological factors are critical to the treatment of women with chronic pelvic pain because the physiologic changes associated with emotional states can alter the recovery process. Bonica et al. (89) believed that perception of pain was influenced by an array of factors along the ascending fibers to the central nervous system. They postulated that stress or other emotional states and the corresponding neurochemical changes could augment nerve transmission at the dorsal horn, spinothalamic tract, or descending inhibitory nerves causing increased pain. For instance, depression can lower lymphocyte levels and increase cortisol levels, whereas anxiety can increase adrenocorticotropic hormone and growth hormone levels. Unmanaged stress associated with the chronic pelvic pain experience can also increase epinephrine, norepinephrine, adrenocorticotropic hormone, prolactin, cortisol, and growth hormone levels, as well as decrease bladder and gastrointestinal motility and increase cardiovascular output, with increases in blood pressure (systolic and diastolic). Emotional topics or increased stress can also significantly increase vaginal wall blood flow. Furthermore, a common physical sequela to psychological stress is muscle tension, which can create and/or significantly exacerbate the pelvic pain experience. This is noteworthy, as many of our patients are being treated for abdominal myofascial trigger points or posttraumatic neuromas, which are obviously sensitive to muscle tension. Any of these psychophysiologic changes could affect treatment efficacy and the recovery process for patients with chronic pelvic pain.

Common Psychosexual Problems

Sexual problems receive little focus in the literature (70). In fact, Van Lankveld et al. (90) stated that “the assessment and management of psychological and psychosexual dysfunction in these patients is rarely addressed.” Patients with chronic pelvic pain, independent of diagnosis, have some constellation of sexual problems. Problems include decreased libido (psychosocial and hormonal), dyspareunia including vaginismus, decreased physical arousal (e.g., decreased lubrication), disrupted orgasmic capacity, and postcoital pain.

The prevalence of dyspareunia in a general gynecologic population is surprising. Glatt et al. (91) found that of 313 consecutive patients attending a routine gynecologic visit, 33.5% reported ongoing dyspareunia. Of these patients, 23.8% reported that they “always” had pain during sex and 55% reported occasional pain.

A number of studies have examined the frequency of sexual problems in the general chronic pelvic pain population. Peters et al. (70) found that 71% of their patients experienced dyspareunia, 42% anorgasmia, and 27% postcoital pain. We (61) found that in our first 76 consecutive patients with chronic pelvic pain, 67.1% were uncomfortable with their sexual frequency and 70.2% reported a decrease in desire. Our patients reported pain during foreplay (38.8%), orgasm (36.5%), and postsexually (80.3%). Lubrication insufficiency was a problem most times or always for 25.6% of subjects. Dyspareunia was common (84.3%) and exacerbated by thrusting (80.3%) and different sexual positions (60.0%). The intercourse pain was described as deeper in the vagina (48.1%) or abdominal (35.0%) versus introital (14.8%). Harrop Griffiths et al. (67) compared the sexual dysfunction frequency of women with chronic pelvic pain (n = 25) and infertility controls (n = 30). They found that 52% of the women had dyspareunia (versus 6.7% of controls), 28% reported inhibited sexual desire (versus 6.7%), 16% reported inhibited orgasm (versus 3.3%), and 28% reported inhibited sexual excitement (versus 16.7%).

A Dutch study (90) investigated the psychological and sexual problems of women with vulvar vestibulitis and found problems with genital pain, lubrication, sexual arousal, and negative emotional interaction with their partner during sex. Interestingly, this study found a significant decrease in the frequency of sexual problems and distress during masturbation. The research found no difference regarding orgasm when with their partner or during masturbation. Nunns and Mandal (92) found very similar results during an investigation of 30 patients with vulvar vestibulitis and age-matched non–chronic pelvic pain controls. These authors found no difference regarding desire, frequency, or orgasm but did find a decrease in lubrication and arousal, in addition to increased negative feelings about making love with their partner. Webster and Brennan (93) found that 58% of patients with interstitial cystitis reported a lack of sexual interest, whereas 48.6% suffered dyspareunia and 68.1% experienced postcoital pain.

The inevitable pelvic changes associated with the aging process can cause sexual problems and result in episodic or chronic pain (94). The menopausal woman, for example, may report vaginal pain caused by vaginal barrel foreshortening and decreased or delayed vaginal expansion. Vaginal lubrication can be significantly delayed or eliminated by vaginal wall thinning, resulting in introital and vaginal barrel discomfort. Menopausal women also report occasional painful uterine spasms with orgasm. They may also report postsexual pain that is described as feeling “bruised” or “sore,” caused by the significant loss of fatty padding in the labia and mons pubis due to hormone changes. The menopausal female may also report a variant of “honeymoon cystitis”–associated intercourse. The changes in the vaginal barrel with menopause allow more direct insult to the urethral passage during intercourse and consequently can cause episodic or persistent postsexual urinary symptoms. It is very important for the practitioner to take seriously any sexual pain concerns reported by aging and menopausal women.

Chronic sexual problems can have a deleterious effect on the relationships of women with chronic pelvic pain. Many couples draw on sexual interaction as their primary, if not sole, means of experiencing or expressing love and closeness. Disruption of this process can be devastating for women with pelvic pain, who are often pressured to be sexual, independent of their pain intensity. Partners often become more irritable, distant, and accusatory, especially when multiple physicians and treatment do not increase the sexual frequency. They may begin to accuse the patient of faking pelvic pain to avoid their “duties,” especially sex. These relationships often become hostile environments that further diminish the libido and sexual function for these patients. Furthermore, they frequently report feeling further ostracized from family and friends due to the social and physical limitations associated with their pain, coupled with the absence of a visual or diagnosable illness or “defect.”

In contrast to our experience, Fry et al. (69) found no difference in relationship satisfaction between chronic pelvic pain couples and controls, even though chronic pelvic pain couples reported increased sexual problems. In fact, a sexual dysfunction clinic couple control group reported significantly more relationship problems than chronic pelvic pain couples, even though both reported similar sexual problems. Low et al. (86) also found marital satisfaction in 81 patients before receiving an exploratory laparoscopy, independent of laparoscopy diagnosis.

Considering the PTSD model, sexual dysfunctions in the patient with chronic pelvic pain may have a self-protective component. Avoidance of sexual activity may help these women manage the possibly conscious or preconscious memories of sexual abuse or trauma. Some of these women have developed a strong fear of “letting go” or “losing control” that they associate with sexual arousal or orgasm. They may also have significantly conflicted feelings about the pleasure associated with sexual activity in light of their possible pleasurable feelings during the abuse.

Chronic pelvic pain and the related sexual problems can also produce significant issues related to identity and femininity. Some of our patients describe decreased feelings of femininity caused by the inability to have sex. This is exacerbated if their partners no longer find them sexually attractive or do not initiate sexual activity because of changes associated with hormone therapy (e.g., hot flashes, bleeding) or surgeries (e.g., disfigurement of genitals with vulvectomy). Even very supportive, concerned partners may back away from sex out of fear of causing or exacerbating their partner's pelvic pain. Furthermore, pregnancy or infertility issues associated medical interventions for pain are often overlooked in working with these patients. When reproductive changes are permanent, as with hysterectomy, the psychological impact should be considered and discussed. Some of our younger patients have been positioned to make a choice between having a family or ameliorating (possibly) their pain.

Gynecologic pain syndromes and the consequent psychological sequelae can have a deleterious effect on psychosocial function. This section has attempted to illuminate the depth and breadth of these problems. We hope that practitioners will use this information to explore psychological problems that may be exacerbating the patient's pain or reducing medical efficacy and not to imply a psychogenic cause of their gynecologic pain. The next section presents general information regarding the psychological evaluation and treatment of women with chronic pelvic pain.

Psychological Evaluation and Treatment

This section is designed to give the nonpsychological practitioner an overview of how psychology can augment treatment efficacy for women with gynecologic pain syndromes. It is not designed to be a comprehensive presentation of all psychological modalities available. We have attempted to present psychological information that directly applies to the patient with chronic pelvic pain and how problems unique to this group of patients can be addressed with psychological evaluation and intervention. Readers are directed to Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92, Chapter 93 and Chapter 94 for more detailed information on psychological testing and treatment options for patients in pain. A more comprehensive presentation of evaluation and treatment procedures for gynecologic pain patients can be found in Elliott (62).

Evaluation

In our experience, treatment plans for patients with chronic pelvic pain rarely involve psychological intervention until all medical diagnostic or intervention options have been exhausted. Consequently, the patient is often transferred (“dumped”) to a psychologist or psychiatrist to treat the problem that is “all in her head.” There is often limited or ineffective communication between the mental health professional, physician, and patient. This causes many of these patients to ignore psychological help and pursue medical treatment from a new physician with a new specialty that can “help” her with her pain. Because of this process, psychology is usually a last resort and attended begrudgingly and sometimes belligerently.

The psychological evaluation of a patient with chronic pelvic pain is critical for the development of an effective treatment plan. Evaluation options are obviously related to the resources available. Some clinics do not have the luxury of a mental health professional or psychometric testing. The increase in health maintenance organization and capitated health care has also tragically decreased reimbursement and thus decreased availability of psychological evaluation and treatment. It is highly recommended that solo medical practitioners find a mental health colleague in the community to involve in the treatment whenever possible. It is most helpful when this collaboration is implemented from the onset of treatment, if not from the onset of the diagnostic process, and not after all other options are depleted.

Initial Consultation. In our clinic, after review of available records, a psychological consult or interview is implemented to collect information about psychological status and coping mechanisms. The patient's fear that the problem is “all in her head” should also be addressed and reassured immediately. Most patients with chronic pelvic pain are very relieved to hear this explanation of our work-up strategy. We then proceed to explain what they can expect during their first visit. Questions and concerns regarding psychological or medical procedures are addressed. We then review the development and characteristics of their pain. It is important to understand the activities or situations that make the pelvic pain worse and under what conditions the pain is better. Previous intervention attempts (i.e., surgical, pharmacologic, and psychological) and the patient's psychological experience with them are also reviewed. Psychosocial, relationship and sexual problems and stressors are discussed, as well as current coping skills and resources. Special awareness is directed to evidence of intense somatic focus and history of physical, sexual, or environmental abuse. Normalization of the psychosocial sequelae associated with chronic pelvic pain is important during this first meeting. Every patient also receives a brief didactic regarding the psychophysiology of emotions such as stress, depression, and anger and the impact on nerves and muscles. The vicious circle involving stress and emotions, muscle tension, and nerve changes is illuminated.

When a psychologist is not on staff and a referral for evaluation or treatment is recommended, the physician must be sensitive to the patient's likely perception of being dumped or seen as having pain caused by psychopathology. The physician needs to take time to quell the patient's fears and explain the psychophysiology of stress as mentioned previously. The physician can greatly enhance this interdisciplinary referral process by providing confident remarks about other patients sent to this psychologist and about how referrals are common.

In our clinic, the information provided during this initial consult is then presented in a team meeting with the physician. Special circumstances are outlined. This might include fear of the pelvic examination due to previous negative or punitive experiences or a phobia regarding needles. This may also include the need to additionally educate an unsupportive or sexually pressuring partner.

The process of listening to and talking with chronic pelvic pain patients is a critical part of treatment. Unfortunately, Grace (95) found in a New Zealand population of patients that a significant portion of these women did not think that their doctor “really understood their concerns,” and they frequently left their practitioner's office without discussing important aspects of the disorder. In fact, only 52% of women being seen by a general practitioner and 62% being seen by a gynecologist felt that their diagnosis was adequately explained. Furthermore, 58% of these women did not feel that their physician took their pain symptoms seriously and they felt that their general practitioner (43%) and gynecologist (24%) presented that nothing was wrong with them. General practitioners (25%) and gynecologists (12%) were perceived to present that the patient's pain was a result of psychopathology. Lastly, 67% of the women reported that they felt their physician expected them to simply put up with their pain.

It is critical that the patient with chronic pelvic pain receive a psychological evaluation with psychometric testing when any of the following are observed: (a) The patient has been referred using narcotics for nonmalignant pain or is being considered for long-term use of opioids; (b) the patient is being considered for an invasive procedure (e.g., implantable epidural pump, spinal cord stimulator); (c) there is a history of medical or pharmacologic noncompliance; (d) there is a history of physical or sexual abuse or trauma; and (e) pain disability seems greatly disproportionate to pathology or there is “excessive pain behavior.”

Evaluation and Diagnostic Tools. The psychometric tools available to evaluate patients with pain are numerous. Each clinical setting has different needs, resources, and psychological expertise in working with chronic pelvic pain patients. Clinicians new to the treatment of this type of pain may consider a more comprehensive evaluation process until more familiarity is achieved. Psychological testing options are not reviewed because evaluation tools are similar to other pain conditions and are presented in Chapter 16. For additional reviews see Turner and Romano (96) and Steege et al. (97). Our clinic uses psychological testing sparingly. We most frequently administer the MMPI-2, a common tool used in the evaluation of pain patients and more recently described for patients with chronic pelvic pain (97,98 and 99).

A special note about the MMPI is especially warranted when interpreting the profiles of patients with chronic pelvic pain. It is common for the pelvic pain patients in our clinic to have significant elevation on scales 1 (hypochondriasis) and 3 (hysteria) and less elevation on scale 2 (depression) (99). This is commonly described as the “conversion V” and sometimes interpreted in reports as evidence of a “conversion reaction.” We recommend against using this specific interpretation or diagnosis without substantial collaborating medical evidence. Remember that these patients are already very sensitive to a psychogenic diagnosis. This configuration in our experience is rarely (if ever) consistent with a hysterical or conversion pain disorder. We believe that this configuration represents hypersensitivity to body function and pain and tendency to overinterpret or misinterpret even benign symptoms. We often use the fairy tale of the “Princess and the Pea” to describe the phenomenon of somatization to the patient.

Another reason for a psychological consultation and testing is to facilitate pharmacologic treatment planning with both analgesic and psychotropic medications. Psychological profiles can help differentiate effective medications or regimens by delineating specific pain and psychological symptoms. For example, we often use a selective serotonin reuptake inhibitor (e.g., sertraline) when there is a combination of dysphoria, irritability, and rumination symptoms. The use of a minimally euphoric analgesic (e.g., methadone) is warranted when there is a history of noncompliance or when there is significant psychological turmoil. Interviews and psychometric testing can also help measure the efficacy of pharmacologic trials with interviews and routine testing (e.g., Beck Depression Inventory).

Treatment Approaches

Pelvic pain research has shown that an integrated interdisciplinary or multidisciplinary approach can significantly enhance pain reduction and recovery. As early as 1977, Beard et al. (100) recognized the importance of an interdisciplinary approach for successful treatment of chronic pelvic pain. He found that for patients with a negative laparoscopy, 11 of 18 showed marked improvement or were pain free with a combination of reassurance or therapy. Later, Beard et al. (101) reported that women (sample size not given) receiving “stress analysis” or “pain analysis” therapies were significantly improved at the end of treatment compared with a minimal intervention control group. Interestingly, at a 3-month follow-up, differences were not maintained, but at 6 months, improvement differences over controls returned.

Kames et al. (64) studied 16 patients who were inappropriate for standard gynecologic methods or who had not been successfully treated with these procedures. Patients received an extensive medical and psychological evaluation. The latter included a broad range of psychometric testing. All patients received psychological therapy once per week that included stress management, self-control procedures (e.g., relaxation and hypnosis), anxiety and depression control, activity management, sex education, and cognitive behavioral therapy. The treatment was reported to be structured but not uniform. The initial phase of psychological treatment involved pain management skills, relaxation tools, and increased awareness of pain or stress triggers. The middle phase focused on goal setting and involvement in appropriate activities, reduction of negative thoughts, and a discussion of sexual concerns common to pelvic pain. The latter sessions involved intervention strategies for individual issues. It is important to note that 50% also received tricyclic antidepressants. This 6- to 8-week program resulted in 67% reporting pain improvement at the end of treatment and 65% at 6-month follow-up. Social activity and sexual activity were reported improved by 44% and 27%, respectively, at the end of treatment and 65% and 79%, respectively, at the 6-month follow-up. At the 6-month follow-up, 92% reported that they were improved and that they were satisfied or highly satisfied with the treatment program.

Peters et al. (70) randomly assigned 106 patients with chronic pelvic pain to one of two treatment groups. In the first group, psychological intervention was implemented only after organic etiology was ruled out via laparoscopy. In the second “integrated” treatment group, medical, psychological, dietary, environmental, and physiotherapy interventions were given equal attention from the onset of treatment. It was reported that 75% of the second group received “psychosocial” treatment,

but no description is given for the therapy modality used. At a 1-year follow-up, the integrated approach provided significant improvement in pain experience, daily activity, and “associated symptoms” compared with the “standard” approach.

Psychological treatment modalities should be chosen based on the individual needs of the patient, which can vary dramatically among patients. Our clinic uses an integrated hierarchical psychological approach. This involves starting with the most basic interventions (i.e., behavior therapy and psychophysiologic interventions) and moving to the next level (i.e., cognitive therapy) only if the previous level intervention attempts were consistently insufficient to manage the pain or psychological issue. Some patients with chronic pelvic pain eventually need intensive psychodynamic therapy to help resolve problems and issues impeding pain treatment efficacy. It is our experience that the most effective treatment approach is a combination of education and didactics and specific structured homework assignments. Patients are often more motivated, compliant participants in treatment when they understand the theory and concepts behind medical and psychological intervention (e.g., nerve, muscle, and emotional interaction). Furthermore, homework is both diagnostic and therapeutic. The homework brings to the surface problem areas along with teaching more adaptive skills. Some authors (98) advocate the use of a 10-session method. This program involves a systematic use of cognitive behavioral therapy, sex therapy, and relaxation training and self-hypnosis techniques. Readers are directed to this helpful article.

Behavioral Therapy. There are numerous articles and books written on the topic of behavioral therapy for pain (102,103), and for more detailed presentations see Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92, Chapter 93 and Chapter 94. There are no known articles recommending interventions specifically designed for chronic pelvic pain. A few areas of note include the use of an activity diary to facilitate a structured behavioral plan to increasingly incorporate realistic activities of daily living as medical treatment unfolds. Many of our patients with chronic pelvic pain feel guilty that they cannot pursue employment and domestic “duties.” They often describe a pattern wherein they have reduced pain and then attempt to “catch up.” They overcompensate and consequently end up being unable to function for the next 1 to 3 days, which causes them to get behind again and perpetuate this pattern. It is very common for patients to underestimate the extent to which abdominal and pelvic muscles are used in even the most basic activities of daily living. Women are often surprised that “limited” activities, such as pushing the vacuum, can reignite their pain. Therefore, we, like other pain clinicians, implement an hourly activity log. This log gives important information for treatment planning and developing more realistic goals between undercompensating when in pain and overcompensating when feeling better. Some form of activity is encouraged to ward off atrophy and to increase endorphin levels. Patients with chronic pelvic pain frequently need a moderated and guided return, both in the case of superstitiously decreased activity caused by the pain and when there is compensatory increased activity due to guilt. The diary helps as a reminder of the maximum or minimum hourly levels set in the therapy session. Behavioral therapy can also help family members develop reinforcement patterns that decrease pain behaviors or secondary gain behaviors. This could be in the form of problem solving and then executing brief but increasing social visits from friends, or it could be in the form of designing trips to locations with easily accessible rest rooms along the way.

We also implement the use of a feeling/stress and pain log. Patients are asked to record her pain and three to five different emotions on a 0 to 5 scale twice daily. The various emotions chosen are individually determined (e.g., irritability, stress, loneliness, rumination, anxiety). This tool is very helpful because many of our patients are extensively focused on somatic sensations and pain and do not see correlations with affective states. Psychophysiology concepts and their usefulness are often reinforced by diary correlation. The chronic pelvic pain patient must be informed that the correlation between emotions and pain is not contiguous and may take 24 to 48 hours to manifest as increased tension and then increased pain.

Psychophysiologic Interventions. The use of progressive relaxation training (PRT), guided imagery, self-hypnosis, breathing exercises, biofeedback techniques, and so forth is well known for treating patients with pain (104). We use combinations of each. Patients are given a handout of scripts for PRT, guided imagery, and breathing exercises and/or a prerecorded audio tape of a staff member reading different scripts. These techniques are especially helpful for patients who are terrified of the pelvic examination or phobic of receiving vulvar or vaginal trigger point injections. We saw a woman who would gag and then vomit at the sight of the needle. Her condition was diagnosed as postsurgical ilioinguinal neuroma and would best respond to local anesthetic injections. We spent a number of sessions teaching this patient breathing exercises and PRT, after which she was able to manage her phobic reaction to the needle and receive the necessary medical treatment. We are using psychophysiologic techniques to help patients when abdominal and pelvic muscle tension increases their pain. Biofeedback is especially helpful when patients have significant problems with somatization. This technique does not cause patients to “stop thinking” about their body but gets them to think differently. Biofeedback and PRT can also be very helpful when provided in conjunction with local anesthetic trigger point injections for mutual enhancement of muscle tension reduction. Furthermore, these techniques can also “force” the patient to take time out during the day and rest. Many of our patients do not give themselves permission for down time that is not “productive.”

Cognitive-Behavioral Therapy. Resources for developing cognitive-behavioral techniques with pain patients are numerous (105,106 and 107), but none has been applied specifically to pelvic pain. These techniques are designed, for example, to teach patients skills that help them more adaptively manage beliefs, thoughts, feelings, and stress that mutually exacerbate their experience of pain (see Chapter 89, Chapter 90, Chapter 91, Chapter 92, Chapter 93 and Chapter 94). Homework is a critical component of cognitive-behavioral approaches. The homework is both diagnostic and therapeutic. The response to homework can give important information regarding personality styles, defenses, and limits of coping skills while at the same time providing more adaptive alternatives.

Many patients with chronic pelvic pain describe a spectrum of negative, pessimistic beliefs that often lead to catastrophizing. This problem is exacerbated by the tendency for these patients to also ruminate. Research suggests that these beliefs are nonadaptive and increase pain (85). Nevertheless, the beliefs need to be initially discussed as understandable, considering the patients' frustrating, disappointing experience during the pursuit of treatment. The patient with chronic pelvic pain needs information regarding the impact of these beliefs on exacerbating her pain and reducing the efficacy of treatment. The specific techniques will not be addressed here; readers are directed to Elliott (62). We also need to discuss realistic “data” with the patient and help her develop a more adaptive data collection system. Our younger patients with chronic pelvic pain are a good example. They develop strong pessimistic beliefs about pregnancy after one physician recommends a hysterectomy. This often leads to depression. It is critical that we discuss the patient's belief system and what “data” she is using to create this assumption. We may need to facilitate a second opinion or correct entrenched misconceptions. Hysterectomy is not always the only option to alleviate pelvic pain.

Patients with chronic pelvic pain have been shown to present with a vast array of psychological or emotional states. These patients often develop symptoms characteristic of learned helplessness (the perceived or real inability to affect or terminate noxious stimuli), which include dysphoria, anhedonia, pessimism, and irritability. Patients need techniques to help them manage, not “control,” their feeling responses to the pelvic pain and to ineffective treatment approaches. Management of feeling techniques can help the patient act as less of a victim to their feelings and to develop a greater sense of self-efficacy. This in turn creates psychological and physiologic changes that can enhance treatment and positively affect the pain experience.

A special note is important regarding management of the hostility common to patients with chronic pelvic pain (69,81). We attempt to teach patients that anger is not a primary emotion and to look for and manage the common antecedents of disappointment, embarrassment, sadness, and so forth. For example, a patient with vulvar vestibulitis came to be very hostile and belligerent. Within a few weeks, staff members were offended by her behavior and refused to work with her. The history revealed a similar pattern in other clinics. We confronted the patient and her husband with this behavior and slowly began to help her see the sadness and emotional pain that caused this “barbed wire defense.”

Treatment should help patients increase awareness of dysfunctional patterns, develop pattern-specific problem solving, and then practice or rehearse the “antidote” plan(s). For example, we saw a patient with chronic pelvic pain and endometriosis who was able to connect the visit of her intrusive mother-in-law with a significant increase in her pain. She described increasing tension in her abdomen and consequent pain as the visit approached. Escalation of pain was common during these visits. We were able to dissect both her belief system and previous lack of coping skill options. We helped her develop a series of “if-then” options. She created “signals” to be used with her husband that indicated different parts of the plan. For instance, if she rubbed her nose, she and her husband were to convene in the kitchen and discuss how to manage her increasing frustration and stress. The patient was then able to rehearse and role-play these signals and other coping mechanisms with a female staff member. The increased sense of self-efficacy and closeness in the marriage was able to ward off the usual negative, pain-escalating effects of the mother-in-law's visit.

Psychodynamic Therapy. The use of psychodynamic techniques for the treatment of pain disorders (108) has been controversial at best. However, with the continued awareness of childhood trauma and neglect in the history of pelvic pain patients, a more psychodynamic approach may become necessary for some patients (see Chapter 93).

A comprehensive psychodynamic history can help with treatment planning for the patient who has not responded to common medical treatments or basic psychological interventions. Traumas, for instance, need to be discussed in a supportive, open environment and not easily mistaken for “false memories.” The historical information can help the therapist and patient make important connections with present defenses or maladaptive behaviors that exacerbate pelvic pain or make intervention ineffective. The psychologist helps the patient see that the past traumas can be triggered by events in the present and consequently affect her pain condition. For example, patients with sexual abuse may have strong trepidation regarding the resolution of their pelvic pain because of the fear that their husbands will try to “catch up for lost time” and treat them in an objectifying, pressuring way similar to their abuse. Therefore, they may have a reflexive contraction due to

anxiety or fear that exacerbates their pain.

A good example involves a patient with lower left quadrant pain and severe dyspareunia who was finally referred to our clinic because a number of gynecologists and a neurologist had not been successful in ameliorating her pain. She had received numerous diagnostic, pharmacologic, and surgical trials. Our team diagnosed her with iliohypogastric neuropathy of unknown etiology and myofascial trigger points exacerbated by a stressful job and poor coping skills. The patient was an active and motivated participant in our program but she did not respond to medical treatments with any continuity; decreasing her overwhelming “work stress” with classic cognitive- behavioral techniques did not help. During a secondary, more intensive history, the patient revealed sexual abuse by her father. The patient did not tell us initially because she was afraid we would diagnose her pain as “all in her head,” as she was told by her last physician. Further discussion revealed that most of the “job stress” was a new boss who looked like her father and who had a similar personality. With this disclosure, the patient was able to observe her abdominal/pelvic “clenching” response every time her boss communicated with her. Luckily, the patient was able to change her job within her company. This change did not cure her pain condition, but it allowed our treatments to be more effective and reduce her pain over a normal, more typical course.

Group Therapy. Group therapy has proved to be a productive, cost-effective modality for pain patients (108). Groups for patients with chronic pelvic pain can be peer-led or facilitated by a professional. These patients can truly benefit from the understanding and discussion of other patients suffering from the same problems and treatment experiences. It is important to note, however, that clinicians should be prepared and available to address the collective questions and frustration, and sometimes hostility, developed during a peer group meeting.

Couples Therapy. The relationship problems (e.g., animosity, abandonment, hurt feelings, limited communication) that develop often require a structured set of skills that facilitate relationship reacquaintance (62). We use a converted version of the skills described under the cognitive-behavioral section to help couples manage accumulated negative feelings and to increase communication efficacy. Of special note is the couple conference. Partners of patients with chronic pelvic pain often need information from a professional that explains the physical, sexual, and psychological aspects of this type of pain. This meeting can sometimes reduce the perpetual distrust, anger, and distance caused by the absence of a specific diagnosis and the prior ineffectiveness of numerous intervention attempts.

Sex Therapy. Sexual problems have been shown to be quite common for women with chronic pelvic pain and consequently can be devastating to their self-esteem and relationship satisfaction. Many of the sexual problems experienced by women with chronic pelvic pain can be successfully treated with sex therapy techniques (62,64). In fact, the treatment of vaginismus (see below) has a 100% success rate when the woman is willing to complete the program. Organic dyspareunia (e.g., that resulting from labial burns secondary to radiation therapy for cancer), on the other hand, can be an exception. Nevertheless, even this problem can be greatly helped by sex therapy using creative problem solving that incorporates the realistic physical limitations and expands the sexual repertoire. It is important that the woman and her partner be given hope and a good referral.

Many psychogenic sexual dysfunctions and disorders have been attributed to an increase in performance anxiety and spectatoring among healthy individuals (109). An increase in maladaptive cognitions (e.g., “Is this going to hurt again?” “Is my partner going to get mad or disappointed?” “Am I ever going to have an orgasm again?”) regarding the capacity for sexual involvement or response is quite disruptive. The woman with chronic pelvic pain also looks for cues and responses that can provide a status report comparing current responses with premorbid responses. Limited information regarding common and normal sexual sequelae associated with this disorder can also confuse, if not thwart, her attempts to cope with these sexual changes. Furthermore, an increase in sensitivity to her partner's reactions and responses is common but exacerbates expectations and increases performance fears. The cumulative result is a significant increase in distractions from bodily sensations and decreased physiologic capacity to respond. Performance vigilance escalates and results in diminished sexual interaction with her partner. Women with chronic pelvic pain may begin to feel a “duty” to provide their partners with sexual interaction independent of their own sexual interest or consequence of increased pelvic pain. It is common for these women to be present in “body only.” During sexual activity done out of “duty,” thoughts are often nonsexual, such as making a shopping list or reviewing work projects, or countersexual, such as thinking about negative aspects of the partner or monitoring body changes. Therefore, women with pelvic pain may pass the time with distracting thoughts until the partner can “get it over with.”

The treatment process must encourage an exploration of “what is available” versus what is missing or unavailable. The realistic limitations provide direction for creative problem solving. Women with chronic pelvic pain (and their partners) may need to redefine their views of sexuality. This may include greater exploration of unaffected body parts. For example, many couples (especially men) use intercourse as a primary source of expressing love in the relationship. The clinician, through the sex therapy, can help the couple expand their sensual and sexual repertoire while broadening their resources for expressing love (e.g., communication skills).

Masters and Johnson (108) described sensate focus as a strategy to decrease performance anxiety and spectatoring. Sensate focus is most effective when prescribed as touching for one's own interest. This means that the patient is to touch her partner (self) in ways that are interesting to the patient. The patient is encouraged to focus on the sensations of temperature, texture, and pressure. Concerns of doing it “right” or for the other person are discouraged. Pleasuring the partner (self), let alone trying to create arousal, is not the goal. However, over time, there is a progression from interest to pleasure to arousal. Lastly, valuable diagnostic information is gleaned from the couple's reactions and difficulties in completing the sensate focus assignments. This information can then be incorporated into developing specialized intervention before proceeding to the next level of sensate focus.

A sex therapy treatment program includes the presentation of pertinent information. This includes the rationale for prescribing the different sexuality exercises. The woman with chronic pelvic pain is also presented with comprehensive information about female sexual anatomy and physiology. In fact, the clinician must be available to discuss any aspect of sexuality that the patient needs to address.

Sensate focus was originally designed for work with couples; however, it can also be very effective for working with women alone. Sexual therapy for women with pelvic pain typically begins with solo assignments in the shower—at first not including breasts and genitals and then including them. With increased focus capacity and comfort, exercises move to the bedroom, where self-examination of her genitals is prescribed. Many women do not have information about the location and sensation of specific parts of their genitals. This continues with a series of self-touching assignments that gradually move toward exploration of maximizing pleasurable sensations without performance pressures. The woman with chronic pelvic pain may need to exert more (or less) direct pressure and experiment with different rates of stimulation (e.g., fast, slow) to determine what types of stimulation are pleasurable and what types result in increased pain. For instance, a vibrator may be included if the patient has decreased capacity for genital sensations due to medical treatments or fear/spectatoring. The woman also continues to refocus from intrusive thoughts that include performance distractions or negative cognitions about her body. Lastly, Kegel exercises are typically assigned to facilitate pubococcygeus muscle tone and, more important, to increase genital awareness and psychological comfort.

Lack of sexual desire is a very common problem of a woman with chronic pelvic pain. It is important to note that this problem is rarely caused by physical or organic etiology, with the exception of pharmacology-induced castration. These problems are almost always a result of fear of pain, psychosocial distress, or conflict in the relationship. It is often the case that decreased libido is a protective measure and should be addressed in an open and supportive way. It is critical to educate partners on how pressure and even supportive attempts to get her “in the mood” are not helpful or effective and cause her to become even more sexually withdrawn. Sex therapy techniques can be very helpful in creating a more conducive environment for the woman to experience and act on her sexual feelings. Fatigue, a common factor in desire changes, needs special problem-solving attention. There is a tendency for women with chronic pelvic pain to feel too tired to “waste” energy on sexuality. Therefore, time management suggestions may be helpful, such as taking a nap before a sexual encounter or dividing more evenly the various household tasks. The touching homework assignments can be redesigned to involve limited physical effort but still provide an opportunity for sensual and sexual expression for the couple.

Treatment exercises for couples (108) provide a structured, boundary-inclusive environment. Neither partner is left with the task of attempting to figure out the intention or lack of intention of the other. This tends to greatly reduce the anxiety and fear associated with a return to sexual expression common to women with chronic pelvic pain. It also decreases the pressure felt by both partners to quickly return to pre-pain patterns of sexual interaction. In addition, we always pace the assignments using the woman's progress and comfort as our guide. This offers her a sense of empowerment and safety concerning her body and sexuality.

A common secondary problem for women with chronic pelvic pain—vaginismus, defined as the involuntary, reflexive spasm of the pubococcygeus muscle resulting from real or perceived threats of penetration—deserves a special treatment note (61,62,109). Treatment of vaginismus typically requires the use of progressive dilators. We use a box of Young's adult dilators starting with the smallest (1½). Pediatric dilators for women with vaginismus are rarely needed. The patient is first taught to redefine her description from “pain” to other words such as “stretching,” “pinching,” “stinging,” “burning,” and so forth. She is also instructed to do Kegel exercises two to three times per day. The first dilator is inserted with the help of an artificial lubricant twice per day for 15 minutes. Over the next days to weeks, she progresses from 30 minutes, to 1 hour, to 2 hours, and finally she sleeps overnight with the dilator. After the second overnight insertion she moves on to the second dilator and repeats the same process. Each subsequent dilator follows exactly the same pattern. When the final dilator is started (usually #4), a decision is made whether the partner will come into treatment to help the transition from the dilator to the penis. In approximately 50% of our cases the partner becomes involved in

specific exercises to help with intercourse.

CONCLUSION

Careful attention to both psychological and medical factors in the woman with chronic pelvic pain can lead to significant improvements in function as well as relief of pain. Very few resources for pelvic pain diagnosis and treatment exist at the present time. This type of pain is common and leads to suffering for patients and their partners. They deserve a higher standard of care than exists in most communities today.

CHAPTER 73

Pelvic and Perineal Pain of Urologic Origin

John S. McDonald and Kenneth M. Alo'

The pain that arises from the female urinary tract and from male urogenital organs is discussed in this chapter. In addition, problems in adjacent structures located within the bony pelvis are also presented. Nearly 75% of patients seeking treatment for urinary symptoms suffer primarily or secondarily from infection (1). There is a tenfold difference between female and male infection rates: 3% of all women have positive urine cultures, while less than 0.3% of men have positive cultures. Approximately half of men with positive cultures have underlying urinary tract pathology (2,3).

Painful conditions in the pelvis and perineum can occur as a result of infection or distension of the bladder or perineum. Expanding neoplasms or extravasation of urine or seminal products into adjoining tissues can elicit severe pain. In the man, for example, extravasation of seminal fluid after vasectomy can produce disabling lancinating localized pain. Some patients undergoing transurethral surgery who are anesthetized below the ninth thoracic nerve dermatome by subarachnoid block can still experience severe pain due to extravasation of fluid into perivesical structures. This fact should serve as a useful admonition to the anesthesiologist and surgeon of the presence of extravasation and their need to consider early termination of the procedure to prevent the occurrence of the transurethral resection syndrome of fluid overload and hyponatremia (4). Such pain is presumably mediated through the somatic nerves supplying the parietal peritoneum over the dome of the bladder and perhaps through the afferent sympathetic nerves that enter the spinal cord far above the tenth thoracic segment. Unfortunately, some of the gravest chronic urinary tract diseases, such as massive dilation due to prolonged obstruction or advanced tuberculosis, may be accompanied by very little urologic pain, possibly because the nerves mediating painful sensations have been altered or destroyed by the disease process.

The first part of this chapter includes a discussion of the innervation of the pelvic urologic organs and male genitalia and some general comments about the pathology and symptoms of pain related to disorders of these structures. The second part of the chapter includes discussion on important aspects of female urologic disease processes. In addition, we discuss the pathophysiology, symptoms and signs, diagnosis, and treatment of certain painful states of the bladder and urethra in both men and women and of the prostate, seminal vesicles, epididymis and funiculus, testicle and appendages, and penis in the man. No attempt is made to provide a complete catalogue of diseases of the male and female urinary system and male generative tract; nevertheless, we include diverse pathologic states and problems likely to confront a pain management physician.

BASIC CONSIDERATIONS

Anatomic and Physiologic Aspects

Innervation of the Bladder and Urethra

Figure 73-1 depicts the nerve supply to the bladder, prostate, seminal vesicles, testicles, and penis, which constitutes a complex network involving many nerve pathways. The following discussion was originally written by John Bonica (5). It is based on descriptions that he summarized by Kuntz (6), Mitchell (7), Netter (8), and Ruch (9) and is a complete review of the study of the nerve supply to the pelvis.

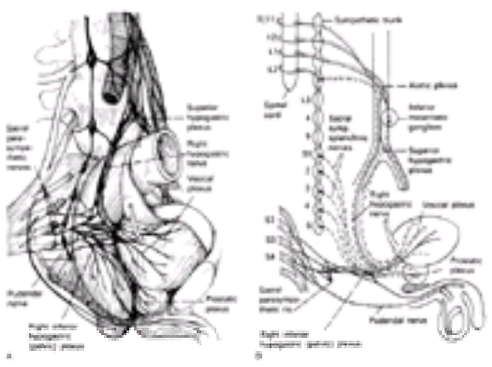

Figure 73-1. **A:** Nerve supply of the urinary bladder and prostate showing the relationship of the various nerve structures to the large intestine and their distribution in the bladder and prostate. **B:** Schematic illustration showing the segmental nerve supply to the bladder, penis, and scrotum. (*Solid lines*, preganglionic fibers; *dashed lines*, postganglionic fibers; *dotted lines*, sensory fibers.)

Bladder

Sympathetic Nerves. The peripheral sympathetic fibers to the bladder originate in the anterolateral cell column of the spinal cord segments at T-12, L-1, and L-2 and sometimes T-11 (see Fig. 73-1B). They then pass sequentially through the anterior roots, the formed nerves, the white rami communicantes, the lowest thoracic and upper two lumbar paravertebral sympathetic ganglia, and thence either through the lower thoracic and upper two lumbar splanchnic nerves to the aortic plexus or caudal to the sacral sympathetic trunk. Those fibers that pass to the aortic plexus proceed caudally to the superior hypogastric plexus, the left and right hypogastric nerves, and the inferior hypogastric (pelvic) plexus to end in the vesical plexus. Some preganglionic fibers synapse in the inferior mesenteric ganglion and some in the superior hypogastric plexus, but the majority synapse in the extrinsic or intrinsic vesical plexuses. Those that pass to the sacral sympathetic trunk synapse therein with postganglionic fibers that proceed through the sacral sympathetic splanchnic nerves to also join the inferior hypogastric plexus.

Parasympathetic Nerves. The preganglionic parasympathetic neurons have their cell bodies in the second, third, and fourth sacral spinal cord segments. Their axons pass through the right and left pelvic splanchnic nerves, known also as *nervi erigentes*, to end in the extrinsic and intrinsic vesical plexus, where they synapse with short postganglionic fibers.

Afferent Nerves. Afferent sensory nerves accompany both the sympathetic and parasympathetic efferent pathways. Many parasympathetic afferent fibers pass to the spinal cord via the ventral roots, and the rest pass through the usual course via the dorsal roots. In addition, the pudendal nerve supplies afferent fibers to the external and internal vesical sphincters and adjacent parts of the bladder. The peritoneum of the dome of the bladder is supplied by afferent fibers of T-11 to L-1

spinal nerves.

Intrinsic Nerves. The external vesical plexus containing sympathetic, parasympathetic, and afferent fibers penetrates the wall of the bladder to join the intrinsic plexus, which includes numerous ganglia. The intramural ganglia are most abundant in the trigone; they become less frequent as the distance from the trigone increases and are probably absent in the fundus. The larger intramural ganglia and some of the smaller ones are situated just below the serosa; other small ganglia are located between muscle bundles. These ganglia constitute relay stations between preganglionic and postganglionic fibers for both parasympathetic and sympathetic pathways. Most of the nerve fibers in the bladder wall are small and unmyelinated, although some are myelinated. Nerve endings with receptors are widely distributed in the mucosa and the submucosa; most of those in the trigone and adjacent areas are connected with afferent fibers that pass to the spinal cord with sympathetic nerves, whereas most of those farther removed from the base of the bladder are connected with afferent components of the pelvic nerves. The parasympathetic fibers supply the detrusor muscle and the sympathetic fibers supply blood vessels, the muscle of the ureters, and the crista of the urethra.

Nerve Function. Animal and human studies (7) have revealed that stimulation of the entire sympathetic supply to the bladder results in powerful contraction of the orifices of the ureters, increased tonus in the trigone and contraction of the internal sphincter, and inhibition of the detrusor muscle. On the opposite side, temporary interruption of the sympathetic supply produces relaxation of the orifices, entire trigone, and internal sphincter and some increase in detrusor muscle activity. In contrast, parasympathetic stimulation elicits contraction of the detrusor muscle and relaxation of the trigone and sphincters.

The nociceptive (pain) pathways from the bladder and urethra are composed predominantly of the afferent fibers contained in the pelvic nerves with their cell body in the dorsal root ganglion of S-2, S-3, and S-4. Numerous human studies detailed in the first edition of this book (5) demonstrated that following resection of the superior hypogastric plexus, there is no diminution of pain caused by distension of the bladder or application of tactile, thermal, or nociceptive stimuli to the bladder mucosa. In contrast, section of the posterior roots of S-2, S-3, and S-4 or injuries of the conus medullaris or the pelvic nerves produce loss of all painful sensation. Langworthy et al. (10) reported vague sensation due to filling of the bladder in cases of paralysis or resection of the sacral nerves, but they regarded conduction of nociceptive impulses from the bladder through the superior hypogastric plexus as highly improbable. Although early clinical evidence seemed to indicate that resection of the superior hypogastric plexus produces relief of severe pain of vesical origin (11), the procedure eliminated spasm of the internal vesical sphincter and produced vasodilation.

Male Urethra. The male urethra is innervated through the prostatic and cavernous plexuses, both of which are part of the pelvic plexus and include parasympathetic, sympathetic, and afferent fibers (see Fig. 73-1). All of these have a similar course as the nerve supply to the bladder. The prostatic plexus is contiguous with the vesical plexus, lies in intimate contact with the prostate gland, and supplies fibers to the neck of the bladder, the prostate, and the prostatic urethra. The cavernous plexus, which may be regarded as an extension of the prostatic plexus along the urethra, gives off branches that communicate with branches of the pudendal nerves to supply the membranous and cavernous portion of the urethra.

Female Urethra. The female urethra is innervated through the vaginal plexus, which is derived from the pelvic plexus, and contains sympathetic, parasympathetic, and afferent fibers. The female urethra is quite short compared with the male urethra, and thus bladder exposure to bacteria and other infectious agents are more a problem for the female compared with the male urethra.

Innervation of the Male Genitalia

Figure 73-2 shows the nerve supply to the male genitalia. The innervation of specific organs is described in following sections.

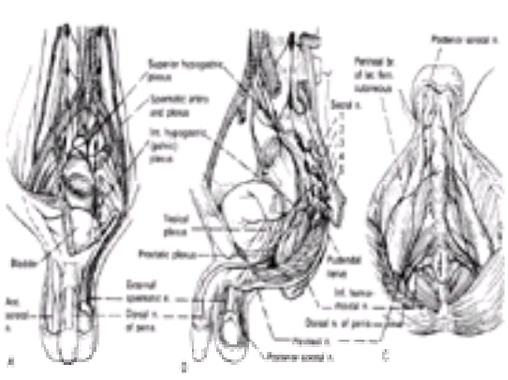

Figure 73-2. Nerve supply of the male genitalia. **A:** Anterior view. **B:** Sagittal view. **C:** Perineal view.

Testis and Spermatic Cord. The testis and the contents of the spermatic cord, which includes the ductus deferens, are supplied by branches of the spermatic plexus, which is derived primarily from the aortic plexus but also from the renal and superior hypogastric plexuses. The spermatic plexus invests the spermatic artery throughout its course and includes chiefly sympathetic postganglionic and afferent fibers. Three groups of nerves contribute to the spermatic plexus: the rostral, intermediate, and caudal groups. Fibers in the rostral group are derived from the aortic and renal plexuses, extend along the spermatic artery, and terminate in the testis. Fibers of the intermediate group arise from the proximal portion of the superior hypogastric plexus, reach and enter the internal inguinal ring to course along the spermatic cord, and finally terminate by supplying the epididymis and the proximal portion of the vas deferens. Fibers in the caudal group are derived in part from a neural complex around the distal portion of the ureter and in part from fibers of the vesical plexus; they supply the distal portion of the vas deferens and epididymis and the seminal vesicles.

The nerves derived from the spermatic plexus are predominantly sympathetic and afferent fibers and transmit nociceptive impulses, whereas those that are derived from the vesical plexus contain parasympathetic fibers and contribute importantly to the supply of the vas deferens and also of the seminal vesicles. Preganglionic sympathetic neurons, which convey efferent impulses to these structures, have their cell bodies in the T-10 to L-1 and sometimes L-2 segments.

Prostate. The prostate is supplied by the prostatic plexus, which is derived from the pelvic plexus and contains sympathetic, parasympathetic, and afferent sensory fibers. Most of the afferent fibers of the testes are components of the tenth thoracic spinal nerve; those that supply the epididymis reach the spinal cord at the T-11 and T-12 segments, while those that supply the vas deferens enter the spinal cord at T-10 to L-1. The course of these nerves to and from the spinal cord is similar to that described for the urinary bladder. Some of the fibers also supply the seminal vesicles and constitute an important supply to the penis.

Scrotum. The skin and subcutaneous tissue and fascia of the scrotum are supplied by (a) small branches of the ilioinguinal nerve; (b) the genital branch of the genitofemoral nerve; (c) the lateral posterior and medial posterior scrotal branches of the perineal nerve, which is a major branch of the pudendal nerve; and (d) the inferior pudendal branch of the posterior femoral cutaneous nerve.

Penis. The sensory nerves of the glans and the skin covering the penis are contributed primarily by branches of the left and right dorsal nerves of the penis, which in turn are branches of the pudendal nerves and consist of fibers derived from the third and fourth sacral nerves. The root of the penis also is supplied by filaments from the ilioinguinal nerves. The compressor urethrae, the ischiocavernous, and the bulbocavernous muscles, which are the voluntary muscles used in the act of ejaculation, are also innervated through branches of the pudendal nerve. The corpora are supplied by two sets of nerves, the greater and lesser cavernous nerves, which constitute the cavernous plexus and arise from the anterior part of the prostatic plexus; these are the nerves involved in penile erection. The greater cavernous nerve passes forward along the dorsum of the penis, joins the dorsal nerves of the penis, and is distributed to the corpus cavernosum of the penis; the lesser cavernous nerves perforate the fibrous covering of the penis and its root and are distributed to the corpora cavernosa and the corpus spongiosum of the urethra and the penile urethra. Vasoconstrictive fibers derived from the hypogastric plexuses join the pudendal nerves to be distributed through its branches to the blood vessels of the penis.

Physiologic Aspects

Micturition. Normal micturition is a complex, unappreciated task that is largely taken for granted until something goes awry. Micturition is part reflex and part voluntary

from a strict definition viewpoint. The reflex is generated from the middle three sacral segments where the reflex center is located in the conus medullaris of the spinal cord; anatomically this is located at the level of the first lumbar vertebral body (12). The reflex center involves afferent and efferent fibers that both send and receive impulses. These centers in turn are under cortical control, with the dual responsibility of facilitation or inhibition of voiding. Habib (13), in stimulation studies, demonstrated that the second sacral nerve played little voiding function; whereas stimulation of the third and fourth sacral nerves played major roles with detrusor contraction and concomitant decreased sphincter resistance. Stimulation of the fourth sacral nerve enhanced voiding due to a decrease in sphincter resistance. Remarkably enough, the sympathetic nerves play no role in voiding. On the other hand, the pudendal nerves, via sphincter control, allow voluntary start and stop of the urinary stream.

Ejaculation. Stimulation of the sympathetic nerves in men and boys causes expulsion of semen by musculature contraction of the seminal vesicles and expulsion of secretions from the prostatic duct due to prostatic smooth muscle contraction.

Erection. Penile erection can occur due to psychic stimulation. Such a process is made possible by transmission via parasympathetic nerves, which reach the cavernous tissue via the prostatic plexus. Although the cavernous tissue also is supplied by sympathetic fibers, these are not essential for erection. More important, sympathetic stimulation generally tends to inhibit erection by producing arteriolar constriction and thus a decrease in blood flow runoff to the cavernous tissue. Erection is characterized by dilatation of the arterioles, which coincides with inhibition of the smooth muscles in the walls of the venous sinuses and partial closure of their outlets through the small smooth channels. Afferent fibers in the pudendal nerves are also important for erection, and their severance causes loss of erection and ejaculation due to paralysis of the urethra, ischiocavernosus, and bulbocavernosus muscles.

At one time it was believed that failure of the discharge of semen after lumbar sympathectomy in men was due to the abolished upper lumbar sympathetic chain. However, Retief (14), in a study of male patients with extirpation of the sympathetic trunk from the T-9 to the L-3 segment, found that ejaculation indeed did take place, but in a retrograde fashion into the urinary bladder. The reason for this was that the internal vesical sphincter was not closed at the time of ejaculation due to the absence of impulses conducted through the sympathetic nerves. Kedia et al. (15) showed that denervation of the deferential ducts prevents peristalsis and aspermia results.

Pathophysiology and Symptoms

Referred pain is quite an important issue in reference to disorders of the genitourinary system. The bladder neck and trigone areas, for example, refer to the urethra, perineum, and glans of the penis or glans of the clitoris; however, pain of prostatic origin refers to the perineal area just behind the scrotum or to the rectum. Generally speaking, however, it is most difficult to localize or target a specific organ on the basis of subjective symptoms because of the intimate association of all the pelvic viscera and all their nerve supplies.

Pelvic pain is often relieved by warmth and sometimes increased by cold temperatures. Patients with urinary symptoms are best off staying in warm surroundings, taking hot sitz baths, and applying heat locally. Medications that increase the frequency of urination such as diuretics or increase central awareness may exacerbate symptoms referable to the urinary system. Thus, caffeine-containing foods and drinks such as coffee, tea, colas, and chocolate should be avoided because they are both central stimulants and diuretics.

Pain Related to the Bladder and Urethra

Pain related to urination is termed *dysuria* and is most often described as burning or scalding in character. It can occur at the beginning of urination, throughout urination, or at the end of urination and may persist after voiding is completed. Initial dysuria is related to lesions of the mucosa of the urethra such as in gonococcal mucositis or to denudation of perineal skin such as in herpetic ulcerations or excoriations due to intense scratching associated with pinworm infestations. When hypertonic solutions such as urine come into contact with a moist mucosal or epidermal surface stripped of its protective covering, a painful stimulus occurs. Total dysuria probably localizes the offending process to the urethra and bladder. Terminal discomfort may be caused by lesions of the bladder, urethra, or prostate. Strangury is a condition of excruciatingly painful, difficult, and slow passage of urine accompanied by spasm of the urethra and bladder. It is usually the result of severe inflammation.

Bladder Disorders. In men, pain caused by bladder disorders may be referred to the distal urethra or under the surface and glans of the penis. The latter occurs particularly when the bladder neck and prostatic urethra are the affected parts. In women, bladder lesions commonly produce referred pain in the urethra, perimeatal skin, and clitoral region.

Urinary frequency commonly accompanies other urinary symptoms and may be a symptom of infection or bladder obstruction when it occurs both at night and in the daytime. Nocturnal frequency, unaccompanied by daytime symptoms, is more likely associated with cardiac problems and nocturnal mobilization of fluid than disease of pelvic organs. Urinary urgency is an almost uncontrollable desire to urinate immediately. It is another irritative symptom due to inflammation, and approximately 10% of all individuals have a degree of bladder instability manifested as urgency (16). Adults who manifest daytime urinary frequency and urgency but do not have nocturia may be reacting to emotional or other stress.

Pain due to distension of the bladder has two components. The first is the intrinsic response to stretch and is felt suprapubically as an uncomfortable need to void. The second is due to lifting and stretching of the peritoneum overlying the bladder dome and is a more visceral and vague discomfort. This visceral sensation, mediated by the splanchnic nerves, is useful to paraplegics and others whose pudendal afferents and sacral nerve connections have been severed because they can readily learn to interpret this sensation as a need to empty the bladder. It may also contribute to the autonomic dysreflexia occasionally seen in such individuals.

Positional discomfort or pain related to activity can occur in patients with bladder calculi. The portion of the bladder with the greatest concentration of nerve endings in relation to area is the trigone. Therefore, patients with bladder stones may experience relief of irritation in the supine position when the stone rolls off the trigone onto another surface, or exacerbation of symptoms with jogging due to the stone bouncing on the trigone. Submucosal extravasation of urine through tears or cracks may be a part of the discomfort felt in interstitial cystitis (IC) and other entities. In these conditions, fixation of the normally mobile and elastic mucosal lining may occur as a result of scarring, with secondary tearing as the bladder distends and pulls the mucosa away from a point of abnormal fixation.

Urethral Disorders. The urethra has a mucosal lining and contains compound glands and ducts in the walls. Pain can occur as a result of acute inflammation secondary to infection, the presence of irritating chemicals such as bubble bath, cyclophosphamide or foreign bodies, and trauma, which may be self-inflicted or produced by iatrogenic instrumentation. Accumulation of secretions in one of the glands lining the urethra can also produce a sensation of fullness or discomfort in the perineum, vagina, or rectum, which, although rarely excruciating, can be severely annoying if it persists. Acute conditions are usually associated with terminal dysuria or even strangury and at times tenesmus. Chronic pain is referred to the perineum, urethral meatus, clitoris, or glans penis.

Pain Related to the Prostate and Seminal Vesicles

An inflamed or distended prostate may cause sensations of rectal discomfort, tenesmus, perineal pain, difficulty in voiding, decrease in stream size, frequency, and ultimately retention of urine, which is severely painful. Marked enlargement of the prostate can sometimes intrude on and compress the rectal lumen to the point of obstructing normal passage through the rectum. On the other hand, severe perineal discomfort and spasm of the levator or perineal muscles can precipitate urinary retention. This is most likely to occur in men following hemorrhoidectomy or in women after gynecologic surgery.

Disorders of the seminal vesicles can be associated with ipsilateral lower abdominal or groin pain as well as referred pain to the gonad, perineum, and penis. Significant lesions of the seminal vesicles that are unassociated with prostatic disease are extremely rare.

Pain Related to the Scrotal Contents and Penis

Infection is the most common cause of distension of the epididymis, which results in pain and tenderness. Chemical inflammation can occur as a result of retrograde flow of urine down the ejaculatory ducts. Such a scenario can occasionally occur traumatically during contact sports or when congenital or acquired obstructing urethral lesions create high proximal voiding pressures.

Pain caused by distension of the epididymis may radiate up the affected spermatic cord into the groin. Since the embryonic origin and nerve supply are almost the same as those of the kidney and renal pelvis, it should not be surprising that the pain may mimic renal colic. The physician should examine the genitalia of any patient

with flank pain and, conversely, check organs in the flank of patients with labial or scrotal pain when there is no local pathology.

Testicular pain can occur as a result of infection, typically viral, or by extension from epididymides infected with sexually transmitted diseases; in association with traumatic rupture or hematoma; and infarction from torsion. Such pain is severe and may be accompanied by nausea and vomiting. Acute congestion of the male gonadal structures as a result of sexual stimulation can also be painful. A smooth muscle contraction of the tough tunica albuginea of the testicle can produce such pain by increasing intratesticular pressure.

As indicated already, pain is frequently referred to the penis from the bladder, especially the bladder neck and trigone, urethra, prostate, and occasionally seminal vesicles. Thus, referred pain is the most common pain experienced in the genitourinary system.

PELVIC UROLOGIC DISORDERS

Diseases of the Bladder

Acute Bacterial Cystitis

Bacterial cystitis is the most common bacterial infection occurring in women, with 30% of women experiencing at least one episode of cystitis during their lifetime (17). Characteristic symptoms of urinary frequency and urgency, dysuria, and often hematuria are present with approximately 80% of cases due to antibiotic-sensitive *Escherichia coli* (18). Underlying structural problems should be ruled out if response to treatment is delayed, symptoms recur rapidly following cessation of antibiotic therapy, or if the symptoms recur three or more times per year. Minimum workup includes renal function and imaging of the urinary tract, especially if fever and pain are also present. Approximately one-third of patients presenting with cystitis have upper tract infections; therefore, a careful history to identify risk factors for subclinical pyelonephritis is important. The pain of acute cystitis lessens within hours of appropriate antibiotic therapy, with associated spasm often responding pharmacologically (phenazopyridine, Pyridium) or with direct heat (sitz baths, heating pads, or urinating in a warm tub). A differential diagnosis of acute dysuria must also include vaginitis or urethritis; therefore, a stepwise diagnostic approach, accompanied by inexpensive office laboratory testing (urinalysis, cytology, complete blood count) is necessary to begin delineating the cause.

Chronic Cystitis

Etiology. Chronic cystitis is most common in middle-aged women but may occur in anyone at any age. The differential diagnosis includes recurring acute bacteriuria with a previously unrecognized focus (e.g., infected stones), a congenital abnormality of the urinary tract, IC, female urethral syndrome, and urinary symptoms of psychosocial origin. The primary diagnostic criterion of chronic infective cystitis is persistence of detectable organisms in culture. This has commonly been accepted as colony counts of 100,000 organisms per mL of urine; however, chronic cases have been reported as clinically significant as low as 1,000 colonies per mL (19). An important criterion is the presence of white blood cells in the urine. Patients with chronic symptoms must be evaluated for anatomic lesions that could contribute to recurrences. These include vesicoureteral reflux, ureterocele, bladder diverticula, urethral diverticula, and vaginovesicular fistulas, as well as infected stones that might be seeding the bladder from the upper tract (20). If *nonpathogenic* organisms are repeatedly cultured in relatively pure growth, they should be treated (e.g., yeast, *Staphylococcus epidermidis*, a-hemolytic streptococci).

Diagnosis and Treatment. Chronic infectious cystitis symptoms are usually less severe than those of acute cystitis. Symptom levels usually vary with the degree of bacteriuria. Nocturia is common with chronic infection, with pain subsiding with antibiotic therapy. Pus may be emanating from a urethral diverticulum and should be looked for on physical examination. Treatment usually involves a loading dose of an appropriate antibiotic, which is then maintained in low dose (nitrofurantoin, 50 to 100 mg, or trimethoprim-sulfamethoxazole, 500 to 1,000 mg per day) for 6 months to years in some patients.

Noninfectious cystitis is clear of significant sediment and bacteria, is rarely nocturnal, and is often associated with depressive or psychosocial problems (e.g., IC). Other causes of depression should be sought out and treated and a multimodal approach initiated to assist with treatment (21).

Interstitial Cystitis

Diagnosis. IC is a medical enigma, the cause of which is unknown. The term IC was first coined by Skene in 1878. In 1915, Hunner described finding an “elusive” bladder ulcer in a group of patients with suprapubic pain, frequency, nocturia, and urgency that had persisted for an average of 17 years' duration. Hunner's ulcers, however, are rarely present, making this a painful bladder disease that can be challenging to diagnose and treat (22). Walsh (23) stated, “IC is a disease of extremes: extremely severe symptoms; extremes of overdiagnosis and underdiagnosis; etiologic theories varying from the abstruse to the fashionable; treatment ranging from the alpha of vitamin prescription to the omega of radical bladder substitution surgery; and sadly often, extreme confusion in medical thinking.” It characteristically presents with unremitting suprapubic pain that worsens as the bladder fills, combined with urinary urgency and frequency both day and night. There may be an associated feeling of incomplete emptying, malaise, and dyspareunia or pain after intercourse. Some patients describe a sensation of ground glass or razor blades in their bladder. Incontinence and dysuria are uncharacteristic. Oravisto's survey of the disease in Finland (24) found the disease to initially progress rapidly then stabilize at a given plateau. The presence of a marked inflammatory response, mastocytosis, and antinuclear antibodies in many patients (22,23,24,25 and 26) suggests that there may be an autoimmune component.

The initial presentation must be differentiated from bacterial cystitis and female urethral syndrome. IC patients typically describe relief during voiding, pressure or discomfort with bladder filling, frequency, urgency; have sterile urine; and are not relieved by antibiotics. Bacterial cystitis patients often describe burning with voiding or are unable to void; have frequency, urgency, and bacteria in urine; are relieved by antibiotics; and have symptoms unrelated to bladder filling (27). Patients with a recently defined urologic disorder called *female urethral syndrome* may have a variant of IC or have nontraditional cystitis infections such as *Chlamydia*. These patients complain of straining to void, urgency, frequency, hesitation, incontinence, retention, or both, and subpubic pain without a definable urologic or bladder abnormality and may have pelvic floor muscular dysfunction (22,28,29 and 30). A careful history offers some insight into these similar presentations. To make a diagnosis, IC requires endoscopy and overdistension of the bladder under regional or general anesthesia. Ordinarily, IC patients experience such pain with bladder filling that they cannot tolerate cystoscopy under local anesthesia; therefore, the bladder must be examined while only partly filled following overdistension. The typical punctate petechiae or glomerulations seen in many places in the bladder mucosa establish the diagnosis. Bladder biopsy must be taken to rule out *in situ* cancer of the bladder, which may have a similar presentation.

Long thought to be a rare disorder of postmenopausal women, IC is now known to be a relatively common malady occurring ten times more frequently in women than men and has been reported in children. Women in their 20s to 40s are most frequently afflicted, with an estimated 500,000 patients in the United States alone (22). Failure to consider IC is the most common reason the diagnosis is missed. The typical IC patient has seen five doctors and has had the disease 4 years before the correct diagnosis is made (22). IC patients are often in acute distress given the often continuous, unremitting pain that cyclically occurs as the bladder fills. This often exacts a heavy physical and psychological toll over the years. Therefore, the importance of a definitive diagnosis cannot be underestimated, as naming the culprit may begin the process of finding relief (22).

Etiology. Patients may experience symptoms, which can fluctuate between mild, moderate, and severe, and these symptoms may be constant or intermittent. Some patients may experience remission spontaneously for weeks, months, and even years. There is thought to be more than one cause for IC, which is why no single treatment works for all patients. Unlike painful bladder disorders of a specific nature (e.g., radiation cystitis, cyclophosphamide cystitis, carcinoma *in situ*), IC has an unknown etiology and variable pathogenesis and presentation. Older women typically have the *classic* form of the syndrome, with significantly reduced bladder capacity (often less than 400 mL under general anesthesia) due to detrusor fibrosis. Older men, however, despite classic symptoms, are often not even assessed for the disease. In one review, classic IC was misdiagnosed as prostatitis, benign prostatic hypertrophy, or both in a series of older men (mean age, 67.3) despite cystoscopic changes in 70% of cases (31). Younger women and occasionally young men tend to have *early* IC, with a larger bladder capacity and fewer abnormalities under cystoscopy. The presentations are not exclusive, however, and there is no evidence to suggest that one presentation evolves into another. Many causes have been proposed for IC, with several possibly contributing simultaneously. Infection, mastocytosis, defects in the bladder mucosal lining, toxic substances in the urine, vascular or lymphatic obstruction, inflammatory processes, and endocrinologic or neurogenic causes have also been suggested (22). Given these unknown variable histologic and historic concerns, treatment should be individualized and multimodal (21,22).

Treatment

Antidepressants. Antidepressants have been used widely in chronic painful conditions. Given their propensity for reducing pain, facilitating sleep, reducing dysthymia,

and known antihistaminic properties (which might combat the effects of mast cells), they have been applied widely in IC. The anticholinergic effects of these medications also increase bladder capacity and improve tone at the bladder neck (hence their use to treat incontinence and enuresis). Small doses of amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan), or nortriptyline (Pamelor) may be titrated to effect but rarely completely ameliorate the symptoms. Antidepressants are discussed in Chapter 85.

Sodium pentosan polysulfate (Elmiron) was the first oral medication approved by the Food and Drug Administration (FDA; 1996) specifically for use in IC. The bladder has a mucin mucoprotein lining, similar to heparin, made up of glucosaminoglycans, which prevent bacteria from sticking to the bladder wall. It has been proposed that a deficiency in this layer allows substances in the urine to migrate into the subepithelial spaces of the bladder and set up an inflammatory response; chemical hyperemia, mastocytosis, and histaminic release lead to eventual fibrosis. An oral analog of heparin, Elmiron may act like a synthetic glucosaminoglycan layer and may thereby increase the antiadherent surface (slipperiness) of the bladder lining, as well as *plug* any leaks in the wall fortifying bladder defenses. A dose of 100 mg three times a day has been suggested for an initial 3- to 6-month period. If pain relief is obtained, a maintenance dose may continue indefinitely.

Hydroxyzine (Atarax/Vistaril) is an anxiolytic and antihistaminic medication that affects mast cell degranulation, which is thought to play a role in some IC patients' symptoms. Atarax can decrease nocturia, daytime frequency, and some pain. Like the antidepressant classes of medication, slow titrations of low doses are recommended to avoid excessive sedation.

Narcotic Analgesics. Some IC patients with severe symptoms who have not responded to standard IC treatments have found relief from various narcotic preparations. With the emergence of many new nonnarcotic therapies, these should be reserved for patients in whom other conventional approaches have failed. Narcotics are discussed in Chapter 84.

Other Oral Medications. Many other medications, including antispasmodics, antiinflammatory agents, and muscle relaxants, have been used by many IC patients to relieve their symptoms.

Food Restrictions. Although not the cause, certain foods and drinks may aggravate symptoms. These include spicy food, alcohol, coffee, chocolate, tea, cola, and acidic items such as orange juice, carbonated drinks, tomatoes, and vinegar. Smoking should be avoided, as it is a well-known bladder irritant.

Bladder Instillations

HYDRODISTENSION OF THE BLADDER. As the first line of treatment, hydraulic distension of the bladder is both diagnostic and therapeutic. Under general anesthesia, the bladder is filled to a pressure of 80 cm of water and kept distended for 5 to 10 minutes. Short-term improvement occurs in about a third of patients (several weeks). This is usually reserved for severe exacerbations; prophylactic distension does not seem to improve long-term results. Bladder rupture has been reported under these circumstances (32). Although intentional rupture has not been advocated as therapy, Higson et al. (33) noted that patients whose bladders have been accidentally ruptured in this way do much better for a longer period of time afterward than those whose bladders remain intact during stretching.

DIMETHYL SULFOXIDE. Approved by the FDA in 1978 specifically for the treatment of IC, dimethyl sulfoxide (DMSO) is the most time-tested and proven remedy for IC (34). The treatment is given once a week for 6 to 8 weeks and as needed thereafter. It is instilled by catheter, and it is retained in the bladder for 15 minutes before voiding. Urethral burning has been reported and irritative symptoms may worsen directly after the procedure. It is excreted via the lungs within days of the treatment. DMSO is thought to relieve symptoms in two-thirds of patients via an anesthetic action on the bladder surface or through an antiinflammatory effect. It may also have cytolytic effects in the submucosal nerve plexuses while sparing the detrusor (35). Most patients require repeated courses of therapy. Some have used DMSO instillation in combination with heparin, corticosteroids, local anesthetics, and bicarbonate (22).

OTHER INTRAVESICULAR INSTILLATIONS. Dilute silver nitrate solutions and oxychlorosene sodium (Clorpactin WCS-90) have been used with mixed results for IC. Clorpactin instillation is extremely painful and requires general anesthesia. Hyaluronic acid (Cystitstat) can be instilled directly into the bladder and is thought to work by replacing the defective glucosaminoglycan lining of the bladder. Cystitstat is initially instilled once a week for 6 weeks and then biweekly when symptoms have stabilized. Clinical trials in the United States are ongoing as efficacy is not known at this time. It was originally designed as a treatment for bladder cancer and is instilled directly into the bladder and appears to work by boosting the immune system. Long-term benefit and untoward effects are unknown (22).

Treatment of Hunner's Ulcers. Hunner's ulcers, present in only a small percentage of IC patients, may be treated with laser, resection, or fulguration. Treatment does not appear to affect the severity of the presenting symptoms.

Transcutaneous Electrical Nerve Stimulation. Electrical stimulation is often used in the treatment of a variety of painful conditions and may be helpful in some IC patients. It may be used daily for up to 8 to 10 hours on the thighs, low back, and lower abdomen, with the primary advantages of reversibility and ease of application. Its mechanism in IC remains unclear. Transcutaneous electrical nerve stimulation is discussed in Chapter 98.

Denervation. In the first edition of this book, Bonica (5) noted that in the 1930s a number of respected clinicians, including Leriche and Mandl, reported relief of pain associated with severe chronic cystitis following a lumbar sympathetic block. These procedures had been prompted in part by the reports of Learmonth and Braasch (36), Nesbit and McLellan (11), and others that resection of the superior hypogastric plexus gave uniformly good results in patients with chronic intractable pain due to cystitis and associated vesical spasm. In view of the fact that the sensory supply to the bladder is primarily through the sacral segments, these authors suggested that relief of vesical pain following the operation was caused by interruption of the nociceptive and vascular supply to these structures. A decade later, however, Jacobsen et al. (37) concluded that “although partial or temporary relief of vesical pain often is observed, permanent relief followed only occasionally, and in this respect, the operation has been found wanting.”

Similar opinions were also published by White and Sweet (38). Repeated hypogastric plexus blockade has also been used with varying degrees of short-term success (39). Bonica (5) also reported complete temporary relief with transsacral S-2, S-3, and S-4 block with 0.15% tetracaine in patients with severe vesical spasm accompanied by intractable pain unresponsive to sympathetic blockade. Continuous infusions for prolonged analgesia in this region were also used to break the pain cycle in severe cases. Neurolytic and percutaneous and direct rhizotomy techniques in this region cause loss of bladder and rectal sensation and penile erection and orgasm; therefore, these approaches are impractical for definitive therapy.

Pudendal Nerve Blockade. Pudendal blockade was first described by Mueller in 1908 for use in obstetrics. Over time, a number of variations in technique have been described, including that of Klink and Kohl, who advocated transperineal and transvaginal approaches, respectively. These techniques evolved due to the repeated difficulty of successful block due to an inability to accurately target the nerve. McDonald et al. reported on the successful use of computed tomographically guided pudendal nerve blockade for diagnostic and therapeutic application in chronic pelvic pain conditions (40).

Surgery. Surgery for pelvic pain and associated dysfunctional voiding syndromes may be appropriate for a small minority (less than 10%) of patients whose symptoms are intractable and where lesser invasive, reversible forms of therapy have failed. In fact, no treatment to date, other than surgery, is significantly effective for the patient whose bladder has irreversible scarring and contraction and a significantly reduced bladder capacity. The healthy bladder holds 800 to 900 mL under anesthesia and 400 mL when the person is awake. Once the bladder capacity shrinks to less than 300 mL under anesthesia, the person may have a capacity of less than 150 mL while awake. In such cases, standard augmentation cystoplasty has been used in the past (41). In other patients, urine has been diverted to a bowel segment or through an intestinal conduit to the skin (42). Attempts at supratrigonal denervation by resecting the bladder from its trigone and reanastomosing it afterward have resulted in contracted useless bladders in some patients (22). However, *definitive* surgical intervention for the majority of these patients should be approached with caution, as it has not uncommonly failed to ameliorate persistent symptoms. It has been postulated that this may be in part due to a neuronal plasticity and wind-up phenomenon (43) (see Chapter 4).

Sacral Nerve Stimulation. Stimulation effects of the cauda equina were initially reported by Blume et al. while attempting to treat patients after failed back surgery (44). Since then the sacral portion of the cauda equina has been stimulated primarily for motor disorders such as voiding dysfunction (45). Stimulation of the sacral nerve roots has been applied by providing low-frequency stimulation to the anterior sacral nerve roots via open and percutaneous approaches through the posterior sacral foramen (45). In September 1997, S-3 sacral nerve stimulation via an external transforaminal approach was approved for urge incontinence by the FDA. This was followed by an FDA-approved investigational protocol for patients with symptoms of urinary urgency, frequency, and pain who had failed conventional IC therapies. However, despite improved bladder motor control and some associated pain relief, both methods have been associated with a high patient dissatisfaction rate. In a multicenter study for urge incontinence, 57 of the 155 patients (37%) experienced an unsuccessful trial of sacral nerve root stimulation. Of the 98 patients who underwent permanent implantation, 39% later required either an electrode revision or system explantation (Medtronic Inc., 1998, Interstim report). Alo' et al.

subsequently reported a modified craniocaudal intraspinal approach for selective lumbar and sacral nerve root stimulation in the treatment of chronic pain (46). This approach may in part address the inherent percutaneous electrode instability concerns described previously. Although preliminary studies using sacral nerve stimulation for IC have not yet been completed, initial results are promising (47).

Radiation Cystitis and Postirradiation Contracted Bladder

Etiology. The effects of bladder irradiation may be separated into two phases. The acute phase is an immediate inflammatory response to radiation consisting of edema, mild infiltration, and some hemorrhage, which usually clears in weeks to months. The chronic phase is a delayed obliterative endarteritis accompanied by bladder scar formation, contraction, and mucosal ulceration, which can occur from 1 to several years following radiation therapy, but usually within 3 years. Increasing use of radiation in pelvic malignancies has resulted in more disorders of this type, although better control of radiation fields has limited the incidence of chronic radiation cystitis.

Symptoms and Treatment

Acute Phase. The acute phase usually presents with symptoms that are similar to those of acute bacterial cystitis: frequency, dysuria, and urgency. The urine is usually sterile, and treatment with anticholinergic drugs such as propantheline, 15 mg four times a day, may help. Some patients require systemic medications such as sedatives or narcotics. Aspirin should be avoided, as it may worsen the bleeding of irradiated mucosa. Belladonna and opiate suppositories per rectum every 4 hours may give relief in difficult cases. Superimposed infection, if proven by culture, should be treated with appropriate sensitive antibiotics. Bladder catheterization and instrumentation should be avoided for the duration of therapy because of the increased risk of infection with the introduction of a foreign body, as well as the local inflammation and trauma that may ensue. If protracted, the acute phase can progress to the chronic phase and ultimately a contracted bladder.

Chronic Phase. The treatment of a painful contracted bladder, which may occur in the chronic phase of postirradiation cystitis, is difficult. The symptoms are similar to those of IC with the added difficulty of hemorrhage, which at times causes clot retention and life- threatening loss of blood. The latter may require endoscopic fulguration. For diffuse oozing, other methods such as balloon inflation within the bladder under regional anesthesia or instillation of protein-precipitating agents, such as 5% silver nitrate or even 10% formalin, have been tried. Augmentation cystoplasty with small or large bowel has been used with limited success in some patients. Urinary diversion has not been useful unless the bladder is also removed. Partial pain relief can be obtained in extreme cases with regional nerve blockade followed by S-3 nerve section or cordotomy in patients with a limited life span (48).

Chronic Tuberculous Cystitis

Tuberculous cystitis may present in severe form much like chronic radiation cystitis. These patients have pyuria with mixed infections, but the pyuria fails to clear with control of the usual pathogens. Tuberculous contacts should be gleaned from the history and if positive should be sought by culture and biopsy. Patients often respond to antituberculous drugs with symptomatic relief. Periodic assessment of the upper urinary tract is indicated as ureteral scarring and stenosis can occur in the presence of antituberculosis drugs. If disease progression occurs to late-stage bladder contraction despite therapy, augmentation cystoplasty or diversion may be necessary. Alternative medication or block therapies may be adjunctive.

Schistosomal Bladder Infection

Schistosomal infection of the bladder, caused by *Schistosoma haematobium*, produces symptoms similar to those seen in tuberculous and postirradiation cystitis with the addition of necroturia (passage of necrotic tissue) and, in late stages, urethral stricture. Cutaneous hyperemia usually accompanies initial infection with itching; late infection may mimic the myriad symptoms of chronic inflammatory processes involving the bladder and urethra. Urethral stricture, pitting and scarring of the glans penis, and palpable perineal fibrous tissue may also be present. The differential diagnosis is aided by exposure in endemic regions of North Africa and the Middle East. Radiographs of the urinary tract may show submucosal or intramural calcification of the affected bladder, ureters, seminal vesicles, and prostate. The disease may evolve into squamous cell carcinoma of the bladder. Treatment of schistosomiasis (bilharzias) is guided by specific antischistosomal agents such as trichlorfon (Bilarcil) and praziquantel (Biltricide), which are used orally. Advanced cases may require all of the measures described for tuberculous and radiation cystitis with or without removal of calculi, treatment of stricture, or both. Endoscopy should be performed on a periodic prophylactic basis to evaluate for recurrent stones and secondary cancer. The chronic and slow progress of this devastating disease may actually destroy some of the nociceptive vesicular fibers; however, pain may be a formidable element given the protean involvement of the urinary tract and accessory genitalia. Nerve blocks, rhizotomy, and cordotomy have all been used for palliation, as this disease is as aggressive as carcinoma of the bladder.

Cancer of the Bladder

In its early stages, transitional cell cancer of the bladder is typically painless. Pain occurs late in the disease usually as the result of metastases, scarring, or postirradiation changes. Bony metastases are treated similarly to that of other mucosal visceral tumors with local radiation followed by specific chemotherapeutic agents. Pain due to ureteral obstruction by intrinsic or extrinsic tumor may be debulked (e.g., local transurethral resection or endoscopic stenting) to facilitate drainage. A silastic stent may be left in place for months; however, it may be difficult to place retrograde and therefore may need to be placed via a nephrostomy antegrade. Pain from progressive disease may require cystoprostatectomy, cordotomy, presacral neurectomy, direct local or neurolytic blockade, pelvic irradiation, or a combination of treatments. Complications from these treatments are many, not the least of which may be erectile dysfunction. Treatment fortunately is available for this side effect including corpora cavernosa implants.

Diseases of the Urethra

Acute Urethritis in Men

Sexually transmitted disease is by far the most common cause of acute urethritis in men, and its symptoms respond dramatically to specific antibiotic therapy. *Chlamydia* infections can become chronic, but the symptoms are usually so mild that reassurance about the natural history of the disease is enough to satisfy all but the most guilt-ridden sufferers. Rarely does sufficient pain develop to require more than the usual management of acute pain; however, if the pain becomes severe and is unrelieved with the use of analgesic medication, several blocks of the pudendal nerve with a local anesthetic or continuous caudal analgesia limited to the sacral segments can be used for several days to provide relief. In the extremely rare patient who has severe persistent and disabling pain that is not relieved with temporary pudendal blocks, neurolytic block or neurectomy can be considered. It is important to note, however, that destructive procedures provide relief for on average 6 (to 12) months, after which the pain returns. Moreover, the neurolytic block can be followed by postchemical neuropathy including sexual dysfunction, neuroma formation, or both, which is likely to involve additional and even more severe pain.

Acute Urethritis in Women

Acute urethritis in women independent of cystitis is most frequently associated with sexually transmitted diseases such as *Chlamydia* infection, herpes, trichomoniasis, and gonorrhea. As in men, the usual response to specific antimicrobial treatment is prompt and gratifying pain relief. Genital herpes may recur with chronically painful lesions, which often require systemic relaxants; if absolutely necessary, a stepladder pharmacologic approach including narcotics (as is commonly applied in cancer pain) can be used. Urethral inflammation can also be produced chemically by bubble bath soaps (49).

Female Urethral Syndrome

The symptom complex termed *urethral syndrome*, which is also called *psychosomatic cystitis* and *chronic urethritis*, is the female equivalent of chronic prostatitis in men and probably acutely affects as many as half of the women aged 15 to 50 years who are said to have cystitis (29,50). Some even believe this is a complex subgroup of IC, vulvar vestibulitis, or both, where chronic urethral pressure and pelvic muscular variations have been shown (30,51). Because the causes of chronic urethral syndrome are multiple, treatment directed only at a single specific cause often fails, especially if it remains organ specific (52). Depression and stress appear to contribute to this entity, as do local trauma, dysfunctional voiding patterns, sexual frustration, vaginitis, concerns about sexually transmitted diseases, and guilt about sexual fantasies and feelings. It is also probable that a variety of minor local problems are operative including blocked and distended urethral glands, prolapsing urethral mucosa, postmenopausal epithelial changes, inflammatory polyps in the urethral mucosa, urinary frequency related to menstrual fluid retention and its diuresis, previous experience with cystitis or sexually transmitted disease, fear of recurrence, or cancerophobia triggered by minimal urethral symptoms.

Symptoms and Diagnosis. Characteristic symptoms include dysuria, burning on urination, and a burning or irritated sensation in the periurethral area or perineum. These symptoms may not necessarily be associated with urination but can be exacerbated by it. Symptoms are most prominent during waking hours, with little or no nocturnal disturbance. Typically, the urinary sediment is unremarkable, and urine cultures grow limited quantities of mixed flora or nothing. The following conditions must be considered in the differential diagnosis: IC, urethral diverticulum, urethral caruncle, stricture, vesicovaginal or urethrovaginal fistulae, vaginitis, vulvar and perineal cutaneous problems, chronic yeast infestation, pinworm infestation, postmenopausal mucosal and skin alterations, diabetic neuropathy, and tuberculosis. If the primary involvement is vaginal, a vaginal discharge usually precedes the urinary symptoms. Vaginal discharge occurring after treatment with antibiotics for urinary symptoms usually is secondary to yeast infestation. Examination of the perineum may reveal excoriation, herpetic lesions, urethral caruncle, or mucosal prolapse. In the case of a urethral diverticulum, gentle stripping of the urethra by stroking through the anterior vaginal wall may express pus through the urethral meatus. In patients with persistent symptoms of this type, an intravenous pyelogram should be obtained to make certain that there are no lesions of the upper urinary tracts producing referred symptoms. Allowing contrast medium to accumulate in the bladder and looking at a voiding film of the urethra is the least traumatic way of imaging this structure. Cystourethroscopy also is required in many of these patients to provide absolute assurance that no serious disease process is present to account for the symptoms (53,54 and 55).

Treatment. The most important aspect of treatment for female urethral syndrome is the process of ruling out serious illness or any potential for serious illness in the organs of the region (52). Carefully listening to the patient, who needs to feel that she is really being heard, followed by a gentle and thorough physical examination enhances the patient's confidence. Then appropriate diagnostic studies to confirm or deny the presence of local pathology must be obtained and reviewed. Lesions found must be discussed and addressed. These diagnostic and therapeutic maneuvers may take several sessions with the patient. If the problem is dysfunctional voiding or sexual behavior, retraining should be considered. Communication problems between partners should be discussed, and strategies for dealing with them presented. The patient can learn to relax the perineal musculature during urination by voiding while in a hot tub. Pelvic biofeedback may also assist with associated pelvic floor dysfunction (30). Encouraging the patient to raise her concerns about premature ejaculation or inadequate foreplay directly with her partner may be all the help necessary. Reassurance that no sexually transmitted disease is present is effective. A frank and practical discussion of the ways of dealing with a persistent problem such as herpes and referral to an appropriate support group are often helpful. Oral nystatin (Mycostatin) to clear the intestinal source of a perineal yeast infestation along with Lactinex powder to reseed the lactobacilli that may have been driven out by previous antibiotic therapy may also be helpful. If postmenopausal changes in the perineal skin and mucous membranes are seen and there is no contraindication, a combination of estrogens and periodic progestational treatment may be useful. Such treatment should be carried with support of a gynecologist. Conjugated estrogens (Premarin), 0.625 mg per day, and medroxyprogesterone acetate (Provers), 10 mg taken from the tenth to the twentieth of the month, provide satisfactory replacement. Before prescribing these, the physician must be aware of potential thrombotic complications and carcinogenicity.

Disease of the Prostate and Seminal Vesicles

Acute Prostatitis

Etiology. In middle-aged men, acute prostatitis is mostly of bacterial origin. Coliforms are the leading offender, although *Staphylococcus epidermidis* runs a close second and is probably the most common agent in diabetics and those with immunodeficiency disorders. Posterior urethritis and therefore (at least technically) prostatitis accompany 80% of the urethritis associated with sexually transmitted diseases. In younger men, the most common cause is sexually transmitted disease, with chlamydial infection and gonorrhea being the leading offenders.

Diagnosis. On presentation the patient has chills, fever, pain in the perineum and rectum sometimes severe enough to inhibit defecation, along with urinary frequency, dysuria, decrease in stream size, and possibly nausea and vomiting. If secondary seminal vesiculitis occurs, there may be pain in the groin. The urine is cloudy, and its sediment is loaded with pus and bacteria. The patient is sweaty, febrile, and obviously ill. The prostate is very tender and enlarged and has a *boggy* consistency, which is similar to the sensation encountered on palpating pitting edema of an extremity. If acute or subacute prostatitis is part of the differential diagnosis, rectal palpation of the prostate must be done with extreme care and gentleness as the potential is high for precipitating a bacterial shower into the bloodstream with sudden septicemia and shock.

Treatment. Treatment for acute prostatitis includes bed rest, extra fluids, appropriate antibiotics, and pain medication. Usually, oral nonsteroidal antiinflammatory agents alone or in combination with narcotics are sufficient, but occasionally parenteral narcotics are required. Hot sitz baths are helpful, and belladonna and opiate suppositories relieve bladder irritability and tenesmus. If retention occurs that necessitates catheterization, it is best to avoid the urethra and place a catheter into the bladder percutaneously above the symphysis with the aid of local infiltration anesthesia. If a urethral catheter must be used, the smallest one possible should be selected. Acute prostatitis rarely causes significant problems with pain relief; chronic prostatitis is another matter.

Chronic Prostatitis

Etiology and Symptoms. Chronic prostatitis, like urethral syndrome in women, probably involves several different underlying processes with similar symptoms, which are merged under one diagnostic label. Patients complain of fullness in the perineum, urethral burning, which may or may not be related to urination, rectal discomfort, and discomfort on ejaculation. In some patients, blocked ducts and trapped secretions in distended prostate glands probably are responsible for the symptoms. Loci of microscopic inflammation may also create symptoms. These same lesions, however, may be found incidentally in asymptomatic individuals whose prostates are histologically examined for unrelated reasons such as death due to trauma or coronary disease. Low back pain is such a common complaint among the general population that it probably is coincidental to chronic prostatitis, or it reflects a musculoskeletal response to the primary problem. Driving trucks, tractors, and construction equipment seems to exacerbate such symptoms.

Diagnosis. The diagnosis and management of prostatitic syndromes is a challenge to the clinician (56). Careful pain history and examination of the prostate fluid and quantitative segmented bacteriologic cultures lead to proper categorization into the recognized forms of the prostatitic syndrome (57,58,59 and 60). It has been suggested that transrectal prostatic sonography may also be a useful diagnostic adjunctive tool (61). However, nonbacterial prostatitis, vesiculitis, and prostatodynia must also be kept in mind within the differential diagnosis if causative organisms have not been identified (62,63). Prostatodynia is a complex of symptoms similar to prostatitis that occurs without objective findings that definitely implicate the prostate gland. Bladder disorders such as internal sphincter dyssynergia, bladder outlet obstruction, tension myalgia of the pelvic floor, or at times, stress and emotional issues may be associated (64,65,66,67 and 68). Much like IC, there is emerging evidence of abnormal T-cell reactivity in a subgroup of prostatitis patients that suggests an autoimmune component to the disease (69,70).

On examination, the prostate tends to be firm and fibrous or boggy. Secretions obtained at massage are variable, but in some patients white cells are found in large clumps. Prostate secretions should be cultured. They are normally absolutely sterile, so the presence of even a few organisms is significant, particularly if they are pathogens. Before the prostate is massaged to obtain secretions for culture, the urethra must be cleansed by partially emptying the bladder. The specimen so obtained is divided into two parts. The first 5 to 10 mL of urine is collected in a tube labeled *VB1* (voided bladder urine 1). Without interrupting the voiding process, the next 150 mL or so is collected in a container, and the last 5 to 10 mL of this portion is collected in a culture tube and labeled *VB2*. Voiding is interrupted, the prostate is then massaged, and secretions are collected in a sterile receptacle held under the meatus. This is labeled *EP1* (expressed prostatic secretion 1). If no secretions are obtained, the patient is instructed to void additional urine, which is collected in two parts, the first part being labeled *VB3* and the last part *VB4*. If, when cultured, there is a higher colony count in EPI or in VB3 than in VB1 or VB4, the bacteria almost surely originate in the prostate.

Therapy. When the four-glass test is positive (71), sensitivities on the culture should be obtained and appropriate antibiotic therapy used (trimethoprim and sulfamethoxazole, regular strength tablets four times a day for 5 days to load and twice a day for the next 45 days). Young individuals should be cultured for *Chlamydia* also. A 6-week course of tetracycline may be reasonable if one suspects chlamydial etiology. Patients who do not respond to such measures may be helped if accumulated secretions are expressed by periodic prostatic massage. Occasionally, such individuals have a urethral stricture that responds to dilation. Pain due to chronic bacterial prostatitis is usually persistent and annoying but not of an intensity to require potent narcotic analgesics. Most individuals in this group are more concerned about cancer or some other long-term danger. If they can be reassured that these are not present, they are generally willing to live with the problem (50). In severe persistent cases of abacterial chronic prostatitis and prostatodynia, however, unremitting refractory symptoms may be seen. For this better recognized growing subgroup of prostatitis patients, a number of new therapies including retrograde balloon dilation, transrectal and transurethral hyperthermia, pollen extract (Cernilton N), electric acupuncture, and low-intensity laser radiation have all been successfully described (72,73,74,75,76 and 77).

Prostatic Calculi

Patients with prostatic calculi are rarely symptomatic and often are picked up when hard nodules are palpated on routine rectal examination. If the stones are multiple,

are in contact with each other, and crepitate when palpated, the diagnosis is made on physical examination. A radiograph of the pelvis usually reveals the offending calcification in the region of the prostate, thus differentiating it from cancer. Patients with prostatic cancer occasionally are misdiagnosed as having calculi. This is most likely to occur if the physician overlooks changes in the size or character of palpable nodules on reexamination. If prostatic calculi become infected or symptomatic, they can be removed by resecting the tissue between the stone and the urethra, which frees the stone into the urethra or bladder, and then crushing the stone and evacuating the fragments (78).

Benign Prostatic Hypertrophy

Benign prostatic hypertrophy is included only for completeness. Other than the pain of urinary retention, for which treatment is straightforward, pain is not a characteristic problem of this disease. Common symptoms are perineal or rectal fullness and, of course, urinary frequency and dysuria. All of these disappear with removal of the underlying obstruction. Chronic calculous prostatitis in the face of benign prostatic hypertrophy may aggravate symptoms and complicate treatment (79).

Cancer of the Prostate

Epidemiology. The cause of cancer of the prostate is unknown, but this cancer affects all races and ethnic groups. Findings of occult cancer of the prostate in autopsy series increases dramatically after 50 years of age to over 80% of those older than 80 years of age (80). Only 1 in 400 individuals over the age of 80 years dies because of cancer of the prostate, whereas 10% of those discovered with the disease under age 60 succumb from it. According to Breslow et al. (81), the incidence of large latent cancer of the prostate is the same as the death rate from the disease in several different racial groups, whereas the incidence of small latent cancer is the same as the general mortality for these groups. The implication of this study is that large latent cancer behaves in a malignant fashion whereas small latent cancer does not.

Diagnosis. Many patients with cancer of the prostate are asymptomatic, their disease being discovered on screening rectal examination. Others present with characteristic obstructive symptoms, which tend to be more unrelentingly progressive than those of benign prostatic hypertrophy. Fifteen percent to 20% present with lumbar spine or pelvic pain due to metastatic bone disease as their first symptom. The prostate characteristically is hard or contains hard nodules on rectal examination, and biopsy of these areas of the prostate yields tissue that is positive for adenocarcinoma. Serum acid phosphatase may be elevated. Osteoblastic lesions may be seen on radiographs of the lumbar spine and bony pelvis or a positive bone scan is obtained.

Treatment. Pain associated with cancer of the prostate is usually related to obstruction or metastases. Advanced or acute obstruction can be relieved by catheter drainage and resection of obstructing tissue. Less acute obstruction in patients unsuitable for excision can be relieved by hormonal control therapy. Hormonal control therapy for pain from metastatic disease provides objective as well as subjective improvement in about 70% of the cases. Synthetic estrogen (stilbestrol) given daily is effective but may take 30 to 60 days to achieve complete palliation, whereas the dramatic relief resulting from orchiectomy occurs within a week after the procedure. Subsequent recurrence of pain may respond to alteration in estrogen dosage or in the type of estrogen. Dramatic claims for luteinizing hormone releasing hormone may prove to be exaggerated, but this drug, like orchiectomy, does not produce salt retention or thrombotic problems, which are common side effects of estrogens. Pain in localized areas of bone involvement, particularly periosteal elevation, responds well to irradiation. Patients with bone marrow replacement respond to transfusion and irradiation for varying periods. Thus far, the use of antimetabolites in advanced prostatic cancer has yielded disappointing results. The management of patients with pain due to terminal cancer is discussed in Chapter 40.

Seminal Vesicle Diseases

Primary disease of the seminal vesicles is extremely rare. Secondary disease related to congenital anomalies of the urinary collecting system is also rare. More common is involvement secondary to prostate infection or cancer. The symptom is pain in the groin on the affected side. The differential diagnosis should include ilioinguinal and genitofemoral neuralgias in patients who have had recent flank or groin surgery (82). Treatment is directed at the primary disease, such as prostatitis and cancer of the prostate.

DISORDERS OF THE EXTERNAL MALE GENITALIA

Diseases of the Epididymis

Acute Epididymitis

Etiology. Acute epididymitis is characteristically due to chlamydial organisms in men younger than 40 years and coliform bacteria in older men; thus, it is a sexually transmitted disease in sexually active young men, whereas in older patients it is usually secondary to obstruction or other changes. In prepubertal boys it can also be associated with urethral obstruction (83,84).

Symptoms and Signs. Typically, the history is one of gradual onset of dull pain in the scrotum followed in hours or days by symptoms of tenderness in the affected epididymis. It is soon followed by swelling and redness in the scrotum, and then symptoms of chills, fever, and malaise. The pain is partially relieved by assumption of the supine position. The pain, inflammation, tenderness, and swelling may radiate up the spermatic cord. There is usually a history of recent sexual exposure and urethral discharge. On examination, the scrotum is often swollen, red, and tender, particularly over the epididymis, which should lie posterolaterally even though it is three or four times normal size.

Differential Diagnosis. The differential diagnosis of acute epididymitis includes torsion of the testicle (85), mumps orchitis, incarcerated hernia, sudden hemorrhage into the testicle, and neoplasm. Pain associated with torsion of the testicle is sudden in onset and often occurs at night; there is no discharge and the urinary sediment is normal. The twisted testicle pain is not relieved by simple elevation. Bowel tones can be auscultated over the scrotum in instances of a prolapsed and incarcerated hernia.

Mumps orchitis is associated with a history of exposure to mumps, parotitis, and possibly elevated serum amylase values. The testicle should be the primarily involved organ; thus, the examination of the epididymis is normal. Acute testicular hemorrhage is typified by a history of trauma, and again, the epididymis is normal. Dramatic relief of epididymis pain is achieved by local anesthetic infiltration of the cord structures with 1% lidocaine or 0.25% bupivacaine. In addition to dramatic relief of pain, such a local block may permit a more thorough examination so as to determine the actual location of the pain in the epididymis.

If there is legitimate concern that the diagnosis may be torsion, the safest course is exploration. We have yet to see scrotal morbidity in individuals with epididymitis who were explored to rule out torsion. On the other hand, in some of these explorations, we have saved some testicles in patients who would have lost them if their torsion had been treated as straightforward epididymitis without the benefit of surgical exploration.

Treatment. Most young men with acute epididymitis are infected with *Chlamydia*; thus, the logical treatment is tetracycline therapy. Men over 40 years of age should be treated with specific sensitive antibiotics effective against coliform organisms as determined by identification cultures and sensitivities. Acute epididymitis is an extremely painful disorder and practically speaking incapacitates those engaged in any physical activity at work or in recreation. Treatment regimens can include up to 50 days of antibiotics, scrotal support, and depending on severity, bed rest or restricted activity for several weeks. Suboptimal treatment may result in the development of chronic epididymitis.

Chronic Epididymitis

Chronic epididymitis, the end stage of unresolved acute epididymitis, is a disabling condition in which the epididymis is chronically swollen, painful, and extremely tender to palpation. This condition can also develop in conditions of recurrent bacterial prostatitis or congenital urethral defects.

Treatment of chronic epididymitis may result in prolonged use of a scrotal support, several months of limited physical activity, and concomitant antibiotic therapy. Some patients require epididymectomy, and some even more drastic measures such as removal of both the offending testicle and epididymis. Before such surgery, several local anesthetic infiltration blocks of the spermatic cord should be tried to see if the pain cycle can be interrupted and perhaps relieved permanently. Infection of the spermatic cord, known as *funiculitis*, occasionally accompanies epididymitis. Chronic funiculitis is almost never seen independently and is usually treated by an

identical regimen as just outlined for epididymitis.

Diseases of the Testicle

Torsion of the Testicle and Spermatic Cord

Etiology. Although torsion is primarily a disease of adolescence and young adulthood, it occasionally occurs in both the very young (i.e., the newborn) and the elderly populations (85). The incidence in a busy general hospital is only a few cases (i.e., three or four cases) a year. Left-sided torsion is twice as common as the right side. The primary cause of torsion is a congenitally induced high insertion of the tunica vaginalis on the spermatic cord, which allows the testicle to rotate within the tunica. Depending on the degree of rotation, which can be as small as 90 degrees or as large as 720 degrees, vascular compromise with ischemia and eventual necrosis of the testicle and epididymis develop over time.

Diagnosis and Treatment. Testicular pain is the primary initial symptom of torsion of the testicle. It is sudden in onset, severe in degree, manifest by exquisite tenderness, and often occurs at night. Often, patients have had a previous similar episode or episodes of less severity, which have resolved spontaneously. On physical examination the affected testicle is often higher than the unaffected testicle; this is in contrast to the condition of epididymitis, in which the affected side is positioned lower. In the twisted testicle, the epididymis is in some position other than the normal dorsolateral location, and the degree of swelling and tenderness varies. Urinalysis is usually normal in patients with torsion, whereas the urine of patients with epididymitis usually contains white blood cells. Local infiltration of local anesthetic around the spermatic cord relieves symptoms and tenderness, allowing a more careful examination of the scrotal contents and possibly manual derotation.

The treatment is immediate derotation or detorsion. This must be accompanied by a surgical fixation to prevent subsequent episodes. The contralateral side should also be protected prophylactically, because the congenital defect underlying the condition is usually present bilaterally.

Torsion of the Testicular Appendages

Although there are four testicular appendages, the appendix testis, a vestigial structure on the upper pole of the testis, is involved in 95% of the cases of torsion. This small (0.1 to 0.5 cm in diameter) pedunculated structure twists on its pedicle, and ischemia with necrosis follows. The highest incidence is in prepubertal patients 10 to 13 years of age (85).

The patient presents with pain of sudden onset, initially localized to the upper pole of the testis. After several hours, however, the pain may be difficult to distinguish from that of torsion of the testicle and cord. Early, on physical examination, a blue dot may be seen through the scrotum over the twisted appendix testis. Local infiltration blockade of the spermatic cord permits a thorough examination, which is necessary to make the diagnosis and also temporarily relieves the pain. The urinalysis is normal. Surgical excision is indicated and results in prompt relief of pain; this aggressive approach can resolve any diagnostic doubts about the possibility of torsion of the spermatic cord.

Orchitis

Orchitis is another completely independent disorder of the male external genitalia and is most commonly caused by a viral agent after puberty. Mumps is by far the most common cause, but coxsackie and other viruses have also been implicated. Pain results from swelling of the testicular parenchyma within a tightly adherent and unyielding tunic. Often, a history of previous viral exposure and involvement of other organ systems precedes the development of testicular pain. There are no urinary symptoms, and, except for proteinuria, the urinalysis is normal. A fever to 39°C is common. Temporary relief may be obtained by infiltration of 1% lidocaine into and around the spermatic cord at the external inguinal ring, because it may resolve the exquisite pain and swelling due to inflammation of the orchitis. Local measures, such as heat and mechanical support, can also help alleviate pain in some patients.

Orchiodynia

Orchiodynia, also known as *orchidalgia*, *orchialgia*, and *testalgia*, is a rare disease of unknown etiology characterized by chronic pain in the testicle. Some patients have a history of trauma to the testicle, and occasionally this disorder occurs following vasectomy. The pain is usually nagging, persistent, and achy but only rarely and fleetingly severe. The pain may be perceived in the testicle but tenderness is variable. If the patient has a history of trauma or inflammation, scarring or atrophy may be evident on examination of the testicle.

Often simple reassurance that no malignancy or other serious or transmittable disease is present encourages the patient to live with the minor discomfort of orchiodynia. Two of the three patients seen by us with this disorder were relieved with infiltration of local anesthetics around the spermatic cord at the external inguinal ring. The injections were repeated two to three times at weekly intervals. Removal of the testicle in these cases is not recommended because the pain usually persists after the testicle is gone. For example, one 91-year-old man whom we have seen for years continues to complain periodically of pain in the testicle 40 years after that organ's removal and 30 years after an ipsilateral seminal vesiculectomy.

Diseases of the Penis

Paraphimosis

In paraphimosis, the redundant foreskin retracts behind the corona of the glans penis and constricts it. The result is similar to that of a tourniquet. Further swelling and edema of the glans make diagnosis and treatment difficult for those unaware of the mechanism of this disorder.

Reduction of the foreskin often is possible after pressure over the glans has reduced the edema and swelling. This is aided by judicious use of local anesthesia infiltrated under the skin and subcutaneous tissue circumferentially at the base of the penile shaft and around the dorsal nerves of the penis and the deep corporeal nerves. Because the nerves to the coronal skin and glans reach them via the corpus spongiosum, it is necessary to infiltrate the corona circumferentially as well. (These same maneuvers apply when anesthetizing locally for purposes of circumcision.) If the edema is great, the foreskin may be reduced following local block with the aid of Babcock's clamps placed on the contraction ring, or it may be necessary to perform a dorsal slit at the bedside. When the patient has recovered and the swelling is considerably reduced, elective circumcision is indicated (86).

Priapism

Priapism, a prolonged painful erection not associated with sexual stimulation, can occur idiopathically or secondary to medications or other disease processes. Patients with leukemia and lymphoma, those undergoing dialysis, and those being treated by heparinization are at increased risk. An initial prolonged episode usually is preceded by a number of short bouts of this disorder. On physical examination the corpora cavernosa are painfully engorged, but the corpus spongiosum and glans are not turgid.

All successful therapy of persistent priapism establishes some form of shunting mechanism between the corpora cavernosa, whose venous outflow is obstructed, and the corpus spongiosum of the glans or urethra, whose venous drainage is normal. In its simplest form, this is accomplished by needle excision of cores of tissue between glans and corpora cavernosa (87). If that fails, a formal shunt will have to be created between the corpus spongiosum and the cavernous bodies, or perhaps a corporosaphenous shunt. Unfortunately, impotence often follows such procedures (88), but this is correctable by insertion of one of the penile prostheses now available (89). Control of pain due to priapism may require administration of opioids or continuous caudal block. Various anesthetics and local measures formerly used in an attempt to treat the problem are not warranted by the meager clinical results obtained.

Peyronie's Disease

Peyronie's disease is characterized by induration and sometimes curving of the corpora cavernosa of the penis. An autosomal dominant inheritable form of the disease has been identified by Nyberg et al. (90). An HLA linkage and association with Dupuytren's contractures also have been established for this inherited form, which occurs as early as the third decade; the more common, less obviously inherited form presents in the fifth and sixth decades. Patients often have no symptoms, but the discovery of a hard plaque in the dorsal shaft raises fears of a malignant process. Some patients notice incomplete erection distal to the lesion and then

discover the plaque. Others have severe angulation on erection, making intromission painful or impossible. Characteristically, the symptoms wax and wane over time, making assessment of treatment results difficult.

The patients most likely to be satisfied with surgical correction are those unable to intromit because of severe angulation due to the plaque and those whose distal erectile dysfunction also creates problems with intromission. Both will probably require penile prostheses in the course of treatment. Those with minor degrees of deformity or curvature usually do well when informed of the natural history of the disease and realize the prognosis for them is good.

Herpes Progenitalis

Herpes progenitalis, one of the most common of the sexually transmitted diseases, causes pain due to the chronic recurrence of small blistering lesions on the skin of the shaft. The painful character of the skin lesion is short lived, but the pain of the social impact of the disease on the individual's life is not.

Treatment with 5% acyclovir (Zovirax) ointment applied locally may increase the interval between recurrence of lesions. Most large communities have support groups that are helpful for patients with herpes.

CHAPTER 74

Pelvic and Perineal Pain Caused by Other Disorders

John S. McDonald and John D. Loeser

The preceding three chapters have discussed various acute and chronic painful conditions caused by pregnancy, diseases of the pelvic viscera, and by other gynecologic and urologic disorders. This chapter discusses pain caused by disorders of bone, joints, and muscles of the pelvis, nerves, and skin, and pain referred to the pelvis from other regions. Because many of these conditions occur in various parts of the body, they are discussed elsewhere in this book (see Part III and also Part IV, Chapter 27, Chapter 29, Chapter 75, and Chapter 77). Therefore, only issues relevant to the pelvis and perineum are presented in this chapter. The material is presented in five sections: Musculoskeletal Disorders; Pain of Neuropathic Origin; Painful Visceral and Dermatologic Disorders; Referred Pain; and Pain Primarily of Psychological Origin.

MUSCULOSKELETAL DISORDERS

Pain in the pelvis is frequently associated with trauma, infection, metabolic disease, or neoplasm involving the bones and joints of the pelvis. Muscular spasm and myofascial syndromes involving some of the muscles in the pelvis, particularly the pelvic diaphragm, are also common causes of pain.

Trauma

Sprains

Etiology and Symptoms and Signs. Sprains of one or more of the numerous ligaments of the pelvis as a result of accidental trauma or some other unusual exertion can be a source of pain. One of the most frequent types is sprain of the ligaments of the symphysis pubis (see Fig. 70-4). During pregnancy, the ligamentous tissues of the pelvis relax and stretch and, with an unusually large fetus or multiple fetuses, sufficient stress might be placed on the symphysis to be a source of pain. The pain is usually dull and aching in character, of mild to moderate intensity, and associated with localized tenderness in the pubic region. Occasionally, direct impact can cause bleeding, with consequent subcutaneous hematoma.

Sacroiliac joint sprain can occur as a result of excessive stress on the joint or because of injury. This condition usually produces pain in the low back and thigh (see Chapter 75).

Treatment. If the patient is seen soon after injury, application of ice to the region is useful to decrease bleeding and inflammation. The pain can usually be controlled by nonsteroidal antiinflammatory drugs (NSAIDs), given alone or combined with codeine or a more potent opioid. In patients who experience moderate to severe pain, it is useful to infiltrate the joint with a local anesthetic (e.g., 0.25% bupivacaine) combined with a corticosteroid. The local anesthetic produces relief of pain for 6 to 8 hours, and the corticosteroid decreases the degree of posttraumatic inflammation.

Fractures

Direct force applied to the pelvis can fracture this structure anywhere. Fractures that involve the pelvic ring are typically produced by compression and can either be single or multiple (1,2). Because a fracture tends to occur across a weaker part of the ring, it is especially likely to be at the obturator foramen or across the wing of the ilium, from the crest to the margin of the greater sciatic foramen. A single fracture in either location allows parts to lift and separate. Treatment is usually conservative. The pain is usually moderate and can be controlled by NSAIDs alone or in combination with a weak or strong opioid.

In contrast, severe trauma invariably produces an unstable pelvic ring fracture as part of multiple trauma. Fu and Mears (3) have noted that patients with multiple trauma who were managed in a community hospital setting, in which expert trauma surgeons were not available, had a high incidence of morbidity and mortality. The advent of rapid transport to specialized trauma centers and the development of effective techniques of internal and external fixation have markedly decreased this morbidity and mortality and have proven effective in reducing the pain, resulting in early mobilization with a consequent decrease in posttraumatic complications, earlier ambulating, and shorter hospitalization.

Pathophysiology. Watson-Jones (2) and, more recently, Pennal and Massiah (4), have classified unstable pelvic ring fractures according to the mechanism of injury. The most frequently encountered mechanism is a lateral compressive force that can produce one of several patterns of anterior or posterior injury. The anterior disruption can be a fracture of one or more pelvic rami, dislocation of the symphysis pubis, or both (3,4). The posterior injury disrupts the ipsilateral or contralateral ilium, sacroiliac joint, or sacrum. Occasionally, multiple posterior disruptions occur. The second mechanism involves an anteroposterior compressive force, which usually disrupts the symphysis pubis, with a wide diastasis. A third type of injury, the vertical shear disruption, is generally produced by the most violent indirect forces. Usually, the disruptive force is transmitted through a lower extremity by way of the hip joint to the pelvic ring (3). Radiologic evidence of a vertical shear fracture includes an avulsion fracture of the ischial spine, with superior migration of the entire hemipelvis. Injury of one or more branches of the lumbosacral plexus, particularly the ipsilateral L-5 root segment, is a frequent accompaniment to this type of injury.

Symptoms and Signs. Invariably, patients who present with an unstable pelvic ring fracture show evidence of other serious injuries to the intraabdominal organs, intrathoracic viscera, central nervous system, or limbs. Depending on the degree and severity of central nervous system injury, patients experience severe pain in multiple body regions. Massive hemorrhage might have occurred, manifested by the signs and symptoms of hypovolemic shock.

Diagnosis. Unless multiple radiographic views are taken, a pelvic instability might not be evident in the conventional anteroposterior pelvic view (3). Radiography should include pelvic inlet and outlet projections; if available, computed tomographic (CT) scanning is most useful because it reveals the pattern and degree of disruption of a severe pelvic ring fracture (3,4). Indeed, bone scans have revealed a number of so-called stable pelvic ring fractures accompanied by undisplaced fracture adjacent to the sacroiliac joint, and this appears to accompany every injury in which multiple pelvic rami are fractured.

Treatment. Fu and Mears (3) have presented impressive evidence that nonsurgical methods do not control osseous bleeding from the fracture site and do not permit early mobilization of patients. Consequently, patients have a high incidence of serious mental, urinary, and pulmonary complications; the latter causing delayed death in 10% to 30% of patients. Moreover, nonoperative procedures have been associated with a high incidence of serious chronic disabilities.

On the basis of these results and personal experience, Fu and Mears (3) have suggested that these patients undergo immediate reduction and stabilization of the fracture to minimize pain and hemorrhage, late pulmonary complications, and various chronic musculoskeletal disorders, which are frequently associated with these massive traumatic insults. Reduction and stabilization are best achieved by external skeletal fixation using an anterior fixation frame, which is simple to apply. In patients who are receiving emergency room care and who are in unstable hypovolemic conditions, rigid external pelvic fixation should be done as soon as blood and fluids have been replaced by intravenous administration. In patients who are stable, primary internal or external fixation of the posterior or anterior site of pelvic disruption should be carried out. In reporting their experiences with 20 patients, Fu and Mears (3) noted that 14 obtained marked relief of pain within a day after application of the frame, and an equal number were out of bed within a week after surgery. Intravascular techniques to control hemorrhage are important in the management of pelvic fractures (5). The management of pain after major trauma is discussed in Chapter 43.

Coccygodynia

Coccygodynia is a common problem and is characterized by pain in the *tailbone*, with radiation to the lower sacral and perineal areas. This condition afflicts women more frequently than men.

Etiology. Coccygodynia may follow a fall in the sitting position in which the patient lands on the coccyx, such as astride a log, or it can follow a direct blow to this region. One of the most frequent causes of coccygodynia is damage to the sacrococcygeal ligament during a difficult vaginal delivery (6). Any of these factors can cause a fracture or ligamentous sprain. Because the coccyx is quite movable and is supported by the sacrococcygeal ligaments, fracture is not as common as a sprain. A chronic sprain can follow repeated microtrauma caused by poor sitting habits, in which pressure is centered on the coccyx. Arthritis, osteitis, osteomyelitis, and other skeletal disorders involving the coccyx and lower sacrum, although rare, have been reported as causative factors. The differential diagnosis of coccygodynia is difficult and often unrelated to outcomes (7,8). Our clinical experience has suggested that psychosocial factors can play a large role in many patients who do not have a history of trauma.

Symptoms and Signs. Pain and tenderness at the tip of the spine or in the coccyx is the most frequent complaint. The pain can be severe, as in fractures, or it can be a dull ache accompanied by bouts of lancinating pain. The pain frequently radiates to the perineal, gluteal, and posterior sacral regions and occasionally down the posterior thigh along the course of the sciatic nerve. The pain and tenderness are aggravated by sitting on a hard chair, particularly in thin individuals with poorly developed gluteal muscles, and by movement of the coccyx by the examining index finger inserted into the rectum. The levator ani, coccygeus, and piriformis muscles are frequently in moderate to severe spasm. The tenderness and spasm may become generalized and involve all the myofascial and ligamentous structures of the posterior wall of the pelvis.

Diagnosis. Diagnosis is based on history and physical examination, including rectal examination. Occasionally, radiography reveals fracture, malalignment of the coccyx, or arthritic changes involving the sacrococcygeal joint. An infectious process is a very rare etiology.

Treatment. Treatment consists of massage, local heat, injection of the joint with a local anesthetic and corticosteroid, and, whenever indicated, psychological therapies. Thiele (9) reported permanent relief in most patients following a series of treatments consisting of massage performed through the rectum and hot sitz baths or diathermy. Usually six treatments given at 3- to 5-day intervals were sufficient. Local injection of hydrocortisone has been reported as effective. If the pain is severe, local infiltration, coccygeal nerve block, or a low caudal block, involving only the S-5 and coccygeal nerves, is effective. This can be repeated several times using a local anesthetic. If the block provides complete but only transient relief of pain, the procedure can be done with alcohol or with a cryoprobe (10) (see Chapter 104). It is unclear what the role of coccygectomy is in this pain syndrome. Because many of these patients are tense, apprehensive, and nervous, psychological assessment and treatment frequently constitute important components of care.

Infectious and Inflammatory Disorders

Osteomyelitis

Osteomyelitis in one or more of the bones of the pelvis, although rare, can cause pain localized to the pelvis. With acute infection patients are usually extremely ill, with high fever, malaise, lethargy, and often vomiting (11). Most patients have tenderness over the affected bone, which can be palpated. This condition is an uncommon cause of pain in the pelvis.

Arthritides

Infectious or septic arthritis and osteoarthritis may involve a sacroiliac joint, causing pain in the hip and buttock with reference to the groin. Degeneration of the interpubic disk can also cause pubic pain. Sutro (12) noted that pregnancy accentuated a degenerative process in the interpubic disk, and these patients can develop localized pain later in life. Arthritides are all discussed in detail in Chapter 27.

Paget's Disease of Bone

Paget's disease of bone, also known as *osteitis deformans*, is a localized disorder characterized by initial excessive resorption and subsequent active deposition of bone. The cause of Paget's disease is unknown. No disturbance of mineral or protein metabolism has been demonstrated; hence, it is not considered a metabolic bone disease. The condition is rare in those below the age of 40 years; among those older than 40 years, the prevalence is said to be approximately 3%, men being affected slightly more frequently than women (13). The pelvic bones are the most commonly involved, followed by the femur, skull, tibia, lumbosacral spine, dorsal spine, clavicle, and ribs (14).

Symptoms and Signs. The most common presenting symptom is pain, which can be bone pain from the active disease process or pain arising from secondary complications, such as nerve compression, fracture, or osteoarthritis. The bone pain is usually continuous and often interferes with sleep. When the pelvis is involved, patients usually experience pelvic or low back pain, or both.

Diagnosis. The diagnosis of Paget's disease is usually not difficult because of the bone deformity (13,14). Radiographic studies demonstrate lytic, sclerotic, or mixed changes. Laboratory studies might reveal an increase in the urinary hydroxyproline level, reflecting increased degradation of bone collagen consequent to elevated bone resorption.

Treatment. Treatment is directed at inhibition of osteoclastic activity, which produces symptomatic improvement and restoration of normal bone architecture. Three classes of drugs are now used to achieve this therapeutic objective: hormones, diphosphonates, and antibiotics. Calcitonin, a polypeptide hormone produced in the perifollicular cells of the thyroid, blocks bone absorption, decreasing skeletal turnover and leading to a mild hypocalcemia (13,14 and 15). The drug is given parenterally; symptomatic improvement is noted in a few weeks, reflected by a decrease in the serum alkaline phosphatase and hydroxyproline levels to 50% of pretreatment levels (15). Standard pharmacologic treatment of chronic pain with NSAIDs and, when necessary, opioids can be used.

Neoplastic Diseases

Primary Bone Tumors

The most common types of primary bone tumors of the pelvis are chondrosarcoma, followed by osteosarcoma, fibrosarcoma, giant cell tumor, and chondroblastoma (16,17). These neoplasms can produce pain that is usually continuous, dull, and aching in character; of moderate to severe degree; and generally localized to the region of the primary tumor. If the tumor encroaches on the sciatic nerve, obturator nerve, or both, however, the pain can be accompanied by neurologic symptoms and signs.

Diagnosis. Because patients with primary bone tumors of the pelvis might be candidates for local resection of the pelvis or for hemipelvectomy, it is essential for the surgeon to determine the local extent of the tumor as precisely as possible (17). Only then can the surgeon accurately predict whether patients require a local resection of part of the pelvis or hemipelvectomy. For a primary bone tumor, it is necessary to ascertain the intraosseous and extraosseous extent of the tumor, which cannot be done by physical examination alone. Consequently, it is essential to carry out extensive diagnostic imaging. The use of conventional radiography to determine the extent of the tumor is complicated by the depth of the pelvis and by its obstruction by soft tissue. Therefore, radiographs taken at 45 degrees of an anterior and posterior rotation provide more information than conventional anteroposterior views (17). Moreover, conventional tomography is more useful than conventional radiography for visualizing the intraosseous extent of the tumor. Skeletal scintigraphy is moderately useful for demonstrating the local intraosseous extent of the tumor in the pelvis. Angiography is helpful for defining the relationship of the tumor to the major intrapelvic vessels. CT scanning is the single most reliable diagnostic procedure for viewing the soft tissue extent of a primary pelvic bone tumor (17). Magnetic resonance imaging is particularly valuable in assessing soft tissue involvement.

Treatment. Local pelvic resection can be used for removal of a primary bone tumor. Marginal excision, a section at the periphery (margin) of the pseudocapsular tumor, is usually chosen for a benign tumor and also for a locally aggressive tumor such as a giant cell tumor or chondroblastoma (17). A wide excision is usually indicated for a low-grade malignancy such as a low-grade chondrosarcoma or a recurrent aggressive Paget's tumor, such as a giant cell tumor. Radical resection (in which the plane of dissection leaves a cuff of normal tissue and continuity with the tumor outside a normal anatomic compartment) is indicated for a high-grade malignant tumor. If the operative procedure is going to be used as an adjunct to other forms of treatment, as in the case of Ewing's sarcoma, the surgeon might elect to decrease the extent of the surgical incision from a radical to a wide excision. Local pelvic resection should not be performed for palliation or in the presence of metastasis because recovery is slow (17). A decision regarding the best therapeutic strategy for particular patients with specific primary bone tumors in the pelvis should always depend on the personnel and resources available and on a collaborative multidisciplinary and interdisciplinary effort.

Metastatic Disease of the Pelvis

Numerous studies have shown that the pelvis is one of the most important and frequent sites of metastasis from such primary tumors as breast, prostate, and, less frequently, thyroid, kidney, bronchial, and rectal tumors (18). Thus, Lenz and Freid (19) carried out radiologic and postmortem studies of 81 patients with skeletal metastasis from breast cancer and found that the pelvis was affected in 51 patients (63%). Among 50 patients with advanced breast cancer, metastasis to the pelvis occurred in 66% of patients (20,21).

Symptoms and Signs. The most frequent symptom associated with bone metastasis is pain, which characteristically develops gradually over weeks or months and becomes progressively more severe. The pain is usually localized and is typically more severe at night. Percussion tenderness at the site of involvement is a highly reliable clinical sign (22). Stretching of the periosteum of the involved bone, either by direct tumor expansion or by weakening of the bone by mechanical stress at the tumor site, precipitates pain in many patients. In most patients, bone metastasis is likely to involve other sites, and the initial site of pain might be elsewhere. In such cases radiographs must be obtained to rule out a pathologic fracture.

Pain is often positional in nature and can be temporarily relieved by shifting weight from the involved area. Expansion of a tumor located in the ischium can cause encroachment on the obturator or the sciatic nerve, or both, causing pain and neurologic deficits in the distribution of these nerves.

Diagnosis and Evaluation. The physical examination is one of the most important elements in the evaluation of patients with osseous metastasis. Patients with severe pain are often heavily medicated, and precise location of the pain requires interviewing and examining patients just before the next dose of medication is administered. Multiple areas of pain are often noted in patients with extensive bone metastasis. Routine radiographs do not reveal bone metastasis until the bone density has changed by 30% to 50%, so it is necessary to use more sophisticated radiographic imaging techniques such as CT and magnetic resonance imaging or radionuclide scanning (22). Occasionally, patients develop pain without bone scan or radiographic evidence. In such cases, it might be necessary to carry out a biopsy, if this is feasible.

Treatment. In general, bone metastasis requires treatment directed toward relieving the pain and preventing fracture of weight-bearing bones. Mauch (23) has firmly stated that, with few exceptions, a radical curative approach to the treatment of bone metastasis is unrealistic, and its attempt only risks treatment complications in patients with incurable disease. Before relying solely on opioid medication, anticancer therapy should be attempted (see Chapter 35, Chapter 36 and Chapter 37). Localized radiation therapy is a highly effective measure in treatment of bone pain, offering partial or complete relief in 75% of patients. Options for radiation and radionuclide therapy are discussed in detail in Chapter 37.

During radiation therapy for cancer, pain should be controlled with appropriate doses of systemic analgesics consisting of NSAIDs, which are specifically effective in the relief of bone pain and, if necessary, supplementation by weak or strong opioids (see Chapter 36). In patients whose pain is severe or excruciating, the use of continuous epidural opioid therapy achieved by the insertion of a catheter into the epidural space and by injection of an opioid should be considered.

Myofascial Disorders

Muscle Spasms

Pelvic muscle spasm in women was discussed in Chapter 72. A similar condition occurs in men, who experience pain in the perineum, rectum, and back that is associated with intense local spasm of the levator muscles. Acute transient muscle spasm can develop following injury to the perineum. In such cases the pain might be moderate, but occasionally is severe enough to disable patients completely. The pain is usually sharp and felt deeply in the perineum, with radiation to the coccyx, sacrum, and rectum. Patients respond to application of deep heat and massage. If the pain is severe enough, injection of local anesthetic into the spastic muscles might be required (see Chapter 102).

An alternate procedure involves administration of a low caudal analgesia limited to the lower three sacral segments. This is done by injecting 4 to 5 mL of a long-acting local anesthetic (e.g., 0.25% bupivacaine with epinephrine 1:200,000), which provides complete pain relief for 8 to 10 hours. In some patients it might be necessary to insert an epidural catheter through the sacrococcygeal hiatus and advance it to the S-3 level. This permits repeated injection of the local anesthetic or continuous infusion using an infusion pump.

Generalized perineal muscle spasm unrelated to trauma can persist and produce chronic dull aching pain felt deep in the lower abdomen, pelvis, perineum, rectum, and lower part of the sacrum (see Chapter 72). In many patients the pain is of mild to moderate intensity and can be exacerbated by intercourse and emotional tension. Drinkwater and associates (24) studied 14 patients with chronic perineal pain who had gained no lasting relief from various therapies and were considered to be on a “nothing further can be done” status. They examined the profile of pain personality, nonpain problems, and attitudes to treatment parameters. In addition to the clinical interview schedule, they administered the McGill Pain Questionnaire, Cattell's 16 Personality Factor (PF) Questionnaire, and the Claybury Battery. They found that the means of all variables in the McGill Pain Questionnaire exceeded (indicated more pain) those quoted by Melzack for menstrual, arthritic, cancer, dental, back, phantom limb, and postherpetic pain (see Fig. 71-1). On the average, the affective subclasses were more frequently used than the sensory subclasses. The mean was low compared with that in psychiatric groups, and the mean 16 PF profile showed significant conscientiousness. They found that all 14 patients were more responsive to behavioral psychological intervention than to psychotherapy. Apparently, most of the patients studied had perineal pain primarily as a result of psychological factors, and behavioral approaches such as stress management and muscle relaxation techniques were part of the general management plan. This is extensively discussed in Chapter 72.

Postoperative Muscle Spasm

Surgery on perineal structures or pelvic viscera, like operations on other parts of the body, invariably produces reflex spasm of skeletal muscles that result in moderate to severe pain. Usually, the muscle spasm and pain occur during the first and the second postoperative days. The treatment of such pain is discussed in

detail in Chapter 41.

Some patients who undergo laminectomy for removal of a herniated disk or for spinal stenosis have repeated bouts of severe muscle spasm in the low back, perineum, and upper thighs. Rather perplexingly, the reflex muscle spasm does not occur during the first 2 days after the procedure, but begins as soon as patients ambulate, perhaps on the third or fourth postoperative day. The spasm and associated severe pain last only a few minutes. These bouts are triggered by movement of the trunk, especially the pelvis, although sometimes they occur while patients lie in bed.

The mechanism of such abnormal reflex responses is unknown, but they might result from sensitization of the spinal cord neurons involved in reflex mechanisms, which is initiated by the surgery and sustained by a postoperative nociceptive barrage. Surprisingly, this problem is not discussed in textbooks of orthopedic surgery.

Therapy is directed toward decreasing the hyperreflexia with pharmacologic agents. Diazepam, given in doses of 10 mg every 4 hours, has proven to be highly effective in terminating the spasm and associated pain. Because this problem follows low back surgery, it is discussed in Chapter 76.

Myofascial Pain Syndromes

Pain in the pelvis and perineum can be provoked by myofascial pain syndromes with trigger points. Because the causes, pathophysiology, diagnosis, and treatment of myofascial pain syndromes with trigger points are discussed in detail in Chapter 29, only brief mention is made here of several syndromes that produce pain in the pelvis and gluteal region with reference to the perineum. These include trigger points in the lowermost portion of the external abdominal oblique, the lower part of the rectus abdominis, gluteus maximus, gluteus medius, and gluteus minimus (25,26 and 27). The pattern of pain produced by trigger points in the lowermost portion of the abdominal wall is depicted in Figure 69-5B. Pain is produced in the groin and testicle, with some radiation to the lower abdominal wall and upper part of the interior thigh.

Trigger points in the lateral border of the rectus abdominis muscle produce pain in the right or left lower quadrant, depending on which side the trigger point is located. Trigger points in the right lower rectus abdominis produce pain and tenderness in the region of McBurney's point, which simulates the pain of acute appendicitis (see Fig. 69-6A). Trigger points in the lowermost part of the rectus abdominis bilaterally produce pain in the hypogastric region. Through somatovisceral reflexes, trigger points can intensify the pain of dysmenorrhea or can cause other types of dysfunctions of the pelvic viscera (26).

Trigger points in one or more of the gluteal muscles and in the piriformis muscle frequently produce pain in the lower back over the sacrum and in the glutei, with spillover pain to the perineum and thigh. Because these syndromes produce pain primarily in the low back, lower limbs, or both, they are discussed in Chapter 75 and Chapter 77.

PAIN OF NEUROPATHIC ORIGIN

Pain originating in the pelvis and perineum was traditionally thought to be commonly due to organ pathology. In the last edition of this book, much of the discussion was focused on organ disorders, and there was a substantial section on pelvic pain without organ pathology. The pelvic pain sufferer was largely at the diagnostic and therapeutic discretion of the physician, who may have chosen conservative therapy if his or her specialty was medicine or neurology or who may have opted for radical therapy if his or her specialty was surgical. Unfortunately, many patients were repeatedly surgically treated with no resolution of their pain and with the disturbing epithet on discharge, “the pain may well be in your head.” We now believe that most chronic occult pelvic pains are caused by neuropathic disorders. Some of these include lesions of the spinal cord, meninges, lumbar or sacral nerve roots, and peripheral nerves that supply the pelvis and perineum. The pathophysiology, diagnosis, and treatment of most of these conditions have been discussed in detail in Chapter 72. Several peripheral neuropathies not considered in Chapter 72 are discussed in detail here.

Central Pain Syndromes

Lesions of the Spinal Cord, Meninges, and Epidural Space

Pelvic pain may be caused by lesions of the spinal cord, nerve roots, and peripheral nerves. These include intramedullary lesions located in the lower lumbar or sacral cord segments (i.e., conus medullaris). Tumor, multiple sclerosis, syringomyelia, abscess, and trauma can occur in this region. Pain from intramedullary lesions is usually spontaneous in nature, burning, diffuse, and poorly localized. It can be further characterized as continuous or explosive and can be associated with hyperalgesia, hyperpathia, and paresthesia. Mass lesions almost always produce back pain and tenderness as well as neurologic signs.

Extramedullary intrathecal lesions can be primary or metastatic. Examples include neoplasms, abscesses, and hemorrhages that initially produce pain localized to the low back and pelvis. The pain often becomes radicular and is aggravated by straining and coughing. Other signs include paravertebral tenderness, paresthesia, sensory loss, muscle weakness, and reflex loss in those lumbosacral spinal cord segments in which the lesion is located.

Epidural spinal cord and nerve root compression may also be produced by a primary or metastatic tumor, hemorrhage, or abscess, all of which may produce pressure on the conus medullaris. These invariably produce low back and pelvic pain, but often also involve the lower limbs. An unusual example of an iatrogenic injury occurred in a patient who had been heparinized and in whom lumbar puncture for subarachnoid block was followed by hemorrhage in the lower lumbar and sacral spinal canal. The patient developed neurologic, sensory, and motor dysfunction in the pelvis, lower limbs, and perineum.

Inflammatory conditions may also be a cause of pain; an example is arachnoiditis of the cauda equina; this condition is characterized by inflammation and fibrosis of the arachnoid membrane and scarring of the nerve roots. In most patients the condition involves multiple segments of the cauda equina, but occasionally it is limited to the roots of the lower three sacral and coccygeal nerves. It is manifested by pain, sensory deficits, and motor dysfunction in the *saddle region*, and is often associated with dysesthesia and paresthesia. This disease was seen much more often when oil-based myelographic agents were used; there is no effective therapy for this condition.

Lesions of the Roots or Spinal Nerves of the Lumbosacral Segments

Lesions of the roots of the spinal cord, or rootlets, produce a radiculopathy, consequent radiculalgia, or segmental pain. Such pain is quite characteristic, with a definite distribution pattern, and can be caused by acute and infectious processes such as herpes zoster, chronic infection, or metabolic or toxic neuropathy. Other etiologies include actual compression of nerve roots themselves by tumor growths, disk protrusions, vertebral fractures, osteophytes, and even pressure exerted by arthropathies; the latter cause encroachment by swelling due to inflammation.

Peripheral Neuropathy

Iliohypogastric, Ilioinguinal, or Genitofemoral Neuralgia

Etiology and Pathophysiology. This is a common peripheral neuropathy in patients who have had surgery or other types of traumas in the lower abdominal wall. The pain is engendered by retraction of these nerves that are located along an incision line. This results in stretch and compression neural injuries. The onset of pain is variable, perhaps related to the intensity of the injury. Many gynecologic patients, for example, have a Pfannenstiel incision that cuts across the regions of the ilioinguinal and iliohypogastric nerves. The actual injury may be from retraction in the lower corners of this incision, where the nerves are located. Many patients have histories of repeated abdominal exploration because of an initial diagnosis of intraabdominal pathology and recurrent operative interventions without resolution of pain. The *diagnostic laparotomy* is becoming less popular nowadays due to the widespread use of laparoscopy, but the latter procedure may also cause abdominal wall neuropathy due to placement of the scope at or near a nerve resulting in the same type of injury that occurs with laparotomy. Some patients may have many nerves injured.

The most common neuropathies in this area are of the iliohypogastric and ilioinguinal nerve. One must also consider injuries of the genitofemoral nerve, the lateral femoral cutaneous nerve, or even multiple nerves. The pathophysiology of the injury can be a stretch or tear or even partial avulsion; the nerve may atrophy and undergo fibrosis (28). Other rarer causes of neuropathy of these nerves include inflammatory disorders such as herpes and pelvic tumors that compress these nerves in the pelvic side wall. Neuralgia may also be consequent to unintentional section of one or more nerves, with development of a neuroma. Applegate wrote an

excellent paper on these neuropathies (29).

Symptoms and Signs. Neuralgia of one or more of these superficial abdominal nerves is characterized by a burning, aching pain in the distribution of the affected nerve. If the iliohypogastric nerve is involved, pain is produced in the inguinal and suprapubic regions, with occasional reference to the hip region. If the injury involves the ilioinguinal and genitofemoral nerves, the pain radiates to the inguinal region and to the anterior part of the labia majora in the female subject or to the scrotum and root of the penis in the male subject, as well as to the inner and anterior surfaces of the thigh. The pain pattern is variable but usually one of four patterns dominate and these include (a) incremental, typified by an increasing pain during the day and maximized with activity; (b) decremental, typified by maximum pain on awakening and gradual improvement during the day; (c) static, typified by a continuous and unchanging pattern throughout the day; and (d) sinusoidal, typified by an increasing and decreasing pattern throughout the day. All of these general patterns can be aggravated by forcible stretching of the affected part, coughing, sneezing, general tension in the abdominal muscles, or vigorous sexual intercourse.

On examination, pain can be triggered by pressure in a narrowly circumscribed area of an operative scar (28). Usually tenderness extends along the course of the nerve from the anterior superior iliac spine to the external genitalia. When the genitofemoral nerve is involved, the internal ring of the inguinal canal can be painful. Associated with pain is cutaneous hyperalgesia and occasionally hyperesthesia, especially to cold stimuli. In some patients, scratching the skin produces less or no reddening on the affected side as compared with the normal side, indicating a degeneration of afferent C fibers. A lesion of the hypogastric nerve can be associated with decrease or loss of the lower abdominal reflex. Similarly, the cremaster reflex may be absent on the affected side of involvement of the genital branch of the genitofemoral nerve.

Diagnosis. Diagnosis is made by history, characteristics of the pain, examination of abdominal scars, and the finding of a peripheral neuropathy. It is typical that the pain is aggravated when the examiner uses the blunt end of a pen to push straight downward along the course of the involved nerve. When these maximum tender points are identified, they are marked with a pen. The patient is asked to lift her head as pressure is placed gently on these marked positions. The pain should be considerably intensified by this maneuver. Infiltration of the affected nerve with a local anesthetic can eliminate the pain and thus help to confirm the diagnosis.

Treatment. The typical pattern of this type of pain is persistence without spontaneous remission (28). A series of local anesthetic nerve blocks with a long-acting local anesthetic, such as 0.25% bupivacaine with epinephrine, done on a scheduled basis for a series of five blocks, should be instituted. Nearly 60% to 70% of patients respond favorably to this therapy by itself. If a sensitive neuroma is detected, and its palpation produces aggravation of the pain, injection of a local anesthetic into the neuroma can relieve the pain and associated symptoms. We do not recommend neuroma injection with 0.5 mL of alcohol or phenol, because this has been associated with the risk of producing postinjection neuropathy. Resection of the nerve proximal to the region of injury or dorsal rhizotomy may be undertaken in severely disabled patients who do not respond to medications or local injections.

Obstetric Neuropathy

Femoral Nerve. The femoral nerve, derived from the L-2 to L-4 spinal nerves, comes off the lumbar plexus and takes form in the psoas muscle. It emerges from the lateral border of the psoas and courses inferiorly downward between the psoas and the iliacus muscles. The femoral nerve enters the thigh after coursing under the inguinal ligament and soon separates into a number of motor and sensory branches. It supplies major motor innervation to the quadriceps femoris muscle and major sensory innervation via the saphenous nerve. A large proportion of femoral nerve disturbances are iatrogenic and are related to surgical procedures (30,31 and 32). The femoral nerve can be injured either in its intrapelvic or extrapelvic portion. The most common cause of femoral nerve injury is abdominal pelvic surgery; abdominal hysterectomy is the single most common procedure to lead to this nerve injury (32). For some time, gynecologists and general surgeons alike have enjoyed the exposure and convenience of the use of self-retaining retractors. Unfortunately, the lateral blades can directly stretch or compress the femoral nerve itself or cause pressure and ischemia along the course of the psoas muscle and femoral nerve in the lateral pelvic wall (31,32 and 33). Factors that increase the likelihood of nerve injury during abdominal and pelvic surgery include thin, muscular patients, the use of a Pfannenstiel incision, and large lateral blades (32,33). Femoral nerve injury can also be associated with various transplantation operations where vascular injury may occur with resultant ischemia and or hematoma near the nerve (34). Laparoscopic operations and other general surgical, urologic, and vascular surgical operations can also be complicated by femoral nerve injuries (30,32,35). Orthopedic surgical procedures can damage the femoral nerve, due to compression of the nerve, hematoma formation, or inappropriate use of retractors. The heat of bone cement and compression during its application can also lead to nerve injury (36,37).

Pudendal Nerve

Etiology. The most common injury to the pudendal nerve occurs during childbirth as documented by the many studies that have originated from England in the 1980s. This condition has commonly been labeled *obstetric neuropathy* (38). Both reversible and irreversible damage due to childbirth has been well documented (39). There are other etiologies, however, and some of these include (a) unilateral pudendal neuropathy with neuralgia that results from trauma due to fracture of the ischial spine; (b) entrapment of the nerve or of some of its branches, which pass through the sacrospinous ligament; (c) nerve compression during its course in Alcock's canal; and (d) damage to the nerve during pudendal nerve block if the nerve is penetrated with a large, dull needle. Axons can be severed in a jagged fashion and intraneural hemorrhage can occur.

Bilateral pudendal neuralgia is extremely rare and can be the result of trauma such as during bicycle or horseback riding, or following injury of the type that occurs when the patient falls and straddles a blunt and firm object (Fig. 74-1). One or more branches of the pudendal nerve can be damaged when surgery or trauma results in scars in the perineal area occur.

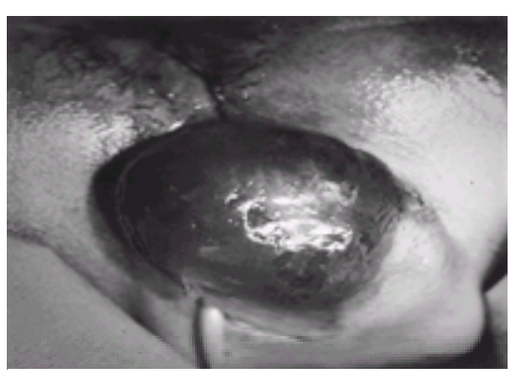

Figure 74-1. Acute traumatic vulvovaginal hematoma. The patient was seen for intense pain and inability to urinate. Treatment consisted of immediate evacuation of the hematoma and ligation of the bleeding sites by figure-eight sutures. The patient's recovery was rapid and uneventful.

Symptoms and Signs. Pudendal neuralgia is variable in reference to symptomatology but is usually characterized by mild to severe burning pain with occasional bouts of lancinating pain, cutaneous hyperalgesia, hypalgesia, deep tenderness, paresthesia, tingling, and subjective numbness. The cutaneous tenderness can be so severe as to prevent the patient from sitting or from engaging in sexual intercourse. Paresthesia can cause the patient to scratch, resulting in irritation of the skin.

Diagnosis. Diagnosis is made on the basis of the history and physical examination and, in the case of trauma or fracture, by radiographic evidence; palpation can reveal a scar involving the nerve or one of its branches. Diagnostic pudendal nerve block with a local anesthetic may allow confirmation of the diagnosis.

Treatment. Posttraumatic neuropathy consequent to needle penetration usually resolves over a period of weeks. Severe nerve damage by fracture can cause the neuropathy to persist for months. *Obstetric paralysis* usually resolves spontaneously in several months. The treatments for neuropathies as discussed in Chapter 19 are applicable to pudendal nerve injury pain. Periods of severe pain can be controlled by pudendal block achieved with 0.25% bupivacaine with epinephrine, using extreme care not to damage the nerve further with the needle.

Anorectal Dysfunction. Anorectal dysfunction is quite common among women. The onset is typically immediately after vaginal delivery, and the impact of the symptomatology increases with age. Women are often too embarrassed by their problem and thus do not talk about or complain to their doctors. Some do choose to

discuss the problem and often find lack of physician interest due to inadequate education and deficient understanding of the various diagnostic and therapeutic options. Anal incontinence causes involuntary loss of gas or feces and it is not a rare condition, occurring in approximately 10% of the population (40,41,42,43 and 44). The ramifications of this disorder cause emotional, psychological, and social problems of a severe nature that can disrupt personal and professional life. By far the most common etiology of anal incontinence is obstetric trauma. Vaginal delivery can damage the anal continence mechanism by direct injury to the anal sphincter muscles, damage to the motor innervation of the pelvic floor, or both (38,39,44). Vaginal delivery can result in significant injury to pathways of innervation of the pelvic floor musculature.

Sciatic and Obturator Neuropathy

Etiology. Neuropathy of the obturator or sciatic nerve, or of the pudendal plexus, can be caused by continuous pressure by the presenting part during a prolonged labor and vaginal delivery; or it can be caused by direct damage by the edges of the obstetric forceps during forceps delivery (45). Usually one or more nerves on one side are involved, but occasionally bilateral involvement occurs. Although obstetricians generally attribute the neuropathy to local anesthesia, most reported incidents have occurred with general anesthesia or no anesthesia at all (45). In some cases the condition developed in parturients who were managed with subarachnoid or epidural anesthesia, but careful evaluation of the symptoms and signs eliminated this cause (see following section).

Symptoms and Signs. Usually, soon after delivery, or 1 or 2 days later, the patient has a burning, aching pain in the distribution of the affected nerve and frequently motor impairment or loss; hence the term *obstetric paralysis*.

Diagnosis. Differential diagnosis is simple if one considers that the symptoms and signs in obstetric neuropathy have a peripheral nerve distribution. Often alleged to be due to spinal or epidural blocks, this concept is most unlikely. Involvement of the roots of a single peripheral nerve and the sparing of other nerves supplied by the same lumbosacral spinal segments is impossible as a complication of subarachnoid or epidural block because, with these procedures, the neurotoxic effect of the local anesthetic is bilateral and involves the roots of all anesthetized nerves.

Treatment. Treatment of obstetric neuropathy consists of rest and appropriate orthotic devices to assist ambulation. Recovery is usually slow but is complete in most patients. Pain is controlled with NSAIDs given over several weeks. If these are not sufficient, they can be supplemented with opioids for 2 to 3 weeks. Long-term beneficial effects can be obtained by referral to physicians who are aware of the pathophysiology of these conditions and who are skilled in their diagnosis and treatment. Unfortunately, such physicians are few and far between, because most have just not been trained in pelvic pain management.

Tumor Infiltration of the Lower Sacrum and Sacral Nerves

Etiology. Metastasis of a neoplasm or primary sacral tumors in the lower half of the sacrum can result in compression of the nerves that contribute to the pudendal plexus and nerves. In other cases the lumbosacral plexus can be compressed by the tumor or marked lymphadenopathy.

Symptoms and Signs. Pain in the distribution of the sacral nerves occurring in patients in their fifth, sixth, or seventh decade is frequently the result of the spread of bladder, gynecologic, or colonic cancer. The pain is dull, aching, and burning in character, is frequently located in the midline, and is associated with a burning or throbbing pain in the soft tissues of the rectal and perineal regions. The pain is aggravated by sitting and lying down.

Examination reveals tenderness over the sacrum and region of the sciatic notch, associated with sensory loss in the perianal region and in the genitalia, and can be accompanied by hyperpathia. The pain and sensory deficit can initially be unilateral but later can progress to bilateral sacral nerve involvement, with consequent sphincter incontinence and impotence.

Diagnosis. Diagnosis is made through the history, physical examination, and imaging, including radiography, CT, or magnetic resonance imaging of the pelvis, all of which show sacral erosion with a presacral mass.

Treatment. Treatment should begin with anticancer therapy (see Chapter 36). Pharmacologic agents, regional anesthesia, neurosurgical procedures, or a combination of these can be used to control the pain, depending on its severity and on the resources available. In patients who have severe unilateral pain, a trial or subarachnoid local anesthetic block followed by subarachnoid neurolysis can be useful (see Chapter 104). With precise technique and skill, analgesia can be produced predominantly on one side. Another option is cordotomy or myelotomy (see Chapter 106). In patients with bladder or anal sphincter dysfunction, alternative procedures include administration of a low caudal block with a local anesthetic; if relief is complete it can be followed by injection of 5% aqueous phenol, phenol in glycerin, or 25% alcohol. Cryoanalgesia is another alternative. Sacral rhizotomy either by radiofrequency or by open surgery can also be used (see Chapter 104).

Phantom Pelvic Visceral Pain Syndromes

Phantom Urinary Bladder Pain Syndrome

Review of the literature reveals that phantom urinary phenomena occur rarely following cystectomy, spinal cord injury, and hemodialysis, in which previous disease of the kidney, urethra, and urinary bladder was present.

Symptoms and Signs. Brena and Sammons (46) reported a case of a 38-year-old woman who complained of midline suprapubic pain that had started 1 year previously, after removal of the bladder for chronic severe cystitis. The patient described the pain as being continuous and feeling like “having a very full bladder,” with recurrent episodes of sharp, burning acute pain. She rated the degree of pain as 90 on a scale of 0 to 100 (0, no pain; 100, intensity of pain comparable with that of labor pain), and further stated that the discomfort was “tearing her nervous system apart.” Treatment with oxycodone, diazepam, and other mild analgesics was ineffective.

The patient's past medical history and social profile appeared normal except for a sharp decrease in social, recreational, and sexual activities because of the continuing pain (46). Physical examination revealed no abnormalities other than tenderness to palpation and a decreased pinprick pain threshold over the suprapubic region in both lower quadrants. She also had tenderness to palpation in the right flank, with a number of trigger points over the paravertebral area in the lumbar back region. Neurologic examination revealed no abnormalities. Brena and Sammons (46) made the important point that their patient had had continuous pain caused by the urinary tract infection prior to surgery. They cited three other reports pertaining to this phenomenon. One involved phantom urinary bladder following cystectomy for recurrent bladder tumors. Another report described seven patients with spinal cord injury who had experienced sensations of unpleasant urinary bladder distension after drinking water. The third report concerned 24 of 35 patients undergoing hemodialysis because of severe renal damage, with average urinary outputs of no more than 500 mL. These 24 patients experienced feelings of discomfort, bladder distension, and an urge to micturate.

Treatment. Brena and Sammons (46) managed their patient with a series of six lumbar sympathetic blocks with 0.25% bupivacaine combined with a course of six applications of transcutaneous electrical nerve stimulation, and relaxation-assertiveness training, given over a 10-day period. At the end of the treatment and at 3 and 6 months' follow-up, the patient reported that the phantom bladder sensation had been reduced to 25% of previous levels and that the suprapubic burning pain and tenderness were no longer present. It has been reported that regional analgesia carried out for several days prior to amputation in patients who had pain in the limb before the surgery and continued for several days postoperatively decreases the incidence of painful phantom sensations (see Chapter 102). This would suggest that patients who have severe urinary bladder pain (or severe pain as a result of other pelvic visceral disease) should receive continuous epidural analgesia extending from T-9 to S-5 for 48 hours prior to removal of the viscus and for 2 to 3 days postoperatively. Although the literature review suggests that phantom bladder is rare, it is likely that the condition has been underreported. Notwithstanding its low frequency, aggressive management with regional analgesia should be considered to relieve the discomfort of patients who experience these phenomena.

Phantom Anus Pain Syndrome

Boas (47) reported that, among 177 patients who had undergone abdominoperineal surgical resection, 40 patients (23%) developed characteristics of phantom anus perineal pain. Analysis of the characteristics of the pain, and especially of the time of onset, revealed that these patients fell into two subgroups, early onset and late onset.

Symptoms and Signs. Patients in the early group experienced phantom anus perineal pain within days or weeks of the surgery, and the pain was rated as having an intensity of 2.1 ± 0.8 on a scale of 0 to 4 (32). Of those in this group, 18 patients (75%) experienced aching pain, 8 (33%) had burning pain, and 4 (17%) had sharp or

stabbing pain. In a considerable number of those in this early group (seven patients) the pain was mild, but among those with burning pain about the nonexistent anus, the pain was of high intensity, having a score of 2.6 ± 0.5.

In the 16 patients who experienced pain months or years after the surgery, the pain had greater intensity (2.4 ± 0.9). In 14 of these 16 patients (88%) the pain was aching, 2 (13%) experienced burning pain, and 6 (38%) had a sharp or stabbing component to the pain; those in this last group (with the sharp stabbing pain) recorded high scores (2.8 ± 0.9). The most common factor that initiated or aggravated the pain in the entire group was sitting on hard surfaces, with tiredness being a significant contributing factor in 25% of all patients. Spontaneous pain was experienced by nine patients (38%) in the early group and by four (25%) in the late group. None of the patients experienced cutaneous numbness or hyperesthesia around the perineal scar.

Treatment. Fifty-eight percent of those in the early group and 69% of those in the late group noted that rest and use of cushions relieved the pain. Systemic analgesic drugs proved to be almost totally ineffective for the relief of early-onset–type pain, but helped some in the late-onset group. Boas (47) reported that intravenous lidocaine administered in doses of 1.5 to 2.0 mL per kg totally abolished the phantom anal pain for several hours. Subarachnoid block, with small doses of a hyperbaric solution of lidocaine, reduced the pain intensity but did not abolish the phantom sensation until the block extended to the T-10 to T-12 spinal cord levels. Boas (47) also noted that the phantom pain could be relieved by a combination of tricyclic antidepressants and antiepileptic drugs, suggesting a neuropathic origin for this pain syndrome.

PAINFUL VISCERAL AND DERMATOLOGIC DISORDERS

Various painful disorders of the skin and subcutaneous tissue can cause pain in the rectum, perianal region, perineum, and external genitalia. These have been discussed in Chapter 32, Chapter 66, Chapter 72, and Chapter 73 and are briefly presented here.

Proctalgia Fugax

This disorder is often a diagnostic enigma for physicians, because by the time the patient comes to the office for diagnosis and treatment, the pain has usually abated. The onset is sudden, is typified by severe stabbing rectal pain, is episodic in nature, and can occur day or night without warning. In some patients, there is sphincter dysfunction; in others there is a pudendal neuropathy. Some believe the etiology may be tied to an intussusception in the bowel. Other physicians, who are frustrated and unable to come up with any explanation, blame psychological problems for the disorder. Treatment can consist of taking an analgesic, applying heat to the area locally, and trying to abort the attacks by taking small doses of b-blockers. In one study of 38 patients 76% experienced complete relief, while another 16% had good relief and only 8% had no change in the status of pain (48).

Rectal and Anal Pain

In addition to fissure *in ano* and hemorrhoids, superficial ulcers of the rectum and anus can be caused by syphilis, tuberculosis, typhoid, dysentery, and, of course, malignant lesions. These conditions cause pain in the rectum, anus, and perianal region that is sharp and burning in character and is aggravated by defecation. These conditions can also be associated with tenesmus, diarrhea, blood or mucus, and spasm of the sphincter muscle. A careful proctoscopic examination can reveal fissure or hemorrhoids and establish the diagnosis.

Submucous Proctitis and Periproctitis

Submucous proctitis and periproctitis, fistula *in ano*, and rectal papillitis and cryptitis can also produce a sharp throbbing pain in the perirectal and perianal regions, but unlike proctalgia fugax that comes on spontaneously, they are aggravated by defecation or walking. The pain is associated with acute tenderness, swelling, and redness, and if the infection is severe, with fever, malaise, and other systemic symptoms.

Pruritus Ani

Pruritus ani from pinworms and other parasites, hemorrhoids, cryptitis, papillitis, and other superficial lesions causes moderate to severe intractable itching of the anal region. This produces the urge to scratch and initiates the vicious circle of scratch, which leads to more itching, which leads to more scratching, which leads to abrasion of the region and development of pain. The diagnosis is made by inspection of the offending cause by inspection, microscopic examination, and careful history.

Furuncles and Carbuncles

The perianal region can also be the site of acute furuncles and carbuncles, which are painful staphylococcal abscesses of one or more hair follicles in the hair-bearing area around the anus. Treatment of most of these dermatologic disorders is considered in Chapter 32. Obviously, if the condition is caused by bacteria, antibacterial drugs constitute the first phase of treatment. Patients with an infectious process, such as periproctitis, furuncles, or carbuncles, should have cultures made of the superficial pustules to determine the antibiotic sensitivity of the causative agent. During the primary therapy it is essential to control the pain, which can range in intensity from a minor annoyance to disabling discomfort, with appropriate systemic analgesics, including opioids if the pain is severe enough.

In case of severe, excruciating pain, temporary relief can be provided by administration of a continuous low caudal block except in cases of infection over or adjacent to the caudal hiatus. This procedure is especially useful for those with pruritus ani, because it provides complete relief of itching for several days and thus breaks the vicious circle mentioned previously. A low caudal block with 0.2% ropivacaine given in volumes of 3 to 4 mL produces analgesia of the last two or three sacral and coccygeal nerves, and thus eliminates the abnormal sensory input from this region without any substantial motor blockade. This treatment can be repeated several times to bring on a desired effect and break the severely painful cycle. Bristow and Foster (49) reported that 10 of 12 patients with severe spasmodic painful tenesmus were relieved with sympathectomy; this operation is rarely used today for this condition.

Dermatologic Disorders of the Perineum and External Genitalia

Injury to the skin caused by superficial trauma and dermatologic conditions can also involve the rest of the perineal area including the female external genitalia, or the scrotum and penis. These conditions include condyloma latum, which produces pain and tenderness if the warts are ulcerated and is associated with muscle spasms. Pain caused by trauma to the female perineum and genitalia is discussed in the section on vestibulitis in Chapter 72. In addition to injury, ulcers, chancroid, and condylomata lata can cause localized pain and swelling in the scrotum.

Another condition that can cause pain and discomfort in the pelvic and perineal area is hydrenadenitis suppurativa, a chronic painful suppurative inflammatory disease of the apocrine glands in the genitocrural area. This is discussed in Chapter 32. Treatment of hydrenadenitis suppurativa requires incision and draining of abscesses and palliative intralesional corticosteroid irrigation. Because this condition is often caused by multiple organisms, a broad-spectrum antibiotic should be used. The therapy of choice has been prompt diagnosis and surgical extirpation of the affected skin and subcutaneous tissue. During the primary therapy for the condition, pain and suffering should be controlled with NSAIDs or, if necessary, by oral opioids or regional anesthesia for short periods.

REFERRED PAIN

Pain Referred to the Pelvis

Pain in the pelvis can be referred from disorders of the abdomen, especially acute appendicitis, acute pyelitis, spasm of the lower bowel from acute infection or chronic bowel disorders, ulcerative colitis, diseases of the kidney and pelvis, pelvic peritonitis, chronic colitis, Meckel's diverticulum, regional enteritis, and lower rectoperineal tumors. These are all discussed in Chapter 66, Chapter 68, and Chapter 69. Less common pain referred to the pelvis includes diseases of the hip and sacroiliac joint, left psoas abscess, aneurysm of the left iliac artery, strangulated retroperitoneal hernia, lower abdominal abscess, and chemical or infectious peritonitis (see Chapter 69, Chapter 75, and Chapter 78).

Pain Referred to the Perineum

Pain referred to the perineum is frequently present with various pelvic gynecologic and urologic disorders, such as cystitis, prostatitis, and diseases of the uterus, and with other less common conditions. Similarly, diseases of the hip joint or upper thigh can sometimes cause pain radiating to the perineum (see Chapter 69).

PAIN PRIMARILY OF PSYCHOLOGICAL ORIGIN

Chronic Pelvic Pain without Obvious Pathology

In a significant number of patients who present with pelvic pain having characteristics of pain of gynecologic origin, no obvious organic pathology can be found, even with comprehensive clinical and laboratory examination. During the 1940s and 1950s various causative factors and hypotheses were presented, including pelvic vascular congestion, functional disturbance of sensory nerves, disturbance of the pelvic sympathetic system, and microscopic lacerations of the uterine ligaments, among others. In the second edition of this book, it was stated that ample evidence had been accumulated to suggest strongly that pelvic pain and associated symptoms without obvious pathology are caused primarily by psychopathology of one form or another. Psychiatric evaluation has shown that many of these women have borderline personality syndromes, neurosis, severe anxiety, depressive trends, and somatization. Chapter 72 addresses this issue and places the psychological aspects in contemporary perspective. It is more accurate to state that diagnostic studies have not identified an organic cause, and that because this pain has such a burdensome psychological impact, many patients have concomitant psychological problems. It is important to realize that the patients do not have psychological diseases that are the primary cause of their disorder, but, more correctly, that they have an ongoing severe pelvic pain problem that consumes tremendous energy and mental reserves and that taxes their psychological coping mechanisms. The history of childhood incest and abuse is common (50). We remain convinced that a neuropathic disorder is primarily responsible for chronic pelvic pain without discernible etiology. How childhood abuse and current stress facilitate such a neuropathic disorder is unclear. On the other hand, there are many women who have similar abusive histories who do not develop pelvic pain. This problem is discussed in Chapter 72.

Orchiodynia

Orchiodynia, also known as *orchidalgia* and *orchialgia*, is characterized by chronic pain in one or both testicles without any obvious pathology, even when the most modern methods of evaluation and laboratory testing are carried out. Although some patients give a vague history of an injury or vasectomy many years before, no abnormality can be found at the time of complaint. The pain is usually nagging, persistent, and achy, but only rarely and fleetingly severe. Evaluation by a physician expert in pelvic pain and in performing various diagnostic blocks should be undertaken in association with a psychosocial assessment.

Rectal and Perineal Pain of Psychiatric Origin

Approximately 10% of psychiatric patients who complain of pain have rectal or perineal pain, although this is usually mentioned as a secondary site of pain (28). Only approximately 2% of patients report pain in these parts as the primary site and, in such cases, the rectal pain is usually associated with severe depressive or schizophrenic illness, although it can be associated with somatoform symptoms. Such patients usually have pain and other symptoms elsewhere in the body (see Chapter 26).

Two types of pain are clearly of psychiatric origin: delusional or hallucinatory and hysteric or hypochondriac. Hallucinatory pain is attributed by the patient to a specific delusional cause, such as pain or a painful object in the rectum or perineum or in the vagina or penis. This type of pain varies from mild to severe and persists until the causal psychological illness remits. The pain can be aggravated by psychological stress. A comprehensive physical and laboratory examination reveals no structural lesion that could lead to the patient's symptoms.

Hysteric or hypochondriac pain is specifically attributable to the thought processes, emotional state, or personality of patients in the absence of an organic or delusional cause, or to a tension mechanism (24,28). This type of pain can be felt anywhere in the perineum or rectum, but, like other types of chronic pain of psychological origin, is extremely rare. In general, female subjects experience this type of pain more frequently than male subjects. Pain is described in simple sensory terms, but complex or affective descriptions are given by some patients. The pain is usually continuous throughout most of the waking hours but fluctuates somewhat in intensity, does not awaken patients from sleep, and usually lasts for more than 6 months. Pain is often present in other areas and can be associated with loss of function without a physical basis. The mechanisms underlying such pain symptoms remain obscure (see Chapter 26).

CHAPTER 75

General Considerations of Pain in the Low Back, Hips, and Lower Extremities

Joseph M. Czerniecki and Barry Goldstein

Disorders of the lumbosacral portion of the spine, hip, and lower limbs cause pain, suffering, and disability more frequently than disorders in any other part of the body. The most frequent cause of pain and disability in this region is musculoskeletal disease or dysfunction of the low back and lower limbs, followed by neuropathic disorders and peripheral vascular disease. Knowledge of the causes, pathophysiology, and symptoms and signs permits the establishment of a correct diagnosis and the development of effective therapeutic strategies. The clinician should have a thorough knowledge of the functional anatomy and biomechanics of the lumbar spine, the sacrum, and the various parts of the lower limbs; of the anatomy and function of the lumbar and lumbosacral plexuses and the major nerves; and of the vascular structures in the pelvis and lower limbs.

This first chapter of Section F discusses the lumbosacral spine, including its functional anatomy and biomechanics; the vertebral (spinal) canal and its contents, specifically a description of the spinal cord and its relation to the various parts of the vertebral canal; nerves to the lumbar spine, pelvis, and lower limbs; sympathetic and somatic segmental and peripheral nerve supply to the hips and lower limbs; and finally, evaluation of the patient, with an outline summarizing the most important aspects and a table summarizing the pain characteristics and other symptoms and signs to help make a differential diagnosis. Various aspects of low back pain are discussed in Chapter 76 and neurologic pain syndromes are covered in Chapter 77. The functional anatomy and biomechanics of the hip joints and adjacent structures are presented in Chapter 78, of the thigh and knee in Chapter 79, and of the leg, ankle, and foot in Chapter 80.

BONY CONSIDERATIONS

Lumbar Vertebrae

Lumbar vertebrae consist of a ventral body and a dorsal neural arch; together they enclose the cauda equina, meninges, and other neurovascular structures. From the neural arch, three processes diverge for the attachment of ligaments and muscle; in the posterior midline is the spinous process while the transverse processes are found symmetrically on either side. The portion of the neural arch between spinous process and transverse process is the lamina, while the portion between transverse process and body is the pedicle. The vertical extent of the pedicle is less than that of the body, to allow room for passage of the spinal nerve (Fig. 75-1).

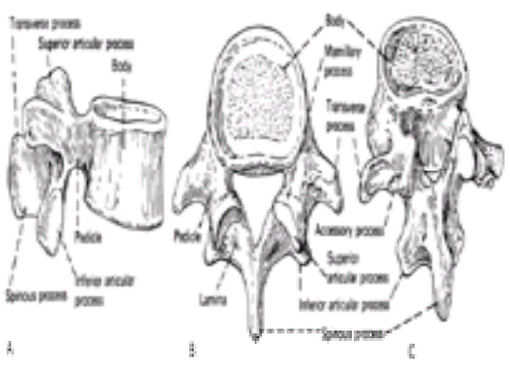

Figure 75-1. Anatomy of a lumbar vertebra. **A:** Lateral view. **B:** Superior view. **C:** Superolateral view. The body is wider transversely than anteroposteriorly, and the spinal canal is triangle shaped. Note the directions of the articular facets. See text for more details.

At the junction of the lamina and pedicle the superior and inferior articular processes of the facet joints project above and below. Motions of flexion and extension and lateral flexion occur at the facet joints (Fig. 75-2). When two adjacent lumbar vertebrae are separated, one sees how the inferior articular processes of the upper vertebra fit medially and posteriorly into the superior articular processes of the lower vertebra (Fig. 75-3). Therefore, each lumbar vertebra provides lateral stability to the overlying vertebra as a result of the buttresslike structure of the articular processes. The junction of the superior and inferior articular processes of a vertebra is termed the *pars interarticularis*. *Spondylolysis* is a term that describes a defect in the pars interarticularis that results most commonly from trauma (Fig. 75-4). Spondylolisthesis is a process by which the vertebra above is allowed to slide forward in relation to the lower vertebra as a result of spondylolysis.

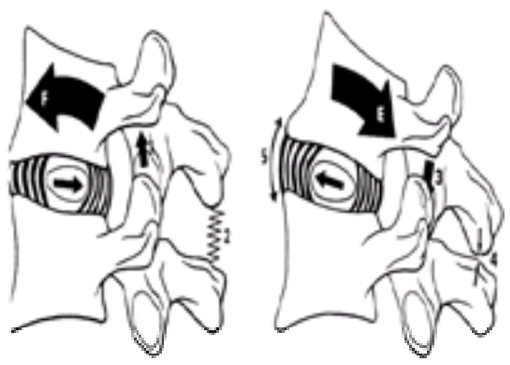

Figure 75-2. Flexion (F) and extension (E) and lateral flexion occur at the facet joints. During flexion of the spine, there is distraction of the facet joints (1) and stretching of the interspinous ligaments (2). During extension of the spine, there is compression of the facet joints (3), the spinous processes (4) come into closer proximity, and the anterior longitudinal ligament is under tension (5).(Reprinted from Kapandji IA. *The physiology of the joints*, 5th ed. Vol 3, Trunk and vertebral column. Edinburgh, UK: Churchill Livingstone, 1987, with permission.)

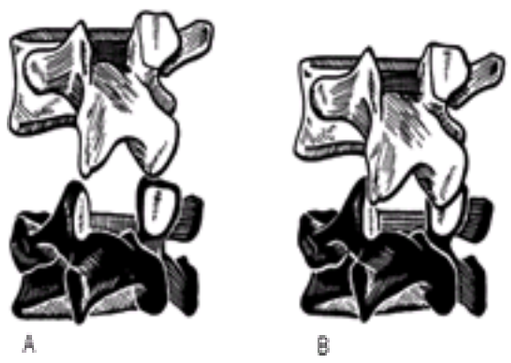

Figure 75-3. **A,B:** The articulations between adjacent vertebrae. See text for explanation. (Reprinted from Kapandji IA. *The physiology of the joints*, 5th ed. Vol 3, Trunk and vertebral column. Edinburgh, UK: Churchill Livingstone, 1987, with permission.)

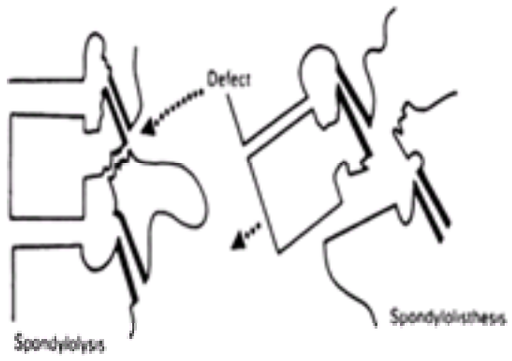

Figure 75-4. Isthmic spondylolisthesis. The basic lesion is a defect in the neural arch across the pars interarticularis. When degenerative changes occur in the subjacent disk, the vertebral body displaces forward, carrying with it the superimposed spinal column and leaving behind the inferior articular facets, lamina, and spinous process. (Reprinted from McCulloch J, Transfeldt E. *Macnab's backache*, 3rd ed. Baltimore: Williams & Wilkins, 1997:164, with permission.)

The lumbar vertebral bodies are kidney shaped when viewed from above and are large and strong. The strength of the body is derived from the dense bony cortex in addition to the trabecular structure of the medulla. The cortex of the superior and inferior aspects, the vertebral plateau, is thickened in the center and contains a cartilaginous plate. The periphery of the vertebral plateau forms a distinct thickened rim. It is derived from an epiphyseal growth plate that is separate from the vertebral body, which becomes fused to the body at about 15 years of age. Abnormal ossification of this rim leads to vertebral epiphysitis (Scheuermann's disease). The bony trabeculae of the vertebral body are oriented along lines of force. The vertical trabeculae link the superior and inferior surfaces of the vertebral body, the horizontal trabeculae link the lateral surfaces, and the oblique trabeculae link the inferior with the lateral surfaces. The intercrossing of these three trabecular systems constitutes zones of maximum structural rigidity. The anterior portion of the vertebral body lacks an overlapping trabecular structure and is therefore more easily fractured. This explains the commonly observed anterior wedge-shaped fracture of the vertebral body, which occurs secondary to axial compression loading, especially when the structural integrity is reduced as in osteoporosis.

Sacrum

The sacrum is a single osseous structure comprised of five fused vertebrae and their costal elements (Fig. 75-5). When viewed from the front it is triangular in shape, with the base of the triangle at the superior margin and the apex inferior. When viewed from the lateral aspect it is curved, with its concave surface anterior and its convex surface posterior. Fusion of the first and second vertebrae may be incomplete, which results in lumbarization of the first sacral vertebra. In contrast, the sacrum may also have an additional vertebral element that may be partially or completely fused to it. *Sacralization* of the fifth lumbar vertebra is the term applied to this process. The sacrum articulates with the ilium at the sacroiliac joint. The synovial portion of the sacroiliac joint has a complex articular surface and is stabilized by broad, strong ligamentous structures. Because of the shape of the articular surface, the ligamentous reinforcement, and the ring-shaped structure of the pelvis, only small movements occur at this joint. These movements are not well appreciated until there is a painful pathophysiologic process such as a trauma or inflammation resulting from ankylosing spondylitis, or Reiter's syndrome.

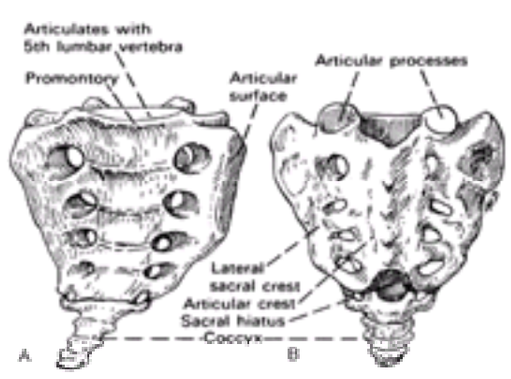

Figure 75-5. Anatomy of the sacrum and coccyx. **A:** Anterior view. The anterior (pelvic) surface is concave, which provides increased capacity to the pelvic cavity, and is crossed by four transverse ridges that separate the five segments of vertebral bodies. The four pairs of rounded anterior (pelvic) sacral foramina communicate with the sacral canal by the intervertebral foramina, through which course the anterior primary divisions of the first four sacral nerves and the lateral sacral arteries and veins. The coccyx is a triangular structure composed of four rudimentary vertebrae. **B:** Posterior view. The posterior surface is convex and is narrower than the anterior surface. In the midline is the median sacral crest, on which are mounted three or four tubercles of the rudimentary spinous processes of the upper three or four sacral segments. The posterior sacral foramina are located between the intermediate and lateral sacral crests, through which pass the posterior primary divisions of the upper four sacral nerves. Between the sacrum and coccyx is the sacrococcygeal hiatus.

Within the body of the sacrum, there is a central canal that tapers toward the distal end and is continuous with the central canal of the lumbar vertebrae, which are above. The sacral canal carries the most caudal nerve roots (S-1 to S-4) of the cauda equina (see Fig. 75-5). The ventral primary rami of each segmental nerve exit via the anterior foramina while the posterior primary rami exit via the posterior intervertebral foramina. The posterior foramina and the sacral hiatus are easily accessible for segmental injections and caudal anesthesia, respectively.

LIGAMENTS

The lumbar spine can be viewed as a series of stacked bony elements. From a functional perspective the bony elements must be held together in a manner that allows sufficient stability to allow the arms and upper body to be maintained in a stable upright posture but at the same time allow a high level of mobility. The stability of the spine is the result of the anatomic structure of the intervertebral disks, the shape and orientation of the facet joints, and the orientation and mechanical characteristics of the ligaments. The ligaments can be classified into two major groups: those that are long and straplike and extend over the length of the spine, such

as the anterior and posterior longitudinal ligaments, and those that are shorter and span only one or two segments (Fig. 75-6).

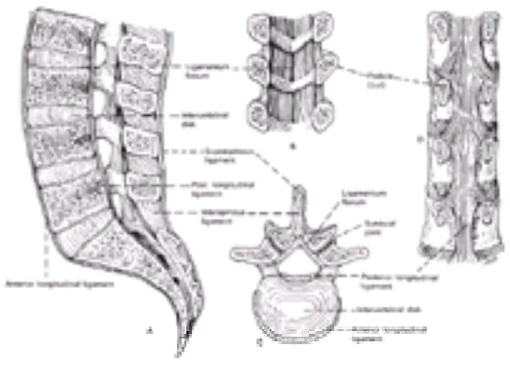

Figure 75-6. Ligaments of the lumbar vertebrae. **A:** Medial sagittal section of three lumbar vertebrae and their ligaments. The vertebral bodies are slightly higher anteriorly than posteriorly, and the intervertebral disk is also higher anteriorly than posteriorly. The interspinous ligaments are thin and membranous and interconnect with adjoining spinous processes, with their attachments extending from the root to the apex of each spinous process. Here they meet the ligamentum flavum anteriorly and the supraspinous ligament posteriorly. Whereas they are narrow and elongated in the thoracic region, they are broad, thick, and quadrilateral shaped in the lumbar region to conform to the shape of the spinous process. The supraspinous ligament is a strong fibrous cord that connects the apices of the spinous processes of the vertebrae. Fibrocartilage is developed in the ligament at its point of attachment to the tips of the spinous processes. The supraspinous ligament is thicker and broader in the lumbar than in the thoracic region. The most superficial fibers of the supraspinous ligament extend over three or four vertebrae, those coursing more deeply pass between two or three, and the deepest ones connect the spinous processes of neighboring vertebrae and become continuous with the interspinous ligament. **B:** Anteroposterior view of the laminae and intervening ligamenta flava in the lumbar region. The ligamenta flava connect the laminae of adjacent vertebrae and are thickest and strongest in the lumbar region. Each ligament consists of two lateral portions that begin on each side of the root of the articular process surrounded by the capsule and extend posteriorly to the point where the two laminae meet to form the spinous process. Each ligamentum flavum consists of yellow elastic tissue, the fibers of which are almost perpendicular to and are attached to the anterior and inferior surfaces of the lamina above and to the superior and posterior surfaces of the lamina below. **C:** Superior view of a lumbar vertebra showing the positions of the various ligaments in the lumbar region. The anterior longitudinal ligament almost covers the anterior surface of the body of the vertebra, whereas the posterior longitudinal ligament covers only a portion of the posterior surface of the vertebra. Note also the cut supraspinous and interspinous ligaments, ligamenta flava, and articular joints. **D:** Posterior aspect of the vertebral body. The laminae and spinous process have been removed to show the posterior longitudinal ligament in the lumbar region. The ligament broadens and becomes intimately adherent as it passes over each of the intervertebral disks and over contiguous margins of the vertebrae. It is narrow and thick over the center of the body, however, from which it is separated by the basivertebral veins. This ligament is broad in the cervical region but at the L-1 vertebral level it begins to narrow progressively, so that on reaching the last lumbar and first sacral interspace it is only half of its original width. See text for a discussion of the implications.

The anterior longitudinal ligament is a broad band that lies on the anterior surface of the vertebral bodies and extends from the anterior tubercle of the atlas to the upper part of the pelvic surface of the sacrum. It consists of several laminae of fibers, the deepest spanning one intervertebral segment, while the most superficial extend over several segments. The anterior longitudinal ligament is thickest centrally, and it becomes progressively broader as it passes in a caudal direction. It is firmly united to the periosteum of the vertebral bodies but is free over the intervertebral disks. The anterior longitudinal ligament functions to limit extension of the vertebral column. In anterior crush injuries of the vertebral bodies, the anterior longitudinal ligament is ordinarily not injured, so that when the injured region is placed in hyperextension, this ligament can act as a splint to hold and fix the bony fragments.

The posterior longitudinal ligament lies on the posterior surface of the vertebral bodies and is therefore within the central vertebral canal. It extends from the posterior aspect of the body of the axis superiorly to the sacral canal below. It is attached firmly to the superior and inferior margins of the vertebrae and to the intervening disks, but over the centers of the vertebral bodies, there is a space through which blood vessels course to and from the posterior aspect of the vertebral body. The posterior longitudinal ligament functions in part to limit flexion of the vertebral column.

The vertebral arches are united by the ligamenta flava, intertransverse ligaments, interspinous ligaments, and supraspinous ligaments. The ligamenta flava are elastic in content and distinctly yellow. They join the contiguous borders of adjacent laminae and are attached to the front of the upper lamina and to the back of the lower lamina. They are stretched by flexion of the spine. Their elastic nature prevents redundancy and buckling when the ligament is slack. Thickening (hypertrophy) of the ligament flava can contribute to compression of a nerve root at the intervertebral foramen.

Three collagenous, segmental ligaments further unite and stabilize the vertebral arch. The supraspinous and interspinous ligaments join adjacent spinous processes; the supraspinous fibers are superficial and join just the tips. They are extremely strong and limit flexion of the lumbar spine. The intertransverse ligaments run from transverse process to transverse process. They are thin and membranous in the lumbar spine. It is thought that they stabilize and limit intervertebral movement during lateral flexion.

The ligaments of the spine are richly innervated by both somatic and sympathetic fibers. A branch of the dorsal primary ramus, the sinuvertebral nerve, innervates all of the posterior ligaments and facet joints (1). A branch of the ventral primary ramus innervates the anterior longitudinal ligament. In spite of their extensive innervation, it is controversial whether or not pathologic processes affecting ligaments are a significant source of nociception for patients suffering from low back pain.

ANATOMIC RELATIONSHIPS OF THE ROOTS AND SPINAL NERVES

The anterior and posterior nerve roots pass through the subarachnoid space and converge to form the spinal nerve at approximately the level of its respective intervertebral foramen (Fig. 75-7). The course of the nerve roots becomes progressively longer and more obliquely directed the more distal the segmental level. Therefore, in the lumbosacral regions the nerve roots and spinal nerves travel an almost vertical course before exiting below the pedicle of the corresponding vertebrae. Each nerve root leaves the vertebral canal through an intervertebral foramen (Fig. 75-7B). These foramina are bounded anteriorly by the posterior border of the intervertebral disk and the adjoining parts of the vertebral bodies, superiorly and inferiorly by the pedicles of the two adjoining vertebrae, and posteriorly by the articular processes and the facet joint, which are linked by the capsular ligament and the lateral edge of the ligamentum flavum. In the lumbar region the foramina are elliptical in shape and are approximately five times the diameter of the nerve root (Fig. 75-8). They are therefore large enough to transmit the spinal nerve, blood vessels, and nerve branches that supply the vertebral column and surrounding soft tissues. Due to the ample vertical dimensions of the foramen (12 to 19 mm in the lumbar region), degenerative changes and loss of disk height tend to result in a smaller foramen, yet even complete collapse of the lumbar disk may produce little evidence of nerve compression. In contrast, the transverse extent of the foramina is much smaller (approximately 7 mm); therefore, any space-occupying lesion that narrows the transverse dimensions of the foramen (bony spur, hypertrophy of the ligamentum flavum, tumor, protruding disk) may more readily result in nerve root impingement.

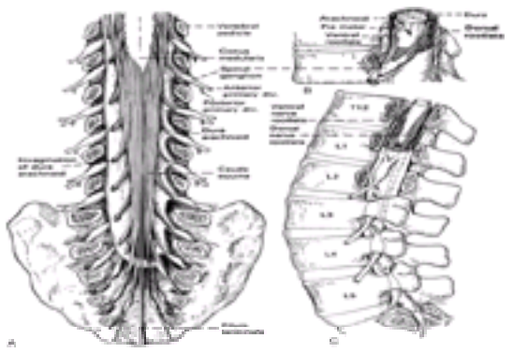

Figure 75-7. Detailed anatomy of the nerve rootlets and roots of the lumbar, sacral, and coccygeal nerves. **A:** Posterior view. **B:** Lateral view at midthoracic vertebral

level. **C:** Lateral view of the lumbar spine. The rootlets and roots of the lumbar, sacral, and coccygeal nerves course some distance before they leave the spinal canal. Gathered from their respective rootlets, they proceed caudad toward their respective intervertebral foramina and traverse the subarachnoid space within the dura-arachnoid sac in their own separate dura-arachnoid sleeves. As the nerve roots of the lumbar nerves descend in the spinal canal, they cross the disk immediately above the foramina through which they exit and then enter the foramina beneath the pedicles. After entry into the foramina on their extravertebral course, each root invaginates the dura-arachnoid and carries the sheath of each into the foramen, so that each of the two roots has its own separate investment of dura-arachnoid as far as lateral to the spinal root ganglion where the roots unite. At this point the two separate sheaths likewise merge so that the formed spinal nerve is invested by a single sheath, which continues for a short distance before it fuses with the epineurium of the spinal nerves. Within the foramen part of the dura fuses with connective tissue and thus anchors the dural sleeve to protect the nerve root from being stretched during movements of the spine. **C:** Within the foramen the smaller anterior (motor) root is located anteriorly and inferiorly near the intervertebral disk. After leaving the foramina the lumbar nerves incline caudad, laterally, and slightly anteriorly. The roots and dorsal ganglia of the S-1, S-2, and S-3 nerves lie in sheaths immediately external to the arachnoid- dura cisterna or cul-de-sac, while the roots and ganglia of the S-4, S-5, and coccygeal nerves lie within their sheaths in the body sacral canal at a considerable distance from the dural cul-de-sac.

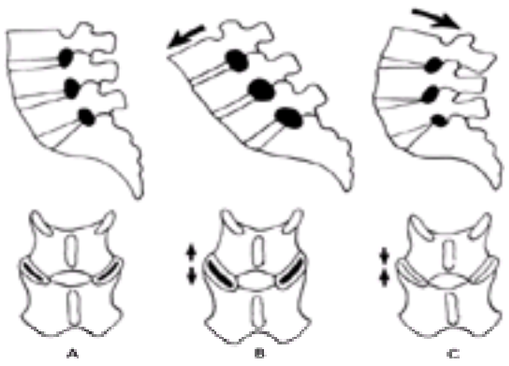

Figure 75-8. Flexion and hyperextension of the lumbar region. **A:** Normal posture showing the relation of the facets as well as the size of the intervertebral foramina and the configuration of the intervertebral disks. **B:** Flexion causes the facets to separate, thus allowing movement in the lumbar area in both lateral and rotatory directions. The intervertebral foramina enlarge and the anterior portions of the disks are compressed. **C:** Hyperextension. Facets approximate each other, thus completely eliminating any lateral rotatory movement and causing a significant decrease in the size of the intervertebral foramen. (Modified from Cailliet R. *Low back pain syndromes*, 3rd ed. Philadelphia: FA Davis, 1981.)

SPINAL CANAL

The shape of the posterior aspect of the vertebral body and the orientation of the pedicles and laminae determine the shape of the spinal canal (see Fig. 75-7). In the upper lumbar vertebrae the posterior aspect of the vertebral body is concave and the pedicles project directly back, creating a general oval shape to the canal. In the lower lumbar vertebrae, the posterior aspect of the vertebral bodies is slightly convex and the pedicles are in a more lateral orientation, therefore producing a more triangular-shaped canal.

The contents of the spinal canal vary depending on the segmental level. The tapered end of the spinal cord, the conus medullaris, may end anywhere between T-12 and L-3 but most commonly terminates at the L-1 to L-2 disk (Fig. 75-9). From its tapered end the filum terminale continues distally to the sacrum and coccyx (see Fig. 75-9). The lumbosacral nerve roots continue in a distal but slightly lateral direction to exit at their respective intervertebral foramina. Surrounding the lumbosacral nerve roots and the filum terminale are the meninges. External to the meninges is the epidural space. It is loosely filled with fat and connective tissue that *pads* the enclosed neural elements but also includes the internal vertebral venous plexus and the branches of the spinal arteries that supply the vertebral column, the dura, and the tissues of the epidural space. The internal vertebral venous plexus receives most of its tributaries from the large basivertebral veins, which drain the vertebral bodies.

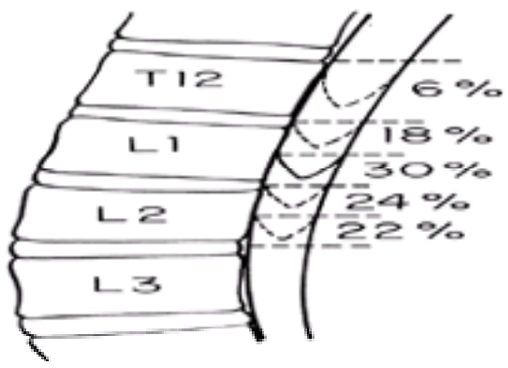

Figure 75-9. Various levels of the lowermost termination of the spinal cord shown in percentages as found in several autopsy studies.

Lumbar central spinal stenosis is a clinical condition that results from narrowing of the central canal and subsequent compression of the lumbosacral nerve roots. It may occur at a single or at multiple segmental levels; however, the L-4 to L-5 level is the most commonly affected. Central stenosis is produced mainly by a combination of osteophytes from the facets (the inferior facets most commonly) and disk degeneration with herniation, ligamentum flavum hypertrophy, or both. The typical symptoms are those of pain radiating into the buttocks and lower extremities, with or without sensorimotor complaints, that is exacerbated by standing or walking.

INTERVERTEBRAL DISK

The vertebral bodies of the lumbar spine articulate with one another through amphiarthrodial joints, which are termed *intervertebral disks* (Fig. 75-10). They are therefore by definition nonsynovial. In the transverse plane the cross section of the intervertebral disk is kidney shaped, corresponding to the shape of the vertebral body above and below. In the sagittal plane the disk is slightly thicker anteriorly than posteriorly, which may in part contribute to the lordotic posture of the lumbar spine (2).

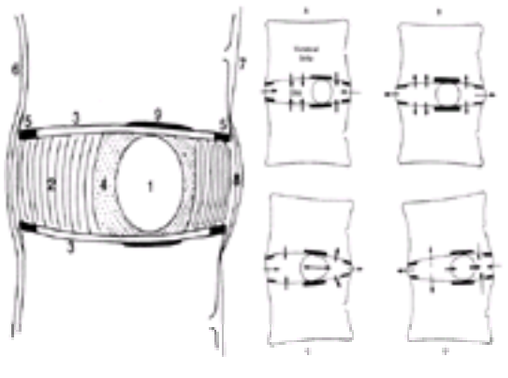

Figure 75-10. **A:** This diagrammatic representation of the intervertebral disk, in addition to presenting the customary nucleus pulposus (1), annulus fibrosus (2), and cartilaginous end-plates (3), also presents the zone of irregular connective tissues surrounding the nucleus (4), the epiphyseal rim (5), the anterior longitudinal ligament being continuous with the periosteum (6), and the posterior longitudinal ligament separating from the concave posterior vertebral body (7), the presence of Sharpey's fibers (8), and a thickened calcified layer capping the nucleus (9). **B:** The nutrient cycle to the disk is schematically depicted. (*A*) The weight is off the disk, permitting the polysaccharide molecules to imbibe fluids essential for nutrition. (*B*) The weight-bearing phase is represented, and the fluid is shown as being expressed from the disk. (*C*) Illustrated is backward bending, which may take place even at rest on an overly firm mattress. Here, while the front of the disk absorbs nutrient fluids, the back of the disk is unable to do so. (*D*) Forward bending, the reverse of Figure C, is illustrated. An additional feature of forward bending is that with sufficient fluid moving posteriorly, hydrodynamics of the disk are upset and the patient may become fixed in flexion. (Reprinted from Paris SV. Anatomy as related to function and pain. *Orthop Clin North Am* 1983;14:476–477, with permission.)

The intervertebral disk consists of two major portions: a central gelatinous portion, the nucleus pulposus, and a circumferential portion, the annulus fibrosus.

Nucleus Pulposus

The nucleus pulposus is enclosed by the surrounding annulus fibrosus at the periphery and by a cartilaginous end-plate on the adjacent vertebral bodies. It consists of water and connective tissue elements including collagen and proteoglycans, as well as cellular components. The proteoglycans and collagen are constantly being degraded and replaced by the cellular structures within the nucleus. Water is the most predominant substance in the disk, accounting for 90% of the total volume (3). Proteoglycans contribute 50% of the dry weight, while collagen contributes only 15% to 20% (4). Although the mechanical properties of the disk are dependent on all of these components, the water content is probably the most important, and it is largely determined by the hydrophilic nature of the proteoglycans. It does, however, also vary with the type and extent of mechanical loading, age, as well as other factors that contribute to the overall nutritional status of the disk.

Annulus Fibrosus

The annulus fibrosus is a structure that is largely made up of collagen. The collagen fibers are attached to the peripheral margin of the adjacent vertebral bodies. The structure of the annulus has been likened to that of an onion. It consists of a series of approximately 20 concentric layers or lamellae. The collagen fibers in each layer are in a parallel arrangement oriented obliquely at about a 50-degree angle relative to the surface of the vertebrae (5). In each consecutive layer the fibers are oriented in an opposite direction to those in the previous layer. In the adult spine the nucleus resides in a somewhat posterior position in the intradiskal space, and the lamellae are therefore thinned in this region. The outer margin of the annulus does have a limited vascular supply and neural supply. The innervation of the outer portion probably includes both nociceptive and mechanosensitive nerve fibers.

In the human the intervertebral disk is the largest avascular structure in the body. Nutrients enter the disk and waste products leave the disk largely by diffusion to and from vascular structures in adjacent tissues. The cartilaginous end-plate that separates the nucleus from the vertebral body above and below is the most important source for nutrients, with the peripheral margin of the annulus providing a secondary source. Smoking, increased age, and vibration result in an accumulation of metabolites and a reduction in oxygen use (4). Mechanical loading seems to enhance disk nutrition as well, as evidenced by studies of the effects of spinal fusion on disk metabolism (6,7).

Anatomic Changes in the Disk during Development

There is considerable controversy about whether the gross, histologic, and biochemical changes that occur in the lumbar spine with increasing age are pathologic or simply a consequence of normal aging. The anatomic changes that are typically seen with increasing age are an increase in collagen content and deposition of lipofuscin and amyloid in the nucleus. In addition, small concentric clefts form in the posterior portion of the annulus that may coalesce to form larger and more radially oriented clefts. The cartilaginous end-plate may show changes of thickening or defects and fissuring with associated Schmorl's nodes. These changes are associated with the development of marginal osteophytes at the edges of the vertebral body adjacent to the disk. Although classically the degenerated disk has a reduction in water content and a reduction in height, the disk height may be increased with age when there is concomitant osteoporosis. Osteoporosis leads to collapse of the vertebral end-plates and an increase in vertical dimension of the disk, especially the central portion (8).

Function of the Intervertebral Disk

The function of the intervertebral disk at its most rudimentary level is to simply allow multiplanar motion between the rigid structural elements of the vertebral bodies. The nucleus behaves as a viscous fluid, and in conjunction with the surrounding annulus, it functions as a shock absorber. Vertical loads cause the nucleus to distort uniformly in a circumferential direction, which subsequently results in distortion of the annular envelope and tension in the collagen fibers of the annulus. The healthy lumbar disk is extremely resilient to vertical loading; in fact, the bony vertebrae undergo fracture before there is evidence of disk injury.

There have been numerous investigations of the changes in intradiskal pressure during a variety of lumbar spine postures and activities (9,10 and 11). This information has been useful in increasing our understanding of the biomechanics of the spine and its ergonomic applications. It is uncertain what the relationship between disk loading, disk injury, disk degeneration, and low back pain might be (12).

FACET JOINTS

The facet joints of the lumbar spine are paired articular structures. Each anatomic motion segment is associated with one pair (Fig. 75-11). These joints are diarthrodial planar joints where the joint surfaces are covered with articular cartilage and the joint is enclosed by a capsule. The facet joints form an articulation between the inferior articular process of the vertebrae above and the superior articular process of the vertebrae below. This sometimes leads to confusion because when the facet joints are viewed in isolation, the inferior, more caudal portion is actually the superior articular facet because it is named from the vertebrae below, and the superior portion of the joint is formed from the inferior articular process of the vertebrae above.

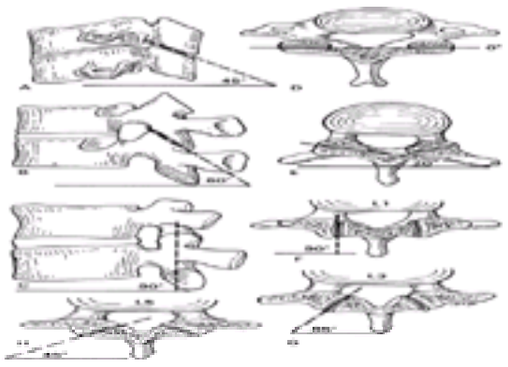

Figure 75-11. Planes of the articular facet surfaces of the vertebral arch joints. Lateral views show the angulation that determines the direction of movement permitted by the vertebral facet in the cervical **(A)**, thoracic **(B)**, and lumbar **(C)** regions. Depiction of the superior surfaces to show the facet planes horizontally. In the cervical region **(D)** they allow anterior flexion and extension, in the thoracic region **(E)** their angle permits an appreciable amount of rotation between consecutive vertebrae, and in the upper lumbar vertebrae **(F)** the facet planes are vertical. As they proceed caudad **(G,H)**, however, there tends to be a gradual transition in the angle of the superior articular process, which gradually faces more posteriorly and less medially, while the inferior articular process gradually faces more anteriorly and less laterally. The lumbosacral joint, the part farthest from the sagittal plane, allows some rotation of the lower part of the lumbar spine. (Modified from Hollinshead WH. *Anatomy for surgeons*, 3rd ed. Vol 3, The back and limbs. Philadelphia: Harper & Row, 1982; and Lindh M. Biomechanics of the lumbar spine. In: Frankel VH, Nordin M, eds. *Basic biomechanics of the skeletal system*. Philadelphia: Lea & Febiger, 1980.)

The facet joints are complex structures whose shape and orientation are not only difficult to define at any specific intersegmental level but they also change as one moves in a cephalad to a caudad direction. In the upper lumbar segments they are vertical with a predominantly sagittal plane orientation, while in the lower lumbar segments they are somewhat less vertical and are approximately halfway between a sagittal and a coronal plane orientation.

Throughout all of the segmental levels the shape of the superior articular process is concave while the inferior articular process is correspondingly convex. In the upper lumbar spine the superior articular process faces medially while the inferior articular process faces essentially laterally. In the lower lumbar spine as the orientation of the joint gradually becomes closer to the coronal plane, the superior articular facet faces both posteriorly and medially while the superior articular facet faces anteriorly and laterally.

The joint capsule encloses the facet joints and is relatively tighter anteriorly and more lax posteriorly. The multifidus muscle attaches in part to the posterior capsule and may exert a *tensioning* effect on the capsule (13,14). The superior capsule has been shown to be stretched and may be injured with axial loads, especially with the spine in extension (15). Attached to the interior surface of the joint capsule at the level of the superior and inferior joint recesses are fibrofatty or fibrous structures. They have been described as meniscuslike, and some authors believe that they may be a source of nociception if trapped between the joint surfaces. Other authors believe that they are too friable to exert tension on the joint capsule and therefore cannot be a source of nociception (16).

The facet joints and capsule are richly innervated through branches from the posterior primary ramus as it exits from the intervertebral foramina. The posterior primary ramus at a given segmental level sends fibers to the facet joint at that level but also to the facet joints above and below the level of the nerve exit (17) (Fig. 75-12). The innervation of the facet joints and capsule appears to be through mechanoreceptors as well as nociceptors, and there appear to be substance P–containing nerve fibers present (18,19).

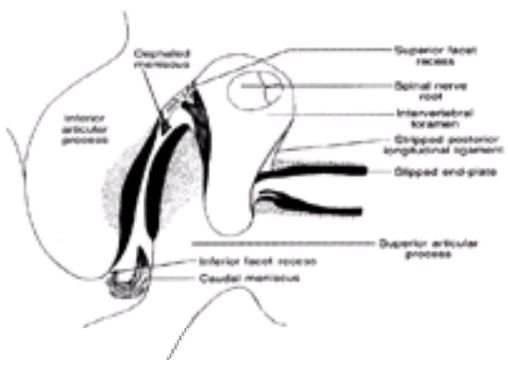

Figure 75-12. A segmental cross section through the facet joint and intervertebral foramen shows the mixed spinal nerve root high up in the foramen opposite a weakened upper portion of the facet capsule and superior articular recess. An inferior recess is at the caudal extent of the joint, as is a larger tonguelike projection of cartilage identified as a meniscus. This specimen also shows a slipped superior cartilaginous end-plate with a stripping of the posterior longitudinal ligament from the periosteum. (Reprinted from Paris SV. Anatomy as related to function and pain. *Orthop Clin North Am* 1983;14:479, with permission.)

Biomechanics and Function of the Facet Joint

The lumbar spine is a structure that includes five motion segments between L-1 and S-1. In the adult the lumbar spine typically adopts a lordotic posture and sits on the sacrum, which is angulated posteriorly. The posterior angulation of the sacrum results in the upper surface of S-1 being oriented 60 degrees to the vertical plane.

The function of the facet joints is to limit and guide the motion of the lumbar spine. The generally sagittal plane orientation of the facet joints markedly limits axial rotation in the lumbar spine. However, the relatively more coronal orientation at the L-5 to S- 1 junction may allow somewhat greater rotation to occur. Flexion of the lumbar spine can be influenced dynamically through the lumbar spine musculature and through the passive restraint of connective tissue. It is interesting to note that in spite of the significant stature of the interspinous and supraspinal ligaments, the facet joints provide the greatest limitation to full flexion. In anatomic studies where the facet joints have been excised, there is a marked increase in the mechanical stresses that the disk experiences (20). During full flexion, contact between the more anterior portions of the superior and inferior articular processes of the facet joints and tension in their joint capsules are the major restraint to motion. In full extension there is stretch applied to the superior aspect of the facet joint capsule, and there may be *bottoming out* of the inferior articular process on the laminae below (8).

The facet joints do not carry significant axial loads with the spine in a neutral position because of their vertical orientation. In extension, however, they have been shown to carry 16% to 20% of the total axial load. The actual anatomic structure of the facet joint that carries the axial load in extension is debated, and in fact it may be dependent on whether the spine and the disk exhibit degenerative changes (21). In the absence of disk degeneration the joint capsule carries significant loads, while in the presence of disk degeneration a greater portion of the load may be borne by the articular surface (22).

As noted previously, the lumbosacral junction is subject to significant shear stresses because of the lumbar lordosis and the posterior angulation of the sacrum. The L-5 to S-1 facet joint bears significant shear stress loads. These shear stresses may in part play a role in the increased incidence of spondylolysis and secondary spondylolisthesis.

LOWER EXTREMITY

General Considerations

The lower extremity predominantly functions to support and move the weight of the body through space. These include skeletal structures; articulations and their supporting structures; and muscle, nerve, and vascular structures. To make a correct diagnosis in the patient who presents with lower extremity pain, one must have a comprehensive understanding of the anatomy, functional biomechanics, and pain characteristics associated with nociceptive input from these structures. In addition, pain experienced in the lower extremity may have an origin in structures outside of the lower extremity; it is therefore important to have knowledge of common patterns of pain radiation and referral.

Osseous Structures

The lower extremity consists of 30 different osseous structures. These include the femur, patella, tibia, fibula, talus, calcaneus, navicular, cuboid, three cuneiforms, five metatarsals, five proximal phalanges, four intermediate phalanges, and five distal phalanges. The major functions of these skeletal structures are to provide structural integrity to the lower extremity; form articulations that allow mobility; form attachment points for muscle, ligaments, and joint capsule; and act as a storage site for calcium and other minerals and as a site for the genesis of hematopoietic tissues. Bone is a dynamic structure that is constantly being absorbed and generated by the osteoblasts and osteoclasts. Because of this, it can repair itself after injury, and its shape and structure are altered by the forces that are applied through it. The attachment points of muscle modify the shape of the bones of the extremities. A good example of this in the lower extremities is the tibial tuberosity, which forms a prominent area of bony enlargement at the attachment point of the patellar tendon. The profound muscle forces of the quadriceps, which are transmitted through the patellar tendon, result in the elevation of the tibia in this region. The bones of the lower extremities are predominantly long bones, with their length being greater than their width. The regions of a long bone include the diaphysis or shaft, the metaphysis, which is the region where a long bone expands as it nears the articulation, and the epiphysis, which is the portion immediately adjacent to the articulation. The long bones of the lower extremity include the femur, tibia, fibula, metatarsals, and phalanges. The other bones of the tarsal region are considered short bones. Pain arising from the osseous structures usually is experienced at the location of the lesion. A stress fracture, malignancy, or contusion usually results in pain where the lesion occurs. There may be some proximal or distal radiation; however, referral of pain of osseous origin to more distant sites is uncommon.

Articulations

All of the joints of the lower extremity are synovial joints with the exception of the distal tibiofibular joint, which is a syndesmosis. Synovial joints have common characteristics in that they are formed as an articulation between two osseous structures. The surfaces of the osseous structures that come into contact are covered with articular cartilage, and the joint is enclosed by a synovial lining, which produces synovial fluid for joint nutrition and lubrication. Exterior to the synovial lining is a joint capsule, which provides a strong connective tissue enclosure to the joint. The joint capsule is subsequently reinforced by ligamentous structures, which provide stability to the joint but also guide and restrain the motion of the joint. Synovial joints of the lower extremity typically allow greater ranges of mobility if the architecture of the joint results in a high level of intrinsic stability.

Hip Joint. The hip joint is an articulation between the acetabulum of the pelvis and the head of the femur. It is described as a ball and socket joint because of the shape of the articular surfaces. This joint has a high level of intrinsic stability because of the deep ball and socket architecture. The stability of this joint is further reinforced by strong ligaments, which span the perimeter of the acetabulum and attach to the neck of the femur. These ligaments are increasingly taut with extension of the hip, and if the center of mass is positioned appropriately relative to the hip joint, the upright posture with hip extension can be maintained with minimal muscle work. One can rely exclusively on passive tension in the ligaments to maintain this posture. Hip joint pain is commonly experienced in the anterior groin area with occasional referral to the anteromedial thigh and the knee. This referred pain pattern is related to the segmental innervation of the hip joint, which includes a significant component of L-3 and L-4.

Knee Joint. The knee joint is an articulation between three osseous structures: the femur, the tibia, and the patella. This joint has little intrinsic stability based on the architecture of the articular surfaces. Its stability is determined almost exclusively by strong ligamentous structures reinforced by dynamic muscle action and to a much lesser extent by the menisci, which deepen the articular contact area of the tibia. Because of its limited intrinsic stability there are greater constraints on its motion. Although its range of motion in the sagittal plane is between 5 degrees of hyperextension and 120 degrees of flexion, there is only a small amount of transverse plane motion and essentially no coronal plane motion. The patella and the patellofemoral joints' primary functions are to redirect the pull of the quadriceps. This effectively increases the extension torque of the quadriceps at any point in its flexion-extension excursion. This function is most important near full extension. In the case of a patient with a patellectomy, the absence of a patella may in fact lead to an inability to extend the knee in the last 10 degrees of extension in spite of having a strong quadriceps muscle.

The location, character, and quality of pain associated with pathophysiologic processes affecting the knee vary. Broadly speaking, painful processes that are caused by diffuse inflammatory conditions such as crystal-induced arthropathies or degenerative conditions such as tricompartmental degenerative arthritis will cause poorly localized knee pain aggravated by activity and relieved by rest. Other processes such as ligamentous meniscal or patellofemoral processes can result in localized pain in a portion of the knee that is reflected in the anatomic location of the structure.

Ankle Joint. The ankle joint is an articulation between the tibia, fibula, and talus. The most common description of this joint is a *mortise and tenon* joint. The mortise is composed of the tibia above and medially and the distal fibula laterally. The mortise of the ankle joint is composed of the dome of the talus. The mortise and tenon architecture of this joint allows for more intrinsic stability, especially in the coronal plane. The bony stability of this joint is further reinforced by the strong medial and lateral ligamentous structures. The motion that occurs at the ankle is predominantly in the sagittal plane.

Articulations of the Foot. There are many different articulations of the foot, each with unique biomechanical and functional characteristics. A detailed description of these is beyond the scope of this section. The general function of these articulations is to provide suppleness to the foot, particularly in the first half of the stance phase when force and impact absorption are critical. In the second half of the stance phase, when force transmission and propulsion of the body and the lower extremity into the swing phase are the most important functions, the articulations of the foot stiffen secondary to changes in the orientation of the articular surfaces and through dynamic action of the musculature.

Arterial Vascular Supply

The arterial supply to the lower extremity begins at the distal aorta, which bifurcates into the right and left common iliac arteries (Fig. 75-13). The common iliacs subsequently branch into the internal and external iliac vessels. The internal iliac perfuses the pelvic structures and the gluteal musculature through the gluteal arteries. The external iliacs continue through the pelvis, exiting under the inguinal ligament, and into the femoral triangle where they become the femoral arteries. Within the femoral triangle, the femoral artery lies between the more lateral femoral nerve and the more medial femoral vein and is easily palpable in this location. Within the femoral triangle, it gives off two major branches: the profunda femoral artery and the circumflex femoral artery. The profunda femoral artery supplies the musculature of the thigh, while the circumflex femoral passes posteriorly and laterally, supplying the posterior and lateral gluteal regions as well as sending a branch to the head of the femur. The femoral artery continues down the thigh in the adductor canal. At the distal end of the adductor canal it travels posteriorly and enters the popliteal fossa, where it becomes the popliteal artery. Within the popliteal fossa it gives off a number of geniculate arteries that supply the knee and its adjacent soft tissue structures. Exiting the popliteal fossa distally it divides into two major branches, the anterior tibial artery and the tibioperoneal trunk, which subsequently divide into the posterior tibial and peroneal arteries. The anterior tibial artery continues down the leg in the anterior compartment and emerges at the anterior aspect of the ankle joint and continues down the dorsal part of the foot as the dorsal pedis artery. The peroneal artery continues in the leg in the deep posterior fossa at the junction of the interosseus membrane and the posterior aspect of the fibula. The posterior tibial artery travels in a distal direction, lying on the tibialis posterior muscle. At the ankle it lies posterior to the medial malleolus into the plantar surface of the foot where it divides into the medial and lateral plantar branches.

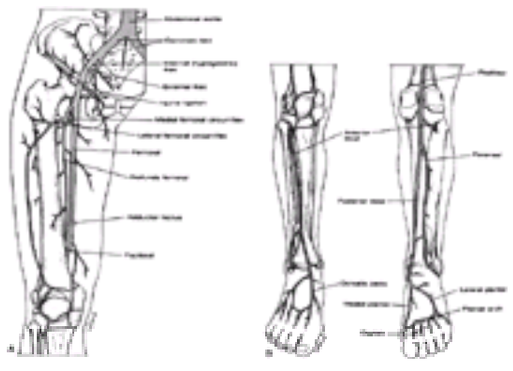

Figure 75-13. **A:** Arteries of the pelvis and thigh. **B:** Arteries of the leg and foot: anterior view (left) and posterior view (right). (Reprinted from Spence AP. *Basic human anatomy*, 3rd ed. Redwood City, CA: Benjamin/Cummings, 1990:320, with permission.)

Arterial supply to the lower extremity can be assessed clinically by palpation or through the use of Doppler evaluation. Typically, the vessels are assessed in regions where the artery is more superficial. This includes the dorsalis pedis artery on the dorsal aspect of the foot, the posterior tibial artery posterior to the medial malleolus, the popliteal artery in the popliteal fossa, and the femoral artery in the femoral triangle.

Pain syndromes that arise from impairment of arterial perfusion vary depending on the acuity and extent of the occlusive disease, the anatomic location of the occlusive disease, and the extent of collateralization (see Chapter 33). Acute arterial occlusion secondary to thrombosis in an area of atherosclerosis or secondary to arterial embolization results in the sudden onset of severe pain in the distal portion of the extremity. The limb is pale and cold to palpation, and there is severe impairment or absence of neurologic function. Chronic arterial occlusive disease results in two major types of pain, claudication and rest pain. The pain in both of these situations is the result of an inadequate blood supply to meet the metabolic demands of the tissues. With claudication, the pain occurs during exercise. Typically, the pain is predictable in onset at a certain walking distance or exercise intensity. It is described as cramping. With femoral-popliteal disease it is typically in the calf muscles, and in aortoiliac disease it may involve the buttock or thigh. Rest pain is typically anatomically located in the forefoot and toes. It occurs with recumbency or with limb elevation, and it is relieved by dependency—for example, when the patient hangs his or her leg over the edge of the bed. Rest pain occurs because limb perfusion is inadequate to meet the metabolic demands of the tissues even at rest. As the patient adopts the recumbent position there is a decrease in perfusion pressure secondary to a reduction in the hydrostatic pressure of the column of blood and pain occurs. When the patient drops his or her leg over the edge

of the bed, there is a slight increase in perfusion because of the hydrostatic pressure of the column of blood within the arterial tree, and the pain is typically relieved.

Venous System

The veins of the lower extremities can be broadly divided into two major groups: the superficial and the deep venous systems (Fig. 75-14). The deep system travels along with the arterial supply to the leg, beginning on the plantar aspect of the foot and extending proximally to travel with the peroneal, tibial, and posterior tibial arteries in the leg. Similarly it travels with the popliteal and femoral arteries in the popliteal fossa and within the adductor canal to the femoral triangle.

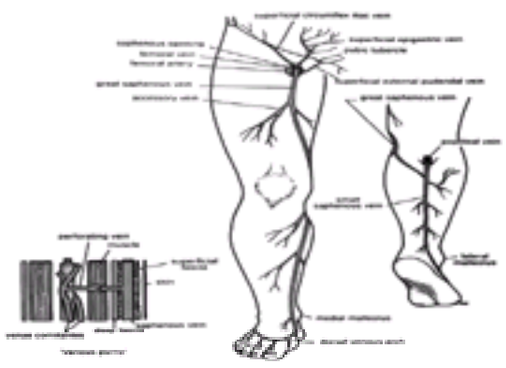

Figure 75-14. Superficial veins of right lower limb. Note importance of the valved perforating veins in the *venous pump*. (Reprinted from Snell RS. *Clinical anatomy for medical students*, 5th ed. Boston: Little, Brown and Company, 1995:523, with permission.)

The superficial venous system is external to the superficial muscle fascia of the leg and thigh. It consists of two systems: the greater and the lesser saphenous veins. The greater saphenous vein has its origin on the dorsum of the foot passing just anterior to the medial malleolus, then traveling up the medial aspect of the leg along with the saphenous nerve. It then moves just posterior to the knee and up the anteromedial aspect of the leg, where it perforates the superficial fascia of the leg and connects to the femoral vein. The lesser saphenous vein begins on the dorsal aspect of the foot and travels just posterior to the lateral malleolus. It then passes up the middle of the leg between the two heads of the gastrocnemius, where it penetrates the fascia of the leg in the popliteal fossa and joins the popliteal vein.

The veins of the leg are thin walled but do have a muscular layer. One of the important anatomic characteristics of the venous structures is the presence of valves, which function to support the column of blood. Valves are very important, especially in light of the fact that humans spend the majority of time in the upright position. The valves, in addition to supporting the column of blood, also assist in directing flow. Flow of venous blood is central and from the superficial to the deep system. Muscular contraction within the closed space created by the muscular fascia results in compression of the veins, and because of the anatomy and functional characteristics of the valves, blood is directed in a cephalad direction toward the inferior vena cava and heart.

Pain related to venous malfunction occurs in a number of pathologic conditions. Most commonly, in the case of valvular incompetence, there is a dull aching pain in the legs, especially in the lower half. The pain is aggravated by prolonged standing and walking and relieved by compression or elevation of the limbs. This pain may be associated with swelling as well as the characteristic changes of chronic venous stasis, which include pigmentation (brawny induration), with or without venous stasis ulcers, which typically occur in the supramalleolar region. In addition to chronic venous stasis, acute superficial thrombophlebitis may occur. Superficial thrombophlebitis results in localized thrombosis and inflammation in a segment of the superficial vein with symptoms of exquisite local tenderness in a portion of the leg in the anatomic location of either the greater or lesser saphenous veins, associated with tenderness, local edema, redness, and warmth.

Nerve Supply

General Considerations. Motor innervation of the lower extremity muscles follows specific organizational features. First, each segmental nerve root innervates more than one muscle, and all muscles are innervated by more than one nerve segment (23).

The cutaneous innervation of the lower limb is provided by nerves that have their origin in the lumbar and lumbosacral plexus. Differentiating between a peripheral nerve and dermatomal pattern of sensory loss requires knowledge of both the cutaneous nerves and segmental pattern of supply. Dermatomal segments are as follows: L-1, midpoint over the inguinal ligament; L-2, proximal medial thigh; L-3, medial knee; L-4, medial ankle; L-5, first web space on the dorsum of the foot; S-1, lateral heel; S-2, popliteal fossa; and S-3 to S-5, perianal skin (see Chapter 8). Peripheral nerve patterns are quite different than segmental patterns. The innervation of the buttocks by peripheral nerves is as follows: the superior cluneal nerves supply the upper buttock, the middle cluneal nerves supply the midportion of the buttock, and the inferior cluneal nerves curve around the lower border of the gluteus maximus to supply the inferior portion of the buttock. The innervation of the thigh is as follows: branches from the femoral nerve supply the anterior and medial thigh (except the proximal medial thigh is innervated by the obturator nerve), the lateral thigh is innervated by the lateral cutaneous nerve of the thigh, and the posterior cutaneous nerve of the thigh innervates the posterior thigh. The innervation of the leg is as follows: the medial leg is innervated by the saphenous nerve, the anterolateral leg is innervated by the lateral sural nerve proximally and the superficial peroneal distally, and the medial sural nerve supplies the posterior leg. The foot is innervated by the saphenous nerve medially, the superficial peroneal nerve dorsally (except the deep peroneal nerve supplies the skin over the first web space), the sural nerve laterally, and the plantar nerves on the plantar surface.

Lumbar and Lumbosacral Plexuses. In all vertebrates, each limb is organized into compartments; the skin and muscles of these compartments are supplied by limb plexuses. In the plexuses, spinal nerves interchange fibers so that the major nerve branches, distal to the plexus, receive contributions from two or more segmental spinal nerves. The evolution of plexuses was an important adaptive structural and functional advancement, allowing further complex neuromusculoskeletal behavior and protection from injury.

All of the vertebrates, including humans, have a similar organization of limb plexuses. From fish to reptiles to humans, each limb plexus has the following features in common: (a) several spinal nerves (connected to spinal cord enlargements) contribute nerve fibers to the plexus, intermingle, divide, and regroup; (b) each spinal nerve divides into a dorsal ramus and ventral ramus; however, only the ventral ramus contributes nerve fibers to the limb plexus; (c) each plexus divides into anterior divisions to supply flexor muscles and the overlying surface of the limb and posterior divisions to supply extensor muscles and the body wall over their respective surface; and (d) each plexus is an organized meshwork of sensory, motor, and sympathetic fibers and innervates most of the extremity. Some plexuses are remarkably complex (the skate has 26 spinal nerves contributing fibers to the brachial plexus), while others are quite simple, such as the lumbar plexus in the human.

The lower limb consists of a flexor and extensor compartment that meets at borders (preaxial and postaxial), marked out by veins. The great saphenous vein marks out the preaxial and the small saphenous vein at the postaxial border. The flexor compartment, innervated by anterior divisions from the plexus, has a richer nerve supply and includes an additional caudal nerve. The nerve supply to these muscles and body wall structures is derived from the *lumbosacral plexus*, which is formed by segmental nerves L-1 to S-4. The plexus is actually one plexus in the fetus but becomes subdivided by the developing pelvic girdle. The plexus is usually studied as two in the adult: the lumbar and the lumbosacral plexuses.

Lumbar Plexus and Its Major Branches. Five lumbar nerves emerge from their respective intervertebral foramina and contribute to the formation of the lumbar plexus (Fig. 75-15). This plexus lies within the substance of the psoas major on the posterior abdominal wall, and its branches emerge through the muscle (anteriorly), laterally, and medially. This is important to remember since the plexus and branches are vulnerable during surgical procedures (e.g., abdominal hysterectomy), disease processes (e.g., psoas abscess), or space-occupying lesions (e.g., abdominal aortic aneurysm) that involve the psoas muscle or posterior abdominal wall. For example, anticoagulant therapy that results in a retroperitoneal hemorrhage might involve one or more nerves of the lumbar plexus dependent on the location of the hematoma. Most of the branches from the lumbar plexus are destined to supply the lower limb but in passage give motor supply to the psoas (especially L-2 to L-3) and quadratus lumborum and sensory supply to the posterior parietal peritoneum. There are five branches of the lumbar plexus.

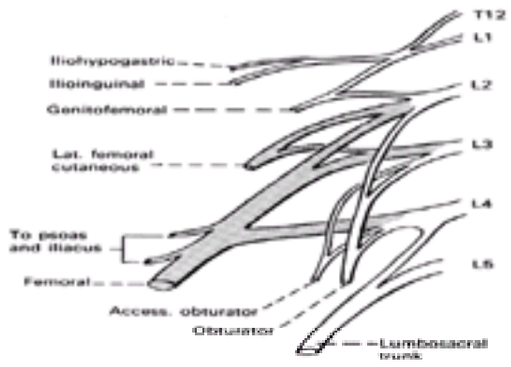

Figure 75-15. The lumbar plexus. The anterior primary division of the L-1 nerve splits into upper and lower branches, with the upper branch joined by a filament from the T-12 nerve to form the common trunk of the iliohypogastric and ilioinguinal nerves. The lower branch joins a branch of the L-2 nerve to form the genitofemoral nerve. The anterior primary division of the L-2 nerve also splits into upper and lower branches. The smaller upper branch takes part in the formation of the genitofemoral nerve, while the lower branch takes part in the formation of the femoral, lateral femoral cutaneous, and obturator nerves. The lower branch of the L-2 nerve, the upper branch of the L-4 nerve, and the undivided L-3 anterior primary division split into ventral and dorsal subdivisions. The dorsal branches form the femoral nerve while the ventral branches form the obturator nerve. The smaller branch of the anterior primary division of the L-4 nerve joins the undivided anterior primary division of the L-5 nerve to form the lumbosacral trunk or nervus furcalis, which takes part in the formation of the sacral plexus.

The *lateral cutaneous nerve of the thigh* is in close proximity to the femoral nerve at its origin and then diverges laterally to lie behind the iliacus fascia on the iliacus muscle (Fig. 75-16). It approaches the inguinal ligament, which it pierces medial to the anterior superior iliac spine, and terminates by supplying the lateral side of the thigh down to the knee. Meralgia paresthetica is a neuropathy, usually secondary to entrapment, of this nerve and results in paresthesias of the lateral thigh extending almost to the lateral knee. Treatment of this condition has included corticosteroid injection (at the point where the nerve pierces the inguinal ligament) and surgical release of the nerve (from the inguinal ligament, from beneath the iliacus fascia, or both).

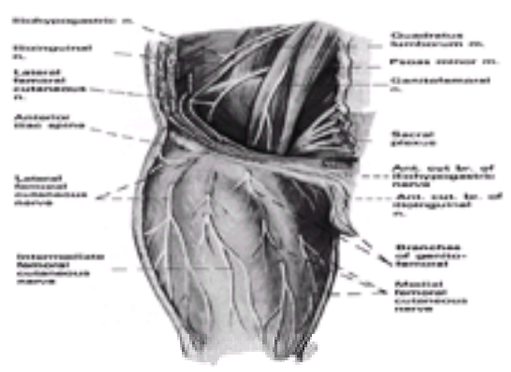

Figure 75-16. Anatomy of the iliohypogastric, ilioinguinal, genitofemoral, and lateral, intermediate, and medial femoral cutaneous nerves. See text for details.

The *femoral nerve* also emerges from the lateral aspect of the psoas muscle and is the great extensor nerve of the thigh (Fig. 75-16 and Fig. 75-17). The nerve travels in the gutter between the psoas and iliacus, supplies the iliacus, and passes beneath the inguinal ligament. It immediately breaks up into numerous branches and supplies both muscle and skin of the anterior thigh. Nerve conduction studies can sometimes be challenging because of this anatomy. Stimulation of the nerve proximal to the inguinal ligament might be difficult with abundant adipose tissue while stimulation distal to the inguinal ligament is often confounded by the early ramification of nerve branches. Motor fibers from the femoral nerve supply the pectineus, sartorius, and the quadriceps. Sensory fibers supply the hip and knee joints (Hilton's law) and most of the skin of the anterior and medial thigh, and the saphenous nerve innervates the skin of the medial leg and foot. In the setting of weak quadriceps, the distinction between a femoral neuropathy, lumbar plexopathy, and L-4 radiculopathy can sometimes be a challenge. In contrast to a femoral neuropathy, however, lumbar plexopathies typically involve the lateral cutaneous nerve of the thigh and might affect the obturator nerve, in addition to the femoral nerve. Contrasting, an L-4 radiculopathy would involve ankle extensors (dorsiflexors) and muscles innervated by the superior gluteal nerve, yet spare hip flexors and the skin of the anterior thigh.

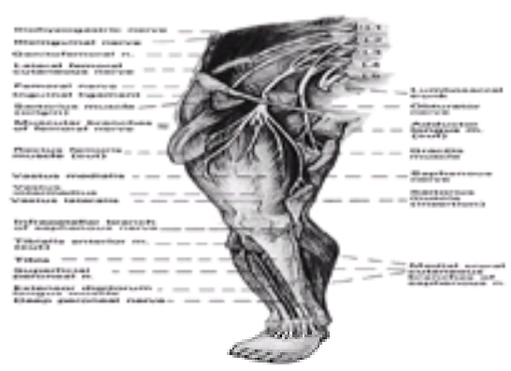

Figure 75-17. Anatomy of the femoral nerves. See text for details.

The *obturator nerve* forms medial to the psoas muscle and lies on the ala of the sacrum, travels along the side wall of the pelvis, and splits into two terminal branches prior to exiting the pelvis through the obturator foramen (anterior and posterior branches). In the thigh, the two branches split around the adductor brevis and terminate by supplying muscle and skin of the medial (adductor) thigh (Fig. 75-18). Motor fibers supply the obturator externus, pectineus (it often receives innervation from both the femoral and obturator nerves), gracilis, and the three adductors (brevis, longus, and magnus). Sensory fibers supply the hip joint and the lower medial side of the thigh. Obturator nerve blocks are less effective if the infusion of phenol or ethanol is superficial and does not affect the posterior branch, since the posterior branch supplies the large adductor magnus muscle. Positioning the needle just external to the obturator notch (foramen) yields the best results, as opposed to a bit more distal placement after the anterior and posterior branches diverge.

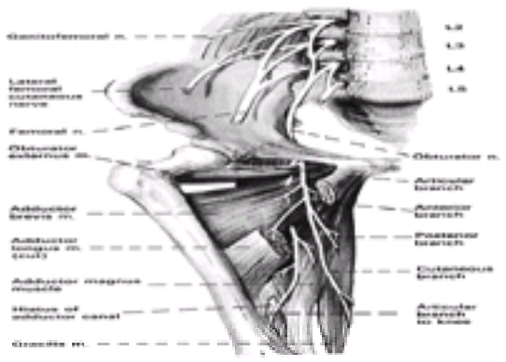

Figure 75-18. Anatomy of the obturator nerve. See text for details.

For completion, the *L-1 segmental nerve* and *genitofemoral nerve* (L-1, L-2) are worthy of mention as branches of the lumbar plexus (see Fig. 75-16). The L-1 segmental nerve is a typical spinal nerve that divides into its two terminal branches, ilioinguinal and iliohypogastric. These nerves supply the lowermost aspect of the abdominal wall (both muscle and skin) and then supply skin of the upper thigh and anterior scrotum. Injury to the nerves (e.g., abdominal surgeries) can result in denervation of the lowermost fibers of the abdominal wall (internal oblique and transversus abdominus) and result in a direct inguinal hernia. The *genitofemoral nerve* emerges through the substance of the psoas muscle and then supplies the cremaster muscle with motor fibers, while the sensory fibers supply the fascia of the spermatic cord and a small patch of skin on the anterior thigh (just distal to the midinguinal ligament). This nerve is of interest because it subserves the cremasteric reflex (L-1, L-2) and is thought to mediate referred pain from a ureteral stone. Indeed, renal colic may result in reflex retraction of the testis as well as radiation of pain into the groin and anterior thigh (see Chapter 68).

Lumbosacral Plexus and Its Major Branches. The lumbosacral plexus is formed by the lumbosacral trunk (from L-4, L-5) and sacral nerves (S-1 to S-4) on the surface of the piriformis muscle within the pelvis. Branches from the plexus arise from the roots and after the divisions as in the brachial plexus. There is remarkable symmetry that aids in learning the 12 nerves of the lumbosacral plexus. Six nerves branch from the roots, and six arise after the divisions. There are three nerves from the anterior and three from the posterior divisions (Fig. 75-19 and Fig. 75-20).

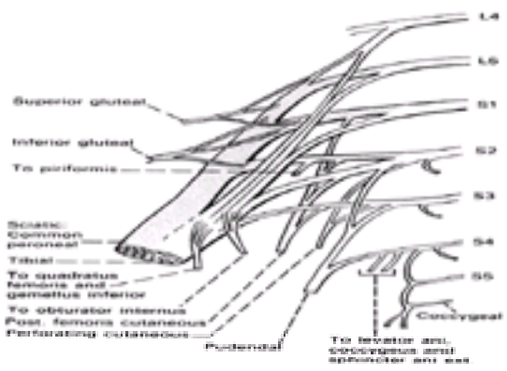

Figure 75-19. The sacral plexus. The large tibial nerve, the nerve to the quadratus femoris and gemellus inferior, the nerve to the obturator internus and gemellus superior, and part of the posterior femoral cutaneous nerve are derived from the anterior subdivisions. The common peroneal nerve, the nerve to the piriformis, the superior gluteal, the inferior gluteal, and part of the posterior femoral cutaneous nerves are derived from the posterior subdivision. The tibial and common peroneal nerves are the two terminal branches and are usually fused together as far as the posterior part of the thigh into what is commonly known as the great sciatic nerve (see Fig. 75-20). (Modified from Clemente CD, ed. *Gray's anatomy of the human body*, 30th Am. ed. Philadelphia: Lea & Febiger, 1985:471.)

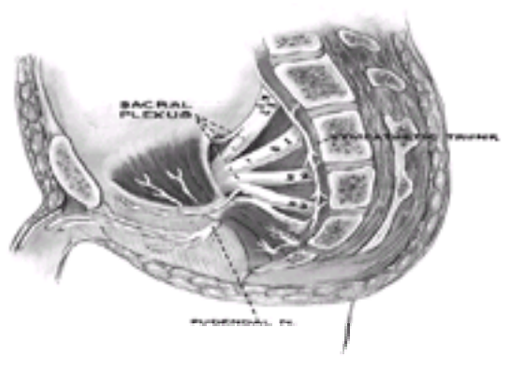

Figure 75-20. Sagittal view of the right pelvis showing the position of the sacral plexus, which is a large, broad, triangular structure lying in the posterior part of the true pelvis in front of the sacrum, from which it is separated by the piriformis muscle. Its broad base is formed by the anterior primary divisions and therefore coincides with the row of anterior sacral foramina and with the L-5 and L-4 paravertebral spaces, while its apex is composed of the great sciatic nerve as it lies in the great sciatic notch. The plexus is covered by the pelvic fascia and is in close relation with the pelvic viscera. Anterior to the plexus are the hypogastric vessels and some of their branches, the ureter, and the sigmoid colon. Some branches of the hypogastric vessels run between the anterior primary divisions before they unite to form the plexus.

The branches that arise directly from the roots of the lumbosacral plexus are primarily important when considering pelvic anatomy and function. The *posterior cutaneous nerve* of the thigh is the only one of significance when considering the lower extremity. It supplies the inferior buttocks (inferior cluneal branch) and the posterior thigh down to the popliteal fossa. Referred pain from the prostate and other derivatives of the cloaca are thought to be mediated along this nerve and must be distinguished from sciatica.

The nerves from the anterior divisions supply flexor and adductor muscles. Two of the three nerves from the anterior divisions are relatively unimportant (*nerve to* obturator internus and*nerve to* quadratus femoris). The *tibial component of the sciatic nerve* is the great flexor nerve of the lower extremity (Fig. 75-21). It supplies almost all of the flexor muscles of the thigh (except the short head of the biceps femoris) and all of the flexor muscles of the leg and sole of the foot. The tibial nerve is rarely injured in the thigh and leg except by penetrating, violent injuries. Complete division results in paralysis of flexor muscles of the leg (calf) and sole of the foot and loss of sensation on the plantar aspect of the foot. After a complete injury, the ankle and foot have a characteristic posture (calcaneovalgus) due to the unopposed action of ankle and foot extensors (dorsiflexors) and evertors.

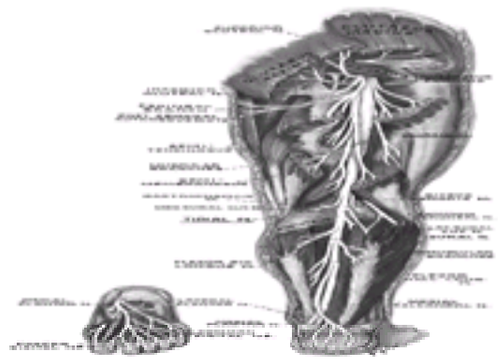

Figure 75-21. **A:** The plantar surface of the foot, depicting distribution of the two plantar nerves and their branches. **B:** Anatomy and distribution of the sciatic nerve and its branches, including the tibial and common peroneal nerves.

The nerves from the posterior division supply the extensor and abductor muscles of the lower extremity. The *gluteal nerves* are motor nerves that supply the gluteal muscles. Using the fact that the gluteus medius arises higher on the iliac bone (as compared with gluteus maximus) assists one in memorizing that the *superior gluteal nerve* innervates the gluteus medius, minimus, and tensor fascia lata. It also arises from a more rostral segment (L-4 versus L-5) than the inferior gluteal nerve. Injuries to the gluteal nerves might occur within the pelvis or after exit through the greater sciatic notch in the buttock. Intrapelvic injuries are typically caused by a mass or an injury that also affects other branches of the lumbosacral plexus (e.g., sciatic). Within the gluteal region, injuries are usually of the penetrating type, iatrogenic in nature by injection, or after violent injuries by gunshot or knife. Injury to the superior gluteal nerve results in weakness of the gluteus medius and minimus revealed by a positive Trendelenburg's sign when weight bears on the affected lower limb.

The *common peroneal nerve* is wrapped with the tibial nerve within the sciatic sheath and gives off one branch in the thigh to the short head of the biceps femoris (Fig. 75-22). In the upper aspect of the popliteal fossa, it branches from the tibial nerve and follows the lateral border of the popliteal fossa and then the medial border of the biceps, giving off genicular nerves to supply the knee joint and the lateral sural nerve. It then becomes subcutaneous just behind the head of the fibula, where it is commonly injured from direct pressure, repeated squatting, prolonged sitting in a cross-legged position, or traction after orthopedic injuries (e.g., medial dislocation of the knee). In the substance of peroneus longus, the nerve divides into its two terminal branches, the *deep and superficial peroneal nerves*. Each of these nerves may be injured within their respective compartment (deep peroneal within the anterior compartment and superficial peroneal within the lateral compartment) by various pathologies including fracture, compartment syndrome, and tumor and from extrinsic compression by tight-fitting clothes and footwear.

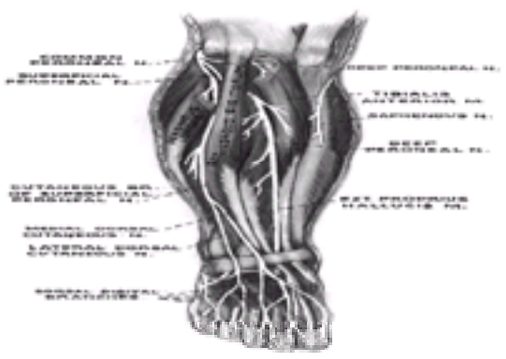

Figure 75-22. Anterior view of the leg showing the course and distribution of the common peroneal nerve into the superficial and deep peroneal nerves and their branches.

The*sciatic nerve* is, in fact, two nerves wrapped within one sheath. Sometimes, it divides into its two components as it enters the buttock and the two nerves simply course downward side by side. In this case, there is no difference in innervation; all of the branches to the hamstrings arise from the medial-lying tibial nerve with the exception of that to the short head of the biceps. In thinking about nerve blocks to the hamstring muscles, many patterns of innervation have been observed. Occasionally, a separate large motor trunk is formed within the pelvis and parallels the sciatic nerve into the buttock and thigh. Typically, separate branches arise at intervals from the medial aspect of the sciatic nerve, but the patterns are variable. Sunderland and Hughes, for example, found variability in the order in which the branches to the various muscles arose, together with an inconstant number of branches. As a case in point, they found a single branch to the long head of the biceps in 50% of the cases, two nerves in 40%, and three nerves in 10% (24).

The sciatic nerve is sometimes injured in its early course by pelvic fractures, dislocations or surgeries of the hip, and penetrating injuries, although the most common injury is from poorly placed gluteal injections. The majority of sciatic nerve lesions affects primarily the common peroneal nerve with a relative sparing of the tibial component. In the thigh, the nerve is rarely injured because extensive soft tissues protect it. As the nerve enters the popliteal fossa, however, it is somewhat more vulnerable to injury. At the apex of the popliteal fossa (a hand's breadth above the knee joint) the sciatic nerve divides into its terminal tibial and common peroneal nerves. Therefore, injuries at the level of the apex commonly damage both components of the nerve, while those below the apex more commonly affect the tibial nerve.

Sympathetic Innervation. The preganglionic fibers for the lower limb originate within the spinal cord (preganglionic fibers arise from the thoracolumbar outflow) from the lower segments (T-11 to L-2). The cell bodies are located in the lateral horn and the axons exit via the ventral roots (Fig. 75-23). They descend in the sympathetic chain to synapse in a ganglion.

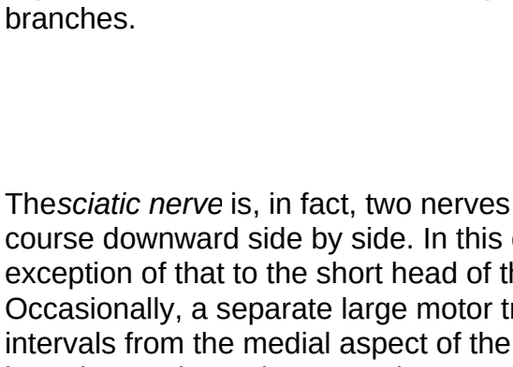

Figure 75-23. Origin and course of preganglionic (*solid lines*) and postganglionic (*dashed lines*) sympathetic fibers that supply the lower limbs. Preganglionic fibers at the T-6 to T-9 spinal cord levels pass cephalad to join those from T-2 to T-5 to supply the upper limb. (Reprinted from Bonica JJ. *Clinical applications of diagnostic and therapeutic nerve blocks.* Springfield, IL: Charles C Thomas, 1959:146, with permission.)

A postganglionic (gray ramus) sympathetic nerve joins each root of the lumbar and lumbosacral plexus after exit from the intervertebral foramina; these sympathetic fibers hitchhike through the plexus and its nerves. Thus, each dermatome of the lower limb is supplied via the cutaneous nerves by sympathetic fibers to innervate

blood vessels, sweat glands, and erector pili muscles. The postganglionic nerve arises from cell bodies in the appropriate sympathetic ganglion from the lumbar and sacral sympathetic chain.

Sympathetic innervation provides a valuable diagnostic aid in localizing nerve lesions. For example, the presence of autonomic disturbance in the lower limb localizes a process to a site distal to where the postganglionic fiber joins with the root. For example, a herniated nucleus pulposus does not affect sympathetic fibers because it compresses the nerve root, but a tumor in the retroperitoneal space presents with both somatic and sympathetic nerve dysfunction.

Muscle

The majority of the mass of the lower extremities is made up of muscle. The chief functional tasks of muscle are to maintain postural stability in standing and other ambulatory activities, and to generate concentric and eccentric contractions to produce and control movements of the lower extremities. The gross motor tasks include a spectrum of complexity, from simple movements to the highly complex tasks that are seen during sporting maneuvers.

A detailed analysis of the origin, insertion, and function of each muscle group is beyond the scope of this work. It is useful, however, to consider muscles as a potential source of nociception. To effectively make a diagnosis of the etiology of pain that is ascribed by a patient to an anatomic area that is muscular, one must consider both local and referred sources of pain.

Muscle and its supporting connective tissue structures are important and frequent sources of nociception in the lower extremities. Pain localized to muscle may be caused by local pathologies, or it may be referred from a nociceptive source in proximal articulations or osseous or neurogenic structures. Common causes of referred pain to areas of lower extremity muscle include radicular processes, peripheral nerve lesions, and spinal or hip arthritis.

Muscle as a Source of Nociception. There are many conditions that can result in muscle pain. A useful organizational structure that is helpful in assisting the clinician determine a diagnosis is to define the pain in terms of its acuity of onset, whether it is focal or generalized, and whether or not it is exercise related.

Focal Muscle Pain. Focal muscle pain is defined as pain arising in a single muscle group or muscle compartment. The most common cause of this type of pain is muscle trauma. The trauma can be broadly categorized into external trauma (i.e., arising from an impact of the muscle group with another structure) or internal trauma, resulting from forces generated by the muscle itself. Trauma to muscle from an external impact results in direct muscle injury, which leads to the development of a hematoma. The onset of pain is sudden and associated with the injury; however, the pain may increase over time as swelling increases. The diagnosis is usually obvious based on the history. Physical examination reveals an area of localized tenderness and swelling at the site of injury, with ecchymosis. Pain is exacerbated by any attempt at generating tension in the muscle either from active contraction or passive stretch. These injuries typically resolve spontaneously with full restoration of function; however, complications including calcification of the hematoma leading to myositis ossificans (25), and a compartment syndrome may occur. Trauma resulting from internal muscle forces results in muscle strain or a frank muscle tear. Typically, the injuries result from a forced lengthening of a muscle group that is being strongly contracted or from a powerful eccentric contraction from the muscle group (25). The lower extremity muscle groups in which this occurs more commonly are the gastrocnemius and the hamstrings. The history is one of sudden onset of pain that results in cessation of the movement. In a muscle strain there is partial rather than complete disruption of the muscle. A muscle *tear*, in contrast, results in a complete discontinuity in a portion of the muscle. This results in a rapid onset of swelling (within an hour or so) and ecchymosis with focal pain and tenderness. The pain is aggravated by any attempt to lengthen the muscle passively or by voluntary contraction of the muscle group. With resolution of the swelling there may be a palpable defect in the body of the muscle.

Tumor is an uncommon cause of muscle pain but must be considered in the patient who presents with progressive pain and localized swelling. Tumors arising from muscle cells are uncommon. Benign tumors of muscle (i.e., rhabdomyoma) almost never occur in the extremities (26). Malignant tumors, usually rhabdomyosarcomas, arise in the extremities more commonly. Typically, these are childhood neoplasms that present with a gradually enlarging mass that may or may not be painful, depending on the extent of tumor at the time of presentation (26). Because muscle is anatomically comprised of tissues other than those of muscle cell origin, tumors of fibrous, lipoid, vascular, and neural structures can also arise within muscle.

Muscle ischemia rarely leads to pain in a specific muscle group. The pain more commonly involves multiple muscle groups within an extremity. The most common underlying pathologic causes of ischemic muscle pain are atherosclerosis, thrombosis, and embolus. Acute embolus results in acute onset of pain with a cool, pale extremity with impaired motor and sensory neurologic function. Chronic ischemic disease may result in claudication, with pain in lower extremity muscles associated with exercise and relieved with rest. A less common cause of acute focal muscle pain related to ischemia is diabetic muscular infarction. In this condition patients with long-standing diabetes present with the sudden onset of acute thigh pain with swelling and muscle weakness. The most common muscle groups involved are the vastus lateralis and the adductors (27).

Acute Generalized Muscle Pain. Differential diagnoses to consider with the acute onset over days to weeks of diffuse muscle pain in the upper and lower extremities, often with a more severe proximal distribution, include infectious myositis, toxic myositis, and drug-induced myositis.

Viral and parasitic infections are the most common infectious causes of acute diffuse muscle pain. The more common viral infections that may result in myositis include influenza, coxsackievirus, and human immunodeficiency virus. With influenza and coxsackievirus infections, the muscle pain begins 1 to 13 days after onset of a flulike syndrome. Associated symptoms include fatigue, muscle weakness, and myoglobinuria. In human immunodeficiency virus myopathy the onset is much more gradual and progressive, with weakness rather than pain being the predominant symptom (28). Many different parasites can affect muscle. The three most common are trichinosis, cysticercosis, and toxoplasmosis. The general presentation is one of relatively acute onset of fever, muscle pain, tenderness, and weakness. Muscle swelling with or without distinct nodularity is a variable feature.

Alcohol is the most common toxin to cause a myopathy. The type of myopathy may be acute or chronic, depending on the extent and chronicity of alcohol intake. Acute alcoholic myopathy can result in the acute onset of muscle weakness and pain that is generalized. Pharmaceutical agents that can cause muscle necrosis are more likely to cause myalgias in addition to weakness as a presenting complaint. Agents that fall into this class include the cholesterol-lowering drugs lovastatin, clofibrate, and gemfibrozil, as well as ipecac when used chronically. Elevations in creatine phosphokinase and abnormalities in electrodiagnostic studies in patients taking these medications help to confirm the diagnosis (29).

Chronic Generalized Muscle Pain. Chronic generalized muscle pain has an onset that is more gradual, extending sometimes over weeks to months. Muscle weakness may or may not be a prominent feature depending on the underlying etiology. The more common causes in this group include polymyositis and dermatomyositis, polymyalgia rheumatica, fibromyalgia syndrome, and metabolic and endocrine myopathies (30). Polymyositis and dermatomyositis are autoimmune connective tissue disorders that can affect muscle in a fairly focal manner or may cause diffuse proximal muscle weakness with muscle pain. In polymyositis there is no cutaneous involvement, but swallowing difficulties may be the result of pharyngeal muscle involvement. With dermatomyositis there is a concomitant characteristic facial rash, with or without an erythematous scaling rash over the dorsum of the interphalangeal joints or the extensor surfaces of other joints. Diagnosis is made on the basis of history, physical examination in association with abnormal muscle enzymes, electromyography, muscle biopsy, or more than one of these tests. Polymyalgia rheumatica occurs in patients over 50 years of age, with a peak onset in the 70s. The characteristic clinical features include pain and stiffness, with more minor complaints of weakness, predominantly in the shoulder girdle musculature but also involving the muscles of the trunk and pelvic girdle. Fibromyalgia syndrome is discussed in detail in Chapter 30 but is included here for completeness. It is a syndrome of diffuse muscle weakness with myalgias and chronic fatigue with a high frequency of depressive symptoms. This syndrome is more common in women than in men. The underlying etiology is not known. Therapeutic interventions include tricyclic antidepressants, aerobic exercise, and behavioral strategies (31).

The majority of metabolic and endocrine processes that can affect muscle function cause weakness of the shoulder and pelvic girdle muscles as a primary complaint. Hypothyroidism and hyperthyroidism as well as hyperparathyroidism are more likely to cause diffuse muscle stiffness and myalgias in conjunction with the weakness (31).

Exercise-Induced Muscle Pain. During exercise, especially during intense or prolonged exercise, there are considerable metabolic and mechanical stresses placed on muscle. These can result in pain either during or in the postexercise period. The etiology of pain during maximal isometric contractions or with repeated maximal concentric or eccentric contractions is not known. Lactate accumulation and alteration of pH were believed to be the primary mediators of pain, but these are no longer believed to be the critical factors. It is possible that accumulation of other metabolites may be more important (32). A number of inherited abnormalities of muscle metabolism can predispose to muscle pain, fatigability, and weakness during and after exercise.

Pain can also occur in muscle in the period after cessation of exercise. This has been termed *delayed-onset muscle soreness*. Delayed-onset muscle soreness occurs

with a greater frequency after a period of unaccustomed exercise and in particular if there is a significant eccentric component to the exercise stress. The location of the pain is specific to the muscle groups that have been exercised eccentrically. Within the muscle group there may be increased pain in the region of the musculotendinous junction. The onset of muscle pain usually is 24 hours after exercise, with a peak at 48 to 72 hours after exercise, and a gradual diminution over the next 24 to 48 hours. It is believed that the etiology of the pain is related to injury to the muscle at an ultrastructural level because of the high forces the muscle is exposed to. The ultrastructural injury leads to localized muscle swelling and an inflammatory response.

Muscle cramp is a sudden onset of powerful involuntary muscle contraction of a muscle group that may be provoked by a minor voluntary muscle contraction with the muscle in a shortened position. Although it may be associated with neurologic or endocrine disorders, it is most commonly associated with exercise. It may occur either during or after a period of intense or prolonged exercise. When it occurs during exercise, it is more common during endurance activities such as marathon running or long- distance bicycle racing. In this context, electrolyte depletion and fluid volume loss are thought to be important contributing factors (32). Muscle cramp is thought to be associated with a hyperexcitability of the motor neuron. The exact portion of the motor neuron that is involved is controversial: It may be the terminal portion that is the source of the high-frequency discharge (33).

Referred Pain in the Lower Extremities. One of the most common sources of referred pain into the lower extremities is mechanical compression, injury, or irritation of a neural structure. The classic example of this is *sciatica* (i.e., pain referred into the posterior thigh and leg with or without pain in the foot related to radiculopathy). Pain in the lower extremity associated with radiculopathy is typically in the dermatomal distribution of the affected nerve root. With L-5 and S-1 lesions the pain is in the previously mentioned distribution. With an L-4 root lesion the pain is more in the distribution of the anterior thigh and medial leg, and with an L-3 root lesion the pain is in the distribution of the anterior thigh. Coughing, sneezing, or straining, which increases intradiskal and venous pressure, may aggravate pain of radiculopathy. The pain may be associated with symptoms of sensory deficit or motor weakness. Specific physical examination findings such as positive root tension signs, sensory disturbance, motor weakness, and reflex changes in the appropriate nerve root distribution may confirm the diagnosis.

Another common cause of referred pain in the lower extremities is related to nerve injury. These injuries include peripheral neuropathies, focal compressive neuropathies, vasculitis, or local direct trauma. The pain is typically referred in the distribution of the affected nerve. For example, the lateral femoral cutaneous nerve typically exits the pelvis just medial to the anterior superior iliac spine at the inguinal ligament and supplies sensation to the anterolateral thigh. This nerve is commonly injured at the point of exit from the pelvis. Injury results in the clinical syndrome with a burning dysesthetic pain in the anterolateral thigh, which is termed *meralgia paraesthetica*.

Pain in the Hip and Gluteal Region

The accurate diagnosis of hip and gluteal pain is a challenge; there are many soft tissue, joint, and neural tissues that subserve pain in the region. In this section, the regional anatomy is presented followed by an overview of common causes of pain in the hip and gluteal region.

Anatomy. The lower limb is articulated to the axial skeleton via the pelvic girdle. The femur joins with the pelvis at the acetabulum and the pelvic girdle articulates with the axial skeleton at the sacroiliac joint. Organizationally, it is useful to consider the pelvic girdle and sacroiliac joint separately from the gluteal and hip regions.

Surface Anatomy and Palpation. The tips of the anterior superior iliac spine and iliac crest are easily felt and may be visible. When the inguinal ligament is traced medially from the anterior superior iliac spine, the pubic tubercle is the first bony landmark palpated. The greater tuberosity of the femur lies quite posteriorly, a hand's breadth below the iliac crest, and is best palpated with the hip relaxed and in an abducted position. The ischial tuberosity is easily palpated when the hip is flexed but covered by the gluteus maximus and more difficult to palpate when the hip is in the extended position. Pain over the ischial tuberosity may represent ischial bursitis, inflamed with too much sitting (*weaver's bottom*). Directly beneath the visible dimples above the buttocks, the posterior superior iliac spines are readily palpated.

Pelvic Girdle. The bony pelvis constitutes the base of the trunk. It supports the abdomen and links the vertebral column to the lower limbs. It is a closed ring made up of three bony parts and three joints. There is a complete interdependence of the various elements of the pelvis, so that impairment at any level affects the structure as a whole and decreases its mechanical resistance. The three bony parts are the two paired iliac bones and the sacrum. The three joints are the two sacroiliac joints and the symphysis pubis that links the iliac bones anteriorly. The bony pelvis is quite different in male and female subjects. The female pelvis is broader and shorter, with a larger pelvic brim. The female bones are also more slender and make a wider subpubic angle.

As a whole, the bony pelvis transmits forces from the vertebral column to the lower limbs. The weight supported by L-5 is distributed equally along the alae of the sacrum and through the ischial tuberosities toward the acetabulum. Conversely, ground reaction forces are transmitted to the acetabulum by the neck and head of the femur. Some of these forces are transmitted across the horizontal ramus of the pubic bone and counterbalanced at the symphysis pubis by a similar force form the other side.

Since the pelvis is remarkably strong, fracture is rare except after the application of great force. Fractures are typically a result of compressive forces and break across the weakest parts of the ring, such as the pubic rami, wing of the ilium, and at the obturator foramen.

Sacrum and Sacroiliac Joint. The sacrum consists of five fused vertebrae that form a single triangular bone that supports the spine and forms the posterior wall of the pelvis. The base is formed by the upper surface of the first sacral vertebra and has an anteriorly projecting edge known as the promontory. The sacrum is markedly curved and tilted backward, so that its first element articulates with the fifth lumbar vertebrae at a pronounced angle. As the sacrum is broader above than below, it fits vertically between the two iliac bones like a wedge. The sacrum is suspended from these bones by sacroiliac ligaments (Fig. 75-24). As forces increase on the spine and sacrum (e.g., during standing), the sacrum is wedged more tightly between the iliac bones as a self-locking system.

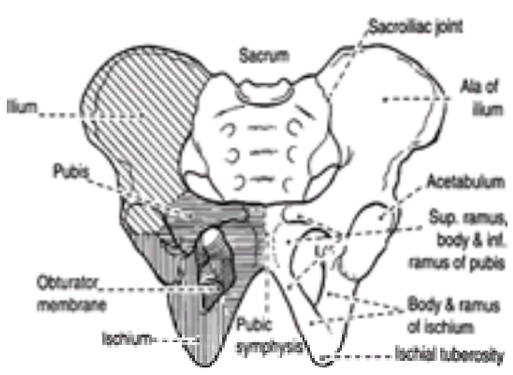

Figure 75-24. The bony pelvis, tilted slightly backward and seen from an anterior view. The three component bones of the pelvic girdle are shaded differently. (Reprinted from Rosse C, Gaddum-Rosse P, eds. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:308, with permission.)

The sacroiliac joint is synovial and a complex articulation between the sacrum and ilium. The articulating surfaces are crescent shaped and marked by corresponding elevations and depressions that fit one into another, thus restricting movement (Fig. 75-25). The joint is further stabilized by a long crest on the articular surface of the iliac bone that fits into a curved furrow along the articular surface of the sacrum. In addition to the osseous features, ligamentous factors promote stability at the sacroiliac joint. The sacroiliac ligaments surround the capsule of the joint and are separated into anterior, intermediate, and posterior portions. In general, these ligamentous bands are weak anteriorly and very strong elsewhere. The iliolumbar ligaments, attaching the transverse processes of the last two lumbar vertebrae to the iliac crest, and the sacroischial ligaments (e.g., sacrospinous and sacrotuberous) are considered accessory ligaments that add further stability to the joint.

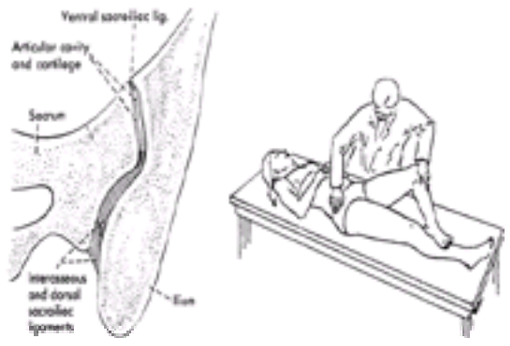

Figure 75-25. The sacroiliac joint. **A:** A schematic transverse section through the right sacroiliac joint. **B:** Testing the right sacroiliac joint. The joint is subjected to stress by pressing on the right anterior superior iliac spine and on the distal end of the left femur after the left hip has reached its limit of movement in the position shown. (Reprinted from Rosse C, Gaddum-Rosse P, eds. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:312, with permission.)

Significant forces and some movement occur at the sacroiliac joint, noted during pregnancy and by the individual who has pathology at the joint, such as sacroiliitis. The movements that occur include small degrees of sliding and rotational displacements. These movements and mechanical forces (e.g., compressive and distracting) are best appreciated when examining the effect of posture on the joints of the bony pelvis. The weight of the trunk during quiet standing acts on the promontory and causes the sacrum to rotate so that the base moves forward (inferiorly and anteriorly) and the apex (along with the tip of the coccyx) moves backward (34). The anterior sacroiliac, sacrospinous, and sacrotuberous ligaments are rapidly put on tension, thereby limiting any further movement. When standing on one foot, the pelvis on the side of the unsupported limb drops. This leads to shearing and rotational forces at the pubic symphysis and the sacroiliac joints, resisted by the ligaments so little actual movement occurs. However, significant movement might occur if the stabilizing ligaments of the sacroiliac joint are lax. This occurs following traumatic injuries to the pelvis, and pain might be felt at every step during walking. Inflammation or abnormal mobility may be a cause of low back pain.

On physical examination, direct examination of the sacroiliac joints is difficult. Therefore, provocative tests that compress and rock the joint are helpful in eliciting signs of sacroiliac joint disease (pelvic rock test, Gaenslen's sign, and Patrick-Fabere test) (see Fig. 75-25). If hip joint pathology is excluded, pain elicited by these tests in the sacral region is indicative of disease in the sacroiliac joint. Traumatic injury to the sacroiliac joints is rare. It is more common that infection (tuberculosis), tumor, or arthritis affects the sacroiliac joint. Sacroiliitis associated with rheumatologic disorders (e.g., ankylosing spondylitis and Reiter's syndrome) is well described and can be a cause of low back pain.

Gluteal Region. Pain in the gluteal region is common. In addition to many tissues that are direct sources of nociception, referred pain to the buttock from the lumbosacral spine has been well described.

The gluteal region consists of soft tissues that join the posterior aspects of the pelvis with the hip joint. The skin over the buttocks and lateral thigh is thick, tough, and poorly vascularized, making it a common site for carbuncles. An abundant layer of subcutaneous fat provides padding and support for weight bearing during sitting and is traversed by cutaneous nerves and small blood vessels. Deep to the adipose layer is deep fascia; a tough inelastic membrane. It varies widely in thickness over the limbs. In the lower extremity, the iliotibial tract is a well-developed region of deep fascia over the lateral thigh (Fig. 75-26). Tensor fascia lata and the gluteus maximus both insert into the iliotibial tract to act across both the hip and knee. The deep fascia is relatively avascular and is richly endowed with sensory fibers. It is exquisitely sensitive. Its nerve supply is that of the overlying skin and not of the underlying muscles. Traumatic injury, overuse, and inflammatory pathologies may cause pain in deep fascial structures.

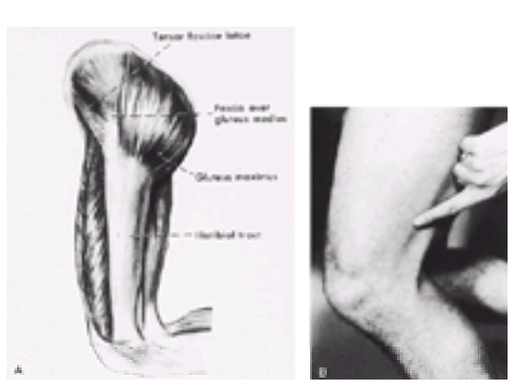

Figure 75-26. The iliotibial tract and the muscles associated with it. **A:** Lateral view of the thigh and gluteal region showing the iliotibial tract, tensor fasciae latae, and gluteus maximus. **B:** The iliotibial tract, seen anterior to the tendon of the biceps femoris, is an important factor in stabilizing the flexed knee when it is supporting the body weight. Note: the right leg is off the ground. (Reprinted from Rosse C, Gaddum-Rosse P, eds. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:320, with permission.)

The gluteal region serves as the origin for the major abductor, extensor, and lateral rotating muscles of the hip joint. Most of the muscles insert onto the greater trochanter or the iliotibial tract.

The gluteus maximus is the superficial muscle in the buttock and is a powerful extensor of the hip. It arises from the posterior aspect of the ilium and the sacrum and inserts into the iliotibial tract and the greater trochanter. The primary action of the gluteus maximus is powerful hip extension; it contracts during activities such as going upstairs and getting up from a sitting position. This contrasts with hip extension during quiet, level walking during which the hamstring muscles are the primary movers. The origin of the hamstrings on the ischial tuberosity is a possible source of pain in the gluteal region. Proximal hamstring sprain or rupture, hamstring tendinitis, and bursitis over the ischial tuberosity may lead to pain in the region of the buttocks, particularly over the ischial tuberosity.

Gluteus medius and minimus are the primary abductors of the hip (Fig. 75-27). Lying beneath the gluteus maximus, both muscles arise from the posterolateral surface of the ilium and insert into the greater trochanter. Abduction of the unsupported lower limb is often clinically tested when side-lying, yet gluteus medius and minimus usually function during walking (Fig. 75-28). Contraction of the ipsilateral hip abductors occurs during the stance phase and prevents the pelvis from dropping to the unsupported side. Weakness of the gluteus medius and minimus manifests as a positive Trendelenburg's test in which the pelvis drops away from the stance leg during walking or single-leg standing.

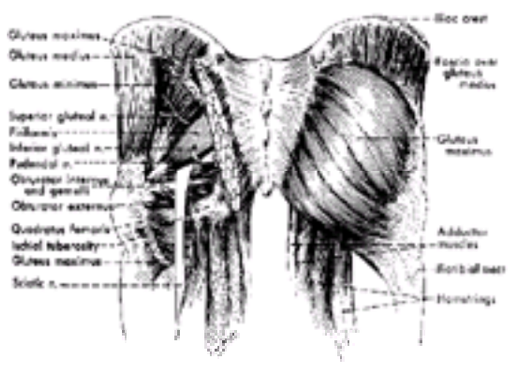

Figure 75-27. Muscles of the gluteal region seen from the back. On the left side the gluteus maximus has been resected and a wedge has been removed from the gluteus medius. (Reprinted from Rosse C, Gaddum-Rosse P, eds. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:321, with permission.)

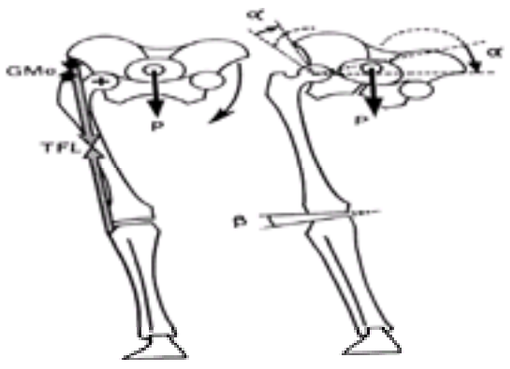

Figure 75-28. Explanation of Trendelenburg's sign. (Reprinted from Kapandji IA. *The physiology of the joints*, 5th ed. Vol 2, Lower limb. Edinburgh, UK: Churchill Livingstone, 1987:49, with permission.)

The tensor fascia lata (see Fig. 75-26) is a muscle that arises from the anterior part of the iliac crest and passes downward and backward to insert into the iliotibial tract. It functions as a flexor and medial rotator of the hip. Several short lateral rotators make up the deepest layer of muscles in the gluteal region and insert into the posterior aspect of the greater trochanter. The piriformis arises from the anterior surface of the sacrum and exits through the greater sciatic foramen surrounded by neurovascular structures that enter the buttock. The piriformis syndrome has been described as a condition in which the piriformis muscle irritates the sciatic nerve, causing pain in the buttocks and referred pain along the course of the sciatic nerve. Patients generally complain of pain deep in the buttocks, which is made worse by sitting, climbing stairs, or performing squats.

Hip Joint and Anterior Thigh. The hip is a stable ball-and-socket joint with spherical articular surfaces. The neck of the femur, which joins the shaft, supports the spherical head. The axis of the femoral neck is obliquely set and runs superiorly, medially, and anteriorly. In the adult it forms an angle of approximately 125 degrees with the femoral shaft. An increase in this angle, coxa valga, occurs in cases of congenital dislocation of the hip. A decrease in the angle, coxa vara, occurs in fractures of the femoral neck and in slipping of the femoral epiphysis. During standing, the coronal plane passes through the center of the femoral head and axis of the femoral condyles, which lie almost completely anterior to the femoral shaft and the axis of rotation at the knee. The head articulates with acetabulum, which is directed laterally, inferiorly, and anteriorly. Its inferior orientation results in an overhanging upper part of the socket, which sustains the greatest compression forces from the head. Therefore, the articular cartilage of the acetabular roof and of the femoral head are thickest superiorly. Dislocation of the hip occurs rarely. In cases of congenital dislocation of the hip, the upper lip of the acetabulum fails to develop adequately and the head of the femur slips out of the acetabulum onto the posterior surface of the ilium. Traumatic hip dislocation occurs after motor vehicle accidents in which the flexed knee strikes a fixed object, resulting in a posterior dislocation of the femur.

Femoral neck fracture is a common cause of hip pain in the elderly. More than 90% of such fractures occur in persons over 70 years of age. Fractures of the upper end of the femur may break the neck immediately beneath the head, through the neck, between the trochanters (intertrochanteric), or below the level of the trochanters (subtrochanteric). The location of the fracture determines whether the blood supply to the femoral head is interrupted with resultant avascular necrosis. This is a problem in the child and the older adult. In the child, the nutrient artery to the shaft of the femur terminates at the metaphysis; in other words, the nutrient arteries are end arteries and do not supply the epiphysis. Therefore, embolism, infarction, and osteomyelitis in the child may result in infarction. In the young child and middle-aged adult, the metaphysis has ossified, and rich anastomoses are established between epiphysis and metaphysis. However, the blood supply changes in the elderly. One of the two major sources of blood, the obturator artery, begins to wither away. Many of the anastomoses become tenuous and the main supply of the femoral head is through small arteries that arise from the trochanteric anastomosis and travel up along the neck of the femur. In the older person, fractures of the femoral neck interrupt the retinacular arteries and the head is deprived of its blood supply. The retinacular arteries may be injured in femoral neck fractures, dislocation of the hip, and slipping of the femoral epiphysis. In contrast, fractures outside the joint capsule (some of the intertrochanteric and all of the subtrochanteric fractures) leave these vessels undisturbed.

The capsule of the hip is loose but extremely strong, strengthened by three named ligaments, each ligament arising from a constituent of the innominate bone (iliofemoral, pubofemoral, and ischiofemoral). All of the ligaments have a coiled or spiral structure secondary to the rotation of the lower limb during development (35). The disposition of the ligamentous fibers runs in a clockwise direction from the hip to the femur, meaning that extension winds these ligaments around the neck of the femur and flexion does the opposite. Therefore, during extension of the hip, all the ligaments become taut as they wind around the femoral neck, clearly demonstrated when an individual with complete paraplegia stands with the hips in extension, *balancing* on the ligaments.

The primary flexors of the hip include psoas major and iliacus (Fig. 75-29). The iliacus muscle is a broad, powerful, fan-shaped muscle that lies beneath the extremely tough iliacus fascia where it arises from the iliac fossa. Its innervation is from the femoral nerve, which is en route to its destination, the anterior compartment of the thigh. In contrast, the psoas muscle arises from lumbar vertebrae within the abdominal cavity (from the posterior abdominal wall), has parallel fibers, and is designed more for excursion than power. The psoas muscle is innervated segmentally by branches from the lumbar plexus, particularly from L-2 and L-3. Weakness of the psoas muscle (e.g., psoas abscess, hematoma) localizes a peripheral nerve lesion to an extremely proximal site, within the lumbar plexus itself or at the level of the roots. During concentric contractions, the psoas is able to flex the thigh or the vertebral column, depending on which segment is fixed. It is important to recall some of the surrounding abdominal anatomy: The appendix overlies the right psoas major, an important clinical relationship to remember as the individual with appendicitis resists right hip extension, which stretches the psoas and causes pain. This is not to be confused with the patient who is tucked into a fetal position to prevent any movement or stretching of the peritoneum, an ominous sign of a perforated appendix.

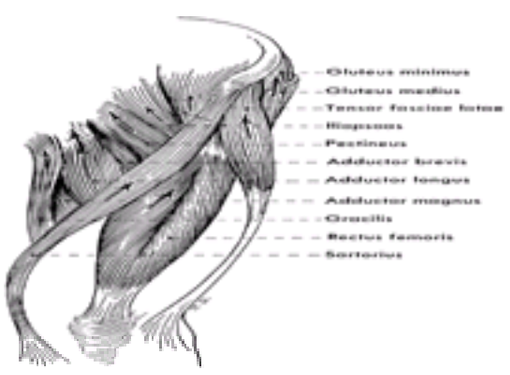

Figure 75-29. Flexors of the thigh. (Reprinted from Jenkins DB. *Hollinshead's functional anatomy of the limbs and back*, 6th ed. Philadelphia: Saunders, 1991:276, with permission.)

The rectus femoris is the one head of the quadriceps that arises from the pelvis and acts as a hip flexor. Two heads of origin attach to the anterior inferior iliac spine and an area just above the margin of the acetabulum. Rupture of the rectus femoris occurs in the young athlete after a forceful contraction of the quadriceps. The

sartorius is a long, straplike muscle that arises from the anterior superior iliac spine, forms the lateral boundary of the femoral triangle as it crosses the proximal thigh, and inserts on the medial tibia. Its action at the hip is flexion and lateral rotation. Rupture of the sartorius from its origin has been described in runners and presents as anterior hip/thigh pain.

The adductor compartment of the thigh consists of gracilis and three named adductors (e.g., brevis, longus, and magnus). All of the muscles originate from the pubis, are located medially in the proximal thigh, and insert into the femur. Sprains and ruptures occur with some frequency in dancers and athletes, particularly the adductor longus muscle.

The neurovascular bundle enters the anterior thigh beneath the inguinal ligament and enters an intermuscular space, the femoral triangle (Fig. 75-30). Pain is common in this region, and a knowledge of the contents of the femoral triangle is important in establishing an accurate diagnosis. The femoral artery can be felt pulsating at the midinguinal point, halfway between the anterior superior iliac spine and the pubic symphysis in the femoral triangle. A finger on the femoral pulse lies directly over the head of the femur, immediately lateral to the femoral vein and a finger's breadth medial to the femoral nerve. The relationship of the vessels and lymphatics within the femoral sheath are best remembered by the mnemonic *NAVEL* (nerve-artery-vein-empty space-lymphatic) (Fig. 75-31). A femoral hernia, more common in women than men, is a hernial sac that passes down the femoral canal and may form a swelling in the upper part of the thigh over the femoral triangle. The femoral artery initially lies in the femoral triangle and then enters an aponeurotic tunnel in the middle third of the thigh (adductor or subsartorial canal) opening through the adductor magnus (adductor hiatus) to enter the popliteal fossa. The upper 10 cm of a line joining the midinguinal point with a central point of the patella represents the artery in the femoral triangle, while the lower 15 cm of the same line defines the artery within the adductor canal. The canal also contains the femoral vein, the saphenous nerve, and the nerve to the vastus medialis. In the individual with femoral triangle pathology, many of these structures may be the source of pain.

Physiatric anatomic principles. *Phys Med Rehabil* 1996;10:605; as adapted from Ellis H. *Clinical anatomy: a revision and applied anatomy for clinical students*, 5th ed. Oxford, UK: Blackwell, 1971, with permission.)

Evaluation of the Patient Presenting with Hip or Gluteal Pain

Three characteristics of pain in the hip and gluteal region are particularly helpful in organizing the clinical evaluation: exacerbating factors, anatomic location, and temporal course of onset.

Organizational Approach. Most musculoskeletal pain is aggravated by local movement and relieved by rest. An individual who has mechanical hip disease most frequently complains of pain while weight bearing as the predominant symptom. Pain and a limp often accompany degenerative joint disease, inflammatory arthritides, a sprain or strain injury of muscle, a fracture, and ligament injury. Pain exacerbated by movement and mechanical loading suggests that there is an increase in tension or pressure in pain-sensitive load-bearing tissues. Pain that persists after activity suggests increasing pressure in a closed space, such as an increasing amount of purulent exudate within a joint capsule. Elucidating the source of pain requires a careful history and physical examination because there are many tissues that receive somatic pain afferents in the hip region (e.g., bone, capsule, synovial membrane, ligament, muscle, and tendon).

The referral of pain into the hip and gluteal regions may have an origin in a number of anatomic locations. Radicular low back pain with associated radiation to the hip and buttock regions occurs commonly. The pattern of pain referral varies depending on the level of nerve root impingement. Pain referral can be either in a sclerotomal or dermatomal pattern. Dermatomal patterns follow nerve root sensory innervation routes (e.g., L-3, L-4 root impingement refer to the anterior or medial hip, whereas L-5, S-1 root impingement refers to the posterior aspect of the hip). Sclerotomal patterns occur in the absence of nerve root impingement. For example, nociception from mesodermal tissues refers to other connective tissues derived from the same embryonic source. When a facet joint capsule or annulus fibrosus from L-5 or S-1 is stretched, pain may radiate into the sacroiliac area and buttocks.

Acute Atraumatic Pain

ACUTE ATRAUMATIC PAIN IN THE BUTTOCK. The major differential diagnoses to consider are presented here.

Claudication pain from internal iliac artery obstruction is usually seen in older adults. Symptoms occur as ischemia develops in the gluteal muscles and is progressively more severe as occlusion worsens. Pain with sustained contraction of the gluteal muscles assists with the diagnosis. Other physical signs of arteriosclerosis are often present in the lower limbs.

Referred pain from a herniated nucleus pulposus (L-5 and S-1) frequently presents as low back and buttock pain (see previous discussion). Provocative maneuvers that stretch the nerve root (straight-leg-raising test and Laséque's sign) reproduce the pain in the buttock and lower limb.

Ischial tuberosity bursitis is an inflammation of the bursa located between the gluteus maximus and underlying ischial tuberosity. Point tenderness over the ischial tuberosity is noted on physical examination.

Referred pain from pelvic disease sometimes is felt as pain in the buttock or posterior thigh. Pain such as that from prostate disease refers along the posterior

cutaneous nerve of the thigh since this somatic nerve arises from same segments as the pelvic parasympathetic nerves that innervate pelvic viscera.

ACUTE ATRAUMATIC PAIN IN THE LATERAL HIP. The major differential diagnoses to consider are presented here.

Trochanteric bursitis is usually a nonspecific, sterile inflammation of the subcutaneous trochanteric bursa (between the skin and the underlying muscle attachments to the greater trochanter) or the gluteus maximus bursa (between the gluteus maximus and the trochanter). Tenderness can be elicited by direct palpation over the greater trochanter. Resisted lateral rotation, abduction, and extension localize pain to the trochanter as well. Occasionally, bacterial infection, gout, or rheumatoid arthritis is the cause, and the appropriate laboratory tests should be conducted on aspirated fluid.

Iliotibial band overuse injury is often seen in dancers and is frequently confused with trochanteric bursitis. Pain is elicited by provocative maneuvers that stretch the iliotibial band such as passive adduction or lateral flexion of the trunk toward the uninvolved side.

Meralgia paresthetica is an entrapment neuropathy of the lateral cutaneous nerve of the thigh (L-2, L-3). The common entrapment points occur beneath the iliacus fascia and as the nerve pierces the inguinal ligament just medial to the anterior superior iliac spine. Pregnancy, obesity, tight-fitting clothing, and direct pressure from a body jacket are causes of meralgia paresthetica. Dysesthesia and often hypesthesia are present with light stroking of the skin within the distribution of the affected nerve.

ACUTE ATRAUMATIC PAIN IN THE ANTERIOR AND MEDIAL HIP REGIONS. Pain emanating from structures within the femoral triangle has already been described. There are also several muscles and associated bursae in the vicinity that may give rise to anterior or medial hip pain.

Lesser trochanter bursitis is an inflammation of the bursa found between the capsule of the hip joint and the overlying tendons of iliacus and psoas major. Provocative maneuvers stretch the overlying muscles (e.g., hip extension) or compress the bursa (adduction and flexion of the hip). Because there is occasionally a communication with the hip joint, intracapsular disease processes might affect the bursa as well. Aspiration of fluid and the appropriate diagnostic tests are necessary if pyogenic infection or rheumatic disease is suspected.

Psoas abscess or hematoma is occasionally present arising from disease in the spine or the retroperitoneal space. Pus arising from lumbar vertebrae tracks along the fascial sheath of the psoas major and presents as a painful swelling in the femoral triangle, sometimes being confused with a hernia.

In a *femoral hernia*, protrusion of peritoneum and intestine is forced through the femoral ring into the femoral canal, presenting as a painful mass. Careful auscultation often reveals bowel sounds, particularly early in the course prior to strangulation. Femoral hernias are more common in women than in men since the femoral ring is stretched in pregnancy and the normal septum of extraperitoneal tissue is no longer able to act as an effective partition in the abdominal wall.

Intraabdominal and intrapelvic disease processes may present as hip and thigh pain since muscles are sometimes directly irritated by visceral disease (e.g., inflammation from appendicitis irritating iliacus or psoas major). If there is significant muscle spasm, the resting posture of the lower limb is affected and stretching the affected muscle increases the pain.

Pyogenic and nonpyogenic arthritis are more common in children, although also seen in adults. A painful hip with fever is the usual presentation, although the diagnosis in an infant is much more challenging. Many organisms have been implicated. Historically, *Staphylococcus aureus* has been the most common organism in pyogenic infections. *Mycobacterium* is the most common nonpyogenic organism. Hematogenous spread, direct extension from osteomyelitis, and direct inoculation are all modes of entry into the joint. Permanent deformity and disability may result from acute septic arthritis if it is not detected early and treated aggressively. *Acute hematogenous osteomyelitis* sometimes precedes the development of a septic joint in children and is primarily a disease of growing bones. The metaphyseal region of the proximal femur is the most common site of infection and also leads to significant destruction of the hip joint if not diagnosed early and treated. The presentation is similar to septic arthritis in that the onset is acute and the infection progresses rapidly. Severe and constant pain in the hip is accompanied by unwillingness to bear weight on the affected limb.

Avascular necrosis occurs as a result of many disease processes that result in the interruption of blood supply to the femoral head. Fracture of the neck of the femur was discussed previously. There are many other diseases that mechanically interrupt the blood supply (e.g., slipped capital femoral epiphysis, hip dislocation), affect blood flow (e.g., sickle cell, arteriosclerosis), or result in secondary affects that impede blood flow (e.g., gout, radiation). Unilateral chronic hip pain is the typical presentation of avascular necrosis. Range of motion is normal until degenerative arthritis develops.

Rheumatoid arthritis is a chronic, systemic, inflammatory disease that chiefly affects the synovial membranes of multiple joints in the body (see Chapter 27). Pain and stiffness are characteristic complaints, particularly following a period of immobility. When the hip is involved, the synovium, surrounding bursae, and tendon sheaths are typically involved. The joint is painful in all areas and tender to palpation. Contractures develop and there is marked restriction of flexion and adduction.

Degenerative joint disease or osteoarthritis is a slow, progressive, articular disease that is characterized clinically by the gradual development of joint pain, stiffness, and limitation of motion. The most prominent pathologic change is the degeneration of articular cartilage. Osteoarthritis is classified as primary (or idiopathic) when it occurs without a known predisposing factor, or secondary when it follows an identifiable local or systemic underlying cause. The predominant symptom is progressive pain that is worse with mechanical loading of the joint and better with rest. There is tenderness to palpation in all areas of the hip. Typically, there is restricted range of motion in flexion, internal rotation, and abduction. The radiographic abnormalities of osteoarthritis include loss of joint space, appearance of subchondral bone cysts, formation of osteophytes, and eburnation (sclerotic bone formation). Osteoarthritis of the hip, also known as malum coxae senilis, usually occurs in older individuals. It may be unilateral or affect both sides; however, approximately 10% of unilateral cases progress to bilateral disease.

Crystal-induced arthropathies are debilitating illnesses seen worldwide and can be associated with a variety of other disease entities. Gout (inflammation caused by monosodium urate monohydrate crystals) is the most common crystal-induced arthritis. Pseudogout is an inflammatory disease caused by calcium pyrophosphate crystals. This disorder also causes acute and subacute monoarticular and pauciarticular arthritis. It has been associated with a variety of metabolic disorders, aging, and trauma. The hip is uncommonly involved in gout.

The *seronegative spondyloarthropathies*, previously called *rheumatoid variant diseases*, are a group of inflammatory joint disorders typically seronegative for rheumatoid factor and characterized by the involvement of sites of insertion of ligaments and capsules into bones (the enthesis). Clinical manifestations result in sacroiliitis, spondylitis (arthritis of the spine), and other abnormalities. This group includes ankylosing spondylitis, psoriatic arthritis, Reiter's syndrome, spondylitis associated with chronic inflammatory bowel disease, such as ulcerative colitis, and reactive arthritis following enteric bacterial infections (dysentery). All diseases in this group have a strong association with class I HLA-B27 antigen. The hip is involved in some of these diseases (e.g., ankylosing spondylitis) and bony ankylosis often results (see Chapter 27).

Pain in the Region of the Knee

To make a diagnosis in the patient who presents with pain in the region of the knee, one must have a detailed understanding of the anatomy of the knee and of the typical pain characteristics of each of the disease processes, as well as the physical examination skills to be able to elicit pain in the appropriate structures. In this section the anatomy of the knee is presented followed by a discussion of the more common causes of pain at the knee, with a subsequent discussion of the physical examination of the patient who presents with knee pain. Chapter 79 contains a detailed description of knee pain and its diagnosis and treatment.

Anatomy. The knee joint is commonly thought of as an articulation between the tibia and the femur, but the patellofemoral articulation should also be remembered.

Tibiofemoral Articulation. The articular surface of the distal femur can be broadly divided into a medial portion, a lateral portion, and a patellofemoral portion, which is somewhat more dorsal and in the midline (Fig. 75-32). In the sagittal plane the medial and lateral femoral condyles are cam shaped (i.e., they have a constantly changing radius of curvature). The posterior portion of the condyle has a shorter radius of curvature and the middle portion is most flat. The cam shape is important to the function of the knee in a number of ways. First, the cam shape determines the motion characteristics at the articular surfaces during flexion and extension. From a fully flexed position, as the knee extends, the joint surfaces of the tibia and the femur undergo a combination of rotation and gliding. The larger the radius of curvature of the cam, the greater the degree of gliding. Second, the cam shape does not allow there to be a single axis of motion in flexion and extension; the knee is therefore not a true hinge joint. The cam shape causes the actual instantaneous center of motion to change throughout the range of motion. Finally, the flattened portion of the cam of the femoral condyles is the portion that makes contact with the tibia during weight bearing in full extension. This flattened portion allows there to be a larger

surface area of contact and therefore reduced contact forces during weight bearing and ambulation.

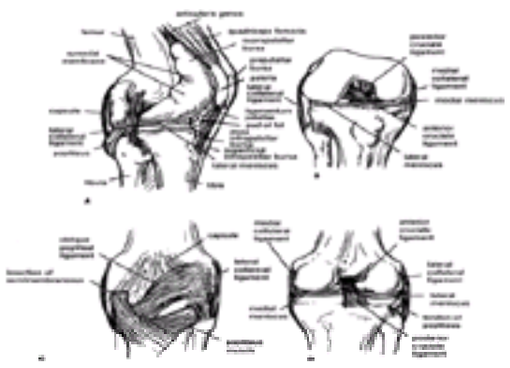

Figure 75-32. Right knee joint as seen from **(A)** lateral aspect, **(B)** anterior aspect, with joint flexed, and **(C,D)** posterior aspect. (Reprinted from Snell RS. *Clinical anatomy for medical students*, 5th ed. Boston: Little, Brown and Company, 1995:580, with permission.)

The articular surface of the proximal tibia consists of two elliptical areas that are shallow in contour and separated by a bony ridge called the intercondylar eminence. The two articular surfaces correspond to the medial and lateral femoral condyles. The depth and contour of the tibial articular surfaces do not correspond exactly to those of the femoral condyles. This is a disadvantage when one considers the optimization of surface area is important for minimizing focal abnormal loading of the articular cartilage. The menisci are paired semilunar or C-shaped cartilaginous structures that deepen the concavity of the tibial articular surface and thereby increase joint stability and the surface area of contact between the tibia and the femur. This minimizes abnormal loading of the articular cartilage. The intercondylar eminence forms the point of attachment of the *horns* of the menisci along with the tibial attachments of the anterior and posterior cruciate ligaments.

Ligaments. From the description of the architecture of the articular surfaces of the distal femur and proximal tibia, it is obvious that the tibiofemoral joint does not have a great degree of intrinsic stability. The stability of the joint is markedly augmented by strong ligamentous structures. Although there are many different ligaments, the four most important ligamentous structures that add to knee stability are the anterior and posterior cruciate ligaments and the medial and lateral collateral ligaments. The anterior cruciate ligament extends from the medial part of the posterior aspect of the lateral femoral condyle and travels distally and anteriorly toward the anterior aspect of the intercondylar eminence of the tibia. It functions to restrain anterior translation of the tibia on the femur as well as anterolateral rotation of the tibia on the femur. The posterior cruciate ligament travels from its origin on the anterior and lateral aspect of the medial femoral condyle to the posterior aspect of the intercondylar eminence of the tibia. Its function is to restrain posterior translation of the tibia on the femur and to limit hyperextension of the knee. The medial collateral ligament is a bandlike structure, which originates at the medial aspect of the medial femoral condyle above the joint line and attaches extensively on the medial aspect of the medial tibial condyle. The deep portion of this ligament has attachments to the medial meniscus and augments the stability of this structure. The major function of this ligament is to stabilize the knee to valgus stresses. The lateral collateral ligament is a cordlike structure that attaches to the prominence of the lateral femoral condyle above the joint line and attaches distally to the head of the fibula. This ligament stabilizes the knee to varus stresses.

Bursae. The knee has a number of bursal structures that may be a source of nociception at the knee. The function of the bursae at the knee as with bursae anywhere in the body is to reduce frictional forces between structures. Some of the bursae at the knee are subcutaneous and reduce friction between the external environment and underlying bony structures. Other bursae lie at deeper anatomic levels (e.g., between tendon and underlying bone and reduce frictional forces between these structures). From an anatomic perspective these bursae can also be divided by the anatomic regions of the knee where they lie: anterior, posterior, medial, and lateral. The anterior bursa includes the suprapatellar, the prepatellar, and the deep and superficial infrapatellar. The suprapatellar bursa lies superior to the patella on the anterior aspect and is continuous with the joint space. Therefore there is swelling in this bursa from any condition that causes a joint effusion. The remaining anterior bursae do not communicate with the knee joint. These include the prepatellar bursae, which is a subcutaneous bursa immediately superficial to the patella, the superficial infrapatellar, which is subcutaneous and immediately anterior to the patellar tendon, and the deep infrapatellar, which lies between the patellar tendon and the underlying portion of the proximal tibia. The posterior bursae include the semimembranosus bursa and the subpopliteal bursa. The semimembranous bursa is on the medial side of the popliteal fossa. It can exist either as a free bursa without a connection with the joint or as a projection of the synovial membrane of the knee joint. Its function is to reduce shear forces between the overlying semimembranosus tendon and the underlying gastrocnemius and posterior aspect of the tibia. Swelling in this structure results in a Baker's cyst, which can be seen as a swelling on the medial aspect of the popliteal fossa. The subpopliteal bursa, which is on the lateral side of the popliteal fossa, is a continuation of the synovium of the joint and is therefore in continuity with the joint. It lies immediately beneath the tendon of the popliteus, separating it from the underlying posterolateral corner of the lateral femoral condyle. The most important medial bursal structure at the knee is the pes anserine bursa. It lies at the proximal medial aspect of the tibia between the overlying pes anserine tendon, which is a common attachment of sartorius, gracilis, and semitendinosus, and the underlying flare of the medial tibial condyle, approximately 3 to 5 cm distal to the joint line. Two small bursae have been described on the lateral side of the knee—one that is located between the lateral collateral ligament and the lateral femoral condyle and one that is located between the lateral collateral ligament and the tendon of biceps femoris. These bursae are much less commonly involved in pathologic processes and therefore are much less commonly a source of nociception.

Patellofemoral Joint. The patellofemoral joint is an articulation between the distal femur and the undersurface of the patella (Fig. 75-33). The patella is a heart-shaped osseous sesamoid bone: It is formed within the tendon of the quadriceps muscle. The articular surface of the patella is posterior. It is typically divided into medial and lateral facets that articulate with the trochlea of the femur. The trochlea of the femur is the distal anterior portion of the femur. It is V shaped in the transverse plane corresponding to the complementary shape of the undersurface of the patella. The V-shaped structure assists the patella in *tracking* optimally on the distal femur during flexion and extension movements of the knee. The primary function of the patellofemoral joint is to act as a pulley and redirect the pull of the quadriceps muscle. As the quadriceps tendon passes over the patella and continues distally to its attachment on the tibial tuberosity, the patella redirects its pull to increase the effective torque of the muscle, especially in the last 10 to 15 degrees of extension.

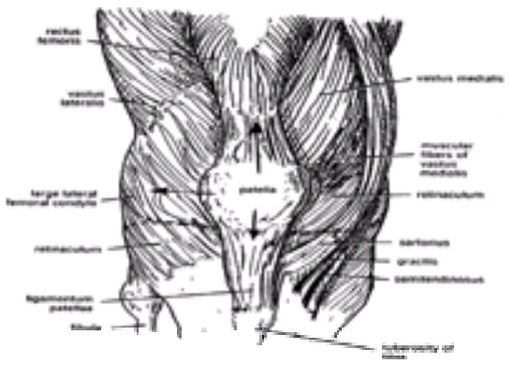

Figure 75-33. The quadriceps femoris mechanism. The lateral and upward pull of the powerful rectus femoris and the vastus lateralis muscles on the patella is counteracted by the lowest horizontal muscular fibers of the vastus medialis and the large lateral condyle of the femur, which projects forward. (Reprinted from Snell RS. *Clinical anatomy for medical students*, 5th ed. Boston: Little, Brown and Company, 1995:528, with permission.)

Muscles Acting at the Knee. The muscles that act across the knee can be broadly defined into extensor and flexor groups. The extensor group is the large quadriceps muscle, which includes the vastus lateralis, vastus medialis, vastus intermedius, and the rectus femoris (Fig. 75-34 and Fig. 75-35). These muscles have their origin on the femur, with the exception of the rectus femoris, which also crosses the anterior hip joint to attach near the anterior inferior iliac spine on the anterior aspect of the pelvis. The muscles come together to form a common tendon, the quadriceps tendon, that inserts into the proximal aspect of the patella. The tendinous continuation of these muscles is the patellar tendon, which originates on the inferior pole of the patella and attaches to a roughened area on the anterior aspect of the proximal tibia. The function of the quadriceps is to actively extend the knee or to control the rate of knee flexion under load. Concentric contraction occurs during

rising from a seated position, climbing stairs, or jumping upward. Eccentric contractions are those that are energy absorbing. Examples of eccentric contractions are climbing down stairs, sitting down from a standing position, or decelerating after a jump. In each of these cases the function of the quadriceps is to control or decelerate the mass of the body. The hamstring muscles, semimembranosus, semitendinosus, and biceps femoris are the most important posterior muscles of the thigh. They all have their origin on the ischial tuberosity at the posterior aspect of the pelvis, with the exception of biceps femoris, which has a second head that also has an origin on the posterior femur. Their insertions include the head of the fibula for biceps femoris, posteromedial aspect of the medial tibial condyle for semimembranosus, and the pes anserine tendon, which inserts on the medial tibial flare, for semitendinosus. The function of the hamstrings, as with the quadriceps, can be divided into concentric and eccentric functions. The concentric function results in active flexion of the knee and the eccentric function is to decelerate and control the forward progression of the tibia. A good example of the eccentric function is in the second half of the swing phase of gait when the hamstring decelerates the forward swinging tibia and foot prior to the next heel contact. The only other muscles that act across the knee are tensor fascia lata, popliteus, and gastrocnemius. Tensor fascia lata, which has its origin on the anterolateral aspect of the iliac crest, inserts into the iliotibial band. The iliotibial band passes on the lateral aspect of the lateral femoral condyle and the lateral knee joint line to insert onto a small bony prominence on the anterolateral aspect of the lateral tibial condyle. The insertion of this tendon and the location of the tendon near the axis of the knee joint give this muscle its relatively complicated functional characteristics. With the knee in full extension the iliotibial band passes anterior to the knee joint, allowing it to function as an accessory knee extensor. However, with the knee flexed greater than 25 degrees, the tendon of the iliotibial band passes posterior to the knee joint and therefore it functions as an accessory knee flexor. The popliteus muscle is a small triangular muscle that has its origin on the prominence of the lateral femoral condyle, and it passes downward and posteriorly to attach into the posterior proximal aspect of the tibia. Its function therefore is to externally rotate the femur on the tibia. The gastrocnemius muscle, which is primarily an ankle plantarflexor, also has weak actions at the knee. It must be remembered that the gastrocnemius muscle has its origin on the posterior aspect of the medial and lateral femoral condyles. The muscle belly travels distally toward the ankle in the posterior aspect of the knee. Because this muscle crosses the knee joint and it travels posterior to the knee axis, it functions as a week knee flexor.

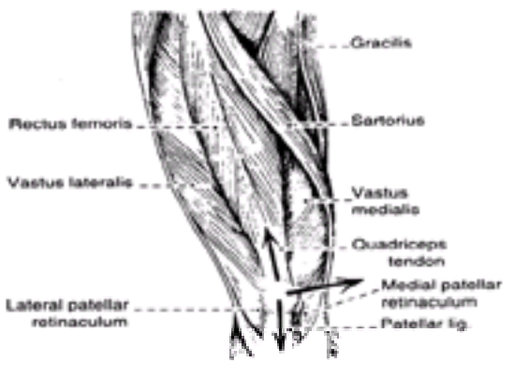

Figure 75-34. The quadriceps: The rectus femoris conceals the vastus intermedius. Note the insertion of some fleshy fibers of the vastus medialis into the medial side of the patella, which helps balance the pull on the patella by the quadriceps tendon and the patellar ligament. Arrows indicate directions of pull. (Reprinted from Rosse C, Gaddum-Rosse P, eds. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:356, with permission.)

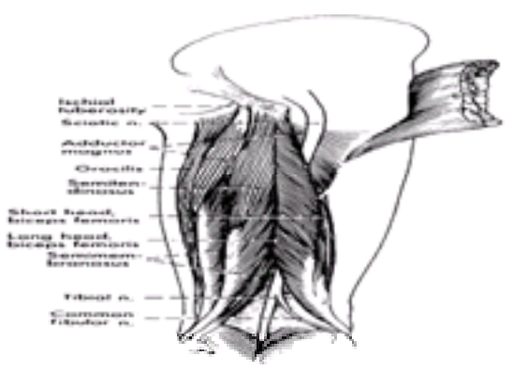

Figure 75-35. The posterior (hamstring) muscles of the right thigh. Gracilis, also shown here, belongs to the adductor group. (Reprinted from Rosse C, Gaddum-Rosse P, eds. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:362, with permission.)

Innervation. The innervation to the knee joint is derived from the major nerves that travel in proximity to the joint. There are branches from the femoral and saphenous nerves on the anterior and medial aspect and from the tibial nerve in the posterior aspect. Anterior pain at the knee joint may originate in the hip joint, which shares a common intervention with the anterior aspect of the knee, or by processes affecting the femoral nerve itself. Posterior pain in the knee in contrast may have its origin in processes that affect the tibial nerve or the first sacral nerve root.

Blood Supply. Blood supply to the knee is primarily through a vascular anastomosis involving the medial and lateral branches of the superior and inferior geniculate arteries, which are branches of the popliteal artery. This anastomosis is reinforced by some branches from the femoral and tibial arteries.

Evaluation of the Patient Presenting with Knee Pain

History and Physical Examination. As with most of musculoskeletal medicine, the diagnosis is made on the basis of establishing a history and performing a physical examination. The key elements of the history include pain location, severity, onset, aggravating factors, relieving factors, and associated factors. In the knee the associated factors that must be considered include weakness, sensory deficit, locking, and instability. An understanding of these elements usually allows the clinician to elucidate the underlying process that is leading to pain.

The physical examination of the patient presenting with knee pain should include an examination of both the intact and affected extremity. Because of the considerable variability in what is considered normal motion, strength, and ligamentous stability, the examination of the intact extremity allows one to determine what is normal for that individual. Depending on the nature of the presenting complaint and what is found on the examination of the knee, a more comprehensive examination of other joints as well as a neurovascular examination may be necessary to establish the diagnosis. Most of the local examination of the knee uses observation, palpation, and the performance of specific examination maneuvers that test the integrity of specific musculoskeletal structures and whether or not mechanical stress elicits pain.

Organizational Approach. There are a number of organizational schemes that are useful in assisting the clinician in arriving at a diagnosis. A useful organizational structure that can be used is to broadly define the pain in terms of its acuity versus chronicity, whether the origin is traumatic or atraumatic, and to determine the anatomic location of the pain. Acute pain has an origin of less than 24 hours in duration, while subacute or chronic pain has a longer period of onset and duration. A traumatic origin is that which has a sudden onset with clearly defined trauma, while nontraumatic pain may have its origin in mechanical loading and stress but the onset is not associated with a singular sudden traumatic event. The anatomic location of knee pain can be categorized as generalized, anterior, posterior, medial, or lateral.

Acute Atraumatic Generalized Pain. The patient presents with relatively sudden onset of pain that is experienced diffusely in the knee. When asked, the patient is unable to point with a single finger to any particularly painful region of the knee. The major differential diagnoses to consider are presented here.

CRYSTAL-INDUCED ARTHROPATHY (GOUT AND PSEUDOGOUT). There are a number of different crystals that may produce joint symptoms. The two most common are calcium pyrophosphate dihydrate, which produces symptoms of pseudogout, and monosodium urate monohydrate, which produces symptoms of gout (see Chapter

27).

Pseudogout most commonly occurs in a patient middle aged or older. Symptoms typically begin with recurrent acute bouts of joint pain and swelling. There may be secondary degenerative changes leading to chronic, subacute pain. The onset of the acute attack may be associated with surgery or severe acute medical illness.

Gout is the acute attack of joint swelling and pain as the result of deposition of disodium urate crystals within the joint. Classically, these symptoms begin at night and most commonly occur in the first metatarsophalangeal joint, but any joint, in particular other lower extremity joints, may be involved. As with pseudogout, the attack may be exacerbated by external environmental stressors.

SEPTIC JOINT. The knee is the most common joint involved in sepsis. The acuity of the onset of symptoms in a septic joint is dependent on the organism involved. In the majority of cases gram-positive cocci are the etiologic agent. Mycobacterium or fungi have a more subacute onset. Septic joints are seen at either extreme of age—childhood or senescence—and are more frequently seen in patients with a history of intravenous drug abuse, a history of intraarticular injection or aspiration, the presence of a joint arthroplasty, or trauma to the overlying soft tissue that allows bacterial invasion.

PALINDROMIC RHEUMATISM. The etiology of this syndrome is not known; some patients evolve into clinical diagnoses of rheumatoid arthritis or systemic lupus erythematosus. Its typical age of onset is in the fourth to sixth decade.

The presentation in each of these conditions is that of the acute onset of severe pain and effusion, often with warmth or redness of the overlying skin. There is little to differentiate the different disorders on physical examination. The patient with a septic joint may be febrile; fever is not associated with the other conditions. The knee is typically held in a flexed position if the patient is able to weight bear through the affected limb. There is an antalgic gait pattern with a shortened stance phase on the affected side. On palpation there is diffuse tenderness, and pain is exacerbated if the joint is taken through a range of motion. The range of motion is restricted in both flexion and extension.

The typical investigative procedure is to obtain radiographs and a complete blood count with differential and perform joint aspiration. The aspirate should be analyzed for a white count, Gram's stain and culture, and the presence of crystals.

Acute Traumatic Generalized Pain. The patient usually presents with the history of significant injury with immediate onset of pain. The pain is diffuse throughout the region of the knee and is difficult to localize to any single anatomic area.

The major differential diagnoses to consider are presented here.

FRACTURE WITH HEMARTHROSIS. Significant trauma to the lower extremity from a fall or direct impact to the extremity can result in bony injury to the distal femur, proximal tibia, or the patella. Fractures that do not involve the joint can usually be somewhat localized by the patient. However, fractures that extend into the joint space can result in a tense effusion secondary to bleeding into the joint space. As the pressure from the effusion increases, there is increasing diffuse generalized pain in the knee.

LIGAMENT INJURY WITH HEMARTHROSIS. The most common ligament injury to result in an acute hemarthrosis is an anterior cruciate ligament injury. This is an intracapsular structure within the knee that is supplied by a vessel within its body. A complete ligament injury results in disruption of the vessel; since it is an intraarticular structure, blood collects within the joint space resulting in a tense effusion. The most common mechanisms of injury are an acute hyperextension injury or a flexion rotation injury. The anterior cruciate ligament may be injured in sport activities, industrial accidents, and, to a lesser extent, motor vehicle accidents. Commonly, there is an audible *pop* at the time of injury as the ligament is disrupted.

The patient tends to keep the knee flexed approximately 30 degrees. Fracture makes it unlikely that the patient will be able to bear weight. Pain limits any effort at examination. Radiography reveals a fracture, is normal, or shows evidence only of an effusion with an anterior cruciate ligament injury. The joint may be aspirated to decrease pain. If this is done and the radiographs are normal, further physical examination maneuvers, in particular Lachman's test, which creates an anterior translation of the tibia on the femur, may reveal abnormal laxity secondary to the anterior cruciate ligament injury.

Subacute or Chronic, Atraumatic, Generalized Pain. These conditions are processes that result in a diffuse synovitis and a subsequent joint effusion without involvement of specific localized anatomic structures. The major differential diagnoses to consider are degenerative arthritis, rheumatoid arthritis, seronegative spondyloarthropathies, chronic crystal-induced arthropathies, and other less common collagen vascular disorders (see Chapter 27).

DEGENERATIVE ARTHRITIS OR OSTEOARTHRITIS. This is probably the most common cause of joint pain in the older patient population. Degenerative arthritis can be either primary or secondary. In patients with primary degenerative arthritis there is usually multiple joint involvement including the spine, hips, knees, and proximal interphalangeal and distal interphalangeal joints of the hands. It is usually symmetric. Secondary degenerative arthritis is either monoarticular or pauciarticular and involves joints with a preceding history of injury that predisposes the joints to secondary changes. The knee and hip are commonly involved in secondary degenerative arthritis. The patient typically presents with a history of progressive onset of pain over weeks, months, and years. The pain is aggravated by activity and relieved by rest. There may be a history of stiffness of the joint, particularly after a period of rest, which is clinically referred to as *gelling.* On physical examination the joint may have a mild flexion contracture. Typically, there is a mild to moderate effusion with pain at the end of range of motion. There may be palpable osteophytes at the joint margin and pseudolaxity secondary to loss of articular cartilage height.

RHEUMATOID ARTHRITIS. Rheumatoid arthritis is an autoimmune disease that affects women more than men, with an onset typically in young adulthood or middle age. It is a symmetric polyarticular disease with involvement of the small joints of the hands and feet, which also commonly symmetrically involves the wrists, ankles, knees, and elbows. Associated symptoms include morning stiffness and general constitutional symptoms of fatigue. On examination the joints are swollen and warm to palpation, and the small joints may be erythematous. Ultimately, with chronic rheumatoid arthritis, typical deformities of the hands, wrists, and feet develop.

SERONEGATIVE SPONDYLOARTHROPATHIES. Included in this group are ankylosing spondylitis, enteropathic arthritis, psoriatic arthritis, and Reiter's syndrome.

Enteropathic arthritis and ankylosing spondylitis are uncommon causes of knee pain. They predominantly involve the spine, the sacroiliac joints, and the hips. They can be a cause of knee pain, but typically there is obvious involvement of other structures at the time of presentation.

Reiter's syndrome is a subacute disorder associated with gut infections with organisms such as *Shigella*, *Salmonella*, or *Campylobacter*. It is also associated with chlamydial infections of the urinary tract. This syndrome results in arthritis, conjunctivitis, and urethritis. The joint involvement tends to be asymmetric, involving lower extremity joints with evidence for a synovitis with pain, effusion, and warmth.

Psoriatic arthritis has a number of variant forms that involve varying distributions of the spine, sacroiliac joints, and peripheral joints. One variant with peripheral joint involvement includes a symmetric process involving the distal interphalangeal joints of the hand. There is also a variant that causes a pauciarticular arthritis that may involve the knees. From a diagnostic perspective, essentially all patients have evidence for cutaneous involvement with psoriasis.

Acute Traumatic Regional Pain Syndromes

ACUTE TRAUMATIC ANTERIOR KNEE PAIN. The most common diagnoses that result in acute anterior knee pain include quadriceps tendon rupture, patellar tendon rupture, fracture of the patella, and dislocation or subluxation of the patella.

Quadriceps or patellar tendon rupture can occur at any age, although it is more common in younger individuals. Typically, the mechanism of injury is that of forced flexion of the knee in conjunction with a powerful contraction of the quadriceps mechanism. This might occur after a stumble or during sports activities. Associated problems that predispose to rupture include diabetes, corticosteroid use, or local injections of corticosteroids. Clinically, the patient presents with severe anterior knee pain with an inability to extend the knee. There is local swelling and tenderness in the area of rupture and a palpable defect. In the case of quadriceps tendon rupture, these physical examination features are present at the proximal edge of the patella, while in the case of the patellar tendon rupture they are seen between the inferior pole of the patella and the tibial tuberosity.

Fracture of the patella can occur secondary to direct trauma such as in the case of a fall on the flexed knee. It can also occur in a similar mechanism to quadriceps tendon rupture or patellar tendon rupture.

Dislocation or subluxation of the patella can occur when the patella subluxes or dislocates from its anterior position at the distal femur. Typically, the patella dislocates laterally. The mechanism of injury is one of forcible use of the quadriceps while the foot is planted on the ground, the knee is flexed, and the femur internally rotates on the tibia. In this position the patella is free from the trochlea of the distal femur and the pull of the quadriceps has a marked laterally directed force vector. The diagnosis is made by observation of the patella on the lateral aspect of the knee in the case of dislocation, although commonly the patella returns to its original position as the knee is extended. In this case anterior knee pain is present with an effusion and pain in the peripatellar region with a positive apprehension sign. The apprehension sign is positive when the clinician attempts to slide the patella laterally, reproducing the position of subluxation or dislocation, which creates distress in the patient.

ACUTE TRAUMATIC MEDIAL KNEE PAIN. The two most important considerations here are a medial collateral ligament injury or a medial meniscus injury.

Medial collateral ligament injury is the most common ligament injury at the knee. It occurs most commonly when there is a lateral impact to the knee region with the foot planted on the ground. The symptoms and presentation vary somewhat with the severity of the tear, but generally speaking there is an acute onset of medial knee pain; over the course of hours to days an effusion may develop, in conjunction with localized swelling, ecchymosis, or both on the medial aspect of the knee. Ligament assessment reveals varying degrees of laxity, while a valgus stress test is applied to the knee at 30 degrees of knee flexion.

Medial meniscus injuries occur in two circumstances: first, during sporting or vocational activities where there is a significant torsional stress to the knee with the foot planted on the ground, and second, during functional tasks that cause the knee to be hyperflexed as occurs during some lifting activities from the floor. The usual presentation is localized medial knee pain with the development of a knee effusion over 24 to 48 hours. Symptoms commonly subside spontaneously, although they may recur with locking of the knee and associated pain. Occasionally, the patient presents with the knee locked at some degree of flexion and with an inability to bend or straighten it from this position. In this context the meniscus is trapped between the articular surfaces of the tibia and femur with associated pain. Physical examination reveals a knee with a trace to moderate effusion and marked local tenderness on the medial joint line, with or without a positive McMurray's test.

ACUTE TRAUMATIC LATERAL AND POSTERIOR KNEE PAIN. Acute pain in these regions is much less common than anterior or medial. Acute lateral collateral ligament injuries can occur but are much less common than medial. The mechanism of lateral collateral ligament injury is an impact to the medial aspect of the knee with the foot planted. Similarly, the incidence of lateral meniscal lesions is also much less common than medial.

Pain in the Region of the Foot and Ankle

Anatomy. The foot and ankle include many osseous, articular, ligamentous, muscular, and soft tissue structures that allow for the complex functional tasks involved in gait and other bipedal activities. These are discussed in detail in Chapter 80. There are a number of key surface anatomic landmarks that can be identified on observation. The malleoli are prominent bony structures on the medial and lateral aspects of the ankle. The lateral malleolus is the distal portion of the fibula, while the medial malleolus is the distal and medial portion of the tibia. The tendons of the long flexors of the toes and the tibialis posterior tendon along with the posterior tibial artery and the tibial nerve pass posterior to the medial malleolus, while the tendons of the peroneus longus and brevis pass posterior to the lateral malleolus. The tendon at the posterior aspect of the ankle is the combined tendon of the gastrocnemius and soleus. There are a number of tendons that pass anterior to the ankle joint, including the tibialis anterior and the extensors of the hallux and the toes. The continuation of the peroneal nerve also passes anterior to the ankle along with the dorsalis pedis artery, which lies immediately lateral to the tibialis anterior tendon. From an architectural perspective the foot is made up of three arches: the medial and lateral longitudinal arches and the transverse arch. The arches of the foot are typically maintained through the underlying architecture of the osseus and articular structures that are supported passively through ligamentous structures and dynamically through a musculotendinous support system (Fig. 75-36). The medial longitudinal arch is obvious on the medial side of the foot. Its curvature is typically diminished during weight bearing. The transverse arch passes in a medial-lateral direction at the level of the metatarsal heads. The soft tissues of the plantar surface of the foot have a specialized architecture designed to dissipate the forces associated with weight bearing and propulsion. The superficial fascia is attached to the underlying plantar aponeurosis by connective elements or septa. There is adipose tissue that is loculated in these spaces and helps to function as *hydraulic* shock absorbers.

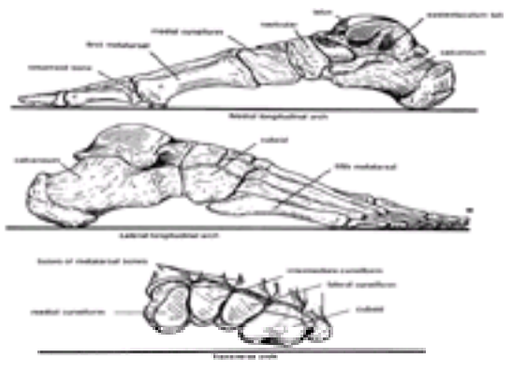

Figure 75-36. Bones forming medial longitudinal, lateral longitudinal, and transverse arches of the right foot. (Reprinted from Snell RS. *Clinical anatomy for medical students*, 5th ed. Boston: Little, Brown and Company, 1995:589, with permission.)

Hindfoot. The hindfoot osseus structures include the distal portions of the tibia and fibula, the talus, and the calcaneus. The two major articular structures in the hindfoot are the ankle or talocrural joint and the subtalar joint. The ankle joint is the articulation between the distal portions of the tibia fibula and the talus. From a structural perspective, this joint is commonly referred to as a mortise and tenon joint. The *mortise* component is made up of the medial malleolus, which is a non–weight-bearing structure; the tibial platform, which is the weight-bearing structure of the distal tibia; and the non–weight-bearing surface of the lateral malleolus. The *tenon* is made up of the dome of the talus. This joint tends to be a stable joint based on the architecture of the interlocking mortise and tenon. Because the dome of the talus is wider anteriorly than posteriorly, the osseus structures fit more tightly in a dorsiflexed position and the joint is therefore even more stable in a dorsiflexed than in a plantarflexed position. The major ligamentous support for the talocrural joint is through the medial and lateral ligament complexes. The medial ligament is the deltoid ligament, which attaches from the tip of the medial malleolus fanning out distally to attach from the medial aspect of the navicular, talus, and calcaneus. The lateral ligament complex comprises three distinct structures: the anterior talofibular ligament, which spans from the tip of the lateral malleolus to the talus, the calcaneofibular ligament, which travels from the lateral aspect of the calcaneus to the tip of the lateral malleolus, and the posterior talofibular ligament, which travels from the talus anteriorly toward the tip of the lateral malleolus. The motions that occur at the ankle joint are predominantly the sagittal plane motions of dorsiflexion and plantarflexion. The muscle groups that produce plantarflexion are the powerful gastrocnemius and soleus, and to a lesser extent the long toe flexors, tibialis posterior, and peroneus longus and brevis. The muscle groups that produce dorsiflexion are tibialis anterior and to a lesser extent the extensors of the toes.

The subtalar joint is an articulation between the undersurface of the talus and the dorsal aspect of the calcaneus. The articular surface is divided into three components or facets. Together these facets allow the calcaneus to glide in a medial-lateral direction underneath the talus. This motion is called hindfoot inversion (medial) and hindfoot eversion (lateral). The muscle groups that cause these motions are tibialis anterior and tibialis posterior, and peroneus longus and brevis, respectively.

The hindfoot performs a number of important functions during ambulation. During walking the foot typically makes contact on the posterolateral corner of the heel. The foot is dorsiflexed and in inversion. The impact of heel contact is absorbed in part by the specialized anatomic structures of the heel pad and by eccentric contraction of the tibialis anterior, which controls the rate of ankle plantarflexion at heel contact, and by eccentric contraction of the tibialis posterior, which controls pronation. In midstance phase the ankle plantarflexors contract eccentrically, controlling the forward rotation of the stance phase leg into dorsiflexion. Finally, in late stance phase a powerful contraction of the ankle plantarflexors generates a push-off function, which, along with the hip flexors, accelerates the leg forward into swing phase.

Midfoot. The midfoot osseus structures include the navicular medial cuneiform, intermediate cuneiform, and the lateral cuneiform, along with the cuboid. These

osseus structures articulate between themselves but also articulate with the talus and calcaneus proximally and the metatarsals distally. These complex articulations are commonly divided into two functional joints. The functional joints include the calcaneocuboid and the tarsometatarsal joints. These articulations allow the forefoot to be abducted and adducted on the hind foot and also allow rotations of the midfoot along the longitudinal axis of the foot. During the stance phase of walking, the alignment of these joint axes determines the rigidity of the midfoot. During early to midstance phase as the foot is pronated, the axes of these joints are aligned and therefore a greater level of mobility is allowed. The foot therefore is more supple during this portion of stance phase, which allows it to absorb medial lateral forces and allows the foot to accommodate to irregular terrain. In mid- to late stance phase the foot tends to supinate, which causes the axes of the calcaneocuboid and tarsometatarsal joints to become oblique to one another and results in a more rigid midfoot. This is of functional importance because the key functional necessity of the foot and ankle complex is power generation by the gastrocnemius soleus and transfer of energy across the foot to the ground. A more rigid midfoot at this point in the gait cycle allows for more efficient force transmission.

Forefoot. The forefoot osseus structures include the metatarsals and the phalanges. The joints of this region of the foot are the metatarsophalangeal joints and the interphalangeal joints. The motions of the metatarsal joints are predominantly into flexion and extension. The prime movers of these joints into flexion are the short toe flexors, which originate in the foot, and the long toe flexors, whose muscle bellies arise within the leg and pass posterior to the medial malleolus into the plantar aspect of the foot and subsequently attach to the toes. The prime movers of the joints into extension are similarly the long and short extensors. The short extensor—extensor digitorum brevis—arises from the dorsal aspect of the tarsals and attaches to the extensor expansion of toes 2 through 4 and the base of the proximal phalanx of the first toe. The long extensors—extensor hallucis longus and digitorum longus—arise on the leg and travel anterior to the ankle joint onto the dorsum of the foot and to the toes. The tendons are restrained as they pass near the ankle by retinacula, which function to prevent *bowstringing* of the tendons.

Blood Supply and Innervation of the Foot. The blood supply to the foot is based on two major arteries. The dorsalis pedis is typically the continuation of the anterior tibial artery in the leg, and the posterior tibial artery is the continuation of a vessel by the same name. The dorsalis pedis artery crosses the anterior aspect of the ankle just lateral to the tibialis anterior tendon and continues into the foot over the medial tarsal bones, where it subsequently lies in the space between the first and second metatarsal. A major branch travels laterally at the level of the proximal metatarsals from which each of the common digital arteries branches off and travels toward its respective web spaces. The posterior tibial artery crosses the ankle with a number of tendons on the posterior aspect of the medial malleolus. The artery divides into a medial and lateral branch. The medial branch travels distally toward the great toe, while the lateral branch travels distally and laterally, forming a plantar arch that divides into the digital arteries. Typically, there are connections between the plantar and dorsal vascular arches.

The innervation of the foot comes from four major nerves. The saphenous nerve, which is a continuation of the femoral nerve, travels down the medial aspect of the leg and supplies sensation to only the medial malleolar region of the ankle. The sural nerve is also a pure sensory nerve that travels down the midline of the leg in a subcutaneous position posterior to the lateral malleolus and supplies sensation to the lateral aspect of the foot and the fifth toe. The deep peroneal nerve travels in the anterior compartment of the leg, traveling across the anterior aspect of the ankle joint to provide sensation to the majority of the dorsum of the foot. The superficial peroneal nerves and the tibial nerve are mixed nerves. The superficial peroneal nerve travels in the lateral compartment of the leg and crosses the anterior aspect of the ankle, where it sends a motor branch to extensor digitorum brevis and subsequently continues distally to the first web space, where it functions as a sensory nerve. The tibial nerve courses posterior to the medial malleolus at the ankle along with the flexor tendons and the posttibial artery. All of these structures pass under a flexor retinaculum, which prevents subluxation. Immediately on exiting under the flexor retinaculum, the nerve divides into a number of branches. The medial and plantar nerves travel distally in the foot, supplying motor function to the intrinsic muscles of the foot and sensation to the medial and lateral aspects of the sole of the foot.

Evaluation of the Patient Presenting with Foot and Ankle Pain

History and Physical Examination. As previously mentioned, the key element to successful musculoskeletal diagnosis is through the history and performing a physical examination. The key element of the history is to define the character of the pain, including location, severity, onset, aggravating factors, relieving factors, and associated factors.

The physical examination of the patient presenting with foot or ankle pain, as with all articular structures, generally includes an examination of both the intact and affected extremity. Depending on the nature of the presenting complaint and what is found on the examination of the knee, a more comprehensive examination of other joints as well as a neurovascular examination may be necessary to establish the diagnosis. Most of the local examination of the foot and ankle involves observation, palpation, and the performance of specific examination maneuvers that test the integrity of specific musculoskeletal structures and whether or not mechanical stress elicits pain. These painful conditions are discussed in detail in Chapter 80.

Acute Atraumatic Hindfoot Pain. The differential diagnosis is similar to this classification at the knee. Acute atraumatic pain in the hindfoot is typically the result of bone or joint inflammation from infection, rheumatoid arthritis, seronegative spondyloarthropathies, or crystal-induced arthritis (see Chapter 27). The ankle and subtalar joints are less commonly involved in rheumatoid arthritis, and when involved, the involvement is usually symmetric in both lower extremities, and it usually occurs in the later stages of the disease. Similarly, pseudogout is relatively uncommon in the hindfoot articulations, but it has been described in these areas. Gout is relatively common in the ankle and has been reported to occur in up to 50% of cases. In all of these conditions, the presentation is one of pain, limitation of motion, limited weight bearing, warmth, erythema, and joint effusion.

Acute Atraumatic Midfoot Pain. The differential diagnoses to be considered are similar to hindfoot pain. Involvement of the intertarsal joints in these processes is much less common.

Acute Atraumatic Forefoot Pain. Rheumatoid arthritis commonly presents with a symmetric distal polyarthritis involving the small joints of the hands and feet. It is relatively common, therefore, to experience inflammatory involvement of the metatarsophalangeal and proximal interphalangeal joints of the toes. The presence of multiple joint involvement, especially involving the joints of the hands and feet, in the presence of general systemic features in conjunction with morning stiffness, should assist the clinician in arriving at this diagnosis. Gout is the most common crystal-induced arthritis to result in acute atraumatic pain and joint dysfunction in the foot. The most common joint involved is the first metatarsophalangeal joint. The presentation, as previously noted, is classically an onset at night with joint effusion, pain, redness, and limitation of range of motion.

Subacute Chronic Hindfoot Pain. Chondral or osteochondral fracture of the talar dome may occur with an inversion injury to the ankle because of impact with the medial aspect of the lateral malleolus. The typical history is one where there has been an inversion strain to the ankle and there is a lack of resolution of symptoms. The patient typically presents with pain that is aggravated by activity and relieved by rest and is located in the anterior or anterolateral portion of the ankle joint. On physical examination there may be a persistent ankle effusion with pain at the end of range of motion. There are few characteristic features that allow this diagnosis to be made on physical examination alone. A high index of suspicion is required to order the appropriate diagnostic tests. If the fracture includes the subchondral bone it may be visible on radiography; if, however, it involves only the articular cartilage, computed tomographic scan or magnetic resonance imaging may be necessary for diagnosis.

Retrocalcaneal bursitis occurs in the retrocalcaneal bursa, which lies between the Achilles tendon and the posterior aspect of the calcaneus at the point of insertion of the Achilles tendon on the calcaneus. *Superficial calcaneal bursitis* occurs in the superficial calcaneal bursa, which lies between the subcutaneous tissues and the posterior aspect of the calcaneus near the attachment of the Achilles tendon. These bursae may become inflamed and painful due to mechanical pressure from footwear.

Sever's disease is an osteochondritis similar to Osgood-Schlatter's disease at the tibial tuberosity, except that it involves the epiphyseal plate at the posterior aspect of the calcaneus. This condition results in pain at the posterior aspect of the heel. It typically occurs in a child about 8 years old. Physical examination reveals localized tenderness as well as pain on forced plantar flexion.

Achilles tendinitis, inflammation in the Achilles tendon, is usually the result of an overuse injury or repetitive trauma injury. It results in the subacute onset of pain in the Achilles tendon proximal to the calcaneus. Stiffness and crepitance may be associated complaints. Contributing biomechanical factors include excessive foot pronation and heel cord contracture. On physical examination there is usually localized tenderness to palpation and pain on resisted ankle plantarflexion and on passive ankle dorsiflexion. There may palpable crepitance or thickening in the tendon.

Subluxing peroneal tendons most often are secondary sequelae of inversion injury to the ankle with disruption of the connective tissue retinaculum at the lateral ankle. Inflammation and pain in the peroneal tendons result from this injury. Physical examination findings include local tenderness of the peroneal tendons at the lateral ankle, with subluxation of the tendons on resisted dorsiflexion and eversion of the foot. Peroneal tendinitis can occur as an overuse syndrome in the absence of

subluxation.

Tibialis posterior tendinitis is most commonly an overuse syndrome. The usual location of pain is at the medial aspect of the distal one-third of the leg, although pain may be localized to any portion of the tendon including its position posterior to the medial malleolus and near its insertion on the medial plantar aspect of the navicular. Associated biomechanical factors include abnormal pronation with hindfoot valgus. Physical examination findings that suggest tibialis posterior tendinitis include pain in the appropriate location along the medial aspect of the tibia, at the posterior aspect of the medial malleolus, or near its insertion on the navicular. Pain is increased, with the appropriate mechanical stressors to the tendon including maximum resistance and maximum stretch of this muscle group.

Plantar fasciitis is a condition that results in pain and limitations in ambulation. There is pain on the plantar surface of the foot near the calcaneus and in particular on the medial aspect of the insertion of the plantar fascia on the calcaneus. It is discussed in Chapter 80.

Painful heel pad results from pain arising from the soft tissues on the plantar surface of the heel. The location of the tenderness is usually posterior to the tender area seen in plantar fasciitis.

Degenerative arthritis of the ankle and subtalar joints can be caused by previous trauma to these joints, leading to secondary degenerative changes. The pain is subacute to chronic in its evolution and, as with degenerative arthritis at any joint, there may be stiffness after a period of immobility. The pain is typically aggravated by activity and relieved by rest.

Subacute and Chronic Midfoot Pain. Midfoot pain is much less common than either hindfoot or forefoot pain, and there are correspondingly fewer differential diagnoses to consider.

Köhler's disease is a condition of avascular necrosis of the navicular bone. The underlying etiology is unclear, but as the term *avascular necrosis* suggests, the suspected etiology is one of interference with blood supply to the bone.

Plantar fasciitis pain is typically maximal at the plantar surface near the calcaneus, but it is not uncommon for the pain to radiate to the plantar surface of the midfoot.

Degenerative arthritis can affect any of the intertarsal articulations of the midfoot. It is often seen after ankle or subtalar arthrodesis. Here, the rigidity of the fused articulation leads to abnormal loading of the remaining joints. The end result is premature degenerative changes and pain on weight bearing and ambulation.

Subacute and Chronic Forefoot Pain. The term *metatarsalgia* is a nonspecific term that refers to pain in the region of the metatarsal heads. It is a term that is used when other more specific diagnoses that also can result in pain in this region have been ruled out. The pain is thought to be the result of abnormal mechanical loading of the soft tissues on the plantar surface of the foot at the level of the metatarsal heads.

Interdigital (Morton's) neuroma leads to pain in the region between the third and fourth metatarsals and may radiate into the third and fourth digits.

Hallux rigidus is usually the end result of degenerative arthritis.

Hallux valgus with bunion is a foot deformity associated with a valgus malalignment of the great toe, and, if of adequate severity, may result in an overriding second toe. Because of the deformity, the medial aspect of the first metatarsophalangeal joint is subject to increased mechanical loads from footwear and a bursa commonly develops. Pain is localized to the first metatarsophalangeal joint.

Freiberg's disease is a relatively uncommon cause of foot pain due to avascular necrosis of the second metatarsal head. Its onset is usually in adolescence with pain associated with activity. Physical examination reveals pain and tenderness with or without enlargement at the second metatarsal head.

Stress fractures can occur in a variety of the osseous structures of the foot, but involvement in the metatarsal is most common. This is an overuse syndrome. An abrupt increase in the loading of the foot by increasing the repetition of loading, as occurs with increasing the distance walked or by increasing the magnitudes of the loads experienced by the foot, as occurs when running, may result in a stress fracture. The chief symptom is that of foot pain in the region of the metatarsals. The pain severity is activity related. On physical examination careful palpation along the length of each of the metatarsals shows a specific region of point tenderness.

CHAPTER 76

A. Primary Care Approach to Acute and Chronic Back Problems: Definitions and Care

Stanley J. Bigos and Gerd Müller

This section is devoted to the management of acute low back and leg pain. It strongly espouses the viewpoint that most low back and leg pain is a self-limited and benign condition, unless inactivity leads to deconditioning. It does not review the myriad of treatments for acute low back pain, as these have been shown by clinical reviews to be of little, if any, value. Passive treatment modalities may transiently relieve symptoms because of specific or nonspecific effects, but they do not alter outcomes. They are, in general, a waste of the public's money.

Although we know something of the pathophysiology of low back and leg pain due to disk protrusion or mechanical instability, we do not have good evidence for the causes of nonspecific low back pain, which is the only diagnosis possible for more than 80% of our patients. In this section, Bigos puts forth the Agency for Health Care Policy and Research (AHCPR) guidelines and the evidence upon which they were based. The goal is to provide the pain management physician with the information necessary to optimally assess and treat patients with acute low back pain.

INTRODUCTION

Back problems generally are transient but can linger as the product of many physical (1,2,3,4,5 and 6) and nonphysical factors (7,8 and 9). The treatment and study of back problems have become models for other pain care issues. This section delineates possible contributing factors for back problems and then discusses the most dependable physical approach to care and a comprehensive nonphysical approach appropriate for the individual practitioner. Recommendations for physical care are based upon the most reliable information from the literature, whereas those for nonphysical care may present new issues for the practitioner. Multidisciplinary pain clinic approaches are discussed in Chapter 11, Chapter 18, and Chapter 109.

The approach presented in this chapter does not question whether the patient truly has pain. Epidemiologic studies of the incidence and prevalence of back symptoms remove such doubts. Practitioners should not neglect the nonphysical factors that influence a patient's response to symptoms and subsequent care. The literature abundantly describes the nonphysical factors encompassing premorbid and postmorbid societal pressures or psychosocial issues (8,10). We assume that clinicians understand that a myriad of combined dynamic individual and situational factors can alter patients' responses to both their symptoms and the care provided. Simplistic attempts to attribute symptoms to a specific factor are classic examples of Mayer's Law: “Where you stand on a particular subject depends upon where you (have to) sit” as is obvious from surveys of those with similar complaints but varied attribution according to type of work (Table 76A-1).

Site	Heavy work	Attributable to work	Light work	Attributable to work
Neck	39	31	45	29
Low back	43	32	42	18

Data from Johnson JA. Work-related and non-work-related musculoskeletal symptoms. *Appl Ergonomics* 1994;25:248-251.

TABLE 76a-1. Percent with complaints related to work

This section is designed to help clinicians practically define problems so as to minimize the duration and severity of the patients' pain and reduce the impact of nonphysical societal pressures. Nowhere in care is a defensible approach more important than for those slowest to respond. This chapter concentrates on reliability in both diagnostic procedure and therapy with the goal to provide help that is in the patient's best interest. The recommendations reflect the most reliable data available on effective treatment and the most practical approach to addressing patient fears.

This chapter presents historical and related developmental issues central to many past misconceptions about care. It reviews epidemiologic information important to patient education and other aspects of care. Treatment will be based upon treating the patient's activity intolerance rather than just the pain. Historical perspectives and occasional theoretical notes are central to the theme of modern back care. Other sections of this chapter address surgical, anesthetic, and psychosocial aspects

of the care of the low back pain patient.

EPIDEMIOLOGY OF BACK PROBLEMS AND HISTORY OF BACK CARE

Back problems are an extremely common medical issue, the most common and expensive orthopedic entity, most expensive industrial injury, and most common cause of disability for workers younger than age 45 years (11,12). Back problems are erratic in their interference with activities. For 90% of working persons, an episode limits regular activity for less than 30 days. Of those seeking medical care, 25% to 40% may have symptoms radiating below the gluteal fold, an indication of sciatica. Approximately 5% have neurologic changes detectable by physical examination, with approximately 2% having strong findings indicative of a good surgical outcome from nerve root decompression (via laminotomy or laminectomy). Half of those with the strong neurologic findings of herniated disk recover sufficient activity tolerance by 30 days to lose any interest in surgery.

Medical frustration with this commonly transient yet occasionally chronic entity is illustrated by up to a ninefold variation in use of evaluation and treatment modalities in different regions of the United States (up to a tenfold variation in different counties in the state of Washington) (13,14). Back problems are seemingly unavoidable (5,16,17,18,19,20,21,22 and 23). The back is one of the most frequent reasons for primary care visits (11) and accounts for approximately 20% of all industrial injuries and 40% to 50% of the costs for all industrial injuries (10,24). Yet, there is no typical, easily identified cause. Only 10% of the claims account for 80% of the cost due to disability, including time off work and permanent disability (10,24). This 80% figure is derived from a cross-sectional survey assessing memory of having a back problem. For approximately one-third of the population, the back no longer feels “young” by age 30; half lose this young feeling by age 35, and three-fourths by age 40 (11). Anyone who lives to 50 years of age can expect to have some limitations due to back problems. Studies indicate that more than half of working age adults admit to having at least 1 day of back limitations each year. A survey by Carey et al. in North Carolina found that more than 20% of respondents remembered back symptoms lasting for more than 1 month in the prior year (25). Sciatica has a slower than expected recovery and is strong tocsin announcing the loss of a young spine's tolerance for activity.

Back problems deriving from heavy physical demands are virtually unavoidable by age 50 years, but interestingly, some persons may not recall experiencing problems. Hultman studied the 20% of Swedes who denied prior back problems by 50 years of age (26). Interestingly, she found that this group had simply forgotten back episodes. Almost all had medical records indicating back treatment. This forgetful 20% had a common characteristic—they were able to work at their own pace, and most were farmers. No doubt they did heavy work. Yet, the farmer noticing a catch in the back has the luxury of deciding to sharpen tools for a day before returning to the fields. Conversely, such a person's memory might have been more accurate if a supervisor had demanded no return to work until the back was fully recovered.

MEDICAL FRUSTRATIONS WITH BACK PROBLEMS AND BACK CARE

Waddell et al. described many of the irrational aspects of back care based upon conventional wisdom (8,9,27). In earlier times conventional wisdom prompted physicians to treat patients with infection by bleeding them, well after the negative impact was obvious. One continuing irrational approach to back problems is the use of screening x-rays even though they provide information beyond what is expected from history and physical examination in only one in 2,500 cases (28). The tendency is to assume that normal aging changes seen on computed tomography (CT) or magnetic resonance imaging (MRI) are an indication of pathology, even in the absence of reliable physiologic evidence. Conventional passive treatments are still championed despite proof of the detrimental impact on both patient fears and physical activity tolerance. Moreover, “hard” work becomes the culprit for causing unpreventable back symptoms if we ignore expected age associations and obvious contributing factors in the backgrounds of hourly workers (29,30). History warns us that we should not be surprised by resistance to rational inquiries that fly in the face of conventional wisdom.

MEDICAL HISTORY OF THE “REST THEORY” CONUNDRUM

Medical hypotheses seemingly inflicted less harm on patients with back symptoms before back problems were declared an injury rather than a part of life. Waddell found in Oman, the Ivory Coast, Nepal, and other areas of the world that back pain is still considered to be a normal part of life, and compared with Western societies, is less debilitating (9,27,31,32,33,34 and 35). Many have posed the question as to why back problems have become such a problem in Western society (36,37,38). A nineteenth-century contributor to the development of Western attitudes was Hugh Owen Thomas, whose unverified “rest” theories have harmed more back patients than any other therapeutic approach (39). Rest not only debilitates the patient but also forces more aggressive considerations when activity tolerance worsens with inactivity. The impact of back problems was minimal until back pain evolved from being a part of life to classification as an injury for workers' compensation and insurance purposes (40,41). Once so categorized, Hugh Owen Thomas' theories came to the forefront with their adoption by orthopedists, who evolved as caregivers for such structural injuries. The unfortunate mantra— “rest to allow recuperation and avoid damage”—persisted despite its poor applicability to back problems.

Ironically, Thomas comes from a long line of Welsh bone setters, who tended to set bones or splint patients to keep them as functional as possible (39). He was the first member of his family to attend medical school but then took up his family's trade. He built his fame upon a hypothesis about the body's natural recuperative properties and based his noble model upon patients with tuberculosis in this era before the antitubercular drugs. This therapeutic approach incorporated rest, nutrition, and recuperation to reduce weight loss and improve the body's resources to fight the infection. Febrile and coughing episodes declined and the patient's energy eventually returned. The stress of physical activity was commonly associated with relapse. Although Thomas' treatise on the recuperative aspects of the body relates well to preantibiotic tuberculosis, he applied this approach to all painful entities, including back pain, and until recently, succeeding generations of clinicians failed to objectively test it. Ironically, his nephew, Robert Jones, became known as the “father of orthopaedic surgery” (42,43).

Tuberculosis or infectious agents cause a small percentage of today's back problems. We cannot evaluate the course of back symptoms by monitoring temperature, cough, and body weight (44). Rest fits poorly into reliable treatment regimens for noninfectious, nonfracture back problems because it debilitates protective muscles and further reduces the patient's ability to comfortably tolerate activity. Early motion with resumption of activity is one of the most important advances in the treatment of musculoskeletal injuries (45).

Biomechanical studies have not altered the treatment approach in a positive direction and perhaps are the source of other irrational theories. The National Institute of Occupational Safety and Health (NIOSH) published a lifting guide in 1980 with the best of intentions to protect workers from back injury. The guide was based on a consensus panel review of three cadaver studies, including one published in the United States in 1957. Another was published in 1962 in Japan, and the third was presented at a meeting but was never published in a refereed journal. The conclusions seem to be based on system failure in an unknown number of cadaver spines from persons at different ages. In an attempt to ensure safety for workers, the panel drew conclusions from these data without considering the differences of *in vivo* spines, including presence of vertebral blood, reinforcing musculature, and the surrounding body structures. Thus, the biomechanically stressed spines failed to correlate well with the experiences of living patients. Later studies of osteoporotic patients cast suspicion on such mechanical modeling; these patients seemed to tolerate activities for which the modeling data predicted fractures (6).

This 1980 guideline had little impact on reducing back problems, so NIOSH reconvened a new panel a decade later, but its recommendations followed a similar pattern of logic. Daily work task maximums were based upon data from estimating the chance of weight loss while on a fixed calorie diet (46). The consensus of this small panel unintentionally provoked rules about work as a cause provoking barratry rather than further science. Unfortunately, the lifting guide has caused unnecessary loss of employment by citizens before retirement age. Within 10 years it was revised with the same data (47). The first guide prompted NIOSH to launch a 10-year planning conference in 1985 that included the goal of eliminating back pain as an industrial injury by 1995 through known ergonomic principles (48). Time revealed the myopia of this effort. Prevention fervor now focuses on repetitive strain and cumulative trauma, factors based upon even less reliable scientific support (12,29,49,50,51,52 and 53).

Reliable data point away from these simplistic approaches. In the last 25 years, job-related requirements for range of motion (ROM), cumulative lifting weight, and maximum lifting weight have, on average, declined, but the disability pensions nevertheless increased by 2,600% to 3,300%. Additionally, in many countries with less strict lifting guidelines, the work force has a lower percentage of lost workdays due to back pain compared with countries with stricter guidelines. The nonphysical aspect of work injury claims is further evinced by increasing the sickness benefit by 20%, resulting in a 20% increase in lost workdays in Sweden (54).

Back injury claims are a complicated web of many factors. Experiencing back symptoms is a common, unavoidable part of life, and the demands and benefits of jobs involving physical labor require regular use of the spine. Reliable data show that a young- feeling back is lost by age 50 years, whether the life's work has been strenuous or not. The only real glimmer of hope for prevention of further debilitation or conditioning is to regain comfortable tolerance. Workers can improve protective muscles and avoid the debilitation of inactivity to reduce the amount of discomfort, recurrence rate, and days of limitations they experience (5,56 and 57). Disability

issues are further discussed in Chapter 17.

To overcome the negative impact of irrational prevention and treatment practices requires a sound scientific foundation. During the 1994 AHCPR Guideline (11) development process, we attempted to review the medical literature for reliable information. The AHCPR panel reviewed more than 11,000 abstracts and compiled evidence tables for those with sufficient information to evaluate reliability. The panel provided “Finding and Recommendation Statements” to interpret the literature and a guide for clinicians who care for a wide range of back patients. Back problems were defined as an episode of limited activity tolerance due to back or back-related leg symptoms. The term *back pain* alone may or may not include sciatica, with different risk factors presented for each condition. Risk factors for the first episode of back trouble, first back claim, repeated back claim, disability, and chronic disability do not coincide (Fig. 76A-1). Thus, the term *back pain* was avoided other than for those specific symptoms. Note especially the hierarchy of decisions made at each phase. The guide emphasizes meaningful measurements of limitation due to back symptoms. The treatment goal for both working and retired patients is to improve comfortable tolerance for needed physical activity.

Figure 76A-1. Level of back problems—related decisions. Note many levels of back problems including the annual percentage of the working population that is affected. Patient understanding can affect some early active decisions and perhaps avoid the later difficult passive decision issues.(From Bigos SJ. *Housestaff handbook for back problems*. Seattle: SpineMate Publications, 1996.)

To what extent do the presence of back symptoms and loss of activity tolerance relate to physical demands and the aging process (Fig. 76A-2)? The question requires a review and further explanation.

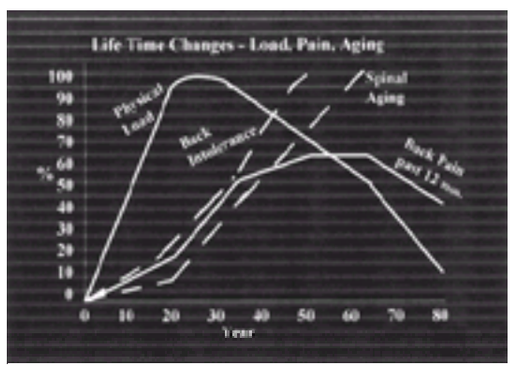

Figure 76A-2. Lifetime changes—load, pain, aging. Note relationships between maximum adult physical load, back pain, and back intolerance relative to spinal aging according to age. (Modified from Videman T, Battié MC, Gibbons LE, et al. Lifetime exercise and disk degeneration: an MRI study of monozygotic twins. *Med Sci Sports Exerc* 1997;29:1350–1356.)

LOSS OF ACTIVITY TOLERANCE DUE TO BACK SYMPTOMS: DEFINITION OF BACK PROBLEMS

Medicine has long preferred to treat discrete variables that can be eradicated, such as treating infection with antibiotics (58). Unfortunately, treatment of back problems is more like training for a marathon. Treatment outcomes are not discrete or dichotomous variables (sick or not sick) but a continuum of responses. As with a marathon, the more a person trains and the younger the age, the better the result. Yet, two persons with the same training may perform differently in the race due to individual variation (59). So it is with how patients cope with the loss of the “young” back's tolerance for physical stress. Despite the best conditioning and medical care available, one basketball star's career ended in his early 30s after he developed back symptoms, whereas another afflicted at the same age continued playing for 8 to 10 more years. Physical variation makes it difficult to predict comfortable activity tolerance in highly motivated athletes. Prediction becomes even more difficult with the addition of nonphysical stress and pressure in patients who are earning salaries far below the multimillion-dollar contracts of professional athletes.

Two challenges should now be evident: (a) It is difficult to predict the outcome of back problems, and (b) it is difficult to solve pain problems in patients who have become extremely inactive. Yet, data indicate a potential to make major differences in the outcomes of both acute and chronic patients if from the beginning we can avoid the debilitation of inactivity (55,57). Evidence confirms two important elements: (a) the need to convince the patient that there is nothing dangerous causing symptoms, and (b) that using the back is not only beneficial but safe. This section reviews potential causes of symptoms, which are the important ammunition needed to convince the patient about the safety of continuing with normal activity. This information also will help the clinician see the logic of the recommendations.

Lost activity tolerance is predicated on many issues. A patient's responses to questions about activity can be altered by perceptions, fears, prior experience, expectations, social or work situation, and medical understanding (60,61,62 and 63). The patient's eventual activity tolerance is a response to combinations of the unavoidable physical experiences and many nonphysical factors that have surfaced relative to considering back problems as injuries. Thus, activity tolerance provides a measurable index for monitoring the sum of medical and nonphysical issues that bear on treatment results (64). The rate at which a patient regains activity tolerance can also clarify the need to consider many issues relative to resumption of work that are important concerns for many back patients.

Understanding the Logic of Treatment for an Activity Intolerance

The knee offers an analogy applicable to the whole musculoskeletal system. With a knee problem, the quadriceps muscles must be conditioned, regardless of whether surgery is required. Pain subsides only after conditioning the thigh muscles sufficiently to compensate for whatever knee problem remains. Adequate conditioning of these protective muscles can return patients to rigorous professional athletics, not because the knee is like new but because muscular compensation is adequate to tolerate the required activity. The protective muscles must be conditioned to a state better than before the knee problem occurred. Until reaching that point, the knee continues to be painful, intolerant of activity, and irritated by even minor mishaps. The knee may become red and swollen with the stresses of conditioning. Sometimes fluid must be removed, which may prompt questions from the patient about why we recommend exercise when there seems to be something terribly wrong with the knee. Then, almost miraculously, as muscular capacity increases, the redness and swelling disappear, and activity tolerance begins to increase. The requirements of muscular conditioning are similar with the spine.

Until we condition protective muscles sufficiently to do their job, any activity is like gardening for the first time in spring after the winter's rest. We may not feel pain when we start gardening, but after our protective muscles fatigue, we are destined to pay a price either that night, the next day, or occasionally immediately. The severity depends on whether the muscles were already compensating for a problem (as in the knee analogy). Do we experience the pain because gardening is a dangerous activity or because something is seriously wrong? Pain more likely results from the lack of conditioning caused by the winter's rest. Only conditioning protective muscles with exercise or continuing to work in the garden eventually allows comfortable activity (although a person who hates gardening may never

overcome the aches or fears of pain).

Unfortunately, training or conditioning cannot be achieved without using the back. Such activity need not be dangerous, although it may not be totally comfortable. Regular use of the back can increase muscular capacity and bone mineral density and improve the capacity of other tissues, which improves the efficiency and the responsiveness of the musculoskeletal system.

Nonphysical Pressures

Costs to employers directly or through their insurance can drive nonphysical factors to exert stress on an employee. Financial pressures result from time loss and indemnity costs, which in some cases triple the medical costs (24). Employers also see lost production and the expense of replacing missing employees. For the employee, inability to resume regular work activities is commensurate with educational level or training and relates to options of facing failure. Lower education triggers a potential for long-term disability, retraining costs, and settlement awards. Avoiding debilitation by maintaining normal activity not only reduces time lost from work but also seems to speed recovery and reduce recurrence of back problems and future work time loss (55,57). Studies have found that activity tolerance can be improved by conditioning protective muscles (65,66), while for workers with strenuous jobs specific back muscle conditioning provides future protection from both symptoms and time loss (56). Unfortunately, it is a rare person who can tolerate using the back as a crane at a regular or rapid pace until retirement age. Thus, many workers with limited education or skills will face nonphysical pressures when they become back patients.

Epidemiologic data provide the assurance we need to give our patients about expectations and influence our care. An important issue for our patients and society, and the care we provide, centers around one issue—the loss of the young-feeling back. Once that occurs, the patient can derive comfort from a simple formula. The treatment section expands upon this theme after back problems are defined in the following section.

POTENTIAL ETIOLOGIES: ACTIVITY INTOLERANCE DUE TO BACK SYMPTOMS

The recommended approach focuses on handling the problem rather than searching for the cause. The clinician is advised to seek factors that may need to be addressed rather than seeking the cause of transient symptoms. As can be seen with the formula, structural and exposure-to-load factors must be considered, given the close relationship between structure and function (e.g., the worse the structural problem, the more conditioning is needed) (67,68 and 69).

Relative Anatomy of the Lumbar Spine

Possible compression of cauda equina or nerve roots below the first lumbar vertebral body is the concept that provokes the greatest concern regarding treatment and requires the most extensive evaluation. The lumbar nerve roots exit around and under the pedicles attaching the vertebral body to the posterior elements (Fig. 76A-3).

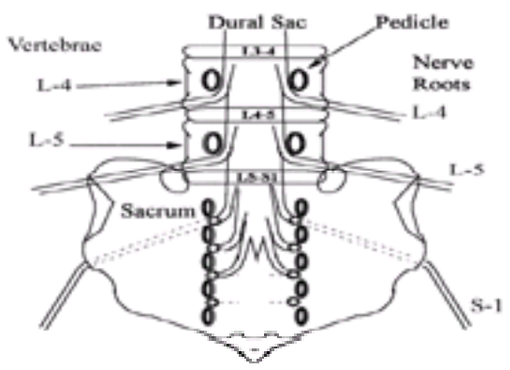

Figure 76A-3. The relationship of the dura, dural sleeves, and nerve roots to the pedicle and central spinal canal. (From Bigos SJ. *Housestaff handbook for back problems*. Seattle: SpineMate Publications, 1996.)

Note the relative relationships between pedicles, transverse processes, facet joints, and ligamentum flavum to the disk space neural foramen and neural contents of the dural sac, which includes the nerve roots (Fig. 76A-4).

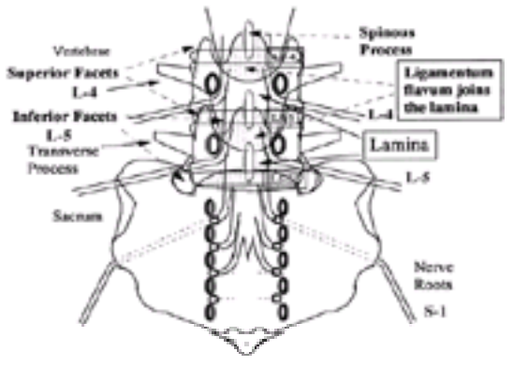

Figure 76A-4. The posterior elements—facet joints, lamina, spinous processes, and interlaminar space covered by the ligamentum flavum relative to neural contents. (From Bigos SJ. *Housestaff handbook for back problems*. Seattle: SpineMate Publications, 1996.)

Studying Figure 76A-5 and Figure 76A-6 relative to the neural contents in Figure 76A-4 explains why disk herniations usually catch the nerve root that exits at the next lower level nerve root foramen. For instance, herniation at L-4 to L-5 usually affects the L-5 nerve root that exits at the L-5 to S-1 foramen, and herniation at the L-5 to S-1 usually impacts the S-1 nerve root that exits through the sacrum.

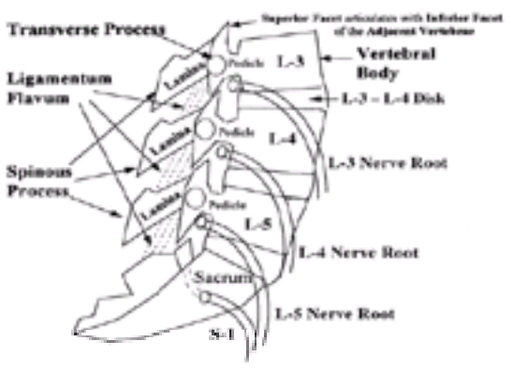

Figure 76A-5. The lateral relationship of the nerve roots to the foramen formed by the facet joints, pedicle, and vertebral body. (From Bigos SJ. *Housestaff handbook for back problems*. Seattle: SpineMate Publications, 1996.)

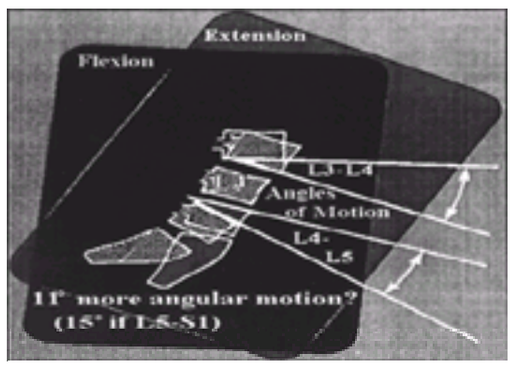

Figure 76A-6. X-ray angular motion of instability. Superimposing a vertebra adjacent to the motion segment to be measured (here, L-4) from lateral films taken at the extremes of motion. The end-plates or posterior bodies can be used to measure the change in angular relationship from hyperflexion to hyperextension. Stress shielding occurs when there are more than 11 degrees of motion than the adjacent segments. (From Bigos SJ. *Housestaff handbook for back problems*. Seattle: SpineMate Publications, 1996.)

The relationship of the pedicles as would be seen on a plain radiograph is also important. Their absence hints at tumor, which tends to affect the vascular pedicle's junction with the body of the vertebra. The pedicle is also an important landmark for finding the nerve root, as can be seen in Figure 76A-3.

A break in the pars interarticularis (between the upper and lower facet articulation of the same vertebra), termed *spondylolysis*, is found in approximately 7% of adults. Such a defect allows the body, pedicle, and superior facet to move forward in half the cases (known as *spondylolisthesis*), leaving the spinous process, lamina, and inferior facet behind to articulate with the adjacent superior facet (see spondylolisthesis in instability).

Aging of the Lumbar Spine

The first visible aging in the human body occurs in the disk. Before gray hair, balding, and wrinkles, changes usually occur in one of the lower two lumbar disks levels. Holt's diskograms found abnormalities in 34% of subjects by age 23 years (70). Necropsy studies found aging changes at one of the lower two levels of the lumbar spine in 75% of subjects by age 28 years and 100% by age 42 years (50,63). Magnetic resonance imaging (MRI) scans have since verified these prior studies (71).

Early disk aging should not be a surprise. The lower lumbar disks are the largest structures in the body without a blood supply after age 12 years (72). Nutrition of the disk relies on osmosis from the vertebral end-plate and periphery (72,73). Sixty percent of oxygen and glucose in a disk diffuse in from the end-plate vascular system and the rest from the periphery, whereas 60% of the sulfoxyl ions and glycosaminoglycans diffuse in from the peripheral disk vasculature and the remainder from the end-plate of the adjacent vertebral bodies. From a clinical standpoint, we can expect early aging in the lumbar spine; 40% of asymptomatic persons by 35 years of age have noticeable radiographic changes (28).

Approximately 15% of teenagers have disk changes seen on MRI, which is much more sensitive than radiography (74). Herniated nucleus pulposus is one expression of aging of the intervertebral disk. Disk aging causes greater demarcation between the outer grizzly annulus fibrosus and the inner jelly of the nucleus pulposus. Also, this nuclear material gradually loses its sulfoxyl ions and the ability of the glycosaminoglycans to hold water. Gradually, the disk becomes less of a hydrostatic cushion, and the nuclear material is transformed from this jelly to more of a crabmeatlike substance. During aging, the outer annulus fibrosis (grizzle) develops posterolateral cracks, where the inner nuclear material may escape into the spinal canal. Nuclear material can irritate the nerve roots both chemically and physically, causing pain and even dysfunction. Apparently approximately one of four to five herniations traps a nerve root and gives the clinical picture of sciatica that is amenable to decompression of the irritated nerve root(s) (74) [see Herniated Disk (45)].

Aging also occurs in the facet joints, but most commonly after changes in the intervertebral disk. Because the facet joints have a stabilizing effect on the spine, most persons lose motion with age, although individuals show marked variation, and loss of motion may be slower in women than in men (75). In rare instances, a relative increase in motion can occur either through stiffening segments above and below one with reasonable motion or through laxity of one segment that allows the adjacent segments to be shielded from stress and become relatively stiffer. Either process can lead to a loss of structural integrity. Both are opportunities for one segment to take most of the motion and become looser, while adjacent segments are shielded to become stiffer. Neurologic elements can be in jeopardy if structural integrity is lost at the loosest junction. This points to the problem of instability.

The aging process in the disk and facets can decrease the space available for neural contents and thus can cause symptoms, such as neuroclaudication, which may require surgery (see Neuroclaudication Due to Spinal Stenosis). The relativity of the aging process to clinical entities is also depicted in Figure 76A-2 (76). The concept of increased motion at one segment is based upon relative increased motion that allows measurable stress shielding of the adjacent segments—for example, the hypermobile segment takes up all the stress and allows 11 to 15 degrees (for L-5 to S-1) more motion than in adjacent motion segments (Fig. 76A-6) or more than 5- mm slipping translation (Fig. 76A-7).

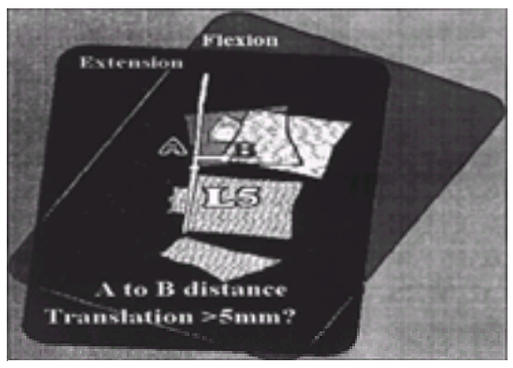

Figure 76A-7. X-ray translation of instability. Superimpose the vertebral image below the slip (here the L-5 image) from the hyperflexion and hyperextension lateral films. The amount of translation can be measured as the distance perpendicular from a vertical line relative to L-5 vertebrae. The distance A to B considering magnification should not normally be more than 5 mm in the lumbar or thoracic spine or greater than 3.5 mm in the cervical spine. (From Bigos SJ. *Housestaff handbook for back problems*. Seattle: SpineMate Publications, 1996.)

The techniques shown in Figure 76A-6 and Figure 76A-7 are used to evaluate potential long-standing instability. The attempt to obtain hyperflexion and hyperextension views can be dangerous after acute trauma and should be undertaken only by spine specialists.

The stress-shielding capacity of the hypermobile segment provides a mechanism to evaluate potential dangers to this lax area with hyperflexion and hyperextension lateral views of the spine (72,77,78). As noted in Figure 76A-6 and Figure 76A-7, we have laboratory baseline criteria for this stress shielding, although many patients meeting these criteria have few abnormal back symptoms. Thus, present treatment data make it difficult to justify using only our imagination to diagnose instability of the spine without added jeopardy of fracture or traumatic dislocation (79).

These extreme displays of lost segmental integrity have not been scientifically related to symptoms. As Swedish orthopedist Alf Nachemson has noted: “Instability

exists, but we do not know what it is and how we define it." We lack convincing data to predict a good outcome for fusion for back pain alone or for the results found on diskogram.

Spondylolisthesis must not be confused with loss of structural integrity and the question of instability (80). Spondylolisthesis is but a measurement of the slip of one vertebra upon the one below. Thus, such slippage requires hyperflexion and hyperextension lateral views. The most common spondylolisthesis or slippage is developmental in origin and is a defect in the pars interarticularis between the superior and inferior facet joint. This defect has not been found in newborn necropsy yet is present in approximately 5% of young schoolchildren and approximately 7% of late teenagers and retiring adults. Approximately half of those with the defect in the pars interarticularis develop a forward slip. Although this defect, known as *spondylolysis*, is potentially pathologic in adolescents and teens (81) due to the potential for slip, no significant risk or relationship to pain exists in adults. In adults the slips rarely progress, even without surgery (82). Once a slip occurs, aging changes commonly allow little motion. Only in cases of spondylolisthesis with slippage of more than 50% on the lower vertebral end-plate is further progression predictable in adulthood (83). Surgery is rarely required to avoid further slip and is not recommended for patients older than 30 years with less than 50% slip in the absence of neurologic findings, unless the slip is combined with hypermotion x-ray findings. Most of the time we are surprised how slips have stiffened in adults.

In summary, by age 35 years, 40% of persons without symptoms show aging changes on radiographs (11). MRI changes are noted in the disks of 15% of teens and 30% of adults by age 30 years (74). Necropsy findings indicate that we can expect a diskogram to be positive in 75% of persons at age 28 years and in everyone at age 42 years. Even when a patient has spondylolysis defects with spondylolisthesis of less than 50%, surgical considerations need to be based upon more than just anatomic findings. Thus, we must be careful in interpreting the anatomic findings if information is lacking on other aspects of the clinical picture.

PHYSIOLOGY: ELEMENTS OF PAIN

Neurologic Components: Diagnosis

The innervation of the spine is fundamental to the physiology of spine pain and is discussed in detail in Chapter 75. The sinuvertebral nerves are the primary innervation of the intervertebral disk. From the posterior primary nerve root these small branches can cross the midline and travel rostrally two levels and caudally three levels (2). The innervation pattern of this nerve alone helps explain the myriad of central, bilateral, or even shifting pain complaints that can originate from spinal structures. A more lateral branch from the nerve root is the posterior rami circumflex, which extends to the facet joints (84). Hypertonic saline injected into the facet joints can cause referred pain as low as the posterior knee area (85). The nerve root complexity and potential autonomic input may further explain various symptoms, including traveling aches, burning skin, deep boring pains, and shocks in various distributions, although we do not know the exact cause of such symptoms. Although we can block sinuvertebral nerves with caudal and epidural nerve root blocks or perform physical and chemical facet joint denervations, the results continue to be unpredictable in clinical studies.

Sciatica may result from both chemical and mechanical irritation of the nerve root. Chemical irritation causes the tougher nerve root to be easily irritated by the softer, crabmeatlike nucleus pulposus. The chemical explanation helps us to better understand the natural history of severe sciatica, which often abates long before there is significant shrinkage of nuclear fragments in the spinal canal (86,87 and 88). The effect of nerve root irritation can be measured through conduction studies such as somatosensory evoked potentials and electromyography (EMG), which help us to distinguish a source of sciatic and neuroclaudication symptoms from herniated disk or spinal stenosis. Unfortunately, our present knowledge of the nervous system explains the painful symptoms in only about 12% of our patients (11).

Physiology of Pain and Treatment: Loss of Muscular Protection

Scientific studies of muscle reveal that between 20 and 50 years of age up to 50% of certain muscular elements are lost through aging and inactivity (89). Thereafter the losses are more rapid, especially with extended periods of rest. Muscular protection lessens with increasing age and the elderly are more susceptible to debilitation with inactivity. The importance of muscular protection can be easily demonstrated by applying a walking cast to an athlete without a knee problem. When the cast is removed after 3 to 5 weeks, the athlete rarely can walk comfortably, let alone run up the stairs. The muscle wasting makes climbing stairs and walking on uneven ground difficult. Until the "well-rested" quadriceps, and especially its vastus medialis obliquus, can be reconditioned sufficiently, activity tolerance is compromised.

Physical conditioning improves comfortable activity tolerance. Preseason training is a painful time for most athletes. During the first few days the athlete struggles to get out of bed the morning after even a short session of competitive activity. By midseason comfortable rising in the morning follows even a maximum effort. The difference is muscular conditioning, which prevents fatigue. Muscle fatigue slows reaction time and reduces the force of contraction, which can hamper the ability of the muscle to protect its own fibers or the joints it spans. Whether the activity is gardening for the first time in the spring after a long winter rest or preseason athletic training, activity beyond the capacity of muscular protection can produce symptoms immediately, that night, or the next morning. Understanding physical conditioning can help patients eliminate misconceptions about work as a cause of back problems. Inactivity may affect not only the muscles and joints, but also the brain and spinal cord. Extreme rest to the point of severe debilitation may have an effect beyond reducing comfortable activity tolerance—it may generate pain. Modern societies can inflict such inactivity upon the body. Periods of inactivity negatively affect the heart; lungs; digestion; bone mass; muscles; and even neurotransmitters such as serotonin, enkephalin, and endorphin (90). Lack of normal input due to physical inactivity might, along with other changes, alter the ability of the brain to process information. Central changes may prompt the brain to interpret impulses from hypoactive muscles and joints as dangerous.

We know that inactivity can induce pain as seen in athletes during preseason training or gardeners in early spring. An extreme example may be sympathetic dystrophylike syndromes induced by inactivity. Beggars have been observed to immobilize an arm under a belt for numerous days until the hand becomes swollen and shiny enough to permit successful begging (I. McNab, *personal communication*, 1979). Physical findings are similar to shoulder-hand syndromes. Tentative active motion generates a grimace, and passive motion arouses protests of severe pain. The pain, stiffness, and swelling seem impossible to control. Treatment is physical activity, aided by pain-relieving procedures and medicines (see Chapter 20).

Chronic back pain patients have similar activity intolerance, although without evidence of swelling and redness. After but a few weeks of inactivity we confront a back conundrum. Recent studies give hope that most of these situations are avoidable by aggressively recommending against the debilitation induced by inactivity (55,57).

Work Activities

The relationship between back pain and work has led to repeated erroneous conventional wisdom statements. The first studies sought to identify defects on screening x-rays (91) and then ROM deficits on preemployment examinations. After researchers blamed the worker for being defective, the pendulum swung to calling back problems a preventable injury. This model set the stage for claiming work to be an injury agent for back problems. If work causes back problems, then we should somehow be able to prevent them in a portion of our population younger than 50 years of age. The association with work seems superficially obvious. Once the back inevitably loses its youthful vigor and an episode of pain occurs, the occurrence of another episode is common, easily triggered by continued activity that may fatigue protective muscles. Yet, the physiology of symptoms has been neglected in favor of a simplistic, mechanically oriented paradigm.

Nonphysical Pain Modulators (Psychosocial Responses)

We should not underestimate the influence of social pressures upon the filing of back injury claims (see Chapter 7, Chapter 17, and Chapter 25). Back-related claims have been studied the most because they are the most common and most expensive of injury claims. One difficulty is in the use of social or psychosocial terms that do not fit into our medical approach of explaining all problems from a single factor. Many authors use the term *psychosocial* quite loosely and even emphasize the importance of evaluating psychosocial factors (92). Unfortunately, they conveniently avoid recommending solutions about this aspect of the back problem. Clinical studies reveal that these "psychosocial" problems reflect a myriad of different and often dynamic factors, with marked individual variations in perceptions and experiences (from experience to disability). Psychosocial problems can result from work and societal expectations as well as the person's response can complicate continuation of work.

Fordyce long ago stated, "People don't hurt as much if they have something better to do." This observation helps us understand why rates of injury claims correlate more to difficulties between labor and management than to mechanical stresses at work (93). Studies show up to threefold increases in claims among workers who experienced labor-management stresses compared with workers with similar demographics and work requirements who did not experience such stresses (94).

A poor economy resulting in threat of layoffs, a change in technical work requirements combined with short duration of employment, and management attitudes better predicted injury claim rates than did variations in physical requirements (10,95). A 10% reduction in the population of middle-income workers and an expanding

lower-income group in the United States from 1970 to 1992 worsened the problem (96). This continued enticement for employers to reduce the number of employees or to terminate older employees before having to begin the balloon payment for retirement funds further exacerbates the situation, for both those who lose jobs and those who remain (36).

The options continue to shrink for workers who face combinations of physical or nonphysical failure at work. Well-trained technical workers are in demand and command higher wages; they file fewer claims and have more employment options. The professional or self- employed rarely make claims whether or not his or her work is strenuous. When facing failure with few options, most persons survive as best they can. Clinicians can expect aggressive survival behavior when a patient is forced to hold onto an injury claim due to a lack of work options or the absence of funded health care outside of the compensation system. Such survival behavior is manifested as embellished symptoms, blame, and latching onto any prior learned rhetoric that may be perceived as helpful. As professionals, we best serve by providing the most reliable and defendable recommendations available. This section is built upon the most reliable data about medical treatment of back and leg pain and the simplest basic concepts available to the individual practitioners who must manage these patients.

DATA-DRIVEN PHYSICAL LOW BACK CARE

It is not difficult to imagine that patients who seek our help have many agendas. The AHCPR panel developed patient discussion handouts covering a minimum of seven agendas that tend to arise within the first 6 weeks of care. Few patients are interested in an issue until it pertains to them, which explains the weakness of offering detailed pamphlets that try to cover all the issues. The agenda items follow a progression as symptoms continue. The agendas address such questions and statements as “What help can I get with symptoms?” “Is the problem dangerous?” “Why does it continue?” “Tell me about special tests.” “What do the special studies mean?” “Now what do we do?” and finally, “What if it does not work?”

Patient education requires specific themes reiterated as questions arise. Prospective studies reveal that the most important issues in the care of back patients center around convincing the patient that nothing dangerous is occurring and that the greatest threat is the debilitation of inactivity (55,57). We can improve the patient's ability to make a good decision irrespective of the physical or nonphysical nature of the problem. Through professional recommendations and compassion we can help patients define options to avoid failure. Thus, the early priorities are to assure the patient that activity is safe, to provide help with symptom control, and to emphasize that the best treatment is to avoid debilitation and safely build comfortable activity tolerance.

Defining Potential Dangers and “Red Flags”

Those who care for patients with back problems are responsible for addressing serious conditions that might be causing symptoms. If any are found, effective options for improving the patient's comfort should be used and efforts should be made to avoid worsening of the condition, including tolerance for activity.

Initial Evaluation

A goal of the initial evaluation for a patient with acute or chronic back pain includes diagnosis of potentially serious causes of back symptoms (Table 76A-2). Most of these efforts are aimed at identifying “red flags” of potentially dangerous conditions or seeking neurologic deficits in the minority of patients who have leg symptoms or identifying a structural deficit that might require attention or definition before treatment can begin. However, for approximately 88% of patients we are unable to provide a defendable pathoanatomic diagnosis that will withstand scrutiny.

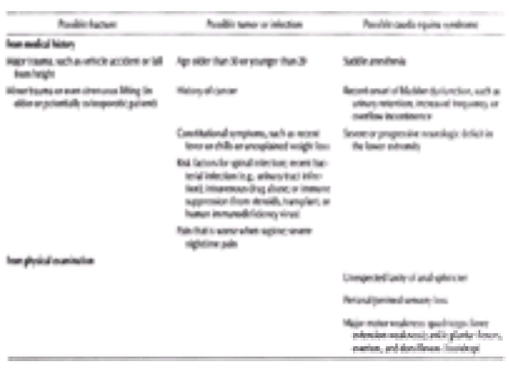

TABLE 76a-2. Red flags for potentially serious conditions

After ruling out “red flags,” the next step is to classify symptoms as back only (no neurologic involvement) or sciatica (neurologic) and then to provide the patient with an understanding of prognosis, workup, and treatment options for dealing with the limiting symptoms.

We can spot “red flags” through questionnaires addressing past medical history, review of systems, present medications, and such measures as the pain drawing with symptoms and an activity visual analog scale. This review is necessary to guide the physical examination and to assure ourselves we have placed the patient in the correct treatment paradigm. The patient, rather than a spouse or caregiver, should fill out the questionnaires. Answers in the patient's own handwriting can help avoid future contention about potentially contestable points.

Specific History

It is essential to take a specific history, if for no other reason than to assure the patient of the physician's thoroughness. Use of questionnaires as mentioned above can facilitate the acquisition of a complete history (see Chapter 12).

The patient should be asked “What symptoms are limiting you? Is it pain, weakness, numbness, stiffness, or other problems?” and “Where on the body have you experienced recent symptoms?” Other questions include the following: “Are the symptoms intermittent or constant?” and “How long have they been the same as now?” Probably the most important question is “How are you limited by the symptoms?” If the patient cannot clearly explain what he or she can't or won't do, it is important to pose questions that ask about specific limitations, as in the following examples:

“Without feeling like you are doing damage, how many minutes can you sit safely, how many minutes can you stand safely, how many minutes or blocks can you walk safely, and how many pounds or kilos can you lift safely?” These questions are best asked eye to eye early in the interview when expectations are highest and intentions least suspect. The reason is that the answers to these queries can help set the starting points for activity recommendations. Should responses be less than 20 pounds or 20 minutes, reassuring the patient that normal activities are safe usually resolves extreme activity restrictions, unless the patient is a true invalid. In the elderly, if walking is commonly limited to less than 20 minutes or 300 yards, ask the following question: “After you have walked as far as possible, can you just stand still to rest and relieve the pain?” If the answer is yes, consider a diagnosis of vascular claudication. This question is aimed at identifying neuroclaudication, which can be caused by spinal stenosis, which is especially common in the elderly. A diagnosis of true neuroclaudication requires the patient to sit, bend over, or squat for a few minutes to supposedly open up the neural canals before continuing walking or other activity.

It is also helpful to understand the patient's interpretation of prior spinal, musculoskeletal, or exercise limitations, including dates and time to recovery and the dates and results of each type of related diagnostic procedure, surgery, or injection.

“What do you usually do to stay in shape?” is another key question. Knowing exercise patterns in the past and present can bring you more quickly to a negotiation point and emphasize the importance of exercise early in the process. Another helpful piece of information stems from the question, “What has given you lasting comfort?” Other useful questions are the following: “What brings you to see me now?” and “Has something changed recently?” The answers will help to understand the patient's expectations about the present visit. If the patient is not working, try to determine what blocks return to work so you can help set goals relative to the prior information about sitting, standing, walking, and lifting. These few questions posed in a specific format can provide the physician with the required information and

avert the need for a belabored “fishing expedition.”

Physical Examination

The focused physical examination for low back pain need not take more than 5 minutes, even in a slow-moving patient.

Standing

1. Normal walking. Normal walking should be fast enough to stimulate the toe-clearing reflexes and eliminate many limps and deviations. Next, ask the patient to walk on heels (testing L-4 to L-5), then on toes (testing S-1 to S-2) before doing a squat and rise (L-2 to S-1), which provides a reasonable index of general strength and proximal muscle debilitation.
2. ROM. ROM is difficult to measure even with the Schober test. Thus, a better approach is to determine whether back muscles are uncoordinated or guarding. Since the introduction of diazepam (Valium), this condition has been called *muscle spasm*. Asking the patient to attempt spinal extension, side bending, rotation, and flexion allows an estimation of muscle fatigue and ROM to the degree that muscles remain in a shortened state on one or both sides at certain levels. A patient who shows extreme guarding and has had recent symptoms of fever and chills warrants investigation for infection of the spine or its appendages.
3. Waddell pain embellishment I, II. Tenderness and simulations can be performed and are discussed later in the section Nonphysical Interference.

Sitting

Sitting provides an opportunity to evaluate more basic neurologic functions. Ankle and knee reflexes can provide reliable objective data for the trained physician whether they are positive or negative; they do not rely on the patient's interpretation or volition.

1. Circumferential measurements. Measurements above and below the knee with differences of more than 1 to 2 cm can indicate possible atrophy. These measurements also require no patient volition or interpretation, so they can also be considered objective if differences between the sides are greater than 2 cm given the difficulty of accurately measuring a soft tissue cone. The remainder of the physical examination requires patient interpretation or volition and so provides the physician only with indexes of suspicion. In general, the examination helps to avoid missing nonback problems (vascular, abdominal, central neurologic, hip, or knee) or points toward a neurologic or nonneurologic workup if the patient is slow to recover.
2. Lower extremity joints. These joints can be evaluated in the sitting position by assessing hip rotation (loss of internal rotation, perhaps from hip degenerative joint disease) and knee stability when the knee is slightly flexed and extended (also note Table 76A-4, III). The clinician also should check for extremes of foot and ankle motion.

I. Tenderness: subcutaneous (or less) pressure to reproduce symptoms
II. Simulation
a. Simulation of loading the spine with the weight of your hands on top of the patient's head to reproduce back symptoms
b. Simulation of twisting the trunk when rotating the shoulders and hips in unison to reproduce back pain (can physiologically reproduce sciatica)
III. Distraction: sitting knee extension to test sciatic tension while distracting the patient with knee or foot examination as the reason for extending the knee (If the patient is comfortable during sitting knee extension, straight-leg raising should not be positive and, if it is, is of questionable significance.)
IV. Nonanatomic distribution of pain as seen on pain drawing (total body or outside the body) or giving away on muscle testing (intermittent efforts)
V. Overreaction: grimacing, complaints, or suffering displays inappropriate for situation or maneuver

From Bigos SJ. Household handbook for back problems. Seattle: SpineMate Publications, 1996.

TABLE 76a-4. Waddell embellishment tests

3. Muscle strength. A slight loss of strength is most detectable in large muscles—hamstring (L-5 to S-1), quadriceps (L-2 to L- 4)—compared with great toe extensors (L-5), toe flexors (S-1 to S-2), ankle dorsiflexors (L-4 to L-5), and ankle evertors (L- 5 to S-1).
4. Waddell embellishment IV. Giving away on muscle testing (discussed later, in Nonphysical Interference).

The supine position provides an opportunity to examine abdomen and pulses, which is especially important in elderly with or without positive “red flags.”

The most reproducible physical test pertinent to the goals of the back examination is straight-leg raising of each lower limb to seek sciatic tension signs. Ask the patient to tell you “stop” if it causes discomfort. The next question is the following: “Where is the pain? On the same side or the opposite one? In the back? In the hip, thigh, knee, or below the knee?”

Back pain during the straight-leg raising test is not pathognomonic of radiculopathy. It is rather a sign of unspecific low back pain.

At the level where raising becomes painful, further raising can help in evaluating the reliability of the patient's report of symptoms, as follows:

- Worse with plantar flexion? (It shouldn't be.) Or dorsiflexion of the ankle? (It should be.)
- Worse with external rotation? (It shouldn't be.) Or internal rotation of the whole limb? (It can be.)

Diagnostic Considerations

Opposite (or crossed) leg raise can irritate the symptomatic limb and is the strongest predictor of an anatomic lesion such as a herniated disk, although pain rarely augments with dorsiflexion and rotation. Because of the gradual onset of nerve root compression with neuroclaudication due to spinal stenosis, the sciatic tension signs are rarely positive (see Neuroclaudication Due to Spinal Stenosis).

No special studies need be considered in the absence of “red flags” or limitations of less than 4 weeks' duration, because 90% of patients regain reasonable activity tolerance from back symptoms and 50% of those with objective evidence of sciatica recover within a month (11). If the patient has been referred from another physician, review of the imaging and physiologic studies, if available, is essential.

It is important to remember that prior surgery makes imaging studies more difficult to evaluate and that conditions change over time. “Red flags” must be addressed before classifying a patient into the back treatment paradigm. A different paradigm must be used if tumor, infection, or metabolic disorders are suspected. They are best assessed through laboratory studies. New bowel and bladder symptoms or obvious multilevel neurologic dysfunction demand immediate neurosurgical consultation and consideration of MRI or myelo-CT scan.

Some fractures may be difficult to see on x-ray, but if suspicion remains high due to the history and continued severe limitations, a bone scan is more sensitive after 7 to 10 days of symptoms. During the acute stage, CT scan should be reserved for patients with a high suspicion of a serious problem on the basis of physiologic or historical indications demonstrated with x-ray film or CT scan.

The clinician can expand the medical examination as required by the specific leads obtained from the standard history and physical examination of the spine. The importance of the interview and the review of systems and past medical history forms cannot be overemphasized.

Once the examination is completed, the clinician can then categorize the patient according to present and future needs. A clinician can feel comfortable explaining the good news and expectations to a patient after ruling out “red flags” if the present episode of limitations due to symptoms has lasted less than 4 weeks. If limitations have persisted longer than 4 weeks, the clinician must decide, based upon limitations, improvement since onset, and threat to the patient's livelihood and mental well-being, whether special studies are warranted immediately or in the future. An executive with symptoms that interfere with racquetball or tennis but that are not a threat to livelihood can be followed for several months. A furniture mover with similar limitations but unable to work for a month would be at great risk of losing his or

her job if the clinician waited 2 to 3 months for the symptoms to resolve. Thus, history, physical examination, and special examinations are the foundation for the statement that there is no danger (psychological validation) in avoiding the debilitation of inactivity. The prescription of activity, rather than rest, is the cornerstone of the management of low back pain.

Medical Attention: Assurance, Comfort, Education

The goal of initial care is to keep the patient's activity as normal as possible to avoid the debilitation of excessive rest and to prevent potential socioeconomic complications. Assurance, comfort, and effective treatment need be addressed for all patients. The *New England Journal of Medicine* article by Malmivaara and colleagues indicates that approaches advocating rest may have been too conservative (55). This report emphasizes a need to assure the patient that there is no hint of anything serious (psychological relief) and to encourage the avoidance of further debilitation by continuing normal activity (physical help). Malmivaara et al. found that even when patients engaged in reasonably heavy work, the symptoms abated faster than for those who had 2 days of rest or who had passive correction techniques that were labeled exercise. If limitations linger, the clinician should provide further education about expectations and assure the patient that further diagnostic studies will be considered.

Assurance and Expectations

An example of how to reassure the patient is the following: “Medicine is pretty good at finding serious conditions and at this time we have no hint of any serious problem. Unless you become too debilitated by inactivity, your symptoms should resolve over the next few days. If you are in the slowest 10% to recover we will again consider special studies to help explain the reason for the delayed recovery. The reality is that no one has been able to explain the cause of back problems that limit approximately a third of us by age 30, 75% of us by age 40, and virtually all of us by 50 years of age. It is good news when we can't explain the exact cause of a back problem because the outcome is better and we can usually start sooner to build comfortable activity tolerance. Now we need to help you feel more comfortable without making your symptoms worse.”

Comfort and Help

Here is an example of advice regarding comfort: “There are many means of helping you with discomfort but nothing totally wipes out the pain and lets you go about your business as usual. Thus, we will recommend the best combination of methods to allow you to stay as active as possible to avoid debilitation and to minimize how much work you will have to do later to regain your physical capacities. It usually takes twice as long to regain conditioning as it does to lose it. Medication can take the edge off the pain. Acetaminophen blocks the pain highway at a different place than other medications, so it works well by itself or in combination. At worst, an episode of pain may last for up to 5 days. That is the longest you might need major help with comfort. Most often your medication will allow you to continue with normal activities. We will try to avoid medication that might cloud your mind or disrupt your normal activity any more than necessary.”

For patients who lack any hint of kidney or liver dysfunction and who are not elderly, a combination of acetaminophen and nonsteroidal antiinflammatory drugs is adequate and more effective than what are commonly considered “stronger” or more dangerous methods. If patients feel manipulation has helped before, remind them that it only helps symptoms and does not correct the problem without the addition of conditioning.

Work Recommendations (for Compassion, Not Safety)

A patient may not be able to tolerate the discomfort associated with required work activities. Compassion for the patient may necessitate some work limitations, for as short a time as possible, until the severest symptoms resolve or conditioning begins to improve activity tolerance. Whenever activities at work are limited for more than 3 to 4 days, an alternative activity (see Treatment: Maintaining or Building Comfortable Activity Tolerance) must be started to minimize the debilitative effect of the work restriction. The two medically justifiable parameters for recommending work limits involve lifting and sitting. The amount and time spent doing each can be negotiated based upon the report of specific limitations in the initial history (patient's perception of safely standing, sitting, walking, and lifting) and the recommendations of the AHCPR Guideline #14 with regard to the duration and progression of work activities. The main goal is to avoid debilitation through inactivity. Prolonged absence from work also leads to loss of physical and social skills, thereby impeding restoration of normal function.

Treatment: Maintaining or Building Comfortable Activity Tolerance

Remember the old Groucho Marx joke: “Doctor, doctor, after surgery will I be able to play the violin?” Doctor: “I would hope so.” Response: “Good! Cause I could never play it before.” Surgery, manipulation, injections, medication, or rest do not train anyone to play the violin, run a marathon, tolerate strenuous activity, or return comfortably to normal activity after being inactive for a while. Only conditioning allows a person to comfortably tolerate activities.

Unfortunately, there is no way to maintain or build activity tolerance without conditioning (see Why Conditioning: A Summary of Explanations for the Patient). Conditioning activities need not be any more dangerous for the spine than sitting at bedside before rising in the morning, but activity may not be totally comfortable. Patients need to understand the difference between hurt and harm (see Chapter 25). Discomfort with conditioning by walking or cycling usually points to a lack of muscular protection and emphasizes the importance of the conditioning activity (97,98,99 and 100). Whether due to inactivity or general or specific structural change, once activity tolerance is lost only conditioning can regain or improve comfortable performance. The three aspects of activity progression are the following: general conditioning for stamina, specific spine muscle conditioning, and general reconditioning, especially resuming work or specific activity conditioning (at work if possible).

General Conditioning for Stamina

General conditioning for stamina consists of speed walking or stationary cycling for 30 continuous minutes at a heart rate of 130 beats per minute (or 120 if older than age 40 years) or jogging for 20 minutes. *Note*: Severely debilitated patients or those with severe lower extremity joint problems may need to start with swimming, which can improve tolerance for essential terrain-oriented conditioning activities. Few severely debilitated patients profit sufficiently from swimming to avoid the walking or cycling needed to build reasonable activity tolerance.

After 5 days per week of conditioning for 6 weeks, general stamina can be maintained thereafter with 2 to 3 sessions per week of 30 minutes each. (Like an airplane, it takes much more energy to get up to altitude than to stay there; 2 days a week of conditioning will maintain it.)

Specific Spine Muscle Conditioning

Recommendations are based upon the original work of Biering-Sorensen (101) and have been best studied by Gundewall et al. (56). The patient should work up to a 4-minute isometric session per night.

Resuming Work or Specific Activity Conditioning (at Work if Possible)

There is no better way to avoid deconditioning than to continue normal activities, as has been demonstrated in prospective studies (55,57).

Education and Reassurance for Those Slowest to Recover

Providing information to patients is important and has long-lasting benefit (57). Assurances, expectations, and the importance of conditioning must be established with each patient. Initial validation and repeated reflection are essential parts of care. Numerous studies (41,102) prove the effect on outcome. Patient confidence is maintained by using validated information and reassurance that if significant improvement does not occur, special studies will be considered to help explain continued limitations persisting 4 weeks or more (11).

The next section is not an attempt to provide surgical guidance but offers information for nonsurgical clinicians who must explain workup and surgical aspects of care to patients. This overview is congruent with surgical information presented in other portions of this chapter.

DIAGNOSTIC CONSIDERATIONS FOR DELAYED RECOVERY

If back symptoms continue to limit activity, especially at work, for more than 4 weeks or if sciatica persists for more than 4 weeks, it is reasonable to consider seeking a cause. Obtaining physiologic evidence can help determine the likelihood that anatomic imaging might lead to a specific diagnosis (11). Anatomic studies alone can be confusing. Normal aging changes (present 30% of the time in asymptomatic 30-year-olds and found in virtually everyone by age 65) may be confused with a diagnosis. Thus, physiologic evidence helps to avoid the limitations of imaging studies (45).

Figure 76A-8, which correlates age with disk findings in normal subjects, illustrates this point. Table 76A-3 notes that imaging studies provide no physiologic evidence. Thus, a clinician who does not consider the whole picture may wrongly interpret aging changes as a cause for present symptoms.

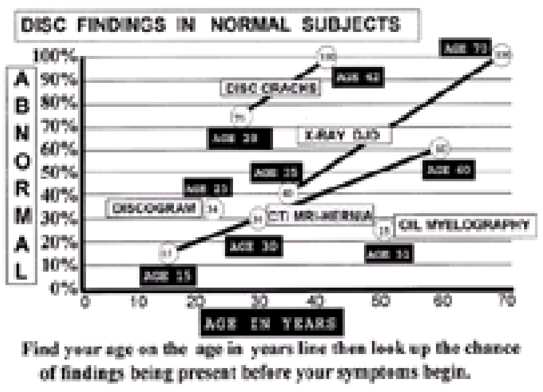

Figure 76A-8. Questionable radiographic diagnoses that increase in frequency with age from imaging studies of patients without symptoms. (CT, computed tomography; DJD, degenerative joint disease; MRI, magnetic resonance imaging.) (From Bigos SJ. *Housestaff handbook for back problems*. Seattle: SpineMate Publications, 1996.)

TABLE 76a-3. Types of contributions toward making a specific diagnosis

A picture of a telephone does not tell you if it is ringing. A picture of a box does not tell you if it is filled with an anvil or foam. If you drop the box on your foot, then you know. You have some physiologic information. A picture of soft tissue or even bone abutting the dura does not show whether the pressure is sufficient to compromise the function of the nerve root. Only physiologic evidence tells us whether the nerve root is compromised. Surgery is effective in relieving pressure on compromised neural contents caused by either herniated disk or spinal stenosis. Imaging pictures guide the surgical approach by defining an anatomic cause for known physiologic compromise.

Physiologic Evidence

In the absence of fracture or dislocation, reaching a conclusion about surgical considerations is similar to television's “Wheel of Fortune” game show. The more letters on the board, the greater the chance of guessing the phrase correctly. Figure 76A-8 presents the chances at different ages of having an imaging test that is diagnostic before the development of symptoms. This chart is based on studies of subjects without symptoms. Table 76A-3 offers clues about how to procure physiologic evidence to avoid the possible confusion of relying on imaging studies alone.

- Laboratory studies (sedimentation rate, blood count, urine analysis) provide indications about a metabolic and more general screen for suspected potentially serious problems (103).
- Bone scan provides a nonspecific structural screen and sensitive physiologic information about bone and joint changes (bony reaction to change in structural loading with fracture/dislocation or architectural changes of tumor, infection, or spondylitis).
- EMG is indicated for constant or near constant limb symptoms of suggestive radiculopathy persisting for more than 4 weeks (an earlier test may provide false-negative results because changes will not be evident until the third or fourth week of symptoms) (see Chapter 13) (104). The diagnostician should look for more than multiple positive sharp waves or fibrillation potential (S-1 compromise can slow H-reflex) as evidence of motor nerve compromise (strongly consider anatomic studies if any muscle is 3+ or more). The physical examination should show obvious signs of a problem at L-5 or S-1 before the diagnostician seeks imaging verification. EMG is not needed if motor, sensory, and reflex tests indicate obvious L-4, L-5, or S-1 nerve root damage or compromise, which is strong physiologic evidence to explain a limitation due to leg symptoms persisting 4 or more weeks.
- Somatosensory evoked potentials (SSEP) can provide information on slowed nerve root transmission in patients with symptoms of neuroclaudication and EMG evidence of motor function changes. SSEP measurements tend to be more sensitive than EMG measurements, although less specific for active compromise of a nerve root.

Anatomic Imaging

Anatomic imaging is used to define a reason for physiologic evidence and to seek conditions that impose upon the neural content of the spinal canal and foramen. The most commonly used techniques are MRI or CT, which are not as invasive as myelography. With both we seek information about pressure upon the spinal cord above L-2 and upon nerve roots in the lumbar spinal canal or in the intervertebral foramen, through which they pass to exit the spinal canal before forming the lumbosacral plexus (see Chapter 14).

- X-ray screening is most useful for seeking a fracture or dislocation. Otherwise, beyond the expectations from history and physical examination, radiographs contribute information on serious pathology in but one in 2,500 cases (11,103). When a radiograph is positive for fracture or dislocation, the clinician may gain additional information with CT scan or MRI, depending upon the patient's clinical presentation and findings.
- CT scan defines bony pathology but may not allow definitive evaluation of the contents of neural canal (74).
- MRI best defines the potential anatomic reason for physiologic evidence, especially intradural and extradural defects; soft tissue visualization is better than that for bone but is potentially distorted by patients who cannot lie still for extended periods of time (15% of patients experience claustrophobia).
- Myelogram–CT scan may be used for patients who cannot lie still, are too claustrophobic for MRI, or who have had prior spinal procedures. This combination provides better intradural resolution than does CT scan alone.
- Myelography may be used when MRI is not possible. In this procedure, radiopaque material is injected into the spinal dural sac. Myelography is best combined with CT scan.

A reasonable approach to MRI interpretation is as follows:

1. Start with the MRI T1-weighted view. Parasagittal views are the best for evaluating fat in the foraminal canal, which vanishes before nerve roots can be compressed. The parasagittal MRI T1-weighted lateral images show fat as white in contrast to the nerve and other tissue in the canal.

   The parasagittal lateral views of the spine are usually displayed from left to right, so the first view in the upper left corner is of the far left aspect of the left foramen, with each picture thereafter moving to the right until the lowest right image is the rightmost aspect of the right foramen. Look for fat in the foramen because any pressure will eliminate the fat before affecting the nerve. Do not be alarmed unless you cannot find fat present in at least two views of the foramen in the parasagittal views. Remember to record the level according to the system in which the fifth vertebra is the one above the sacrum, the fourth is two above, and so on. The foramen is described according to the vertebral body above and below—for example, L-5 to S-1 foramen or interspace, L-4 to L-5.
2. Next, look at the parasagittal MRI T2-weighted lateral images, which make water seem white in contrast to other tissues. Thus, these images give views similar to a lateral myelo-CT, in which the myelographic dye makes the cerebrospinal fluid white, as does the T2-weighted image. Here, look at the contours of the spinal canal and potential indentations upon the white, fluid- filled dural sac, which contains the nerve roots before they exit through the foramen. One can also evaluate alignment of the vertebral bodies that form the anterior wall of the spinal canal.
3. Finally, evaluate the T2-weighted cross-sectional images to evaluate indentations upon the dural sac and its white, watery fluid contents and nerves. Think of the sac as a long water-filled balloon that should be convex unless resting upon something that flattens it out or indents it. We are most interested in the indentations that cause the sac to be concave, which may indicate pressure on the neural contents that could explain physical findings or EMG abnormalities relative to complaints of sciatica.

In summary, T1-weighted (fat-white) parasagittal lateral views let you look for fat in the foramen that is obliterated before there is pressure on nerve roots. T2-weighted (water-white) parasagittal views of the canal allow you to assess the contours of the vertebral alignment and compression of the white, water-filled dural sac. T2-weighted (water-white) cross-sectional views provide evaluation of the normally convex or flat dural sac, which might have a concavity due to pressure on the sac and its contents. Any doubts about the numbering or left to right or right to left display on parasagittal views should prompt a phone call to the neuroradiologist for verification.

An important point on all imaging studies is that overreading is a necessity for the neuroradiologist. Only such emphasis can satisfy all potentially interested parties who might review the scan; it also alerts the less adroit to points of interest, clinically significant or not. Radiologists frequently report normal age-related changes as pathologic.

Specific Impressions

Sciatica Due to Herniated Disk

The history of back and leg symptoms with strong physiologic evidence of nerve root compromise on physical examination or EMG (95% L-5 or S-1) and corresponding anatomic verification on MRI, CT, or myelogram are indications to consider surgical decompression by removing the offending disk material and any loose nuclear material within the disk (diskectomy), usually through hemilaminotomy (widening the opening between the lamina) (105,106). The patient who can function with less than 3+ EMG findings and who does not have surgery commonly recovers within a few months, with a recurrence rate of approximately 60% in the next few years.

Surgery can reduce the recurrence rate to approximately 10%, depending upon demands placed on the back, with strong findings that surgically treated manual workers miss fewer days due to back problems during the first 4 years after onset (106,107). After that period, there seems to be no difference in recurrence rates. Surgery is a luxury for speeding recovery when a patient has very strong findings. Generally, the more obvious the findings, the more certain the recovery. The greater the compromise of the canal, the better the results with surgery. Herniated disk recurs at the same level in 2% to 4% of cases. An important point is that surgery does not make the back feel 18 years of age again. Back functioning will still be limited depending upon muscular conditioning relative to what the back will be asked to do. The key is to make certain that herniation is the cause of symptoms. In many cases, removal of disk herniation may solve a problem present before symptoms began and that is not the cause of symptoms. In such cases surgery is not a solution and may even worsen the symptoms. Again, the lesson is to not rely exclusively on anatomic imaging studies alone.

For patients with prior diskectomy, reliance on physiologic information is even more important. First, scarring may alter imaging findings, while diminished physical findings may be related to the reduced nerve root mobility due to scar (108). Patients who did not respond to the first diskectomy present even more difficult management challenges (109). Theories abound as to why. Surgeons traditionally blame scar but every postoperative patient has scarring. The wrong diagnosis or postoperative diskitis may be the reason for failure (110). Great caution is required in diagnosing recurrence within a few months after surgery or assessing the patient whose symptoms worsen immediately after first diskectomy. Both situations can involve a myriad of issues. A surgically battered nerve root may produce EMG changes for more than a year and can be an enticement to attempt to decompress (uselessly) an already sensitive nerve root. An old adage was that positive sciatic tension signs plus one neurologic finding yielded a 65% chance of correct diagnosis. This adage is a dangerous guide for patients with a possible recurrent disk herniation. Acute EMG changes, not polyphasic waves, with corresponding imaging findings greater than would be produced by scar, are the safest indications of the need for another decompression. However, we must be guarded in our expectations of results relative to those expected with first procedure.

Neuroclaudication Due to Spinal Stenosis

The diagnosis of spinal stenosis is common, although it is but a physical finding related to the condition that is most amenable to surgery—neuroclaudication. The diagnosis is better determined by history than by imaging studies. Surgical results are most appreciated by older, retired patients who have experienced a gradually decreasing activity tolerance, especially in walking (neuroclaudication) and standing (related to extension of the lumbar spine), which cause leg or feet symptoms. These patients can find relief by flexion of the lumbar spine to decrease the ligamentous enfolding that crimps the intradural neural contents. If spinal stenosis occurs before age 60, consider the diagnosis of diabetes or other general metabolic problems or congenital stenosis due to short pedicles. Most patients have at least intermittent symptoms for months before seeking medical care.

Physical examination tends to be unimpressive and without evidence of sciatic tension signs of straight-leg raising; weakness and atrophy may be symmetric, as are the diminished reflexes. EMG changes tend to be minimal due to the gradual nature of the compression, but some positive sharp waves and fibrillation potentials are indicative of active disease. SSEPs can further help surgical planning by identifying levels of nerve root compromise to guide which nerve root foramina need special attention during surgical decompression (111). Anatomic studies, either myelogram MRI or myelo-CT scan, can verify central decompression (achieved through subtotal laminectomy with removal of the ligamentum flavum along with redundant anterior facet capsule, osteophytes, and sometimes diskectomy) (112). Foraminal decompression commonly requires removal of part of the anterior facet and perhaps partial removal of the inferior pedicle. The surgical decompression is not preventative and should be performed only when the patient feels compromised enough by the walking limitations to undertake the risks. Bowel and bladder compromise is an emergency indication for decompression. Those who respond best to surgery tend to be those who are most limited in walking distance (neuroclaudication less than 300 yards) and who must sit or squat to relieve the walking symptoms before continuing (113). Segmental fusion may be considered if there is accompanying retrolisthesis, spondylolisthesis, or (developmental degenerative slip) with motion.

Spondylolisthesis

In the American population, 3.5% have slippage of either L-4 vertebra on the L-5 or L-5 vertebra on the sacrum due to bony disruption between the facets (spondylolysis) early in life. A slip of more than 25% can compromise the nerves at the involved level. The limb findings and EMG changes are commonly more vague than with herniated disk and may be bilateral or unilateral. Surgical decompression is similar to that for spinal stenosis and fusion is usually required, as the disk tends not to show the aging signs and stability usually found in spinal stenosis. Thus, there is a greater chance of further slip with decompression given the usually underdeveloped facet joints. In general, the younger the patient (younger than age 30 years), the better the fusion result due to the decreased likelihood of a diagnostic dilemma posed by vague back symptoms. In instances of the latter, 25% to 40% of patients have vague leg symptoms, leading to the unverified misdiagnosis. Many patients without slip of 50% or more do not experience problems until the normal aging brings spinal stenosis, at which time the aging at slipped level leaves little residual motion.

Medical Arthritis (Seronegative Spondyloarthropathy)

Medical arthritis (seronegative spondyloarthropathy) (see Chapter 27) includes ankylosing spondylitis, Reiter's syndrome, psoriatic spondylitis, and their related

expressions of spinal symptoms (114). These tend to be multisystem diseases that require medical observation and the right combination of medication to keep the patient functioning. Once the vertebrae are stiff and brittle, minor trauma can cause fractures with serious consequences. Except for psoriatic arthritis, these disorders mostly occur in men, with onset between 20 and 40 years of age, and symptoms, especially stiffness, that are worse in the morning. After rising, it may take the patient an hour or more to reach the best attainable functional level, as the symptoms decrease with mild activity (83). The prudent clinician rarely considers surgery except for an unusual case of severe deformity (115).

Segmental Instability

The concept of increased motion at one segment is based upon relative increased motion that allows measurable stress shielding of the adjacent segments—for example, the hypermobile segment takes up all the stress and allows 11 to 15 degrees (for L-5 to S-1) more motion than in adjacent motion segments (Fig. 76A-6, x-ray angular) or more than 5-mm slipping translation (Fig. 76A- 7, x-ray translation). It is still controversial to fuse a motion segment that does not move after surgical decompression (116).

Nonphysical Interference

Spine-limited patients commonly find themselves facing dilemmas when they must use their backs as a crane to survive. Such dilemmas manifest in expressions of fear, anger, or survival behavior that we commonly view as unpleasant or even dishonest. Clinicians may observe altered views of self or others and concentration on the insurance industry injury contest for the assignment of blame more than a focus on the medical problem at hand. The threats of failure commonly lead to embellishment of symptoms. The safest interpretation is that the patient has reason to question whether the clinician has his or her best interest in mind. Embellishment and anger seem to be attempts to enlist help in the contest over liability. Increasingly, we are finding that these nonphysical factors, commonly termed *psychosocial*, are dynamic and reactive (117). It is important to remember, however, that nonphysical threats to the patient's self-esteem, livelihood, future, or other loss can significantly influence the patient's response to caregivers (8).

The Waddell tests and the clinician's personal impression are probably the best predictors of a slower than expected physical recovery. The potential combinations of nonphysical pressures, be they economic, psychological, or social issues, make a search for the specific cause impossible. No matter what the combination of perception and threat, the clinician should try not to be too judgmental. Recognize that survival behavior is a common response, although not very effective at the human level. In nature an animal's survival behavior is an aspect of being prey or predator. Sometimes such behavior is effective; other times it is not. A survival game must have a winner and loser, so both sides use betrayal to gain an advantage over the adversary. A bird feigns a broken wing away from the nest, a lizard changes color or fans out to appear larger, a zebra bears stripes, and a lion's coat is camouflage in high grass. All are a natural part of survival in the animal kingdom. Embellishment of symptoms is a more sophisticated expression of survival behavior that should not be interpreted as a deliberate attempt to deceive the physician, but as a tocsin that the patient feels trapped and is seeking help and understanding in the best way he or she knows.

Zero to two positive Waddell tests are normal, whereas three or more positives warn the clinician of nonphysical interference that can confuse the history and physical examination. In the latter case the clinician needs a more objective focus to avoid overreacting to nonobjective findings that require the patient's volition or interpretation. Clinicians should also be warned that nonphysical pressures may alter the patient's response to the care provided and perhaps lower the expectations related to outcome for both surgical and nonsurgical efforts (8,118). Although other approaches are available to the individual clinician, these simple tests can help to avoid overlooking potential difficulties (Table 76A-4).

The specific nonphysical reasons for slow recovery are usually numerous. Whatever the nonphysical reason for slowed or delayed recovery, the approach is the same: Overcome the fear of physical activity through validation and reflection techniques, and help the patient defuse reactions to the unknown by gathering enough data about options to encourage more logical decisions (see Slow Recovery Approach: Validation and Reflection).

FURTHER TREATMENT AFTER DIAGNOSTIC OR SURGICAL PROCEDURES

After seeking reasons for slow recovery, we return to a similar but altered treatment paradigm. Whether due to the period of reduced activity or to changes in the motion segment, the focus is now on gaining comfortable activity tolerance. No shortcut exists; the only recourse is conditioning to avoid fatiguing protective muscles and to prevent their owner from causing symptoms or irritation. After diagnostic or surgical procedures, nothing should stand in the way of the needed conditioning. The first step is to assure the patient as part of the validation and reflection process that there is nothing dangerous to fear and that comfortable activity tolerance can be gained only by overcoming or avoiding the debilitation of inactivity. This best approach is a gradual return to activities or exercise in conjunction with a gradual return to activities. In either case, there is no pill, massage, manipulation, injection, or surgery to provide comfortable activity tolerance. The only way to regain comfortable activity tolerance is through conditioning protective muscles.

Why Conditioning: A Summary of Explanations for the Patient

When Will the Pain Go Away?

Review the example of the knee. It makes no difference whether knee surgery is required. Recovery comes only after conditioning the thigh muscles to the point of compensating for whatever knee problem remains. Adequate conditioning of the protective muscles allows some patients to return to rigorous professional athletics, not because the knee is normal, but because there is adequate muscular compensation to tolerate the required activity. The protective muscles must be conditioned beyond their capacity before the knee problem. Until conditioned to that point, the knee continues to be painful, doesn't tolerate activity, and can be irritated by any minor mishap. The knee becomes red and swollen, sometimes requiring draining of fluid that prompts the patient to question the exercise regimen when there seems to be something terribly wrong with the knee. Then, almost miraculously, the redness and swelling resolve and activity tolerance begins to improve as the muscular capacity increases. It is similar with the spine.

Until our muscles can do their normal protective compensatory job, any activity is like gardening for the first time in spring after resting all winter. Once we tire or the muscles we are using begin to fatigue, we can pay for it that night, the next day, or even right away. The severity of symptoms depends upon whether protective muscles are already compensating for some change, as in the knee analogy above. At age 18, we're a little stiff; by 50 we may notice much more stiffness, but both result from the same physiologic phenomenon. It is not associated with dangerous activity or a serious problem, but only a winter's rest. It usually takes a few days or weeks of working in the garden, practicing a sport, or working at a demanding job before muscles become sufficiently conditioned to do their normal protective job of allowing comfortable tolerance.

Conditioning Requirements

Our best science indicates that conditioning involves addressing two weak links that can keep protective muscles from reacting fast enough to protect the spine. The most obvious is fatigue of the specific back muscles, which slows their reaction time. Also, if the owner of those muscles becomes even a little tired, general muscle reaction slows and coordination is impaired. Such explanation will help patients understand how a lack of general stamina can prolong symptoms and how training specific spine muscles provides protection from future problems.

Medical Goal

Nothing, surgical or nonsurgical, makes the back young again after a few weeks of limitation or significant sciatica. The goal of treatment is to gain sufficient muscular protection to reduce the frequency and severity of future back problems.

Conditioning

The conditioning process starts first with completion of general conditioning. These activities are done 5 days per week for 6 weeks and involve either continuous jogging 20 minutes or continuous walking or stationary cycling that keeps the pulse above 120 to 130 beats per minute for 30 minutes. After only 4 weeks of general conditioning, a second phase of specific back muscle conditioning can be started, with the patient working up to 4 minutes daily for 4 weeks to gain muscular protection. Both phases can be started at once but for deconditioned patients tolerance is much poorer.

A third phase is not focused on treatment of the spine but is an attempt to regain what we tend to lose when we are inactive due to back symptoms. Thus, this is a general reconditioning phase for arm, leg, and abdominal muscles. Dips for the arms can be performed in any armchair. Leg exercises include either squats at the sink or the old ski conditioning exercise of assuming the sitting position against a wall without a chair. The abdominal muscle conditioning demands only mild exercises. All can be performed in less than 5 minutes of effort and usually can be added after 4 weeks of specific spine muscle conditioning.

An additional phase II exercise for upper back and neck is also available. Once a person's shoulders will tolerate 100 continuous small arm circles done slowly, they are performed as rapidly as possible to involve the upper back and neck muscles. Canned goods (tuna to pears) and even weights can be added to further improve conditioning.

Work hardening should be reserved if at all possible for gradual return to activities at work. The basic concept is to have the patient perform as many specific but limited tasks as possible. If the patient is unable to tolerate one circuit of an activity, then repetitions need to be built with limited load (two-thirds to three-fourths of the requirement) until one circuit can be completed. Then the patient should begin two-thirds to three-fourths of full-load building with repetitions beyond what is required before gradually increasing the load to the normal level. The speed of progression and eventual end point may be predicated upon many physical and nonphysical factors. A work-hardening approach performed in the normal work milieu increases the chance of success and markedly reduces costs.

Slow Recovery Approach: Validation and Reflection

Patients are stymied by slow recovery or a parade of continuous obstacles to gaining reasonable activity tolerance through conditioning. If return to work is the expected outcome, the patient may well be struggling to survive in a confusing contest. The patient may perceive return to work as guaranteeing failure. A sense of being trapped in this contest causes patients to embellish symptoms and augment pain behavior. A clinician's harsh judgment can only worsen the situation. It helps to remember that survival in the jungle is based upon confusing the enemy. We commonly see patients make clumsy attempts to enlist our help. Patients may regard the clinician as a predator in the contest until we can convince them that we have their best interest in mind. We also must look at ourselves when we continue to see such behavior because it means we have not convinced the patient that we are not just another predator. No species chooses failure to resolve a contest. A person's failure to overcome limitations can be due to innumerable combinations of physical, emotional, cognitive, and social factors. Patients benefit more from our honest help than our judgment of their legitimacy (61).

Nonphysical Interventions

Validation and Reflection

When recovery is slow, review the history, physical findings, and special study findings to be sure no “red flags” have emerged. Validate again that there is no hint of anything serious standing in the way of building comfortable activity tolerance. As a helpful partner, use reflection techniques to explain the need to build activity tolerance through conditioning. Most important, use reflection techniques to show concern for slow progress and difficulty in reaching activity goals.

“If it is this difficult now (to regain activity tolerance), what is the chance that it will be easier as you get older? What will you do if, for any reason, you do not get back to your former job or activity? If there is any question, let's gather some information about your options, just in case. You may not need to know options immediately but they could be important for planning over the next few years or sometime before retirement age.” These statements provide the patient with validation and acceptance that you truly have his or her best interest in mind. Such acceptance is a turning point in any individual or multispecialty approach to the patient.

This validation and further reflection can help the patient feel much more in control, with the knowledge that he or she is not tied to a particular outcome if in a feared “return-to-work contest.” Offer to help the patient start a spiral notebook to record information about options (11) and review notebook progress on each visit. Only information and understanding deemotionalize decision making.

No Effort about Options/Further Reflection

Some patients may require coaxing to gather information about possible options. The patient's lack of response to a few suggestions to gather information provides another opportunity to show concern by providing reflection about the apparently inappropriate denial. In such cases, the clinician might state, “It is quite unusual for spine symptoms alone to keep someone from making a few phone calls to figure out how to save one's own livelihood and perhaps the future of his or her family. Usually other issues are involved. I think you need see a counselor to sort out the reasons for such behavior.”

If the patient trusts that you have his or her best interest in mind, the patient usually asks, “Reasons such as what?” The ensuing discussion provides an opportunity to review common reasons. The reason for such denial can be personal habits, denial, or social factors.

Approaching emotional issues can at first result in anger and avoidance. Referral for psychiatric evaluation and treatment can be helpful for both the patient and the physician.

DIFFICULTIES WITH THOSE WHO CANNOT FIND FAILURE ALTERNATIVES

“It Didn't Work!”

Those without reasonable options tend to demand the unavailable. Groves described the “hateful patient” in a number of scenarios (119). Most important, he related what he described as the passive-aggressive patient. Without showing distress, the patient smiles before responding to recommendations by saying, “Didn't work! Now what are you going to do?”

This patient does an excellent job of transferring the problem to the clinician. Thus, it is important to not chase the pain but attack the activity intolerance with activities no more stressful than sitting on the side of the bed before rising. Should this type of conditioning be uncomfortable in the absence of red flags, it can expose the present lack of muscular protection and validate further the importance of conditioning.

Validation that there is no dangerous problem and reflection about what you have to offer must include the expected result of gaining the ability to tolerate reasonable activity. Those who have unreasonable expectations about future tolerance may benefit from the stories of athletes such as the professional basketball players. The question always must turn to “But where are the people who can continue such strenuous activity after 60 years of age?” Equally important is to review the failure of medical science to explain the cause of symptoms in 88% of the patients we see. Thus, workup is not aimed at the cause of symptoms but to find serious conditions or alterable reasons for slow recovery—for example, either neurologic compression or lost structural integrity that can slow the conditioning needed to regain comfortable activity tolerance.

Anger

Patients trapped in failure have but two options. They can escape or become depressed. Without the emotional energy from accomplishment or the camaraderie of interacting with others, depressive tendencies are almost guaranteed.

A person who lacks a sense of accomplishment or even self-indulgence (considered selfish by most blue-collar patients) can head down a path toward depression unless interrupted. Anger can be a short-term interruption on this slippery path. Unfortunately, anger does not always strike its target and can confuse the clinician's efforts to determine the true sources of the patient's dilemma. Usually, simple questions such as “Is there something I've done?” or “You seem very angry” can refocus the patient's aggravation in the right direction and away from you. Should you sense an inappropriate disturbance, offer to help the patient with a referral to a counselor or psychologist. Sometimes the patient's anger is with your inadequacy to solve the problem. Fortunately, other than tarnishing of your name, anger dissolves and requests cease as soon as the patient finds an enabler. Thereafter, the patient may have unreasonable hopes about nonphysical problems and no longer feel a need to function. Unrealistic validation may allow avoidance, at least for a while. Some patients later return to you when the enabler's ability to support avoidance evaporates or fails to solve the external pressures related to the patient's failure to function. Then the clinician must resume further honest validation of

nothing serious and reflection toward improved conditioning.

CONCLUSION

Everyone who lives to age 50 experiences back problems. Occasionally, someone will challenge this statement. Simply point out that it is a rare person older than age 50 who could lay a driveway by hand over the weekend and then play basketball on Monday, as most of us could when we were 18 years of age.

Back problems affect society (i.e., all of us). We all pay for this most expensive industrial injury, musculoskeletal problem, and most common cause of disability under age 45. The person who moves furniture, carries cement bags, or must quickly unload heavy objects pays most directly. His or her livelihood and even the family future can be threatened by back problems. These symptoms may slow down the housewife because there is no one else to do her chores. The same symptoms may inconvenience the lawyer, administrator, or physician by interfering with a racquetball game or tennis match without threatening income or future. Back problems cost us all either in our personal productivity or in the prices of the goods we purchase because of the increased disability costs incurred by employers.

Where does medical care fit in? In recent years, some have questioned whether care for back problems is optimal. A ninefold difference in the use of different evaluation and treatment techniques in different parts of the country has been demonstrated in the United States, the country with the world's highest rate of back surgery. Newer and newer technology and growing numbers of providers and approaches to treatment have not halted the rising costs of back problems, even with the advent of managed care. More scientific information indicates that a limited physical understanding of back problems can compound nonphysical pressures. Medical science will have few solutions to the real problem until we realize that the back cannot be used as a crane until age 65 and that psychosocial problems are often not diagnosed but are the result of a complex combination of present and prior experiences.

The definitions and resultant treatment considerations can help the clinician avoid complicating the patient's problem by employing an honest scientific basis for medical recommendations. Back problems are rarely emergencies. The real decision maker continues to be the patient. We help most by giving the patient the clearest advice and understanding of what medical science finds reliable and warning against becoming physically debilitated by inactivity. Relying upon scientific literature can also avoid fingers pointed at the clinician when a patient must defend a lack of progress. This point brings us to our most difficult patients and greatest challenge.

Surviving an injury contest can greatly emotionalize the patient's life and decision making. Being able to assure patients that they “deserve the most dependable recommendations medical science provides” affords the clinician an opportunity to help the patient build comfortable activity tolerance and prepare for difficult decisions. Rather than facing the old paradigm of “Didn't work, Doc! Now what are you going to do?” a professional and a friend can remain an ally to the patient facing both the physical and the nonphysical aspects of return to work (119).

The literature supports the clinician who adroitly sets reasonable expectations and helps the patient avoid both physical and nonphysical pitfalls. Reliable data can help the clinician be more efficient and effective and remove the sting of having to see another time-consuming back patient. The prudent physician will

- Never be put in the position of being accused of treating only the patient's head. Red flags and examination information are always needed to assure the patient and the clinician that there is no physical problem to block conditioning.
- Remember the Groucho Marx joke, and that only conditioning begets comfortable activity tolerance.
- Realize that only the computer on the patient's shoulders can weigh the different (nonphysical) pressures, fears, and understanding needed to make a reasonable choice of options.

Nowhere in the literature have both elements of acute care been better illustrated than in the work of Malmivaara and Indahl (55,57). The nonphysical should be addressed with strong assurance that there is “no hint of anything bad that should stand in the way” of the most important aspect of physical treatment—“avoiding the debilitation of continuing activity by continuing normal activity as soon as possible.” For debilitated patients, the message of Gundewall (56) provides the next step for future protection, as discovered by Biering-Sorensen (101).

Perhaps as a friend as well as a clinician, we can help patients face serious decisions in a more informed and less emotional fashion. We can support the collection of information needed for making those decisions by avoiding harsh judgment when behavior varies in the emotional battle for survival through avoidance of facing real or perceived failure.

Despite the incentives for surgeons to perform surgery, we shall remember how rarely complications of dural leaks, ileus, blood replacement and reaction, discitis, battered root, and scarring are encountered after the conditioning needed to improve activity tolerance. This is particularly important when surgery makes so little difference in the final outcome except to speed pain relief in patients with very strong findings (107,120).

This section has tried to capture the essence of our strongest scientific data and the best elements of multidisciplinary approaches that can be provided in a practice. Those patients who are more disturbed, entrenched, abused by or abusing their local medical community or those requiring more hand holding may require a team approach (see Chapter 11). Other sections of this chapter cover treatment of pain and spine surgery. For pain patients with a lumbar spine component, we have stressed activity issues that are critical to the restoration of well-being.

CHAPTER 76

B. Role of Surgery in the Treatment of Low Back Pain and Sciatica

Jeffrey J. Wise and Gunnar B.J. Andersson

Although it has been estimated that 60% to 80% of the population experience at least one episode of low back pain during their lifetime, the majority of these episodes are self-limiting (1,2). Regardless of treatment, low back pain episodes usually resolve spontaneously within a few weeks. The presence of leg pain (sciatica) influences the recovery rate negatively (1,3). The lifetime prevalence of sciatica is 2%, and 10% to 25% of these patients develop persistent radiculopathy (3). The lifetime prevalence of lumbar surgery in the United States is approximately 3% (3). The annual incidence of surgery in 12 countries is depicted in Figure 76B-1. In Scandinavia the surgery rate is only 1%, and in England even less. What accounts for this difference? Taylor et al. (4) noted substantial variations in spinal surgery rates by region in the United States, as well as the number of spine surgeons per capita. When is surgery on the spine indicated (5)?

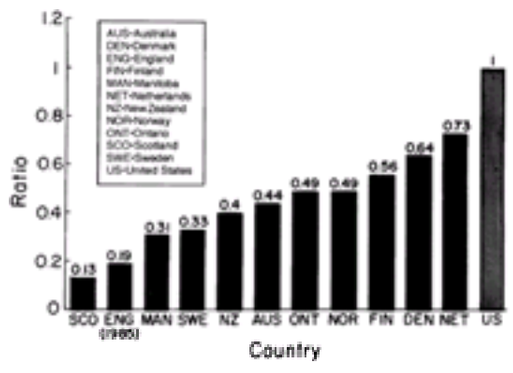

Figure 76B-1. Incidence of spine surgery in the United States. (From Cherkin DC, Deyo RA, Loeser JD, et al. An international comparison of back surgery rates. *Spine* 1994;19:1203.)

Surgery for lumbar disk disease should be performed only when nonoperative treatment fails, barring a few surgical emergencies. Nonsurgical management should be attempted for at least 4 to 6 weeks but may last as long as 6 months or more depending upon the patient's condition. Nonoperative treatment is addressed in a previous section of this chapter, and thus, will not be discussed here.

There are several major indications for spinal surgery: neoplasms, infection, inflammatory disorders, and deformity. Discussion of the surgical indications and operative procedures for all of these conditions is beyond the scope of this chapter. Rather, we examine the most common indications for spinal surgery, the degenerative conditions of the lumbar spine: herniated nucleus pulposus, spinal stenosis, and instability with degenerative spondylolisthesis.

SURGERY FOR THE HERNIATED DISK

Natural History

In considering the surgical treatment of any disease process, the natural history must first be determined. An intervention is not warranted if the natural history of the disease is not altered in a beneficial manner. Classically, disk herniations present as leg pain and/or numbness after an episode of acute low back pain. However, herniations may be asymptomatic (6). Leg symptoms, such as pain, numbness, or weakness after a dermatomal distribution, are referred to as *radiculopathy*. Back pain may occur concomitantly or may precede radicular pain by as little as a few hours or as long as a few days. Quite often, the initial low back pain diminishes and the leg weakness, numbness, or pain persists. Variations in pain patterns may be explained anatomically. The sinuvertebral nerve may be irritated from disk and annular material encroaching on the posterior longitudinal ligament or from direct compression of this nerve. Disk herniation can lead to activation of the inflammatory cascade that chemically irritates the nerve root, producing leg pain, numbness, or weakness. Isolated leg pain may result from a large extruded herniated disk fragment that directly compresses the nerve root.

The natural history of asymptomatic lumbar disk herniation is unknown, as is the natural history of untreated symptomatic herniations. This is so because in the presence of symptoms, treatment interventions have always occurred. Treatment may be as simple as activity modification, often combined with the use of over-the-counter medication. The natural history of the most severe variation of a herniated disk, the cauda equina syndrome, is also unknown (7).

Hakelius found in a 1970 study that 75% of patients with herniated nucleus pulposus responded to conservative treatment, usually within 10 to 30 days. Only 19% of patients went on to require surgical treatment (8). In 1983, Weber performed what is still considered the “classic” study on the treatment of lumbar disk herniation (9). This study is often misquoted as a natural history study, when in fact it is not. Two hundred eighty patients were studied, of which 127 were randomized to conservative and surgical treatment groups. Of the 280, 67 were selected for surgery based on their clinical symptoms, whereas 87 responded to conservative treatment and therefore were not randomized. Among the randomized patients, 17 crossed over from nonoperative to surgery in the first year (26%); at that time (1 year) 90% of the patients had a good outcome with surgery as compared with 60% with nonoperative treatment. However, at 4-year and 10-year follow-up intervals there were no statistically significant differences in outcome between the two groups. Weber's study also showed that the type of treatment did not alter recovery of motor or sensory functions. This confirmed Hakelius' earlier finding (8). With mild weakness, motor strength tends to return over a 3- to 6- month period. However, if the motor deficit is severe (less than grade 3 out of 5 strength), the recovery is often insidious and incomplete. If the onset of muscle weakness is temporally related to the onset of symptoms, then surgery is the treatment of choice.

When these studies are carefully analyzed, several methodologic flaws are found. The control group underwent significant clinical intervention—a 2-week hospital stay. Many patients were excluded based on their symptoms (54.3%). If patients in the nonoperative groups had disabling symptoms, they underwent surgery (26%). Because patients were transferred from the nonoperative treatment group during the study period, the outcomes of this treatment group were actually worse than reported. These studies demonstrate that short-term relief of symptoms is better with surgery, but the long-term patient outcomes are not significantly different when the conservative approach is compared with surgery, at least not in patients whose pain is not intractable. Tendon reflexes did not usually recover after either conservative or surgical treatment. Approximately one-third of the patients in both groups were left with some sensory deficit that did not influence their overall

function.

More recently, Saal and Saal reported 90% good or excellent outcomes for 64 patients with lumbar disk herniations (10). These patients were treated with epidural steroid injections and active physical therapy. Surprisingly, the results were not affected by either the size of the disk herniation or the presence of a neurologic deficit. Only three of 15 patients with an extruded fragment required surgery. They also reported a 75% to 100% resorption of the herniation in a smaller group of patients, whereas another 36% had a 50% to 75% decrease in size of the disk herniation (11). A follow-up study demonstrated that the larger the disk herniation, the greater the resorption (12). Thus, the presence of a disk herniation is not in and of itself an indication for surgery. And, when surgical risk is poor, patients can be advised that over time the chance of recovery is good.

Finally, disk herniations may be present without producing any symptoms at all. Two studies have demonstrated a large incidence (21% to 28%) of posterior or posterolateral disk herniations in asymptomatic subjects (6,13). In these same studies, disk bulges were found in 52% to 56% of patients. The asymptomatic herniations, like symptomatic herniations, are most common at the L-4 and L-5 levels and least common at the L-1 and L-2 levels. This distribution corresponds to that of disk degeneration— more caudal disk levels degenerate at earlier ages and to a greater degree. Thus, the presence of a disk herniation discovered on an imaging study is not an indication for surgery in the absence of clinical signs and symptoms that can be localized to the imaged abnormalities.

Indications

Interventions for medical conditions are expected to alter the natural history of a pathologic process. If there is no benefit to an intervention, the risks of the intervention cannot be justified. Interventions must also be cost effective. As stated above, patients who undergo surgery for a herniated lumbar disk tend to have more rapid relief of symptoms, but good long-term results are typically obtained in those patients who are treated conservatively. It must be stressed that the patients' diagnosis must be confirmed by history and must correlate with objective physical findings and imaging findings.

The only absolute surgical indication for lumbar disk herniation is the cauda equina syndrome (7). This syndrome is characterized by bilateral lower extremity weakness and pain, saddle anesthesia, urinary retention, and diminished rectal tone. Although there is little debate that surgery is indicated for a patient with a cauda equina syndrome, the timing of surgery remains somewhat controversial. Kostuik et al. showed that there was little difference in functional outcome whether surgery was performed within 6 hours or after an average of 3.3 days (7). Shapiro demonstrated better results if surgery was performed within 48 hours (14). In a metaanalysis of the literature, Ahn et al. found worse outcomes when surgery was delayed by more than 48 hours after the onset of symptoms (15). Once this diagnosis has been established, surgery should occur as rapidly as it can safely be performed. There is no role for observation in the treatment of a cauda equina syndrome, but there is also no reason for an unplanned rush to the operating room.

Several relative indications for surgery for lumbar disk herniation exist. These include gross motor weakness, particularly when progressive, loss of bowel or bladder function, recurrent incapacitating episodes of radicular leg pain, and severe leg pain persisting despite 4 to 6 weeks of appropriate conservative treatment. The best window of opportunity for successful surgery is before 3 to 6 months. Persistent symptoms may be due to chronic pathologic changes in the nerve root that are related to prolonged compression. Motor weakness is a relatively strong indication for surgery. Although Weber's study demonstrated that patients with a 75% to 100% resorption of the herniation and neurologic deficits may recover fully without surgery, his study did not include patients with severe motor deficits, and many surgeons believe (without real scientific proof) that recovery is accelerated with surgical intervention (9).

When evaluating recurrent radiculopathy as an indication for surgery, it is important to note that the likelihood of a recurrence increases with each recurrence. After the first episode of radiculopathy, 90% of patients' symptoms resolve and do not recur. After a second episode of radiculopathy, 90% of patients' symptoms improve, but 50% of patients will have recurrent symptoms. After the third episode, 90% of patients will get better, for a period of time, but 90% of these patients go on to have recurrent sciatica. Surgery, therefore, should be considered after the second episode of radiculopathy (caused by a disk herniation) and strongly recommended after the third.

If failure of conservative treatment is considered as an indication for surgery, the treatment should have been appropriate. Patients should undergo no more than 2 to 3 days of bed rest; a trial of nonsteroidal antiinflammatory medications taken regularly for 3 to 4 weeks; and possibly nerve root blocks, epidural injections, and physical therapy. After 4 to 6 weeks of such treatment, and only if the patient has appropriate physical findings such as a positive straight-leg raising test that are objectively confirmed on a radiographic study (computed tomography, magnetic resonance imaging, or myelogram), the patient may be considered a surgical candidate. This, of course, assumes that the patient does not develop a cauda equina syndrome or major motor deficits. Potential secondary gain issues, including worker's compensation claims and litigation, must be evaluated before determining a patient's suitability as a surgical candidate. In addition, a psychological evaluation may be appropriate for some patients (see Section C of this chapter). Patient selection is crucial to successful postoperative outcome. The point cannot be overemphasized that the patient's history must be substantiated by physical findings and radiographic studies. Patients with secondary gain issues have poorer surgical results, as do patients demonstrating nonorganic physical findings (16). In addition, patients with diabetes mellitus may have a relative contraindication to surgery, as their outcomes have been shown to be poorer than patients without diabetes (17).

In conclusion, there is a lack of prospective randomized data on surgical indications for lumbar disk herniation. In “Consensus summary on the diagnosis and treatment of lumbar disk herniation,” published in *Spine*, the panel recommended further prospective study to better define surgical indications and determine the timing of surgical intervention during the course of the symptomatic period (18). At the present, every patient must be evaluated on a case-by-case basis, taking into account the issues discussed above.

Alternatives and Procedures

There are two goals in the treatment of lumbar disk herniations: Relieve neural compression and avoid creating instability. One should look at this type of surgery as a procedure focusing on the nerve root and not on the disk. Success in treating lumbar disk herniations relies heavily on patient selection. The alternatives for treatment include the following:

A. Chemonucleolysis
B. Percutaneous diskectomy
    1. Mechanical
    2. Laser
C. Open surgery
    1. Posterior approaches
        a. Standard laminotomy and diskectomy
        b. Limited approach/microdiskectomy
        c. Far lateral diskectomy (Wiltse approach)
    2. Anterior approaches
D. Arthroscopic diskectomy

Chemonucleolysis

Chemonucleolysis was first used clinically by Lyman Smith in 1964. The procedure involves injection of chymopapain, an extract of latex of papaya. Chymopapain is a proteolytic enzyme that affects the proteoglycan-water aggregation in the nucleus pulposus. Proteoglycans are negatively charged molecules that combine with water. Glycosaminoglycan side chains are cleaved by the positively charged chymopapain molecule. Proteoglycans then lose their ability to hold water. The loss of water causes the disk to deflate and release pressure from the nerve root. Chymopapain has no effect on collagen molecules except in very high concentrations; thus, the majority of the disk is left intact.

Chemonucleolysis is indicated only for contained disk protrusions causing sciatic pain that have been unresponsive to conservative care. This injection is contraindicated when there are extruded and sequestered disk herniations and in patients with a cauda equina syndrome. Relative contraindications include previous chymopapain injections, previous surgery for lumbar disk herniation, spinal stenosis, severe degenerative disk or facet osteoarthritis, and spinal instability (spondylolisthesis) (19). Chymopapain should not be used during pregnancy or in disk herniations above L-1. The final contraindication to chymopapain injection is an immunoglobulin E–mediated sensitivity, which is present in 0.35% of patients. Chymopapain should therefore be avoided in patients with a history of sensitivity to products containing chymopapain, such as meat tenderizers, beer, cheese, and toothpaste. The procedure should be preceded by testing to identify

chymopapain-sensitive individuals.

Procedure. Chemonucleolysis is usually performed under local anesthesia with sedation as needed. The lateral position is recommended, although it may be performed with the patient prone. The correct level should be identified with fluoroscopy. The sacrum must always be visualized and the preoperative radiographs checked for lumbarization or sacralization of vertebra to ensure the correct level is approached. The correct needle insertion site is approximately 10 cm lateral to the posterior midline of the back and the angle of needle insertion is 45 degrees to the horizontal plane of the back. Under fluoroscopic guidance, the needle is advanced to the correct disk space. The tip of the needle should be centered in the disk space on both anteroposterior and lateral x-ray views. Once this position is verified, 0.75 to 1.00 mL of chymopapain is injected [1,000 units of chymopapain (Chymodiactin)]. Care must be taken not to injure nerve roots or to inject into the thecal sac, because chymopapain is neurotoxic.

The procedure is performed on an outpatient basis. Severe spasm and back pain may occur immediately after injection. This can be managed with muscle relaxants and oral analgesics. Lumbar corsets may be used for comfort. Exercise and physical therapy are begun after 4 weeks.

Automated Percutaneous Lumbar Diskectomy

Addressing a herniated disk through a needle is achieved by chemonucleolysis, as described previously. Drug- and technique- related complications triggered the interest in alternative methods, which did not involve the use of pharmaceuticals. First introduced in Japan in the mid-1970s, the use of a mechanical device to remove a herniation using a percutaneous method was approved for use in the United States and elsewhere in the mid-1980s. The first, more widely used device to accomplish this was the Nucleotome System (20). The technique involves inserting a trocar into the disk, passing a cannula over the trocar until it rests on the annulus, and then penetrating the annulus with a trephine. Once the annulotomy is made, a probe is inserted through the cannula into the disk. The probe is then activated to start the cutting and suctioning actions. The principle is to cut the disk into fragments, which are washed out through the probe. The probe is worked around inside the disk space to accomplish the maximum amount of disk removal. An alternative technique uses laser technology to remove disk tissue (21).

The results of percutaneous diskectomy using the above techniques remain open to question.

Standard Laminotomy and Diskectomy

Laminotomy with diskectomy has long been the “gold standard” for treatment of lumbar disk herniations. Approximately 300,000 procedures a year are performed in the United States. Patient satisfaction approaches 95% when selection is appropriate. Statistically, the complication rate is low. There is approximately a 5% rate of recurrent disk herniation at the same level, which may occur anytime from several hours to several years after the index operation. The infection rate appears to be less than 0.5%, the risk of neural injury is less than 0.5%, and the mortality rate is less than 0.1%. The most frequent complication is a dural tear, which after treatment does not influence the end result. However, if nerve roots are injured when the dura is torn, long-term pain and neurologic deficit may ensue.

Procedure. Although there are differences in how this procedure is performed, the following describes the authors' preferred method. The patient is placed in the kneeling position on an Andrews-type frame. This position allows the abdomen to hang freely, thereby diminishing epidural venous return and minimizing intraoperative bleeding. The procedure is performed under loupe magnification with the use of fiberoptic headlights. A 4-cm incision is centered over the midline of the back. The interspinous spaces may be palpated along with the iliac crest. Radiographic localization should be performed to identify the correct level. The lumbodorsal fascia is incised in the midline, followed by unilateral exposure of the spinous process and lamina of the level above and below the disk herniation. Subperiosteal dissection of the paraspinal muscles is performed laterally to the facet joint. Care is taken to preserve the facet capsule to avoid creating instability. A Taylor or self-retaining retractor is placed. The correct level is again confirmed by palpation or radiograph. The ligamentum flavum is then identified and elevated off of the inferior portion of the cephalad lamina with a curette. A hemilaminotomy is performed by removing a small amount of the inferior portion of the superior lamina (Fig. 76B-2). The end point of laminar resection is the area where the superior portion of the ligamentum flavum inserts. An angled elevator may then be passed from cephalad to caudal beneath the ligament in the epidural space. This maneuver separates the ligament from the underlying dural sac. Appropriate parts of the ligament are then removed with Kerrison rongeurs. Due to the distal takeoff of the S-1 nerve roots, an L- 5 to S-1 disk herniation may be approached by beginning the hemilaminotomy inferiorly on the S-1 lamina as opposed to superiorly on the L-5 lamina. In either case, the epidural space is visualized, and additional bone from the lateral aspect of the lamina is removed as needed to safely identify the lateral edge of the nerve root. The root may be immobile and erythematous when observed and can be mistaken for a disk fragment. The nerve root is gently mobilized medially with an elevator and, once mobilized, may be retracted with a nerve root retractor. A sequestered disk fragment should be visible at this point and may be removed with pituitary rongeurs (Fig. 76B-3). A bulge in the annulus fibrosus (protrusion) causing root compression may be incised and the disk space then entered with a pituitary rongeur to remove any free disk fragments. Nuclear material not easily removed should be left intact to preserve disk stability. At the end of the operation, the nerve root should be freely mobile from the takeoff on the thecal sac and out through the foramen. The foramen should be probed with a Woodson elevator or similar to ensure that no fragments have migrated that may compress the nerve root and to ensure that there is enough space in the foramen for the exiting nerve root. The epidural space should be probed ventrally as well to ensure that no free fragments remain. Hemostasis is achieved. The dura may be left exposed, covered with a substance such as Adcon (Gliatech Inc., Cleveland, OH) or with a free fat graft. The effect of an interposition membrane on final outcome has been studied (22). Clinical outcome does not depend on which material is used to prevent epidural fibrosis formation. The patient may be ambulatory with assistance the day of surgery and discharged or, more typically, stay overnight. Walking is encouraged postoperatively, while lifting, bending, and twisting are avoided for 4 to 6 weeks.

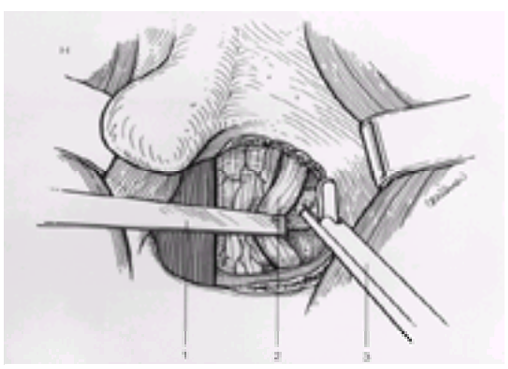

Figure 76B-2. Hemilaminotomy. (1, nerve root retractor; 2, spinal nerve root; 3, pituitary rongeur.) (From An HS, Riley LH, eds. *An atlas of surgery of the spine*. London: Martin Dunitz Ltd; and Philadelphia: Lippincott–Raven, 1998:188.)

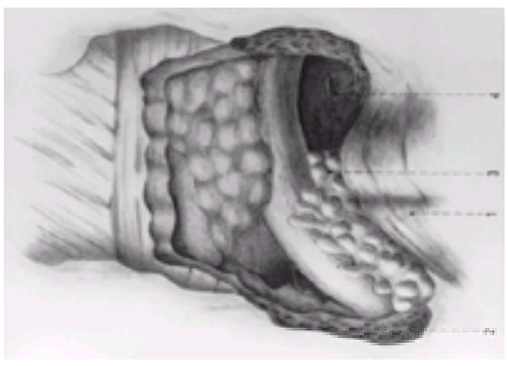

Figure 76B-3. Sequestered disk fragment. (1, zygapophyseal articulation; 2, resection extended caudally and laterally; 3, loose intervertebral disk sequestrum; 4, perforation site and height of the intervertebral space.) (From Reulen H-J. Neurosurgical operations. In: Bauer R, Kerschbaumer F, Poisel S, eds. *Atlas of spinal operations*. New York: George Thieme Verlag, 1993:332.)

Limited-Approach Diskectomy/Microdiskectomy

Limited-approach diskectomy/microdiskectomy is similar to the standard laminectomy, but the skin incision is only 1 to 2 inches long, extending from the midpoint of one spinous process to the spinous process at the next level. The fascial incision is just lateral to the midline so as not to destroy the competency of the supraspinous ligament. Subperiosteal dissection should proceed as with standard laminectomy. The microscope may then be moved over the operative field. Some surgeons may use the microscope from the outset of the procedure. The procedure from this point on is similar to the standard laminotomy except for the use of the microscope. Most studies have demonstrated no statistically significant difference in patient outcomes when comparing the standard laminotomy and microdiskectomy. Postoperative care is also similar.

Far Lateral Diskectomy (Wiltse Approach)

When a lumbar disk herniation is located foraminally or lateral to the foramen, it may not be amenable to removal through standard midline posterior approaches. In these cases, a paraspinal muscle-splitting approach is used, as recommended by Wiltse. The patient is positioned in the kneeling position as for the standard diskectomy. The skin incision is two finger's breadths or approximately 4.5 cm from the midline. The length of the incision may vary. The fascial plane of dissection is between the multifidus and longissimus muscles. The fascia between these muscles is incised and curved medially at the distal end and laterally at the proximal end to aid in retraction (Fig. 76B-4). Finger dissection should split the plane between these muscles, and the transverse processes may be palpated below. Self-retaining retractors are placed. The transverse membrane between the transverse processes is visualized. A Kerrison rongeur may be used to detach the membrane from the superior facet, pars interarticularis, and inferior portion of the transverse process. The nerve root is usually displaced laterally by the disk fragment. Pituitary rongeurs are used to remove free fragments of disk. The disk space may then be entered to remove any remaining free fragments. Postoperative care involves ambulation the night of surgery, overnight hospital stay, and avoidance of lifting and bending for 4 to 6 weeks.

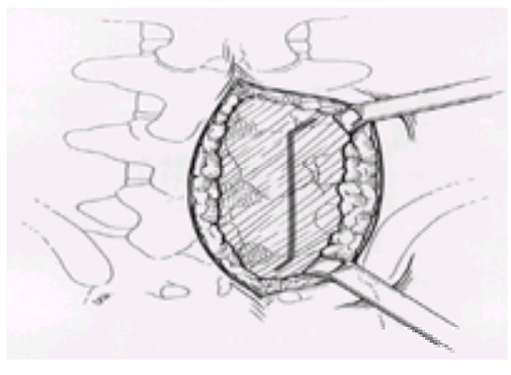

Figure 76B-4. The Wiltse paraspinal muscle-splitting approach. (From An HS, Riley LH, eds. *An atlas of surgery of the spine*. London: Martin Dunitz Ltd; and Philadelphia: Lippincott–Raven, 1998:196.)

Anterior Approach

An anterior approach, although possible, is rarely indicated for primary surgery on lumbar disk herniations. The surgical results are similar, but the risks and morbidity of this approach are much greater than posterior approaches and cannot be justified. The anterior approach is reserved for other anatomic abnormalities.

Arthroscopic Diskectomy

Arthroscopic diskectomy developed from biopsy techniques (23). This procedure is primarily used for disk protrusions at the L-4 to L-5 and L-5 to S-1 levels. Above these levels, disk herniations must be subligamentous to be removed safely. The procedure is contraindicated in patients with severe neurologic deficits, cauda equina syndromes, or migrated sequestered disks. Prior diskectomies and high-riding iliac crests may be relative contraindications to this procedure. No prospective randomized controlled trials have been performed comparing arthroscopic diskectomy with other techniques. Several authors have reported good results (24,25). It is a technically demanding procedure with a steep learning curve and should not be performed by surgeons without specialized training.

Procedure. The patient is placed prone on an adjustable radiolucent frame to flatten lumbar lordosis. The abdomen is left hanging freely to decompress Batson's plexus and reduce epidural venous bleeding. Fluoroscopy is used with the **C**-arm on the symptomatic side of the patient. Local anesthetics are used so that the patient is awake during the procedure and may respond as neural structures are approached. The triangular working zone on the disk surface is bounded by the nerve root superiorly and anteriorly, the transverse process inferiorly, and the superior facet medially. The skin entry point is identified by fluoroscopy and is at the disk level approximately 11 cm lateral to the midline. A 6-inch, 18-gauge spinal needle is passed at a 45-degree angle to the horizontal down to the disk space. The tip of the needle should be at the interpedicular level on the anteroposterior x-ray view. The needle tip should be at the posterior portion of the disk on the lateral x-ray view. Once the position is confirmed, the trocar is removed and a guidewire is passed through the spinal needle. The needle is removed, with the guidewire left in place. An arthroscopic cannula is then passed over the guidewire to the disk space. The annulus is identified. The nerve may then be probed with a small guidewire through the cannula. Cannulas are advanced into the disk space by cutting through the annulus with the trocars. Lidocaine-soaked patties may help alleviate annular pain. Pituitary rongeurs may be passed through the cannula, and under x-ray guidance, disk fragments are removed. A mechanical shaver also exists to aid in disk removal. The portals are closed with single stitches. Postoperative care is similar to standard diskectomy.

SURGERY FOR SPINAL STENOSIS

Clinical Syndromes

Spinal stenosis can be defined as a narrowing of the vertebral canal, lateral recesses, or vertebral foramina. Based on location, it can be divided into central (vertebral canal) or lateral stenosis. It can have different etiologies, most frequently degenerative, and does not always result in clinical symptoms. The most common symptom complexes are neurogenic intermittent claudication and radiculopathy.

Natural History

Patients with spinal stenosis tend to have an insidious onset of symptoms. Exacerbations may be produced by activity or trauma. However, very few natural history studies of lumbar spinal stenosis have been performed (6,27,28,29,30,31 and 32). Thus, predicting which patients will benefit from surgical intervention is difficult, if not impossible. Most of these studies include only small numbers of patients. In addition to the scarcity of clinical data, the natural history of spinal stenosis is further confounded by the limited knowledge of the pathophysiologic effects on compression of the spinal nerve roots and cauda equina.

In 1978, Blau and Logue reported on two patients with neurogenic claudication (26). One patient had no change in symptoms over a 7-year period and the other patient experienced a slight increase in difficulty ambulating with leg pain over 10 years. Several other small reports documented success of conservative treatment or insidious progression in the early neurosurgical literature. One study showed that a lumbar corset may provide relief of symptoms (27). In another study, myelography was found to be predictive of outcome with nonoperative treatment. Patients with complete or severe myelographic block fared poorly with conservative treatment (28). Five patients underwent conservative treatment after myelography. One patient had improvement in neurologic symptoms, whereas the other four patients remained stable. Over time, one patient's symptoms improved, whereas two remained the same and two deteriorated slightly. Obviously, the results of this study are not statistically significant due to the retrospective design and small sample size.

In 1991, Johnsson et al. performed a 3-year follow-up study on patients with lumbar stenosis, half of which were treated nonoperatively and half with laminectomy without fusion (29). Diagnosis was confirmed by partial block on myelograms. All patients showed evidence of neurologic injury by electromyography. They found that

in 32% of the patients the symptoms remained unchanged, 42% of the patients improved, and 26% deteriorated. The authors concluded that symptom progression was slow and conservative treatment could be safely exercised for 2 to 3 years. This study was followed by an observational study of 32 patients treated conservatively over a 4-year period (30). Only 15% of patients reported improvement in their pain on a visual analogue scale, whereas 70% remained unchanged. With respect to walking, one-third of the patients improved, one-third remained the same, and one-third deteriorated.

Another 35 patients were studied by Wardlaw and MacNab (31). These patients were treated nonoperatively, and success correlated both with a history of back pain of less than 5 years' duration and a history of leg pain for less than 6 months.

The largest study to date on nonoperative treatment of spinal stenosis was performed by Saal et al. (32). These data have yet to be published. Fifty-two patients were enrolled in this study. Nonnarcotic analgesics controlled pain in 33 of the 52 patients. Walking was unrestricted in 36 of the 52 patients. Only four patients ended up needing surgery.

None of these studies is prospective and randomized. In addition, the sample size is small in all of the studies. However, most patients seem to have symptoms that stabilize. Further study is required to validate the present natural history data. Currently, one cannot predict which patients will require surgical intervention. Once the natural history is known, risk factors for failure of conservative treatment can be identified. Current indications for surgical intervention for spinal stenosis are discussed below.

Indications for Surgery

The purpose of any surgical procedure for spinal stenosis is to improve function and diminish pain. As with all types of spine surgery, proper patient assessment is vital to surgical success. This is not a life-saving procedure, but one that should improve the quality of life. Each patient must be evaluated to rule out other causes of leg pain and claudication, such as peripheral vascular disease, referred hip or knee pain, or osteoarthritis of the hip or knee. The extent to which a patient's activities of daily living and lifestyle are affected is particularly important in deciding on surgical treatment.

As with lumbar disk herniations, a radiographic study that corresponds to the patient's symptoms is imperative before undertaking surgery. Patients should undergo at least 4 to 6 weeks of conservative treatment, including rest, nonsteroidal antiinflammatory medications, and physical therapy. Epidural steroid injections may be attempted, although they are controversial because of a lack of good scientific data about effect.

Persistent leg pain and poor function despite conservative treatment are the primary indications for surgery presuming other causes of pain have been excluded (33). Severe neurologic deficit is another indication for surgery (34). Duration of symptoms and response to conservative treatment should not delay surgical intervention when neurologic involvement is present. A relative indication for treatment is lifestyle alterations due to pain (33,34). If a patient has difficulty ambulating due to pain, surgery is indicated despite a lack of neurologic findings.

Contraindications to surgery may include poor overall medical health. However, chronological age is not an absolute contraindication to surgery (33,35). Physiologic age is a more critical factor. Radiographic findings in the absence of clinical symptoms are never an indication for surgery (6,36).

Most studies show a 70% improvement in pain and function as compared with preoperative levels. Patients should understand that the surgical procedure may not alleviate all of their pain. Some residual back and/or leg pain may persist after surgery. Preexisting degenerative arthritis may be a source of these persistent symptoms.

In general, surgery alleviates pain and improves function but may not reverse neurologic deficits. Results of surgery are better in patients with localized lesions rather than global changes. Postural improvement in symptoms was shown by Ganz to predict surgical success (37). Ninety-six percent of patients with postural improvement of symptoms had relief of pain after surgery. Only 50% of patients whose symptoms did not vary with posture had postoperative relief.

Several factors have been shown to predict poorer outcome in spinal stenosis surgery. Poorer outcomes may be expected if radiographic findings do not correlate with the patient's symptoms. Also, female gender, litigation, prior lumbar surgery, and concomitant spondylolisthesis have been associated with poorer outcomes (38,39).

Alternatives and Procedures

Alternatives to noninvasive conservative treatment of spinal stenosis include epidural steroid injections and surgical treatment. Surgical treatment for spinal stenosis involves decompression of the cauda equina, nerve roots, or both. Anatomically, compression may occur in several zones within the spine. Classic symptoms of neurogenic claudication are usually caused by central stenosis— that is, narrowing of the vertebral canal. This narrowing may be produced by thickening of the ligamentum flavum, osteophytes from the facet joints, and/or degenerative bulging/herniation of the intervertebral disk. Stenosis in the lateral recess usually produces radicular symptoms. The nerve root exits, after branching from the thecal sac, through the lateral recess, beneath the pedicle and out through the foramen. The lateral recess is bounded by the medial pedicle wall laterally, the posterolateral corner of the vertebral body, and the ligamentum flavum. Hypertrophy of the ligamentum flavum combined with a trefoil-shaped epidural canal creates the greatest risk for nerve root compression. Finally, foraminal stenosis involves the exiting nerve root only and produces radiculopathy. Foraminal narrowing may be caused by facet osteophytes, narrowing of pedicular distance between two levels because of loss of vertebral disk height, or disk bulging.

Surgical treatment for spinal stenosis must address the anatomic areas of nerve compression to be successful (40). In fact, a frequent cause of failure of surgical treatment is inadequate decompression in one of these anatomic regions or the failure to recognize that one of these regions is stenotic on preoperative films.

Principles

Every attempt should be made to identify the levels from which the patient's symptoms are produced. Not all radiographic stenotic levels must be decompressed. For most cases, the levels to be decompressed should extend from the pedicle above to the pedicle below the stenotic intervertebral segment. It is usually unnecessary to move more caudally to the lamina below or cephalad to the lamina above. For example, if stenosis is isolated to the L-4 to L-5 level, only the L-4 lamina need be resected. Decompression may proceed until a pulsatile dural sac is exposed. Central stenosis is decompressed in the midline and as far lateral as necessary. Lateral recess stenosis may require resection of the medial facet joint, whereas foraminal stenosis requires further facet resection. If an entire facet joint or greater than 50% of both facet joints at one level are removed to decompress the nerve roots, segmental instability may be produced (41). Instability is more likely to be created when intervertebral disk heights are normal. Degenerative disks with height loss and osteophyte formation may stabilize the segment. This is discussed below.

Laminectomy

The patient undergoes either general or spinal anesthetic and may be placed prone on either an operating room table with chest rolls, a Wilson frame, an Andrews table, or the Jackson table. The abdomen is left hanging freely to decompress the epidural veins. Care must be taken to keep pressure off of the eyes to prevent retinal ischemia. Compression stockings and/or sequential compression devices are used. The rate of deep venous thrombosis below the knee is 5% to 6% with stockings alone (42). The rate of proximal thigh deep venous thrombosis is much lower. Radiographs should be used to localize the correct levels for surgery; a midline incision is then made. The lumbodorsal fascia is identified and incised in the midline. Dissection continues subperiosteally to expose the spinous process, lamina, and facet joints bilaterally. The facet joint capsule is preserved. Leksell rongeurs are used to remove the spinous processes. A curette is then used to elevate the ligamentum flavum from the anterior surface of the inferior portion of the lamina (Fig. 76B-5). A Kerrison rongeur is used to resect the lamina from caudal to cephalad just medial to both facet capsules (Fig. 76B-6). A Woodson elevator may be used to ensure that the ligamentum flavum is not adherent to the underlying dura. This helps to prevent cerebrospinal fluid leaks. If the dura mater is adherent to the ligamentum, a high-speed diamond-tipped burr may be used to thin the lamina. If the lamina still cannot be elevated safely, it may be thinned to a flake of bone and left attached to the dura, as this should not cause neural compromise. Once the lamina is removed, the pedicle can be identified and the nerve roots found and traced out the foramen. If the lateral recess is narrow, the medial portion of the superior facet may be undercut to remove osteophytes and widen the foramen (Fig. 76B- 7). Alternatively, an osteotome may be used to resect the medial aspect of the facet joint.

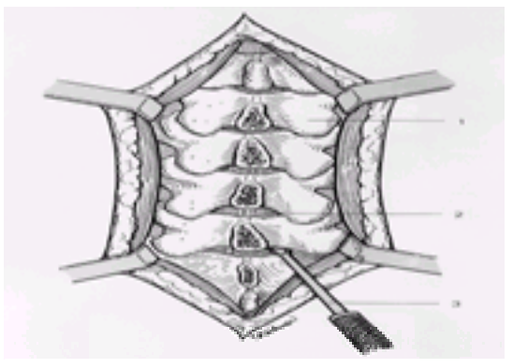

Figure 76B-5. Laminectomy in spinal stenosis. After exposing the ligamentation flavum, a curette or similar instrument is used to separate the ligament from the underside of the lamina. (1, L-2; 2, ligamentum falvum; 3, curette.) (From An HS, Riley LH, eds. *An atlas of surgery of the spine*. London: Martin Dunitz Ltd; and Philadelphia: Lippincott–Raven, 1998:192.)

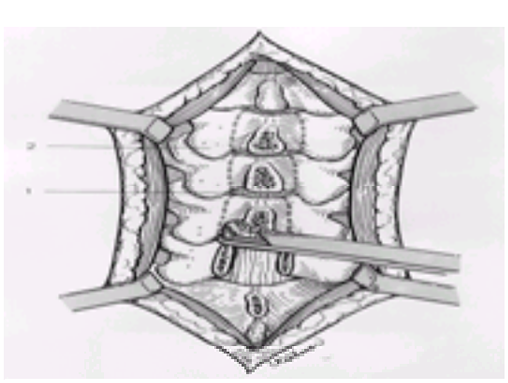

Figure 76B-6. Laminectomy in spinal stenosis. A Kerrison rongeur is used. Usually the laminectomy is done from caudal to cephalad. (1, ligamentum flavum; 2, L-2.) (From An HS, Riley LH, eds. *An atlas of surgery of the spine*. London: Martin Dunitz Ltd; and Philadelphia: Lippincott– Raven, 1998:192.)

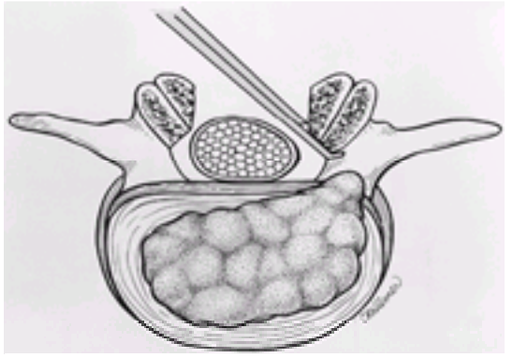

Figure 76B-7. Undercutting of the facet is usually done from the opposite side. (From An HS, Riley LH, eds. *An atlas of surgery of the spine*. London: Martin Dunitz Ltd; and Philadelphia: Lippincott–Raven, 1998:194.)

The disk space may then be inspected and any herniation removed. As long as the thecal sac is not compressed centrally and the symptomatic nerve roots are freely mobile from the thecal sac and out through the foramen, the decompression is complete. The procedure is repeated for additional stenotic levels. A free fat graft may be placed over the exposed dura or it may be left uncovered. Ambulation is begun the night of surgery in patients in whom fewer levels are decompressed. Walking is encouraged at home, although lifting, bending, and twisting are avoided for 4 to 6 weeks. Physical therapy is instituted as needed.

Limited Laminectomy

A limited-approach diskectomy dissection may be used if patient symptoms and radiographic stenosis are limited to one level and one side. Dissection is similar to a limited-approach diskectomy. The entire hemilamina on the affected side is resected, as is the ligamentum flavum. The facet may be undercut as needed to decompress the lateral recess and foramen, and the herniated nucleus pulposus is removed if present.

Fusion

The role and technique of fusion are discussed in the indications and techniques section on spinal instability.

SURGERY FOR DEGENERATIVE SPINAL INSTABILITY

Natural History

Defining degenerative lumbar spinal instability is difficult. No universally accepted description of what constitutes clinical lumbar instability has been provided. The set of clinical symptoms that is created by spinal instability has also not been defined. Several authors have attempted to describe instability through clinical, biomechanical, or radiographic definitions, but none has been uniformly agreed on. Regarding the lumbar spine, the most consistently used criterion for instability is either 10 degrees of angular motion or 4 mm of translation on controlled lateral flexion-extension radiographs (43). Determining the natural history of a diagnosis that cannot be defined is impossible. In this section, we restrict our comments to that spinal instability that presents as degenerative spondylolisthesis. In general, the natural history of degenerative spondylolisthesis is variable. It is not only the instability that is a problem in these patients, but narrowing of the spinal canal also occurs as one vertebra slips on its neighbor, causing stenosis (ring-on- ring phenomenon). Progressive loss of disk height also occurs (44). Rarely does the degenerative spondylolisthesis slip more than 30%.

There are at least two causes of degenerative spondylolisthesis. With aging, morphologic changes of the intervertebral disk and facet joints occur, which weaken the structure mechanically. Some facet joints are more sagittally oriented and are more likely to allow the slippage, which leads to degenerative spondylolisthesis (45). This type of spondylolisthesis occurs most commonly at L-4/ L-5. L-5 radicular pain is common as the slip progresses, due to compression of the L-5 nerve root. Lateral flexion-extension radiographs may show either increased translation or, more commonly, no abnormal motion.

Iatrogenic instability is created when decompression during a laminectomy is so significant that it produces an unstable motion segment. Biomechanical studies have demonstrated that removal of more than 50% of both facet joints or complete resection of one facet joint will destabilize a motion segment (41). In contrast, severe degeneration of the disk and osteophyte formation may stabilize the motion segment. Patients with spondylolisthesis and large disk spaces with minimal osteophyte formation will often be destabilized by posterior decompression (46).

Several studies have confirmed progression of spondylolisthesis (instability) after posterior decompression for spinal stenosis (46,47 and 48). These studies

demonstrated that the outcomes for surgery on spinal stenosis with degenerative spondylolisthesis are better when a fusion is added. Arthrodesis prevents progression of spondylolisthesis and stabilizes the decompressed segment, which may prevent back pain, leg pain, or both (49). An algorithmic approach to spinal stenosis and instability is shown in Figure 76B-8 (43).

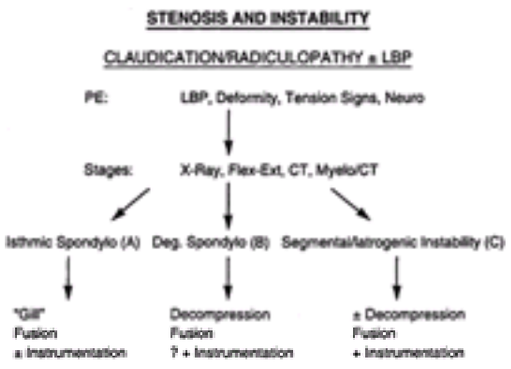

Figure 76B-8. Algorithm of the approach to a patient with spinal stenosis. (CT, computed tomography; Deg. Spondylo, degenerative spondylosis; Flex- Ext, flexion-extension; LBP, low back pain; Myelo/CT, myelogram/computed tomography; Neuro, neurologic findings; PE, physical examination; Spondylo, spondylosis.) (From Hanley EN Jr, Spengler DM, Wiesel S, et al. Controversies in low back pain: the surgical approach. In: Schafer M, ed. *Instructional course lectures*. Vol 43. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:422.)

Indications

The indications for surgical treatment of spinal stenosis with degenerative spondylolisthesis are similar to those for isolated spinal stenosis. Degenerative spondylolisthesis has an undefined natural history and it is thus difficult to predict which patients require surgical intervention. One estimate of the percentage of patients with this condition that require surgery is 10% to 15% (50). According to Frymoyer, indications for surgery include cauda equina dysfunction with evidence of complete neurologic block at the corresponding level and progressive muscle weakness of functional significance (i.e., footdrop or quadriceps weakness). Progressive and incapacitating radicular pain and claudication failing to respond to conservative treatment are other indications (50). Radicular pain is a particularly important indication when activities of daily living are altered or sleep disturbance is present. Isolated back pain is not a good indication for the surgical treatment of this disease. Patients with isolated low back pain are best managed conservatively.

Several studies have examined the risk factors for poor operative outcomes (51,52). Instability was the most common cause of failure (52). Instability is likely to have diminished since the routine use of arthrodesis when decompressing spinal stenosis associated with degenerative spondylolisthesis was shown to be more effective (46). As one might expect, increased age, multiple medical comorbidities, and longer periods of observation of symptomatic patients were associated with increased risk of surgical failure (51,52 and 53).

As with all procedures on the spine, the patient selection process is crucial. Subjective complaints must be verified objectively with physical findings and corresponding lesions on roentgenographic studies. Surgery is not indicated in asymptomatic patients with a spondylolisthesis.

Surgery for spinal stenosis involves decompression of compromised nerve roots. When degenerative spondylolisthesis is present, most surgeons feel that a concomitant intertransverse process arthrodesis is indicated (54). A controversial issue remains if and when instrumentation should be used to augment the fusion.

In 1991, Herkowitz and Kurz demonstrated superior results in patients who underwent decompression with posterolateral intertransverse process fusion as compared with decompression alone (46). Fifty patients were prospectively randomized into the two groups. The groups were statistically well matched. At 3-year follow-up, back and leg pain was significantly better in the fusion group. In addition, the spondylolisthesis increased in only 28% of the patients with a fusion, whereas 96% of patients had slip progression without a fusion. Thirty-six percent of patients had a radiographic pseudarthrosis but the presence of a pseudarthrosis did not appear to affect the clinical outcome (“stable pseudarthrosis”). The only time a fusion may not be indicated is when patients have underlying systemic disease, which may greatly increase the risk of complications (53).

Newer fusion techniques have been advocated such as posterior lumbar interbody fusion and anterior lumbar interbody fusion, but no prospective, randomized controlled trials have been performed. However, fusion rates tend to be high with these techniques.

The use of instrumentation to augment fusion in these cases is more controversial (55,56 and 57). The purpose of internal fixation is to add additional stability to the spine, allow correction of deformity, protect neural structures, increase the fusion rate, and decrease rehabilitation time. However, pedicle screw placement is a technically demanding procedure. Screws are placed in a structure that is only a few millimeters larger than the screw. Improper positioning of screws can lead to loss of fixation and neurologic injury. In addition, pedicle fracture and screw breakage are known complications.

In one trial comparing instrumented with uninstrumented fusions, Fischgrund et al. found that while the fusion rate was higher with instrumentation, there was no statistically significant difference in clinical outcome (55). France et al. performed a multicenter, prospective, randomized study that also found no difference in patient outcome whether or not instrumentation was used (58). In contrast, a large cohort study on pedicle screw fixation concluded that the benefits of screw usage outweighed the risks (56). The instrumented group had an 89.1% fusion rate as compared with the 70.4% fusion rate without instrumentation. Improved spinal alignment, shorter time to fusion, better clinical outcome, and better neurologic recovery all characterized the instrumented group as compared with the uninstrumented group. Reoperations, medical complications, and deaths were similar between the two groups. Nork et al. found that patients who underwent decompression and instrumented fusion for degenerative spondylolisthesis had improved functional outcomes using standardized Short Form-36 questionnaires (59). This is the first study to examine functional outcomes in relation to surgical results. However, there was no uninstrumented control group with which to compare the results. Thus, at this point, no consensus can be reached on the use of instrumentation in augmenting fusion after decompression for degenerative spondylolisthesis.

Accepted surgical indications for the use of pedicle screw fixation usually include (a) correction of deformity (kyphosis, scoliosis), (b) fusion of motion segments after decompressive laminectomy, (c) recurrent spinal stenosis with iatrogenic spondylolisthesis, and (d) translational motion of greater than 4 mm in flexion and extension or greater than 10 degrees of angular motion as compared with adjacent levels on flexion and extension.

In the authors' experience, instrumentation is best used to augment fusions in younger patients and patients with large intervertebral disk spaces. In older patients with osteoporotic bone, instrumentation is best avoided to decrease the operating time and reduce complication risk and secondary hardware dislodgment. Many degenerative spines have narrowed disk spaces and bridging osteophytes, which may confer stability and thus obviate the need for instrumentation. Although no solid data exist, lateral flexion-extension radiographs may assist in the decision-making process. If no gross motion occurs, instrumentation may be avoided. With gross motion preoperatively, the likelihood of the spondylolisthesis progressing after decompression is high and the use of instrumentation should be considered.

Newer instrumentation techniques such as the use of metal (stainless steel or titanium) cages have been advocated. These are alternative techniques for obtaining a fusion, but no prospective randomized clinical trials have been performed. Decompression is still required to treat the stenosis. These modern trends will require further study prior to advocating their use.

Alternatives and Procedures

The alternatives for interventional treatment of spinal stenosis with degenerative spondylolisthesis include epidural steroid injections and surgery. Epidural steroid injections are discussed in Section D of this chapter. The surgical treatment involves decompression for the spinal stenosis. After decompression there is an increased likelihood of progression of the deformity without concomitant fusion, as well as poorer relief of back and leg pain (46). The majority of data now supports the addition of an arthrodesis to decompression for the treatment of spinal stenosis with degenerative spondylolisthesis.

Current alternatives include intertransverse process arthrodesis alone or in combination with instrumentation. Also, a limited- approach “lumbar laminaplasty” technique has been advocated.

Intertransverse Process (Posterolateral) Fusion

Patient setup for this procedure is similar to that for spinal laminectomy. The skin incision extends from one level above to one level below the fusion area. A decompression is performed as described in the section on spinal stenosis. The dissection is similar except that arthrodesis requires exposure of the transverse processes. Subperiosteal dissection is performed laterally down the lamina and over the facet joint, usually removing the capsule. Dissection proceeds cephalad around the pars interarticularis out over the dorsal surface of the transverse processes to be fused. Facet joints at the level above and below the fusion levels should be preserved, along with their capsules. Transverse processes should not be broken, and the intertransverse membrane should not be penetrated anterior to the transverse process during the dissection. The facet joints, lateral aspect of the superior facet, the pars interarticularis, and the dorsal surface of the transverse processes are decorticated using either an osteotome or power burr. This prepares the recipient bed for graft placement. The graft is then harvested from the iliac crest, usually through the same incision. If the patient has a wide pelvis, a separate incision is made directly over the crest. On one side the subcutaneous fat is elevated from the lumbodorsal fascia. The posterior superior iliac crest is identified. The fascia is split in line with the iliac crest and the muscle is dissected subperiosteally over the outer table of the ilium. An osteotome is used to remove corticocancellous strips of bone from the outer table of the ilium. Gauges and curettes are used to remove additional cancellous bone down to but not penetrating through the inner table of the ilium. The graft is then divided in half and packed between the decorticated transverse processes to be fused (Fig. 76B-9).

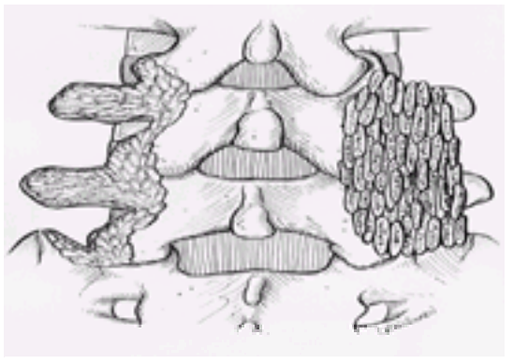

Figure 76B-9. Posterolateral fusion. Bone is placed over the transverse processes. (From An HS, Riley LH, eds. *An atlas of surgery of the spine*. London: Martin Dunitz Ltd; and Philadelphia: Lippincott–Raven, 1998:218.)

Postoperatively a lumbosacral orthosis is used for at least 3 months to stabilize the back and allow the fusion to heal. Ambulation and physical therapy are begun the day after surgery.

Instrumentation—Pedicle Screw/Rod Constructs

When a fusion is augmented with instrumentation, the setup and dissection are similar to those for arthrodesis (57). After decompression is performed, the pedicle screws are placed. The entry point for pedicle screw placement is identified. The entry occurs at the junction of the intertransverse process line horizontally and the lateral edge of the superior facet (2 to 3 mm lateral to the pars interarticularis) vertically (Fig. 76B-10). This point is 1 to 2 mm below the facet joint. A burr is used to open the dorsal cortex and a marker is placed. Radiographs are then taken to check the entry site and direction of the markers. Preoperative computed tomography or magnetic resonance imaging scans will help locate the entry point and direction of screw placement.

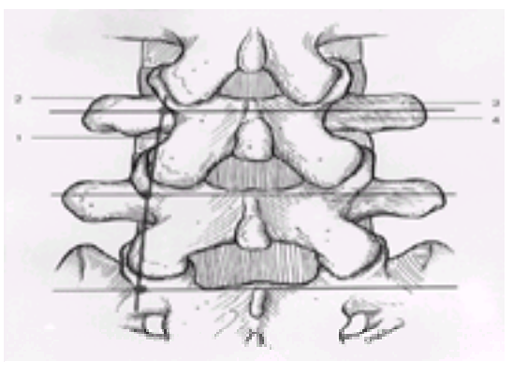

Figure 76B-10. Pedicle screw entry points. Typically the entry point is at the crossing of a vertical line connecting the lateral edges of the bony crest extending from the superior articular facets and a horizontal line which bisects the transverse process. (1, pars interarticularis; 2, transverse process; 3, interim edge of facet joint; 4, lateral edge of crest.) (From An HS, Riley LH, eds. *An atlas of surgery of the spine*. London: Martin Dunitz Ltd; and Philadelphia: Lippincott–Raven, 1998:231.)

A pedicle probe is used to sound the pedicle. The depth may be estimated from preoperative scans. Care must be taken to check the radiographs for cephalad/caudal direction of screw placement and to direct the probe medially. The most common error is to penetrate the lateral pedicle wall. Once the pedicle is sounded, a small probe is placed to palpate the medial, lateral, inferior, and superior walls of the pedicles. No holes in the pedicle should be present. If a hole exists, the entry path must be redirected. The hole is then tapped and reprobed to ensure that the tap did not violate a pedicle wall. If a decompression has been performed, the medial and inferior pedicle wall can be directly visualized to check for pedicle fracture. These two directions are the most critical, as the nerve root passes just medial and inferior to the pedicle.

At this point, the autogenous bone graft should be placed so that the hardware does not block its insertion. The screws are then placed. Screw diameter should be measured off of the preoperative studies. The screw diameter should fill the pedicle but be no larger than the inner cortical diameter of the pedicle. Ideally, all screws should be parallel to the end-plates.

Two types of connections are possible. Plates may be placed directly over the screws on each side of the spine. Washers then connect the plate to the screws (Fig. 76B-11). The second option involves connecting rods to the screws on both left and right sides. Many different implant systems are available. The rods should be bent into anatomic lordosis and fashioned to preserve sagittal alignment. Adding a cross connector between the left and right rods increases torsional rigidity. A brace may or may not be used postoperatively. Physical therapy is begun the day after surgery. The usual hospital stay is 3 to 4 days. The fusion usually takes a minimum of 6 to 9 months to fully consolidate.

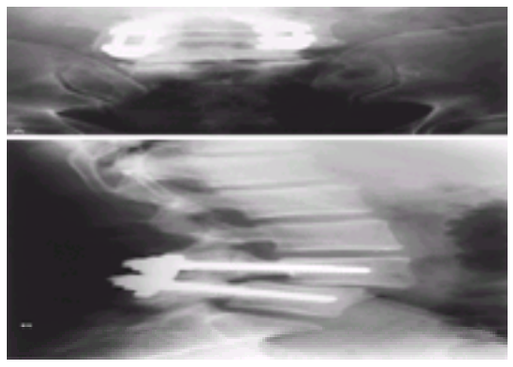

Figure 76B-11. Anteroposterior **(A)** and lateral **(B)** radiographs of a fusion with screws and plates.

Laminaplasty

A newer technique that has not yet gained wide acceptance is lumbar laminaplasty. This is a limited approach procedure indicated for one-level stenosis only. Bilateral nerve compression may be addressed. The significant advantage of this procedure is that stability may be preserved in patients with low-grade spondylolisthesis without performing a large fusion operation. The approach does not sacrifice the spinous process, the supraspinous ligament, one hemilamina, or either facet joint and thus preserves segmental stability.

A unilateral limited approach similar to that for a diskectomy is performed on the more symptomatic side. The lumbodorsal fascia is not incised in the midline but several millimeters toward the symptomatic side to preserve the supraspinous ligament. The hemilamina is resected as for limited laminectomy. An osteotome is then used to thin the spinous process on the more symptomatic side. The anterior surface of the spinous process is undercut to increase visualization to the contralateral side. Decompression is performed on the symptomatic side by removing the hemilamina and ligamentum flavum. The contralateral side may then be decompressed by retracting the thecal sac ventrally and using a Kerrison rongeur under direct vision to resect the ligamentum flavum and undercut the superior facet. Decompression is complete, but stability is preserved. This operation may be particularly useful for elderly patients in poor medical health who need symptomatic relief without the risk of a large fusion operation (60).

CONCLUSION

It should be understood, based on the preceding, that surgery for lower back pain is rarely indicated. In the majority of patients, pain will respond to nonoperative treatment. With the appropriate diagnosis, indications and technique, surgery can be extremely successful and return many patients to a high quality of life. When diagnosis, indications, and techniques are poor, disastrous results can occur. The right patient, right diagnosis, right indication, and right technique are the “four R's” of spinal surgery.

CHAPTER 76

C. Failed Back Surgery Syndrome

Anne Louise Oaklander and Richard B. North

DEFINITIONS

Failed back surgery syndrome (FBSS) refers specifically to persistent or recurrent, chronic pain after one or more surgical procedures on the lumbosacral spine. *Failed back syndrome* commonly refers to the same condition, although it more properly describes persistence of back pain after unspecified treatment. The term *failed back* commonly is used to refer to both circumstances, but it implies functional failure of the back, as opposed to failure of treatment or surgery.

EPIDEMIOLOGY

Like other diseases with iatrogenic components, FBSS has a prevalence proportional to the prevalence of lumbosacral spine surgery. In the United States, where spine surgery exceeds 300,000 operations per year (1,2), 10% to 40% of lumbar spine operations result in FBSS (3,4 and 5). In the context of more than 25% point prevalence and more than 80% lifetime incidence of low back pain in the general population (6), the impact of these figures should create concern.

The first report of FBSS (7) followed the original description of surgical treatment of lumbar disk disease (8) by only 1 year. New invasive procedures such as percutaneous diskectomy and chemonucleolysis, while reducing some morbidities, have broadened the indications for treatment and thus added new categories of treatment failures. Finneson's aphorism “No matter how severe or intractable the pain, it can always be made worse by surgery” (9) should be kept in mind.

ETIOLOGIES

Patient Selection

Inappropriate or premature selection of patients for surgery is the most common cause of FBSS (10,11,12,13,14 and 15). Retrospective reviews of FBSS patients indicate that less than half had met standard criteria for their initial operation (11). Patients deterred from inappropriate surgery at the neurosurgical evaluation may continue to “doctor shop” until they find a willing surgeon. Thus, inappropriate behavior by both patient and physician can contribute to FBSS. The natural history of low back and sciatic pain, including that from disk herniation, is ultimately favorable in most cases, so if the indications for surgery are unclear, surgery can often can be delayed to attempt conservative management or to allow more time for decision making, with little effect on long-term outcome (16).

Nerve Injury

The second most common cause of FBSS is persistence of pain due to irreversible neural injury. This can occur despite appropriate patient selection and successful performance of the surgery. Preoperatively, it should be explained to the patient that the primary goal of surgery is to prevent further worsening rather than to reverse existing damage. In a patient who needs surgery (because spontaneous recovery is not expected) it is usually unrealistic to expect a complete return to full premorbid function with total absence of pain postoperatively. The surgeon and patient should discuss the odds of achieving various levels of pain relief. Equipped with realistic expectations, a patient with partial pain relief after surgery may consider this a satisfactory outcome rather than FBSS.

Persistent neural injury can be divided into two types; these can occur alone or in combination. The first, which largely affects the dorsal roots, consists of direct injury or death of neurons (e.g., due to spinal root compression by a herniated disk). Risk factors for this primary form of damage include the severity of the lesion, closer proximity to the neuronal cell bodies, and longer duration of the lesion. It has been noted that delaying decompression of acute disk herniation for longer than 6 months after onset is more likely to result in persistent postoperative pain. The condition of the patient, including age, coexisting neuropathy, and other medical factors, may also influence the recovery of neural function after surgical decompression. In general, the severity of loss of primary afferent neurons has been shown to be a risk factor for chronic neuropathic pain after several types of neuronal injuries (17,18).

In contrast, a second type of chronic neural injury can continue to improve long after surgery. It consists of transsynaptic changes in higher-order sensory neurons within the central nervous system (CNS). It has long been known that repetitively stimulating nociceptive nerve terminals leads to local sensitization and hyperalgesia but was only more recently appreciated that there are also effects on cells within the spinal cord and brain. The development of reliable animal models of neuropathic pain has enabled investigation of these chronic alterations in connectivity and organization; however, most have not been confirmed in CNS tissue from human pain patients. This postinjury response, described in detail in Chapter 19, includes reversible as well as irreversible physiologic changes such as central sensitization, complex pharmacologic changes, and frank anatomic changes within the spinal cord and brain (e.g., sprouting of nonnociceptive mechanoreceptive neurons into nociceptive pathways within the substantia gelatinosa) (19,20 and 21).

It is important to explain to patients that just as their muscles and bones require months to heal after their surgery, injured neural tissues may continue to normalize over months and years as well. One can also hope that partial pain relief after surgery will lead to improvements in psychosocial function, which may allow improved tolerance (and perhaps descending antihyperalgesic effects) of any residual pain. Sometimes one positive medical intervention is enough to shift the FBSS patient out of a downward spiral into an upward one that leads to improvement in quality of life. That pivotal treatment is more likely to be a rehabilitation program, treatment of depression, or medical control of pain than another surgery.

Technical Success of Surgery

A less common cause of FBSS is inadequate surgery. Examples include the persistence of unrecognized lateral recess stenosis or lateral disk herniation. A sequestered free disk fragment can be missed (22,23 and 24). Myelography can be definitive if the postsurgical magnetic resonance imaging (MRI) is equivocal.

Occasionally spinal instability can persist after fusion, most commonly because of failure of the fusion. Instrumentation (pedicle screws, plates, interbody cages) may reduce the incidence of this technical problem, but the clinical benefits are less clear. The use of tobacco is a major risk factor for failure of bony union; fusions may

be postponed until tobacco abstinence is achieved. Rarely, despite an apparently successful fusion of either the anterior or posterior spinous elements, some motion persists, and a second fusion may be beneficial.

New Damage to Nerves or Spine

Another type of FBSS consists of painful syndromes resulting from a new pathologic process initiated by the primary surgery. Well-recognized complications of spinal surgery include damage to nerves, dura, joints, and muscles, all of which can produce pain. Examples include the creation of segmental instability after a generous laminectomy, pars fractures, or pseudoarthrosis after an inadequate fusion (25,26 and 27). The acceleration of degenerative changes at levels adjacent to a spinal fusion (transition syndrome) is thought to result from added movement at adjacent levels, which of necessity occurs after fusion. Radiographic imaging of the spine during flexion and extension is often helpful in diagnosing this syndrome. In addition to the persistent neural damage discussed above, there are risks of *de novo* injuries to the nerve roots or spinal cord during surgery. Appropriate technique, including the use of intraoperative electrical monitoring when necessary, should minimize this complication.

Extensive Fusion

Extensive fusions or extensive instrumentation can produce secondary problems of posture such as loss of the normal lumbar lordosis (flat-back syndrome). Abnormal position can induce or accelerate degenerative changes and lead to new pain problems. Postural problems are readily diagnosed by x-ray, and postsurgical patients at potential risk for these syndromes may require periodic x-rays indefinitely.

Nonsurgical Complications

It should be noted that not all painful complications of the perioperative period result from the surgery itself. Invasive diagnostic studies or fluoroscopic procedures can also occasionally cause chronically painful complications. These include infections or arachnoiditis from procedures such as provocative discography, administration of epidural steroids, and myelography, which may have been mitigated in part by the transition from oil-based to water-soluble contrast media (1,28). Postsurgical scarring or inflammation of the meninges (arachnoid fibrosis or arachnoiditis) can produce patchy neurologic findings that are difficult to interpret. Although clumping of the lumbosacral nerve roots is sometimes visible on routine MRI, spinal myelography may demonstrate subtler cases. The value of epidural steroids for long-standing cases is unclear, as is the effectiveness of further surgical or percutaneous procedures attempting to “remove the scarring.”

PSEUDO FAILED BACK SURGERY SYNDROME

Patients or physicians may erroneously perceive their low back surgery as unsuccessful if their previous pain, or a new pain, returns after a pain-free interval after surgery. This may represent recurrent pathology at the level of surgery or at other levels (4,29). It is helpful to explain to patients that surgery does not protect against progression of underlying degenerative processes such as osteoarthritis, nor does it protect against the need for future surgeries. There are probably underlying biological variables, such as in the structure of collagen, that predispose certain individuals (or families) toward recurrent back problems. Patients who have had one low back surgery are at increased risk for having another in the future (5). It is not clear whether this represents an underlying susceptibility or a high prevalence of FBSS, but probably it reflects both. Identification of biological risk factors predictive of a poor outcome from back surgery would help to minimize future FBSS.

The pain that can accompany axonal regeneration can be mistaken for FBSS. Although new neuronal cell bodies cannot be created in adults, the damage is often to the axon (e.g., compression of a nerve root), which can regenerate if not too severely damaged. If the cell body of the sensory neuron in the dorsal root ganglion survives the trauma, it may be able to regrow new axonal processes once the compression is surgically relieved. Axonal regeneration can be associated with persistence or worsening of pain. This is attributed to accumulation of sensory transductive molecules at the distal ends (growth cones) of the regenerating axons. The clinician may be able to identify how far regeneration has proceeded along a peripheral nerve by tapping over the nerve until paresthesias are produced (Tinel's sign). The maximum rate of regeneration corresponds to the rate of fast anterograde axonal transport [approximately 1 mm per day (30)], and thus this phase of recovery can last for months or more than a year. This pain and paresthesias must be distinguished from FBSS pain, as in fact they are a sign of recovery. They should not be considered an indication of worsening nor provoke reoperation. Rare patients can have persistence of their radicular pain for months after surgery with total or near-total resolution of pain once reinnervation of the distal target is completed.

DIAGNOSTIC EVALUATION OF THE PATIENT WITH FAILED BACK SURGERY SYNDROME

Because poor diagnostic evaluation leading to inappropriate primary surgery is one of the major causes of FBSS, it is imperative that further diagnostic evaluations be correctly performed and interpreted, despite the added complexity of diagnosis of FBSS patients. For these reasons FBSS patients are often referred to a tertiary care center experienced in dealing with difficult pain patients and equipped for specialized diagnostic testing that may be required. Figure 76C-1 summarizes the diagnostic evaluation of the FBSS patient, consisting of history, physical examination, diagnostic imaging studies, and ancillary evaluations. Because this material is covered in depth in other chapters, we discuss only those issues specific to FBSS patients. In general, the diagnostic evaluation of FBSS patients should follow the same pathways as for other back pain patients; some additions are noted below (see Chapter 12, Chapter 16, Chapter 75).

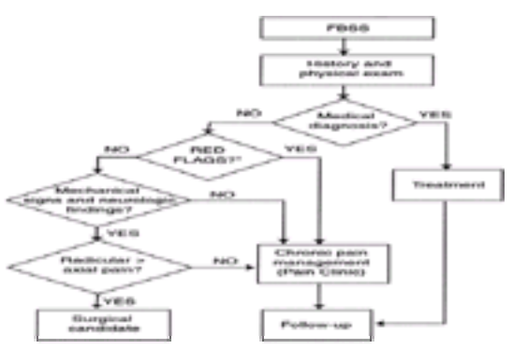

Figure 76C-1. An algorithm for the assessment and management of patients with failed back surgery syndrome (see text). (FBSS, failed back surgery syndrome; RED FLAGS, multiple operations without good indication and with poor results, psychosocial issues, inappropriate medications, etc.) (After North RB. Chronic low back pain and failed back surgery syndrome. In: North RB, Levy RM, eds. *Neurosurgical management of pain*. New York: Springer-Verlag, 1997:342.)

Medical History

As in other areas of medicine, a properly taken history is more cost-effective than any diagnostic procedure. In addition to the standard approach to patients with low back pain (see Chapter 12 and Chapter 75), additional information should be obtained from FBSS patients, including relevant reports of previous surgeries, films, and physical examinations. It is critical to know whether a current neurologic abnormality or abnormal x-ray indicates new or progressive disease or are residua of a previous problem that was already definitively treated. It is particularly important to take a detailed history of the patient's pain characteristics. The low back pain of 5 years ago may have different characteristics and causes than the current low back pain. The progression (or not) of the pain syndrome, including pain-free intervals and effects of various treatments, should also be noted. The psychosocial history should also be obtained to understand the effects of the FBSS pain on the individual's functioning. Issues related to secondary gain, psychiatric problems (see Chapter 26), or both should be clarified. Any pending or former lawsuits connected with the primary low back surgery should be identified.

Prior records and operative notes, when available, are invaluable. As noted earlier, the patient whose pain persists despite surgery that was clearly indicated and properly performed differs substantially from the patient whose pain persists after procedures whose basis is unclear.

Physical Examination

Physical examination should include pertinent musculoskeletal, neurologic, and tension signs and also functional signs. The standard medical and psychological criteria applied to select patients likely to benefit from a primary neurosurgical procedure still apply. Other considerations specific to FBSS patients are discussed below. One important issue is the detection of physical findings predictive of poor outcome of a repeat surgical procedure (31). Abnormalities such as weakness or sensory loss that appear and disappear at various times, change location, or are manifest only during the formal examination but not as the patient uses the “affected” part are suggestive of secondary gain or psychological problems and argue against repeat surgery until these issues are better understood. However, some so-called nonphysiologic or functional findings can result from objective pathology—for example, patchy “nonanatomic” sensory loss is common with lumbar arachnoiditis. Hyperalgesia after nerve injury can present as “superficial” lumbosacral spine tenderness. Although it predicts a poor response to standard lumbar spine surgery (32), the cause is physiologic rather than behavioral. Like other physical findings, these must be considered in context.

In patients with prior surgeries, it can be difficult to distinguish among residual effects after successful treatment (e.g., persistent footdrop after nerve root compression), abnormalities that remain untreated (e.g., lateral recess stenosis), and iatrogenic problems. In a patient who may never have met the standard indications for his or her first operation, the yield of reoperation to correct iatrogenic problems is probably low. Documentation of previous examinations is critical. If asked, the patient often knows valuable information about the duration and progression of any abnormalities noted on examination. Deep tendon reflexes, in particular, often remain abnormal despite adequate surgical decompression, with or without persistent pain, and so, although objective, they have limited specificity.

Diagnostic Imaging Options

A diagnostic imaging decision tree is summarized in Figure 76C-2. Chapter 14 and Section A of this chapter review in detail the use of diagnostic imaging before a first low back surgery. Although the same principles generally apply to FBSS patients, the interpretation of imaging studies is more difficult in FBSS patients because they may have superimposed anatomic abnormalities produced by their primary surgery and they may have had instrumentation that compromises the quality of certain imaging modalities.

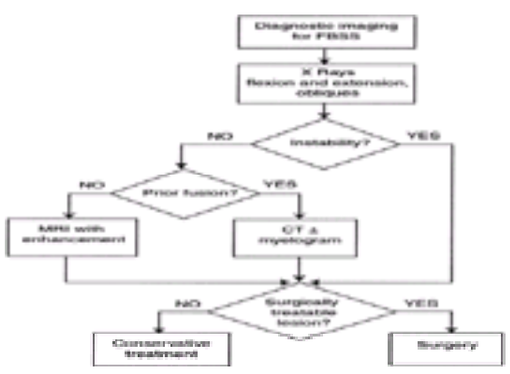

Figure 76C-2. An algorithm for the use of imaging studies in patients with failed back surgery syndrome. (CT, computed tomography; FBSS, failed back surgery syndrome; MRI, magnetic resonance imaging.) (After North RB. Chronic low back pain and failed back surgery syndrome. In: North RB, Levy RM, eds. *Neurosurgical management of pain*. New York: Springer-Verlag, 1997:343.)

The specificity of imaging studies in identifying clinically significant abnormalities in FBSS is limited, just as it is limited in the general population. The longest experience has involved myelography—exclusively with water-soluble contrast agents in recent series and often combined with computed tomography (CT)—in assessing candidates for reoperation. Long-term outcome assessments have been reported for patients selected for treatment on this basis (12).

Intravenous contrast-enhanced imaging studies can distinguish between postsurgical scarring and recurrent, retained, or new disk. CT was used first for this purpose (33,34); as experience accumulated, it became clear that this technique showed abnormalities even in asymptomatic patients (35). In current practice, CT for this purpose has been largely supplanted by gadolinium- enhanced MRI. In a comparison of the two modalities in 130 reoperation cases, MRI was said to be more useful than CT (36); in practice, of course, imaging techniques commonly complement one another.

It has been known for more than a decade that MRI with gadolinium helps to differentiate between postsurgical scar and recurrent or retained disk fragments (37), a distinction to which some authors give special attention (38). The association between pathologic findings on MRI and clinical symptoms, however, is not always clear, even when the identification of pathology is accurate, as confirmed by repeated surgery (38,39). In part, this simply reflects the limited yield of repeated operation for anatomic abnormalities that may have caused irreversible neural injury. Beyond this, however, it is clear that many abnormalities seen on contemporary imaging studies are asymptomatic, in the FBSS population as in the normal population (40). Even patients studied after successful surgery have significant morphologic abnormalities, some simulating recurrent disk herniations with mass effect (41,42). Direct comparisons between postoperative MRI studies in symptomatic and asymptomatic patients have shown no significant differences (43,44 and 45). Postsurgical scar is associated to some extent with symptoms, but it is not clear whether this correlation reflects a cause-effect relationship (scar causing pain) or common cause (pathology causing pain and also causing scar). Adjuncts to surgery to reduce postsurgical scarring assume the former; prospective studies are under way in an attempt to show their usefulness.

MRI avoids the potential morbidity of subarachnoid contrast studies, which have been implicated in the etiology of arachnoid fibrosis (1). MRI has limitations, however, in defining bony anatomy, which often can be better visualized by plain x-ray and CT. Three-dimensional reconstruction of CT information can be useful in the assessment of fusions (46).

The specificity of diagnostic imaging studies in FBSS (and for low back pain in general) is not well established, but chronic low back pain that is not explained by medical disease or ongoing FBSS is commonly considered an indication for imaging in some form. Imaging tests are often repeated, year after year, as the FBSS patient journeys from one pain treatment center to another.

Ancillary Aids to Diagnosis

Additional forms of evaluation may be useful in certain FBSS patients. The usefulness of electromyography in differentiating acute and chronic muscle denervation is an example: Nerve conduction studies can be helpful in assessing the location and severity of damage to nerve roots. Unfortunately, they predominantly detect impulse transmission in large myelinated fibers. The small-diameter axons conducting nociceptive impulses are better assessed in small punch skin biopsies, which, when immunolabeled, permit visualization and counting of small nociceptive endings in the skin (17,18). The utility of this method for evaluation of radicular injury has not been explored.

In some patients with repeated episodes of pain and unsuccessful surgeries, there are underlying medical conditions that predispose to chronic pain. Examples include peripheral neuropathies, treatable arthropathies such as gout and rheumatoid arthritis, and connective tissue disorders such as the Ehlers-Danlos syndrome. Examining other organ systems and taking a complete medical history will sometimes indicate that the FBSS patient needs more comprehensive medical evaluation rather than another surgery. Recognizing these underlying conditions is important in selecting patients for further surgical and nonsurgical treatment; in some cases, one can hope that disease-specific treatment will improve the patient's pain.

Psychological Testing

Psychological factors should be routinely considered in evaluating patients with FBSS (11,47,48), as in patients contemplating an initial surgery (see Sections B and C of this chapter and Chapter 16, Chapter 24, Chapter 25 and Chapter 26). Several authors have reported poor outcomes of reoperation in patients with psychological problems (32,49,50,51,52 and 53). These assessments have mostly been retrospective; however, prospective psychological studies can be difficult to design and interpret (54). Abnormal psychological findings or test results are commonly assumed to represent a premorbid trait (55,56,57 and 58); however, chronic pain and

other serious diseases commonly have psychological sequelae such as major depression, even in patients with no prior psychiatric history. Therefore, abnormal results of psychological testing in pain patients may reflect a consequence rather than a cause of the pain (59).

In fact, psychological testing can be used as an outcome measure in itself—for example, changes in Minnesota Multiphasic Personality Inventory profiles have been reported after successful treatment of chronic low back pain (60). Accordingly, depression and other psychological findings in a patient who has failed treatment should not be assumed to be primary and thus a contraindication to reoperation; they should be evaluated and treated separately. If concerns arise about whether psychological problems are causing pain or vice versa, it can be quite helpful to refer the patients for treatment of their psychological problems and reevaluate them once their psychological problems are better controlled or at least better understood. When considered as one among many potential prognostic factors, psychological testing explains only a fraction of the overall variance in treatment outcome, and it should be considered as one among other selection criteria. We have found standardized psychological testing helpful in identifying comorbidities requiring treatment, but in patients whom we have identified as candidates for a specific procedure (e.g., spinal cord stimulation) it explains a very small fraction of the variance in treatment outcome (48). Accordingly, we consider its prognostic value limited, at least in patients carefully selected by other means.

Diagnostic Blocks

Radiologic testing is increasingly successful at identifying anatomic abnormalities but still provides no information about the clinical significance of those abnormalities. The dissociation between abnormal radiologic findings in the low back and clinical significance is notorious and probably contributes to the performance of inappropriate back surgeries (and thus FBSS). The admonition to “treat the patient, not the x-ray” is critical for FBSS patients. For this reason, temporary diagnostic blocks using local anesthetics can be helpful in contributing functional information about the source of pain to the diagnostic evaluation. FBSS patients frequently have more than one anatomic abnormality in the lumbosacral spine, often at several levels. Their original surgery may have created additional anatomic abnormalities such as scarring or abnormal alignment. Because diagnostic and therapeutic decisions are more difficult in FBSS patients and the outcome of revisional surgeries worse than for the primary surgery (32,52), it is appropriate to invest more effort in identifying which (if any) of the visualized anatomic abnormalities are actually contributing to the pain.

A series of nerve root blocks can be useful in the evaluation of FBSS patients with multilevel anatomic abnormalities. It can be helpful to keep the patient unaware of exactly which level is being blocked; the use of anesthetics with different durations of action or of saline control blocks can also increase diagnostic utility (61). By knowing which abnormalities are contributing to a patient's pain syndrome, surgery can be limited to those levels rather than undertaking a higher-risk, multilevel procedure.

One caveat is that temporarily abolishing the patient's pain by blocking neuronal activity at a specific location does not equate to knowing that those neurons are the “pain generators,” or primary site of pathology. For instance, a patient with allodynia may experience relief of pain by a nerve root block, which temporarily eliminates incoming messages from the painful area; however, if the major pathophysiologic abnormality is within the dorsal horn of the spinal cord, a procedure directed at the primary afferent axons (e.g., foraminotomy or neurectomy), of course, will not address it directly.

In practice, temporary blocks with local anesthetic have had limited prognostic value in selecting patients for ablative surgery. Loeser reported limited predictive value of nerve root blocks before rhizotomy (62), and our experience with dorsal root ganglionectomy is similar—favorable response to blocks did not translate into long-term pain relief (63). Temporary nerve blocks have been noted to afford temporary pain relief even when performed distal to root or peripheral nerve lesions presumed to be pain generators (64,65 and 66) and even when performed contralateral to the site of a unilateral lesion (67). This phenomenon is not easily explained in terms of placebo or systemic effects of local anesthetics; it is more likely to relate to a central mechanism that responds to temporary interruption of a major afferent input. Response to a single temporary block may be a necessary condition, but is by no means sufficient to localize a pain generator or predict the results of a surgical procedure. Data on the predictive value of a negative response to a nerve block are lacking.

The usefulness of temporary blocks in the absence of defined anatomic abnormalities, such as with trigger point injections into muscle, has not been shown to have predictive value for reoperation. Repeated temporary local anesthetic blocks are generally not a useful treatment option for chronic pain.

Provocative Diskography

The rationale for performing provocative diskography is to determine whether mechanical loading of individual disks reproduces an individual patient's characteristic pain. Because negative results of diskography at a given level argue against the usefulness of diskectomy or fusion, diskography can be especially helpful in avoiding further unnecessary surgery in FBSS patients. It can also be helpful in minimizing the number of levels at which surgery is performed in a patient with multilevel disk abnormalities. Strongly positive results at a single level with negative results at other levels can give both patient and physician more confidence in the likelihood of success of a contemplated surgical procedure at that level. As with other diagnostic blocks, inappropriate responses can identify patients with behavioral factors, who should not be considered for repeat surgery at that time. Diskography remains, in spite of 30 years' use, a diagnostic study of uncertain reliability.

TREATMENT OPTIONS

FBSS can be a difficult and frustrating syndrome to treat. Many FBSS patients have had pain for a long time, have had multiple interventions fail, and often have financial and psychosocial difficulties because of their chronic pain. Additionally, patients may travel from great distances, which complicates the logistics of diagnosis and long-term follow-up. Many physicians avoid FBSS patients. In general, an algorithm should be followed, starting with conservative and reversible treatments and progressing logically toward more invasive and/or irreversible procedures only if needed. It may be appropriate to refer patients to centers that specialize in the less common procedures. Often, combining approaches (e.g., rehabilitation plus medications) is more successful than instituting either alone. It is important to emphasize to the patient that a logical progression of treatment options is being followed, and if one approach fails, other options remain. The multidisciplinary treatment options for FBSS are many, so it should never be necessary to abandon or tell a patient with FBSS (or other types of chronic pain) that nothing more can be done. This raises the frightening possibility that the pain will persist indefinitely. When a clinician has nothing further to offer within his or her specialty, the patient should be referred to a colleague with more expertise or an alternative approach to offer. Even when a patient's pain is intractable, a relationship with a reliable and trusted clinician who understands the patient's plight and who is willing to help with the associated issues that accompany chronic disease can provide great solace to the patient and tremendous professional satisfaction to the clinician.

Evaluation of the literature on treatment of FBSS is not straightforward, because different outcome measures are used, and methods of obtaining follow-up vary widely (68). The most common assessment is the patient's self-reported pain relief; other measures reflect pain relief indirectly. Patient satisfaction with treatment (“Would you go through this operation again for the same result?”) is also commonly assessed (4,12,25,32,69). A common criterion for “success” is a minimum of 50% estimated pain relief. Medication requirements usually are considered, as are abilities to engage in various activities of daily living. Return to work is given particular emphasis by rehabilitation programs (70) and is considered by many surgical series as well. When data from disinterested third-party interviews are compared with office and hospital records, the latter appear to overestimate the results of treatment (71,72,73 and 74). Reports of the outcome of reoperation and behavioral/rehabilitation programs are commonly based upon chart review, but a few have used disinterested third-party interviews (12,25,32,70).

Medical Options

A trial of conservative treatment is usually the first option for most patients with true FBSS. Options include medical treatment, rehabilitation, and management of other contributing medical factors, such as obesity or depression. Rehabilitation is central to the management to FBSS patient regardless of candidacy for any neurosurgical procedure. The results of an aggressive rehabilitation/behavioral program are very often favorable, as assessed by disinterested third-party methods (70), and may obviate the need for reoperation. In general, these programs are applicable to all patients with FBSS; they complement neurosurgical intervention in selected cases. This type of comprehensive diagnosis and treatment is presented in Chapter 11, Chapter 18, and Chapter 109. The methods used to treat primary low back pain, described previously in this chapter, are usually appropriate for FBSS patients as well. Medical management of FBSS patients (and chronic pain in general) is underused due to lack of education of both physicians and the public about medical options for treating pain. Patients who have already had one unsuccessful surgery should be even more strongly considered for a detailed trial of medical management. This may take months, or even several years, because there are many drugs that help some of these patients, but no one medication or class of medications has universal efficacy.

Patients with current or previous alcohol or drug dependency problems should be evaluated and treated, if necessary, before consideration of any procedure. However, addicts are not immune from legitimate indications for repeat surgery or from the need for chronic medical management of pain. A patient who has been well controlled on methadone maintenance or who has completed a rehabilitation program is much easier to diagnose and manage than someone acutely abusing drugs

or alcohol. Collaboration with a specialist in addiction medicine can be helpful in ensuring that these difficult patients are being appropriately treated. A skilled practitioner may be able to successfully manage both conditions simultaneously. Because FBSS patients, by definition, have continued chronic pain, they are very likely to be using pain medications, including opioids. Although physical tolerance can develop (as with some other types of medications), the majority of these patients do not display behavioral signs of addiction. Use of chronic opioid analgesics is not a contraindication for reoperation. Actually, aggressive medical management, including the chronic use of opioids where appropriate, should be more often tried as a means of avoiding further surgery, particularly in individuals with a low probability of pain relief after reoperation. Some patients can be treated satisfactorily with stable doses of opioid analgesics over long periods of time. Unfortunately, most clinicians are not taught how to medically manage chronic pain. They should not hesitate to refer to a pain specialist and should be prepared to resume the management of their patient once a stable drug regimen has been instituted. Abstinence from opioid analgesics often is used as an outcome measure (4); accordingly, it easily can be overemphasized as a prognostic factor.

Percutaneous Fluoroscopic Procedures

An increasing variety and number of percutaneous fluoroscopic procedures are being performed for FBSS patients. This must be motivated in part by reimbursement rates, because there is a paucity of information about the indications for and success rates of these procedures. As these procedures become more common, it is imperative that they be rigorously evaluated and that standard methods be developed. This is most advanced for the facet denervation procedure.

Degenerative disease of the zygapophyseal joints (where adjoining vertebrae overlap dorsal to the spinal canal) is an underappreciated cause of low back pain and of pain radiating to the buttocks or upper legs. Patients with pain of facet origin usually present with axial and predominantly proximal radicular-type pain, worsened by lumbar extension, and not associated with sciatic tension signs or unexplained neurologic findings. Because these joints are innervated by terminal twigs of the medial branch of the posterior primary ramus, it is presumed that these “nonanatomic” sensations are due to convergence upon second-order sensory neurons within the spinal cord. Particularly in the case of FBSS patients, where reoperation is intrinsically less desirable than a primary surgery, it can be useful to determine whether facet arthropathy contributes to their low back pain. Because this problem can be effectively addressed by low-risk percutaneous radiofrequency lesioning, it is often worthwhile to consider this nonsurgical option. In some patients with multifactorial pain, reducing the total pain burden by percutaneous facet denervation enables the patient to better tolerate his or her remaining pain.

Assessed by disinterested third-party interview, facet denervation has been “successful” (at least 50% relief of pain) in just under half of our patients at 3-year follow-up (67). This result, in fact, compares favorably with our experience with reoperation. Furthermore, in our experience, the morbidity of facet denervation has been nil. In other series, patients with a history of prior low back surgery reportedly respond less well to facet injections or denervations (75,76,77,78,79,80,81,82,83 and 84), but this has not been the case in our experience. The selection of patients by temporary diagnostic blocks, however, shows limited specificity.

There are much fewer data about other percutaneous fluoroscopic procedures for FBSS patients. They have an appeal because they avoid a surgical procedure, but most ablative surgical procedures for FBSS have poor results (see below). Data supporting the use of epidural steroids, lysis of adhesions, radiofrequency lesioning, and phenol injections into either nerves or dorsal root ganglia are preliminary and allow no definitive conclusions as to their usefulness.

Surgical Approaches

Surgical options for FBSS patients fall into three categories:

1. Anatomic procedures, which attempt to correct the pathology responsible for generation of pain
2. Ablative procedures, which attempt to block pain transmission by destroying some portion of the nervous system
3. Augmentative procedures, which reversibly modulate activity in the nervous system by electrical or chemical means

Anatomic Procedures

It is important to remember that the favorable outcomes after reoperation are less likely than for primary surgeries (12,32), and thus reoperation should be considered only for a distinct, well-defined minority of FBSS patients. Persistent or recurrent chronic pain may be attributed to a surgically remediable lesion, and surgery should be proposed only after thoughtful diagnostic evaluation and after failure of more conservative treatment.

Occasionally, patients require reoperation urgently after a primary low back surgery. These conditions, which should not missed, can be difficult to diagnose because of routine postoperative pain. Usually they present with new signs or symptoms in addition to the ongoing pain. Diskitis, abscesses, or other infections are usually associated with the systemic clinical and laboratory signs of infection. Perhaps most urgent is epidural hematoma. These patients usually present with widespread lumbosacral dysfunction, including leg weakness and bladder and bowel dysfunction. Immediate decompression may allow these devastating complications to reverse. Neural structures, including the spinal cord or nerve roots, may also be impinged upon by a retained disk fragment or newly implanted hardware. Rarely, instrumentation can induce stenosis at adjacent segments, which can require immediate revision.

Patient Selection for Surgery. The American Association of Neurological Surgeons (85) and the American Academy of Orthopedic Surgeons (86) have published criteria for patient selection for elective lumbosacral spine surgery. These are applicable to FBSS patients as well as to patients without prior surgery. They include the following:

1. Failure of an extended program of conservative therapy
2. An abnormal diagnostic imaging study (myelogram, CT, MRI) showing nerve root or cauda equina compression and/or signs of segmental instability consistent with the patient's presenting symptoms and physical findings
3. In patients with radicular pain complaints, conformity to physiologic dermatomal or sclerotomal patterns and one or more of the following: (a) corresponding segmental sensory loss, (b) motor loss in the appropriate segment(s), or (c) abnormal deep tendon reflexes in appropriate segment(s)

In patients who have previously undergone surgery, it can be difficult to distinguish the residual effects of prior insults that have been treated definitively (e.g., persistent hyporeflexia after disk surgery), abnormalities that have remained untreated (e.g., lateral recess stenosis), and iatrogenic problems. In a patient who may never have met the standard indications for his or her first operation, the yield of reoperation to correct iatrogenic problems is low.

Outcome of Repeated Lumbosacral Surgery. A number of reoperation series have been reported, with the range of “success” rates varying from 12% to 100% (12). The absence of standard outcome measures in these studies made metaanalysis and assessment of prognostic factors difficult (87). Adverse outcome and loss of neurologic function are only rarely reported but may be common (12,32,88). Morbidity, as recorded in office and hospital records, was minimal, but patients commonly report regression in neurologic function, activity levels, and medication requirements after surgery (12). A review using disinterested third-party interview methods suggested a long-term rate of “success” (at least 50% pain relief and patient satisfaction, at 5-year mean follow-up) of one-third (12). This is significantly less than that reported for other less-invasive options such as spinal cord stimulation (89). In prospective, randomized comparison with reoperation, spinal cord stimulation is significantly more effective by multiple outcome measures (67). It is not clear how patients who choose reoperation would have fared without surgery, but it is evident that selection of patients for repeated operation should proceed conservatively.

Decompression and Fusion. Reoperations may be considered in two broad categories: decompression and fusion. Large series of decompressive reoperations, specifically identifying those without fusion, have reported widely varying success rates, as above. Among decompressive reoperations, recurrent disk herniation at a previously operated level can be reoperated with generally good results. Repeat microdiskectomy has been successful in more than 80% in some series (90), and within one large reoperation series, previous diskectomy was a favorable prognostic factor (12). Central or lateral recess stenosis that was overlooked or undertreated at an initial surgery or that may have evolved at adjacent levels is a common indication for reoperation.

The role of fusion in lumbar disk disease is not well defined; there has been no prospective, randomized trial of fusion (91). Notwithstanding this, outcome studies have reported a significant association between technically satisfactory fusion and clinically satisfactory outcome (92). Likewise, repair of pseudarthrosis is highly successful clinically when successful technically adequate (93). Of course, this is vulnerable to bias of ascertainment—patients with persistent symptoms are most likely to be evaluated extensively, with some resulting diagnosis made.

Prognostic Indicators. A number of prognostic factors have been identified for patients undergoing repeated operation; they may or may not be significant for individual patients and should be considered in overall context. For example, women have been reported to do better than men (4,12). This is a statistically significant

but clinically minor consideration. Relatively favorable outcomes have been reported in patients with a history of good results from prior surgeries (25,32,50,52,94); this is not surprising to the extent that patients who respond favorably to a query about the operation under study are more likely to respond favorably to similar questions about prior operations. Patients who have undergone a small number of prior operations (32,52) reportedly do better after reoperation. Epidural scar requiring surgical lysis is an adverse prognostic factor (32,50,95,96). Operative or myelographic findings of disk herniation have been reported as favorable indicators (4,25,32,94,95,97). Patients with radicular pain reportedly have fared better than those with primarily axial pain for reoperation as for other treatments (*vide infra*) (32,98). Patients with a pseudarthrosis of a prior fusion appear to have inferior outcomes (49,94). The role of spinal instrumentation, like the role of fusion in the management of FBSS, is a matter of considerable controversy; like the technical details of reoperation, it is beyond the scope of this discussion. Patients who are still working immediately before surgery have been reported to have superior outcome from reoperation (12,94); workers' compensation status may (4,49,50,53) or may not (12,94) be associated with poor outcome.

Ablative Procedures

Persistent postsurgical lumbosacral pain can occur on the basis of continuing disease or injury in a ligament, joint, muscle, or disk (chronic nociceptive pain), or it can reflect abnormal function of a previously injured neural structure. This type of neuropathic pain is pathologic in that it persists after tissue healing and serves no physiologic function. Abnormal neural activity, which is interpreted as pain, can originate in a neuroma (99) or in dorsal root ganglia (100,101). Large myelinated afferents, which normally do not signal pain, have been shown to be involved in hyperalgesia after nerve injury (102). Any of these mechanisms of pain generation would be expected to respond to ablation of primary afferent neurons. However, the animal models of pain have taught us that significant changes within the CNS accompany perturbations of peripheral input (21). Persistence of these mechanisms may underlie the frequent treatment failures reported after these ablative procedures.

The results of open surgical ablative procedures for FBSS have been disappointing. A few series have reported favorable short- term results (62,103,104,105,106,107,108 and 109), but extended follow-up has demonstrated only modest results (62,106,108). It has been shown that dorsal rhizotomy does not interrupt all afferent input; contrary to the “law” of Bell and Magendie, there are numerous ventral root afferents with cell bodies in the dorsal root ganglia (110). These afferents may allow persistent input from peripheral pain generators to persist after dorsal rhizotomy. Removal of the entire dorsal root ganglion should thus be more effective than rhizotomy. This has not been confirmed in practice. The longest published follow-up (more than 5 years) in patients assessed by third-party interview showed no “successes” (63); other series have shown variable efficacy (111,112,113 and 114). Presumably the failure of these procedures to relieve pain testifies to the importance of central pathophysiology. Ablative procedures can compromise the results of other neurosurgical procedures. For example, implantation of a spinal cord stimulator has a lower yield after dorsal root ganglionectomy (63). Primary afferent ablation also depletes opiate receptors on dorsal horn neurons and might thereby compromise future pharmacologic therapy. With the exception of percutaneous facet neurotomy, ablative procedures have had a relatively poor outcome for FBSS and significant morbidity. Minimally invasive, reversible treatments such as spinal cord stimulation have a more favorable ratio of benefit to risk. It should be noted that the pathologic human tissues, such as dorsal root ganglia, that are removed during these procedures are exceedingly valuable to scientists investigating pain pathogenesis and that arrangements should be made preoperatively to make these tissues available to qualified investigators.

Augmentative Procedures

The rationale behind these approaches (described in detail in Chapter 99 to Chapter 101) is reversible modulation of sensory input (noxious as well as nonnoxious) to the CNS, or processing in the CNS, in an attempt to inhibit pain generation or hyperalgesia. “Neuromodulation” may use electrical stimulation or chemical infusion techniques. Although originally based on the gate control theory (20), the actual anatomic and biochemical mechanisms underlying electrical stimulation are not fully understood.

Implantable devices for pain control have the advantages of being minimally invasive and reversible. Thus, they are intermediate on the continuum between medical management and surgery.

Spinal cord stimulation is a reversible “neuroaugmentative” technique that has been successful in a majority of FBSS patients for up to 20 years (74). It compares favorably with reoperation (89) as assessed retrospectively, and more recently by prospective, randomized study (67). Spinal cord stimulation is traditionally more effective for radicular than axial low back pain (115), but with ongoing improvements in devices and their implementation, axial pain is more accessible (116). FBSS has been the most common indication for spinal cord stimulation (74).

Transcutaneous electrical nerve stimulation was developed to screen patients for implanted stimulation techniques; it uses external electrodes and follows the same rationale. Its prognostic value is limited, but it gives patients useful experience and is itself adequate therapy in some. Therefore, it is commonly prescribed before considering an implant.

Other neuroaugmentative methods less commonly used in FBSS include implantable peripheral nerve stimulators. These are usually considered in patients with pain attributable to a single well-defined nerve injury. Implantations usually need to be proximal to the injury and thus may not be helpful for radiculopathies. Thus, FBSS patients are not the group most likely to benefit from this approach. FBSS is also one of the most common indications for implantation of chronic electrodes into various locations in the brain. In contrast to the other augmentative procedures, this is one of the more invasive techniques, and so it is usually used only when many other treatment options have failed. This approach is discussed in more detail in Chapter 101. The use of implanted pumps for subarachnoid infusion to deliver opiates intrathecally (and, it is hoped, to minimize systemic complications) has been reported in small numbers of patients with FBSS; reported successes (117,118,119 and 120) have been tempered by reported complications (121,122,123 and 124). Patient selection criteria await further study and precise definition, as discussed in Chapter 103.

CONCLUSION

FBSS presents a challenge to the clinician as well as the patient. Inappropriate primary surgery is the most common cause. Diagnosis is more difficult than in unoperated patients. A logical progression of treatment options should be followed, starting with rehabilitation and medical management. The majority of patients will not need reoperation, and those who do will have a worse outcome, as a group, than those undergoing their first low back surgery. Thus, the onus is on the clinician to diagnose and treat these patients skillfully and with compassion. Patients commonly require referral to a multidisciplinary pain center or to other specialists for attention to all facets of the FBSS.

CHAPTER 76

D. Psychological Screening of Spine Surgery Candidates: Risk Factors for Poor Outcome

Andrew R. Block

Although only approximately 1% of individuals who experience back pain ever require surgery (1), approximately 280,000 spine surgeries are performed each year in the United States (2). Approximately 85% of these procedures involve laminectomy and diskectomy and 15% are spinal fusions. Spine surgery often brings dramatic improvements in the patient's experience of pain and functional abilities. For example, Malter and colleagues, examining the effectiveness of laminectomy and diskectomy in the treatment of spine pain, found that those patients receiving surgery had significantly greater quality of life at 5 years postoperation than did patients provided conservative care alone (3). The results of this study also showed that the cost-effectiveness of laminectomy and diskectomy exceeded that of the medical treatment for hypertension, as well as that of single artery bypass grafting in coronary heart disease. Hence, there is real utility in spine surgery.

Unfortunately, the results of surgery for chronic low back pain are not uniformly positive. Turner et al., reviewing all published research on spinal fusion, found that only approximately 65% to 75% of all patients achieved satisfactory clinical outcomes. In these studies, poorer outcome was associated with a number of factors, including greater numbers of fused levels and the use of instrumentation (4). Similarly, Hoffman and colleagues, in a literature review on laminectomy and diskectomy, found that the mean success rate of this procedure for relief of spine pain was 67% (5).

Poor surgical results can have significant impact on the patient, the physician, the employer, and the third-party payer. The patient, of course, continues to remain disabled, with perhaps even greater pain, increased medication dependence, and more emotional difficulty than prior to the surgery. The pain may be so great, or the surgery so unsuccessful, that reoperation is required, as is the case in 10% of those who undergo laminectomy and diskectomy (5), and 23% of those who undergo spinal fusion (6).

The patient after failed surgery places many demands on the health care system, often requiring increasing medications and expensive multiple treatments. Patients often feel frustrated and discouraged. The physician may become angry with the patient for not responding to treatment, and the employer is always concerned about his or her obligation to pay compensation to a permanently disabled worker.

There has been a growing interest in identifying those patients at risk for having a poor response to surgery aimed at relieving chronic back and leg pain. If a means for such identification could be developed, not only would patients be spared the burden of suffering a failed procedure, but significant cost savings also would accrue. If one considers that approximately 235,000 laminectomy and diskectomy procedures are performed each year and approximately 25% of these result in failure, then approximately 58,750 patients each year continue to experience pain (2). The average cost of a laminectomy and diskectomy, including hospitalization and postoperative rehabilitation, is approximately $18,000 (7). Therefore, a screening procedure that correctly predicted all laminectomy and diskectomy failures would save 58,750 × $18,000 = $1,057,000,000 per year, in health care costs alone, minus the costs of the screening procedures.

PSYCHOSOCIAL FACTORS ASSOCIATED WITH POOR SURGICAL OUTCOME

The research on surgical outcomes for chronic pain has increasingly demonstrated that among the strongest predictors of poor results are psychosocial factors. Many elements of the patient's personality, emotional state, and history can combine with contingencies in the patient's social and vocational environment to militate against good surgical results. The purpose of this section is to alert physicians to the potential presence of such psychosocial risk factors and review their effects on surgical outcome.

Personality and Emotional Factors

There are many pathologic physical conditions that can lead to the experience of low back pain. It is the goal of the spine surgeon to correct such conditions, or to minimize their ability to generate perceptible pain. Pain, however, is a subjective experience, and correction of the objective pathology underlying it may fail to achieve relief. The literature, as well as clinical experience, reveals that the pain may linger even after technically successful surgery. Obviously, factors far beyond the operating room in the realm of the patient's psychological makeup and social situation likely contribute to the inconsistent outcomes observed.

Perhaps the strongest set of factors that have been shown to influence the manner in which individuals perceive and react to back pain is related to basic personality characteristics. The American Psychiatric Association (1997) defines *personality* as “deeply ingrained patterns of behaviors, which include the way one relates to, perceives and thinks about, the environment and oneself” (8). According to this description, personality can exert wide-ranging influences over both thoughts and actions. These characteristics can determine, for example, whether people typically become depressed, anxious, or angry in response to stress. Personality may also influence one's need to maintain control, to draw attention to himself or herself, or to withdraw and become sullen. More germane to presurgical psychological screening (PPS), personality factors can exert strong influences on perception of the pain, the emotional impact of pain, and the actions one takes to achieve pain relief.

Personality factors can be reliably identified through the use of *objective* psychological tests, such as the Minnesota Multiphasic Personality Inventory (MMPI). The MMPI has been frequently used in studies attempting to predict outcome following spine surgery. Table 76D-1 lists the major studies that have used the MMPI with spine surgery patients. The results demonstrate that elevations on several MMPI scales have been found to be associated with poorer surgical outcomes. In examining this table we must recognize that the MMPI not only assesses enduring personality traits, but also more acute emotional reactions. For example, depression, as assessed by the MMPI, may be a reaction to the pain and lifestyle changes engendered by the spine injury or may be more of a chronic feeling state. The results of the MMPI cannot be used to make such a differentiation. However, as is discussed in the following section, the relatively enduring nature of many of the traits displayed on the MMPI may significantly influence the outcome of spine surgery.

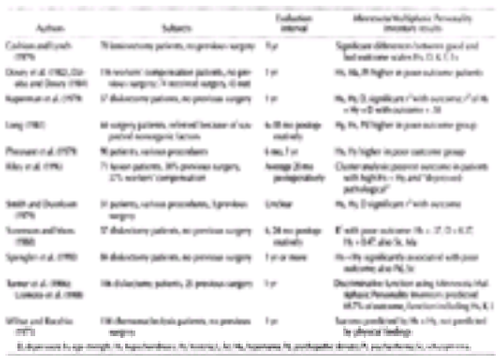

TABLE 76D-1. Studies examining the relationship of Minnesota Multiphasic Personality Inventory to spine surgery outcome

Pain Sensitivity: Minnesota Multiphasic Personality Inventory Scales for Hypochondriasis and Hysteria

A large body of research has demonstrated that chronic pain patients frequently display excessive *pain sensitivity*. For example, research has found that patients with functional gastrointestinal pain syndromes may be hypersensitive to pain signals arising from the gut. Using balloon distension of the esophagus in patients with noncardiac chest pain, Barish and colleagues found that distension caused pain in 56% of patients compared with 20% of normal controls (9). Similarly, Coffin and colleagues reported that patients with nonulcer dyspepsia showed greater sensitivity to balloon distension of the stomach than did normal subjects (10). Fibromyalgia patients, too, have been shown to be more pain sensitive than normal subjects to pressure, noxious heat, and electrical impulses (11). Finally, Schmidt and Brands reported that chronic low back pain patients were extremely sensitive to a cold pressor test (immersion of the forearm into an ice water bath), reporting higher pain levels and tolerating the ice water for a shorter period of time than did a control, nonpatient group (12).

Pain sensitivity, as a personality factor, can be assessed by the MMPI Hypochondriasis (Hs) and Hysteria (Hy) scales (13). These scales are the ones most commonly elevated in general chronic pain syndromes and in spine surgery candidates (14). The major difference between the two scales is that Hy, in addition to pain sensitivity, measures a tendency to deny psychological and emotional problems, as well as to minimize discomfort experienced in social situations. There is a strong correlation (*r* = .53) between the two scales, and thus they are often both elevated at about the same level.

We (15) have administered the MMPI to low back pain surgical candidates undergoing three-level lumbar diskography, and found that Hs and Hy elevations were associated with false-positive reports of pain (pain reproduction on injection of normal-appearing disk). Interestingly, the majority of patients who had such false-positive pain reports at one disk level also had concordant pain reports (i.e., pain reproduction on injection of an abnormal or disrupted disk) at another level. These results demonstrate that excessive pain sensitivity significantly influences pain perception even in patients with objectively identifiable pathophysiology.

Most studies examining the value of the MMPI in predicting spine surgery outcome have found at least one, if not both, of the scales Hs and Hy to strongly predict poor surgical outcome (see Table 76D-1). In some studies the predictive value of these two scales far exceeds that of medical diagnostic tests, such as radiography, computed tomographic scans, or neurologic signs (16). Such results parallel those in other chronic pain syndromes, finding that Hs and Hy elevations predict poor treatment outcome for syndromes as diverse as temporomandibular joint dysfunction, gastrointestinal disorder, and nonsurgical back pain (17,18,19 and 20).

Anger: Minnesota Multiphasic Personality Inventory Scale for Psychopathic Deviate

Anger and chronic pain are often intertwined. The anger experienced by chronic pain patients can sometimes be quite severe. Fernandez and Milburn, for example, asked chronic pain patients to endorse the intensity of 10 different emotions they were experiencing and found that anger was given the highest ratings of all emotions assessed (21).

Anger as a personality trait is assessed by the psychopathic deviate (Pd) scale of the MMPI, which also evaluates rebelliousness toward authority and aggressiveness (13). Elevations on the Pd scale have been found in at least five studies to be associated with poor surgical outcome (16,22,23,24 and 25). There are numerous reasons why anger may have a negative impact on reduction of pain. First, anger may lead to maladaptive lifestyle changes, such as poor health habits, lack of physical exercise, or excessive use of drugs or alcohol (26). Such maladaptive behaviors may have a negative impact on the patient's commitment to postoperative rehabilitation. Furthermore, anger has been shown to have an adverse effect on many health conditions, such as cardiovascular disease, headaches, asthma, and many others (27,28). Such adverse effects may be mediated by excessive activation of sympathetic nervous system efferents or changes in the immune system, perhaps influencing the healing process (27). Finally, anger directed at specific individuals or institutions may maintain pain symptoms beyond the expected period of healing. DeGood and Kiernan have found chronic pain patients who are angry and blame their employer for their injuries report high levels of emotional distress and have poorer response to treatment (29). It may be that for patients who experience intense anger, continued postsurgical pain reports may be tied more closely to such feelings than to any improvement in the pathophysiologic basis of the pain.

Clinical Depression: Minnesota Multiphasic Personality Inventory Scale for Depression

Many chronic pain patients experience some level of depression. For up to 85%, the intensity of this emotional experience is sufficient to meet the diagnostic criteria for clinical depression (30). Depressive symptoms include depressed mood, diminished interest in almost all activities, weight loss or gain, insomnia or hypersomnia, agitation or psychomotor retardation, fatigue or energy loss, feelings of worthlessness or guilt, impaired concentration, and recurrent thoughts of death [adapted from *Diagnostic and Statistical Manual*, fourth edition (DSM-IV)] (8). Depression can be assessed by scale D of the MMPI. Elevations on scale D are found in most studies to be associated with poor outcome of elective spine surgery (22,23,25), although in several studies no relationship was reported (16,31,32 and 33).

Chronic pain patients who are depressed may fail to respond well to spine surgery for a number of reasons. First, individuals with depression have been found to be more likely to focus on negative rather than positive events (34). Kremer and colleagues (35) demonstrated that such tendencies can affect the chronic pain patient's perception of the improvements in function that result from treatment. In this study, activity levels of patients undergoing interdisciplinary rehabilitation were unobtrusively observed by trained staff members. Patients also recorded their own activity levels on an hourly basis. Although all patients demonstrated objective improvement in activity levels as a result of treatment, those who were depressed tended to underreport their improvements. Thus, depressed patients who undergo spine surgery may also fail to see the gains they have made. Depression has also been shown to be associated with a low threshold for induced pain (36). Perhaps the surgical patient may be focused on the body and hypervigilant for pain even if its pathophysiologic basis has been corrected and the nociceptive stimulation greatly reduced.

In examining depression, it may be critical to consider whether the symptoms predate the back injury or are of relatively recent onset. For many patients, depression may be a personality style or a chronic emotional condition (i.e., dysthymia). For others, depressive symptoms, such as decreased concentration, sleep disturbance, and weight change, may be a direct result of the experience of protracted pain or disability (37). Chronically depressed patients may respond more poorly to any surgical procedure aimed at pain relief compared with those patients whose depression is reactive to their medical condition and symptoms. Surgical recovery in more acutely depressed patients may actually be facilitated if clinical depression is adequately treated, through a combination of antidepressant medication and short-term psychotherapy. The improvement in depressive symptoms, including a likely decrease in pain sensitivity, may lead the patient to feel relieved by surgery beyond the correction of pathologic changes in the spine.

Chronic Anxiety and Obsessions: Minnesota Multiphasic Personality Inventory Scale for Psychasthenia

Chronic back pain engenders many difficulties for the patient. Often patients are quite anxious, worrying about paying their bills and fearing that they will lose their jobs. They may be concerned about the many changes in family interaction caused by pain and limitations. Most of all, the spine surgery candidate has to face uncertainty about improvement in pain and functional ability. Such fears and worries, combined with more chronic tendencies toward emotional distress, obsessions, and compulsions, are assessed by the MMPI psychasthenia (Pt) scale. Patients with Pt elevations tend to be stubborn, rigid, and self-critical (DSM-IV, 1994). In four studies, Pt elevations have been found to be associated with adverse outcomes of spine surgery (see Table 76D-1). It may be that to the extent that the patient has chronic tendencies toward worrying and experiences high levels of anxiety, any improvements resulting from spine surgery may be denigrated, while continued minor

symptoms or irrational fears may become the focus of attention.

General Comments on the Minnesota Multiphasic Personality Inventory

The use of the MMPI with chronic pain patients has generated a great deal of controversy. One criticism of this test arises from its theoretical psychoanalytic underpinnings. Indeed, early use of the MMPI with chronic pain patients attempted to distinguish between those patients who had organic pain and those with *psychogenic pain*, pain arising from the conversion of some unresolved psychosexual or developmental conflict into a physical symptom (38). Gamsa has cautioned that there is little evidence to support such *dualistic* Freudian speculations (39). Nonetheless, the large body of research just reviewed demonstrates that the MMPI, stripped of its theoretical underpinnings, is effective as a predictor of surgical outcome. Unfortunately, as Main and Spanswick correctly point out, MMPI results are often communicated to physicians, not on an actuarial, probabilistic basis, but rather categorically in dualistic terms, indicating the presence or absence of some psychiatric syndrome or dysfunction traits (40).

A number of other criticisms of the MMPI, identified by Main and Spanswick (40), rest on methodologic grounds, including the representativeness of the populations used in developing the MMPI, the nature of items used, overlap between MMPI scales, and doubts about the worth of some of the MMPI scales. Although all of these criticisms certainly are valid, the MMPI has proven to be an effective tool. Even Love and Peck (41), who heavily criticize use of the MMPI with chronic pain patients, state, ". . . a relationship does seem to exist between MMPI scores and response to medical treatment. This suggests that the MMPI should be included in the assessment and planning of surgical interventions."

COGNITIVE FACTORS

Although the MMPI assesses general personality and emotional factors, it is neither designed specifically to address the problems of chronic pain patients, nor does it assess specific patient thought patterns and pain-coping strategies. A growing body of research, however, demonstrates that patients' thoughts and beliefs concerning their pain can strongly affect treatment outcome (42,43). Such cognitions and coping strategies have been demonstrated to influence the level of pain experienced by the patient, level of functional ability, and adjustment to the pain and efforts to overcome it (43,44 and 45).

Coping Strategies

Coping strategies may be defined as specific thoughts and behaviors individuals use to manage their pain or their emotional reactions to pain (46). Coping strategies may affect the patient's level of attentiveness to pain, the ability to persist in the face of pain, and the extent to which the patient feels entitled to be taken care of as a result of the pain. There are a number of questionnaires available to assess pain-related coping strategies, including the Vanderbilt Pain Management Inventory and the Ways of Coping Checklist (46,47). However, the largest body of research on coping in chronic pain (and the only research directly applied to surgical screening) has used the Coping Strategies Questionnaire (CSQ) (48).

Gross administered the CSQ preoperatively to 50 lumbar laminectomy candidates (49). Patients who obtained good results from surgery indicated on the CSQ that they felt better able to control the pain and also indicated they were more self-reliant. Other coping strategies assessed by the CSQ, such as hoping and praying and catastrophizing, were associated with poor surgical outcomes. These results are consistent with several other studies demonstrating that more passive coping strategies and perceived lack of pain control tend to be associated with greater pain levels, higher opioid consumption, greater levels of depression, and poorer treatment outcome (48,50,51). Additional studies on cognitive aspects of pain, using questionnaires other than the CSQ, have identified similar findings. Worse subjective symptoms and poorer treatment outcome are found in chronic pain patients who tend to have negative self-statements, tend to catastrophize (e.g., greatly overestimate the impact of minor negative events), and have strong beliefs that all pain should be avoided (44,45,52). Taken together, these studies demonstrate that pain and its impact are mediated by the manner in which the patient thinks about the experience of pain and the strategies he or she has available to cope with the pain.

BEHAVIORAL FACTORS

Back pain clearly is influenced by personality factors, emotional states, and cognitions, as well as anatomic factors. The patient's experience of pain, and the display of behavioral indications of pain, can also be influenced by the responses of others. Pain behavior always occurs in a social context, communicating to observers that the patient is in distress. Observers, in turn, may react to such behavior with attempts to relieve the patient's pain, help him or her to avoid further problems, or be supportive of limitations in activity. Employers, and even the insurance system, may also inadvertently support pain behaviors through provision of disability benefits or time off of work. Unfortunately, such solicitous responses from others, while well-intentioned, may serve to reinforce or reward pain behaviors, increasing the likelihood that patients will continue to show and experience pain (53). Failure to alter reinforcement of pain behavior may contribute to prolonged disability after spine surgery and noninvasive treatment of spine injury.

Spousal Reinforcement of Pain Behavior

Spouses may feel strong empathy with the patient, experiencing an increase in their own arousal level when the patient appears to be experiencing pain (54,55). Such physiological and cognitive responses to pain displays may motivate the spouse to behave toward the patient in a solicitous fashion, unwittingly reinforcing pain behavior. Reinforcing actions might include taking over the patient's jobs or responsibilities, giving the patient medication, and encouraging rest while discouraging activity. Family members may be more likely to pay attention to the patient when the pain appears greatest, and to ignore the patient at other times, such as when the patient is engaging in alternative *well behaviors*.

A number of studies have shown that responses by the spouse can exert a strong influence on patients' pain behaviors. Block and colleagues, for example, found that patients who receive a high level of attention or solicitous responses from their spouses were more likely to report high pain levels in the spouses' presence than were patients with nonsolicitous spouses (56). Lousberg and colleagues extended this result, finding that patients with solicitous spouses showed decreased physical exertion on treadmill performance in the presence of the spouse (57). Similar results have been obtained in a number of other studies (58,59). By extension, it would appear that spousal solicitousness may have a negative impact on surgical recovery and should be assessed prior to surgery, by measures such as the West Haven-Yale Multidimensional Pain Inventory (60).

Family members may provide emotional disincentives for improvement in another way. Numerous studies have demonstrated that marital distress is high among chronic pain patients (61,62). We have shown that dissatisfied spouses have more negative outcome expectations for the patient and tend to attribute the patient's pain to psychological causes (54,63). It is likely that spouses who are dissatisfied would be less supportive of the patient. Social support, particularly from the spouse, has been found to be an important influence on compliance with medical treatment recommendations (64) and recovery from invasive surgery, such as hip replacement (65). Thus, patients who report high levels of marital distress or have unstable or unsupportive marital relationships may have a poorer surgical prognosis. Marital dissatisfaction should be assessed in the surgical candidate, using measures such as the Locke-Wallace Marital Adjustment Inventory, which focuses on marital satisfaction (66).

Litigation

Kennedy, in a frequently cited quotation about patients involved in litigation, coined the term *compensation neurosis*, "a state of mind born out of fear, kept alive by avarice, stimulated by lawyers, and cured by verdict" (67). Studies of chronic pain patients do not support this concept of compensation neurosis. Yet, it is clear that cultural and social factors can influence chronic pain behaviors. In countries other than the United States, where litigation for accidents is uncommon, continuing pain from injuries is less common. In Lithuania, where few drivers are covered by insurance, virtually no individuals involved in car accidents report disabling *whiplash* type pain at 1 to 3 years postaccident (68). In New Zealand, which has a no-fault system for work-related injuries, workers experience less intense pain and have fewer emotional and behavioral difficulties than do injured workers in the United States (69). Thus, patients who are in litigation do appear to have greater pain complaints and levels of disability than do nonlitigating patients.

However, when an examination is made of the effects of litigation on treatment outcome, the results are complex. Schofferman and Wasserman found that low back and neck pain patients improved despite litigation (70). Norris and Watt found no statistically significant changes in the symptoms of litigating patients after their claims were settled (71). For conservative pain management it appears that, while litigating patients may have significantly increased pain complaints, for most claimants, disability from injury does not resolve following the settlement of litigation (72).

Despite the previously mentioned results, it appears that litigation surrounding an injury can exert greater influence on spine surgery outcome than on the conservative treatment of pain. Finneson and Cooper found that both “history of law suits for medicolegal problems” and “secondary gain” predicted negative results of disk surgery, a result corroborated by Manniche et al. (73,74). Junge et al. found that Swiss patients who were applying for disability pensions had poorer diskectomy outcomes than did nonapplicants (75). Such results do not mean that litigation patients are making up their symptoms (i.e., malingering), because surgical candidates do have a pathophysiological basis for the pain. Furthermore, an often-cited survey of orthopedic and neurosurgeons by Leavitt and Sweet found that malingering occurred in less than 5% of patients (76). However, the results with litigating surgical patients imply that, in some cases, reinforcement of pain in the form of anticipated financial gains may increase sensitivity to pain, making patients “somatically hypervigilant” (77) and less responsive to treatment.

Workers' Compensation and Disability Payments

A more immediate source of potential reinforcement for pain comes in the form of workers' compensation and other disability payments to those injured on the job. Such payments often begin at the time of injury and continue until the patient has been declared to have reached *maximum medical improvement*. A number of studies have shown that spine surgery outcome is reduced in patients receiving workers' compensation payments (78,79 and 80). Hudgins, for example, examining patients 1 year postlaminectomy, found that those receiving workers' compensation were the least likely to be working and to report pain relief (81).

Poor treatment results among workers' compensation patients, however, may not arise solely from economic considerations. Rather, workers' compensation patients have a number of additional issues that may lead to reports of high pain levels and poor treatment outcome. First, these patients have frequently been unable to work for extended periods at the time of surgery. Research on chronic pain has clearly shown that the length of time a patient has been nonfunctional strongly influences treatment outcome. Dworkin et al., using multiple regression to examine the relationships among compensation, litigation, and employment status (time off work) in 454 patients undergoing treatment for chronic pain, found that only time-off work (and not workers' compensation or litigation) predicted treatment outcome (82). Responses to treatment by patients receiving workers' compensation may be influenced by job and workplace factors such as job dissatisfaction (83), heavy physical job demands (75,78), and high levels of anger or blame toward the employer (29). Regardless of the cause, workers' compensation is so widely recognized as a risk factor that Frymoyer and Cats-Baril have proposed that *compensability* is one of the strongest predictors of excessive disability among back injury patients (84). Thus, compensation status should be noted as a potential risk factor for poor outcome following surgery. We should be cautious, however, in noting that compensation is a *relative risk* factor and may not be predictive of treatment response in any particular case. Rather, it should be included as one factor along with others described throughout this chapter (see Table 76D-3).

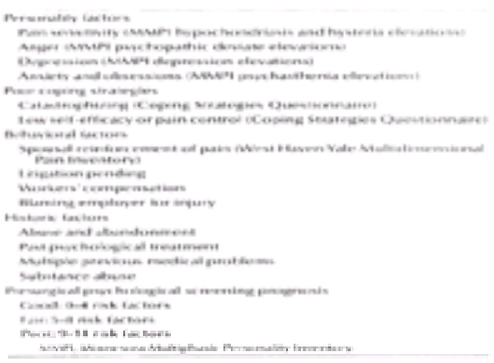

TABLE 76D-3. Presurgical psychological screening risk factors for poor surgical outcome

Historic Factors

The ways in which individuals respond to and cope with painful spine injuries are strongly influenced by their previous life experiences. Research has demonstrated a number of historic elements in the background of the spine surgery candidate that can negatively impact surgical recovery.

Abandonment and Physical and Sexual Abuse

A disproportionately high number of chronic back pain patients have been the victims of abuse or abandonment as either adults or as children. In one study, more than half of the patients evaluated at a multidisciplinary pain clinic had a history of at least one form of such abuse. In 90% of the cases the abuse occurred during adulthood (85). These figures are substantially higher than the base rate in the U.S. population.

One unfortunate consequence associated with victimization is that such patients respond poorly to spine surgery. Schofferman and colleagues (86) found an 85% failure rate from spine surgery among patients with a significant history of childhood abuse and abandonment, compared with a 5% failure rate among patients lacking such a traumatic history. A study by Linton (87) suggests that experiences of sexual and physical abuse may predispose individuals, especially women, toward chronic pain, thereby reducing overall spine surgery results. This study surveyed a sample of the general population in Sweden, as well as chronic pain patients, about their history of physical and sexual abuse. All subjects, whether patients or not, were also questioned about any chronic pain symptoms they might have had. Among the female chronic pain patients, 35% had an abuse history. Many of the nonpatient women also reported experiencing chronic pain. For nonpatient women reporting “pronounced pain,” frequency of physical abuse was 8% and frequency of sexual abuse was 46%. For the nonpatient women reporting no pain, frequency of physical abuse was 2% and frequency of sexual abuse was 23%. Further analyses of the results determined that the chances of developing chronic pain were increased fivefold by physical abuse and fourfold by sexual abuse. In this study there appeared to be little association of abuse with pain for the men. Surgery may eliminate the physical cause of pain; however, prior history of abuse continues to be present and may confound the outcomes of surgery.

Premorbid Psychiatric Diagnosis and Emotional Distress

Many chronic pain patients have diagnosable mental health problems. Kinney et al. (88), for example, found that among those reporting low back pain, 100% with chronic pain and 61% with acute pain had diagnosable psychological conditions. Lower incidence rates were reported by Coste and colleagues (89). As noted earlier in the discussion of depression, psychological problems may predate the injury. For example, Fishbain and colleagues found that 58.4% of the chronic pain patients they studied had diagnosable long-term personality disorders, while Reich and colleagues reported a 37% incidence of such disorders (90,91). Preexisting psychological problems, whether emotional or personality based, have been found by a number of authors to be associated with poor results from spine surgery (92,93). It would seem likely that patients with preexisting psychological problems, especially those who have had prior psychiatric treatment, might be less well equipped to deal with the stress and difficulties involved in recovering and rehabilitation following spinal surgery.

Previous Medical Use

Not only is a history of previous psychological treatment associated with poor outcome, but a preinjury history of multiple physical problems also does not bode well for surgical outcome. A number of authors have found that patients who report many illnesses and physical symptoms do not respond well. Frymoyer et al. (94), for example, found that a history of multiple physical complaints was associated with high levels of back-related disability. Ciol and colleagues (95) reported that higher numbers of previous hospitalizations were associated with greater risk of lumbar spine reoperations in a Medicare population. Wiltse and Rocchio (33) determined that high scores on the Cornell Medical Index, a measure of past illnesses and current bodily symptoms, were associated with poor outcome of chemonucleolysis.

The influence of previous medical problems on surgical outcome appears to parallel results reported earlier in this section noting that excessive pain sensitivity, as assessed by the MMPI Hs and Hy scales, is also a predictor of poor surgical outcome. It appears that patients whose personality and medical history predispose them toward reporting many physical symptoms may have more difficulty experiencing a reduction in back pain and disability as a result of spine surgery, perhaps related to their preoccupation with bodily processes and hypervigilance to noxious sensations.

Substance Abuse

Excessive use and abuse of opioid medication and alcohol appear to be red flags for poor surgical outcome. To the extent that patients depend on such substances, their responsibility for pain relief and improvements in functional ability through participation in postoperative rehabilitation may be diminished. It is clear that many chronic pain patients use excessive amounts of opioids. For example, Polatin and colleagues (90,93) found that 19% of spine pain patients entering a work-hardening program had a substance abuse history, and even higher rates were reported in other studies. Unfortunately, there is little research addressing the relationship of substance abuse and spine surgery outcome. The only study to directly report such results is that of Spengler and colleagues (96), who examined 30 of their spine surgery failures and found that 25 were “continually abusing medication and alcohol.”

Determining when a patient is abusing drugs or alcohol is not as easy as it might seem. In recent years there has been an increasing acceptance of the use of analgesic substances, including opioids, in patients with chronic pain. A number of studies have demonstrated that chronic opioids provide significant pain relief in chronic pain patients (97,98). Thus, some surgical candidates may be taking doses of opioids at the time of evaluation, which, just a few years ago, would have been considered unacceptable. One could argue that patients who are denied opioids by their physicians are not necessarily abusing substances when they seek pain relief through street drugs or alcohol. After all, if prescription opioids provide significant pain relief, is the patient at fault for seeking relief through other means when a physician will not prescribe such medication? Extensive use of substances should only be considered a risk factor if the patient meets DSM-IV criteria for substance abuse, and especially when these medications or alcohol provide inadequate pain relief and do not help to maintain the patients' functional ability (8).

SUMMARY AND APPLICATION

A growing body of research (94) reviewed in this chapter indicates that psychosocial factors can strongly influence spine surgery outcome. These results suggest that PPS should be included as a component of the diagnostic process in many spine surgery candidates. Table 76D-2 provides a set of general referral guidelines that a physician can keep in mind when considering the need for PPS. When the surgeon, comparing a patient with other spine surgery candidates he or she has evaluated, judges that the patient displays four or more of these points listed in Table 76D-2, a referral for PPS should be initiated. Such a referral is especially critical to the extent that the planned surgery is highly invasive (involving multiple levels, instrumentation, and so forth), is exploratory, involves a reoperation, or when the pain is particularly protracted (greater than 1 year in duration).

Excessive pain behavior
Symptoms inconsistent with identified pathology
High levels of depression or anxiety
Sleep disturbance: insomnia or hypersomnia
Excessively high or low expectations about surgical outcome
Marital distress or sexual difficulties
Negative attitude toward work or employer
Emotional lability or mood swings
Inability to work or greatly decreased functional ability (<1 mo)
Escalating or large doses of narcotics or anxiolytics
Litigation or continuing disability benefits resulting from spine injury
Referral considerations
0–1 items: not necessary to refer unless desired by patient
2–3 items: consider referral for presurgical psychological screening
4+ items: strongly consider referral for presurgical psychological screening

TABLE 76D-2. Referral guidelines for presurgical psychological screening

The major psychosocial factors contributing to poor surgical outcome are listed in Table 76D-3. PPS surgical prognosis is based on the number of these risk factors identified. Research from our laboratory has found that patients with nine or more risk factors are at risk for poor surgical outcome. In our study, 204 spine surgery candidates underwent PPS, using a semistructured interview and psychological testing including the MMPI. Outcome of spine surgery was assessed at approximately 6 months postoperatively. Poor outcome (measured in terms of continued pain greater than 4 on a 10-point scale, continued use of opioid medications, and severe activity restrictions) was obtained in 83% of patients having nine or more risk factors. Poor results were obtained in only approximately 18% of patients with fewer than nine risk factors. Such findings parallel those of other researchers who found, using a similar *scorecard* approach to identifying risk factors, that patients with a high level of overall risk respond poorly to spine surgery (16,73,75). For a more complete discussion of determination of prognosis, as well as psychological intervention in surgical candidates, see Block (7).

The results reviewed in this chapter demonstrate that spine surgery may not be very effective when applied to patients having a high level of psychosocial risk. For such patients, more conservative intervention appears more appropriate and effective. Through the use of PPS the surgeon can reduce the costs arising from futile procedures and can help the high-risk patient avoid a downward slide into increasing pain and disability. Based on the PPS, surgeons may decide to (a) deny elective surgery; (b) postpone elective surgery until psychosocial factors are addressed; or (c) proceed with surgery but involve psychologists early during rehabilitation.

CHAPTER 76

E. Epidural Steroids for Low Back Pain

Miklavz Erjavec

"In this age of accountability it is imperative that therapies with questionable benefits be critically evaluated.'

Kepes, 1985 (1)

In 1953 the French team of Lievre et al. reported the first use of epidural steroids for the treatment of sciatica (2). In 1961 in the United States, the report by Goebert et al. appeared to confirm the promising results epidural steroids offered in individuals suffering from radicular pain (3). Since that time, physicians sympathetic to the suffering of patients with spinal and radicular pain syndromes have been enthusiastic in their support of this promising nonsurgical approach to the treatment of an all-too-often refractory condition. Has there been overzealous endorsement of epidural steroids? Spaccarelli tabulated the results of 26 noncontrolled epidural steroid studies performed up to 1996 and noted that in those studies 65% of patients demonstrated improvement (4). If this is so, then why is it that with the proliferation of pain clinics and physicians with added training in pain management performing tens of thousands of epidural steroid injections per year, we see an ever-increasing prevalence of low back pain and its associated disability (5)? More and more pain clinics are treating patients who have failed to respond to epidural steroids.

The answer probably lies in the hazard of uncontrolled clinical trials and our limited ability to scrutinize the available literature in a truly scientific manner (see Chapter 81 and Chapter 82). Lievre et al. reported epidural steroid injections in only 46 patients with an ill- defined clinical diagnosis of "sciatica." The dose and volume of injected hydrocortisone were not stated and there was no control group. Eight patients said they had very good results, 15 had good results, eight had a mediocre response, and 15 were considered failures. This has initiated a 50-year binge for the medical use of a novel treatment on hundreds of thousands of patients worldwide without the benefit of a properly conducted, prospective, blinded, randomized clinical trial. Could Goebert have understood the connotations of his statement with regard to his own epidural steroid study when he said, "There is no yardstick for measuring pain, but, unquestionably, many of these patients had real pain that was relieved by the treatment"?

The difficulties in studying the benefits of epidural steroid injections are numerous. First, one has to look at the natural history of back pain. Waddell stated that, at some stage in their lives, 80% of the human race will experience low back pain, and a total of 80% to 90% of low back pain will recover in 6 weeks irrespective of the administration or type of treatment (Fig. 76E-1) (5).

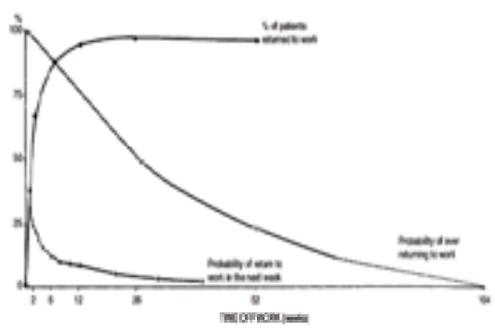

Figure 76E-1. Return to work as a function of time away from work because of low back pain, showing the proportion of patients returning to work with time and the diminishing probability of returning to work in the short term or ever. (From Waddell G. 1987 Volvo award in clinical sciences. A new clinical model for the treatment of low-back pain. *Spine* 1987;12:632–644, with permission.)

Thus, the power of a study involving epidural steroids in the first 6 weeks after the onset of low back pain needs to be enormous if one wants to demonstrate an effect greater than that of the natural history of back pain alone. Next is the difficulty in identifying homogeneous study populations. Should patients with all causes of low back pain with or without radiculopathy be included in a study sample— those with bulging disks, protruded disks, herniated disks, spinal stenosis, foraminal stenosis, facet disease, osteophytes, back strain or sprain, or facet subluxation, for example? We know that 37% of a population with no spinal or radicular pain were found to have disk abnormalities on myelographic imaging, so one must ask what is the association between radiological pathology and pain (6)? Are two patients with similar pain syndromes, one with radiologic evidence of spine pathology and the other without, eligible as subjects in the same study? Which one has a greater chance of a positive response? There is also the unquestioned influence of psychosocial factors when dealing with chronic pain syndromes. Bigos et al. showed in a longitudinal prospective study of 3,020 aircraft assembly workers that apart from preexisting back problems, job dissatisfaction and a high score on the hysteria scale of the Minnesota Multiphasic Personality Inventory have the highest predictive value in determining which workers would report a back injury (7). It has been extremely difficult to control for such psychosocial factors in efficacy studies using epidural steroids.

The problems in producing scientifically sound studies are numerous, and those who do large numbers of these procedures have been remiss in reporting their outcomes in a useful way. We will now address the proposed mechanisms of action of epidural steroids and the evidence to support those mechanisms and then examine the few well-controlled clinical studies and their wide range of results. It is interesting that recommendations for the use of this currently widely used but often clinically disappointing treatment vary enormously from person to person and committee to committee, even though all have reviewed the same literature.

PROPOSED MECHANISMS OF ACTION OF EPIDURAL STEROIDS

In assessing a patient with radicular pain one, should attempt to elucidate the pathologic processes responsible for the patient's symptoms. In simple terms, pathologic processes leading to pain can be divided into the following:

1. Degenerated or herniated disk
2. Nerve root compression by disk or bone
3. Irritation or inflammation of the nerve root
4. Sustained neuronal activity due to nerve injury or central changes

Several elegant radiologic studies using myelograms, computed-assisted tomography, and magnetic resonance imaging have demonstrated the presence of varying degrees of spinal pathology, including herniated nucleus pulposus, foraminal stenosis, and nerve root compression in asymptomatic individuals (6,8,9). The common age-related prevalence of radiologic evidence of degenerated and herniated disks in asymptomatic individuals should caution one against attributing radicular symptoms to radiologic defects. Even when a herniated disk is believed to be responsible for a patient's symptoms it is dangerous to conceptualize the herniated disk as a space- occupying lesion that has been proven to resolve with the application of epidural steroids.

It is not known how often nerve root compression is responsible for radicular symptoms of pain. A nerve root may be put under compression by a disk herniation, usually only when disk material extends laterally into the intervertebral foramen. The axis of rotation of the spine during flexion and extension is located anterior to the spinal canal such that the spinal canal lengthens approximately 7 cm in forward flexion in the average adult. The dura is firmly anchored at its cranial end to the base of the skull and distally is relatively fixed by way of fibrous tissue between the root sleeves and the intervertebral canal. Thus, neural tissues do not slide up and down the spinal canal during spinal motion but undergo a change in length by passive stretch (10). The spinal cord ends at approximately the L-1 level in the average adult. Because 95% of lumbar disk herniations occur at the L-4 to L-5 or L-5 to S-1 levels, there is ample room for disk lesions to expand before actual compression of spinal nerves occurs (11).

Experience gained by neurosurgeons doing spinal surgery under local anesthesia shows that inflamed nerves are exquisitely sensitive to manipulation (touch, stretch), whereas simple compression of normal nerves results in a painless loss of motor and sensory function (12). These findings suggest that pain associated with disk pathology is not due to compression but rather to tensile forces put on nerves that are fixed within the spinal canal and whose length must increase (particularly in flexion or during straight-leg raising) to accommodate the presence of a herniated disk. It is difficult to conceptualize a possible mechanism of action of epidural steroids on pain caused by tensile forces on spinal nerves if, indeed, tensile forces are a cause of pain. It is also difficult to understand how steroids can relieve the compressive forces on nerves by lesions such as osteophytes, foraminal stenosis, and spondylolisthesis.

There is good evidence in the literature that radicular pain can be produced by the inflammatory effects of the nucleus pulposus on nerve roots. Saal et al. looked at the phospholipase A_2 activity of the disk material of patients undergoing diskectomy. Phospholipase A_2 is an enzyme responsible for the liberation of arachidonic acid from cell membranes at sites of inflammation, which is considered to be the rate-limiting step in the production of prostaglandins and leukotrienes (13). They found phospholipase A_2 activity from disk material to be up to 100,000-fold more active than any other phospholipase A_2 yet described. McCarron et al. injected homogenized nucleus pulposus into the epidural space of dogs. The dural sac, spinal cord, and roots were then examined by gross inspection and microscopic analysis. There was clear evidence of an inflammatory response to the injected nucleus pulposus material in the study dogs as compared with dogs whose epidural spaces were injected with normal saline as a control (14).

Several anatomic characteristics of nerve roots and spinal nerves make them more susceptible to inflammation than peripheral nerves (Fig. 76E-2) (12).

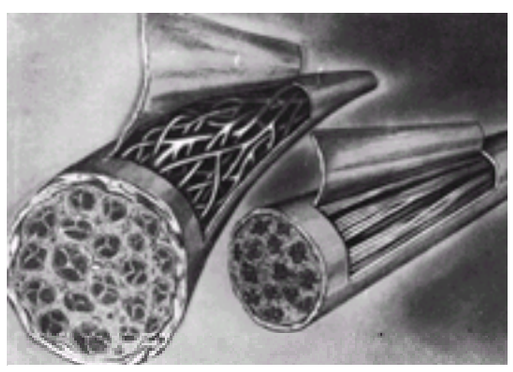

Figure 76E-2. Anatomic differences between a peripheral nerve (*left*) and a nerve root (*right*). See text for discussion. (From Murphy RW. Nerve roots and spinal nerves in degenerative disk disease. *Clin Orthop* 1977;129:46–60, with permission.)

Peripheral nerves have a dense epineurium consisting of loose elastic and fatty tissue that serves a protective role, shielding the nerve from mechanical pressure. This property is well developed in areas of bony prominences, such as where the peroneal nerve travels around the fibula. Peripheral nerves also have a perineurium, a dense sheet of fibrous tissue in which bundles of collagen are arranged in a circular, oblique, and longitudinal arrangement. On the inner surface of the perineurium is a layer termed the *perilemma*, which functions as a diffusion barrier against chemical irritants. The nerve root has no perineurium, and the other protective structures are either thin or lacking. The fibers in a peripheral nerve repeatedly divide and fuse to form plexi along the nerve length, giving them the ability to withstand stretch in response to tensile forces. Nerve root fibers run in parallel and are more susceptible to deformation from tensile forces. Peripheral nerves are well vascularized by the vasa vasorum. Nerve roots have a tenuous vascular supply consisting of a distal system from segmental branches in the vicinity of the dorsal root ganglion that runs proximally and a proximal system from the vasa corona that runs distally, with a relative area of hypovascularity in the middle (12). Another anatomic feature is the poor lymphatic drainage of nerve roots. It is easy to understand how nerves with little protective coverings are susceptible to the intense inflammatory effects of disk material. Furthermore, due to the sparse blood and lymphatic supply of nerve roots, it is difficult for the products of inflammation to be removed once they begin to accumulate, thus predisposing the nerve fibers to inflammation, invasion by fibroblasts, and, ultimately, intraneural fibrosis.

The antiinflammatory effects of steroids include a decrease in edema, fibrin deposition, local migration of leukocytes, phagocytic activity, capillary proliferation, fibroblast proliferation, and deposition of collagen and its cicatrization. It is intuitive to expect that inflamed nerves, whose existence is often confirmed at the time of surgery, should respond to the antiinflammatory effects of steroids. This leads to the puzzling question of why epidural steroids do not produce an effect in all patients with radicular symptoms. One obvious answer is that the pain is not truly radicular in origin—for example, those individuals with low back pain radiating into the buttock or to the knee. This type of pain may be attributable to processes such as myofascial and facet pain syndromes, which should be clinically distinguished from pain of radicular origin. Another possible explanation is that chronic nerve inflammation from exposure of nerves to a herniated disk or the chronic seepage of disk material from degenerated and desiccated disks produces chronic inflammation, which results in intraneural and perineural fibrosis. Holt correlated the histology of disk degeneration with adjacent spinal nerves in a cadaver study (15). When the disk was histologically normal, the adjacent nerve was also normal in 92% of cases. When the disk was degenerated, the adjacent nerve showed intraneural fibrosis in more than 60% of cases, a correlation statistically significant at the .001 level of confidence (15). In patients having surgery for herniated lumbar disk, Lindahl and Rexed demonstrated intraneural fibrosis in 78% of dorsal nerve roots taken for biopsy (16).

Thus, nerve roots and spinal nerves may be susceptible to stretch, ischemic, and inflammatory injuries, with little ability to clear the resulting inflammatory elements that accumulate, leading inexorably to an end-stage process of intraneural and perineural fibrosis that may not be amenable to any form of therapy. The role of epidural steroids in this situation can be questioned. Patients who respond to epidural steroids may represent those individuals who have a limited exposure to the inflammatory effects of disk material. Patients who demonstrate dramatic but short-lived improvement in symptoms may have chronic exposure to disk material, with return of symptoms as the effects of steroids dissipate. And lastly, those with no relief may be suffering from neural fibrosis, which is refractory to all known forms of medical therapy. As some patients do show dramatic improvement with epidural steroids the challenge in the future will be to identify which group of patients do respond. This, of course, depends upon being able to effectively determine the etiology of the patient's pain. Whether epiduraloscopy will be proven useful remains to be determined by proper trials.

There is a group of patients who have radicular pain with no demonstrable radiologic lesion, or similarly, had apparently successful surgical correction of spinal pathology and suffer persistent postoperative radicular pain. A popular recent explanation for this is the phenomenon of central neuroplasticity, as discussed in Chapter 3, Chapter 4 and Chapter 5. Nerve injury may lead to a state of central hyperexcitability or spontaneous activity in neurons such that pain may be perceived after a nociceptive impulse has ceased or normal neuronal activity is exaggerated and/or modified such that it is represented centrally as a painful phenomenon (17,18 and 19). Central nervous system changes are sometimes used by those who are proponents of the addition of local anesthetic to steroids in an attempt to “reset” neuronal activity. Some also believe that the addition of local anesthetic or opioids to epidural steroids may allow relaxation of paraspinal muscle spasm and block the nerves to facet joints, allowing for reduction of minor joint subluxations (20). However, two studies have not been able to detect any difference between normal saline and local anesthetic injected into the epidural space for the relief of low back and radicular symptoms (21,22). Some physicians advocate the use of local anesthetic with epidural steroids as a means of confirming correct placement of the injection into the epidural space by evidence of sympathetic and sensory block.

In this author's opinion, addition of a local anesthetic is of questionable benefit and adds the unnecessary risks of allergic reactions and the problems associated with local anesthetic toxicity or inadvertent administration into the intrathecal space. Furthermore, some patients will develop a motor block and will be unable to ambulate immediately, causing an unnecessary delayed stay in the treatment area. Sympathetic and proprioceptive blockade can also lead to troubling symptoms. An

interesting occurrence is the complaint by alarmed patients of marked increase in their pain coinciding with the resolution of local sensory block usually late in the evening well after the patient has left the treatment center. This could represent a patient's perception of worsening pain in contrast to several hours of relief from sensory block, or the consequences of preferential prolonged block of pain inhibitory fibers, or a central pain state.

There are numerous reports from the radiologic literature on the high failure rate of needle placement within the epidural space when positioned without the use of fluoroscopy and contrast material (23,24). This is not an experience familiar to most well- trained anesthesiologists, and the author sees little role for non–pain-trained physicians performing epidural steroid injections, particularly if it comes at the added expense and risk of fluoroscopy and the injection of contrast material.

NONRESPONDERS

An alternative approach to determining who will benefit from a treatment, when it is recognized that all recipients of the treatment do not respond, is to try to determine in whom the treatment is not beneficial. This has been looked at in two studies on epidural steroids.

Jamison et al., in an uncontrolled study, evaluated 249 patients referred to a pain center with low back and radicular pain attributed to a variety of different diagnoses (25). Each patient was given a comprehensive pain questionnaire and Brief Symptom Inventory Checklist to complete and underwent a thorough physical examination as well as a computed tomography scan, magnetic resonance imaging, and/ or electromyography. Patients were assessed for pain intensities after one epidural injection of methylprednisolone, 120 mg, in 0.5% lidocaine, 3 mL, and normal saline, 3 mL, at 1 day, 2 weeks, and 1 year after treatment. Mean visual analogue scores were 5.55 pretreatment, 4.5 one day after treatment, and 4.15 two weeks after treatment. Two weeks after treatment 155 patients reported a decrease in pain, 42 reported no change in pain, and 52 reported an increase in pain. Presence or absence of specific diagnoses or physical findings was not predictive of short-term response. Four factors were identified that best predicted poor outcome 2 weeks after treatment:

1. Greater number of previous treatments for pain
2. More medications taken
3. Pain not increased by activities
4. Pain increased by coughing

One hundred thirty-one patients were assessed at 1-year posttreatment. Factors that predicted no benefit 1 year after treatment were the following:

1. Pain does not interfere with activities.
2. Unemployment due to pain.
3. Normal straight-leg raise test before treatment.
4. Pain not decreased by medication.

Results of physical examination and presence or absence of structural pathology did not predict outcome at 1 year.

Hopwood and Abram looked at 33 factors derived from patient evaluation and physical examination in 209 patients undergoing epidural steroid injections to investigate factors that may influence outcome (26). Patients underwent an injection of epidural triamcinolone, 50 mg, in 1% lidocaine, 3 to 5 mL, and received a second or third injection if they received little or no relief from their previous injection. Univariate analysis showed an increased risk of treatment failure with the following:

1. Lower levels of education
2. Smoking
3. Lack of employment at start of treatment
4. Constant pain
5. Sleep disruption
6. Nonradicular diagnosis
7. Prolonged duration of pain
8. Change in recreation activities
9. Extreme values on psychological scales

EPIDURAL STEROID OUTCOME STUDIES

Epidural steroids have been the subject of many studies and reviews; controversy has focused upon their efficacy (Table 76E-1) (1,4,27,28,29,30,31,32,33,34,35 and 36).

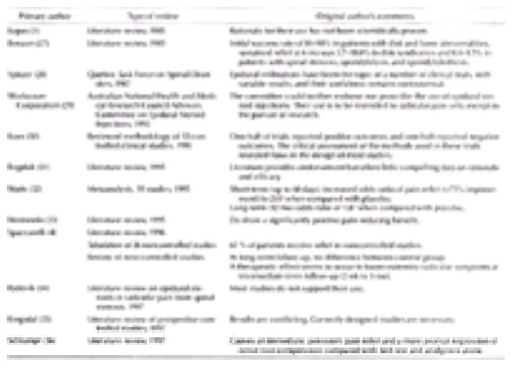

TABLE 76E-1. Reviews of the epidural steroid literature and the author's comments

It is worrisome that the reviewers listed in Table 76E-2 (22,37,38,39,40,41,42,43,44,45,46 and 47) have all had access to essentially the same literature, and yet they have produced a wide range of opinions on the efficacy of epidural steroids. Inspection of published reviews of this procedure reveals a trend: The more critical and discerning an author is with regard to the methodology of the epidural steroid studies, the less the author promotes epidural steroids as having a positive outcome. This point can best be illustrated in a review by Koes et al. (30). This group reviewed the efficacy of epidural steroids in 12 randomized clinical trials appearing in the literature before 1995, assessing the methodologic quality of these 12 trials by rating each study on a possible 100 points based on established criteria for generally accepted principles of interventional research (30). Out of a possible 100 points, four studies scored more than 60 points, four studies scored between 50 and 60 points, and four studies scored less than 50 points (see Table 76E-2).

Primary author	Points scored out of 100	Efficacy of epidural steroids
Snoek (41)	72	Negative
Matthews (42)	67	Slightly positive
Breivik (43)	63	Positive
Cuckler (44)	62	Negative
Bush (40)	59	Positive
Serrao (45)	52	Negative
Klenerman (46)	50	Negative
Dilke (38)	50	Positive
Rocco (47)	49	Positive
Ridley (39)	47	Short term only
Beliveau (37)	45	Negative
Yates (22)	17	Positive

*Reviewed by Koes, their results and methodologic score out of a possible 100 points.

Modified from Koes BW, Scholten RJ, Mens JM, et al. Efficacy of epidural steroid injections for low back pain and sciatica: a systematic review of randomized clinical trials. Pain 1995;63:279–288, with permission.

TABLE 76E-2. Twelve controlled clinical trials on epidural steroids [a]

The median score was 52 points, indicating the overall questionable methodology of the trials. The Dilke (38) and Snoek (41) studies will be used to illustrate common methodologic shortcomings. Dilke randomly assigned 100 consecutive inpatients to a treatment group who received methylprednisolone, 80 mg in 10 mL of isotonic saline into the epidural space, and a control group who received isotonic saline, 1 mL, in the interspinous ligament. The injections were repeated once if necessary. In the treatment group, 21 of 35 patients reported pain relief, whereas 11 of 36 patients in the control group reported pain relief, 60% and 31%, respectively, reporting pain relief in each group. At 3 months, one out of 44 patients had severe residual pain in the treatment group and six of 38 had severe pain in the control group. Three of 36 patients did not return to work in the treatment group, and 14 out of 35 did not return to work in the control group. Major methodologic flaws included the lack of differentiation between new-onset, chronic, and recurrent pain in the inclusion criteria. Approximately 30% of the patients are unaccounted for in the results. Decision for duration of bed rest, cotherapies, suitability for return to work, or need for surgery were all at the discretion of multiple clinicians in charge of their own patients, with no standard criteria for each of the aforementioned decision-making processes. Dilke stated that the trial did reveal significant differences in favor of the treated group with respect to pain relief and disability.

In 1977 Snoek studied 51 patients with acute herniated disk and neurologic deficits documented by myelography (41). They were randomly assigned in a double-blinded prospective fashion to receive an epidural injection of methylprednisolone, 80 mg, or isotonic saline, 2 mL, epidurally. Two hundred patients were assessed for suitability for the study. One hundred forty-nine patients were excluded for reasons consisting of motor paralysis, cauda equina syndrome, intolerable pain, or previous surgery. Follow-up at 48 hours showed no difference between the two groups with regard to pain relief, consumption of analgesics, and improvement in neurologic function. Interestingly, Green et al. (48) demonstrated that in patients responding to epidural steroid injections, 37% will respond in 2 days or less, 59% will respond between 4 and 6 days, and 4% will respond after 6 days. Snoek's follow-up at 48 hours may have missed many potential responders. Snoek then followed up long term with a chart review between 8 and 20 months, noting that the incidence of patients continuing on to surgery in each group was the same—14 in each group, for a total of 28 of 51 patients. This high surgical rate leads one to question the threshold criteria for surgery in his institution. One must question the fate of the 149 of the initial 200 patients who were excluded from the study for reasons of intolerable pain, motor paralysis, and so forth. Physical therapists blinded to the study rated 70% of the treatment group as improving, whereas they rated 42% in the control group as improving. This may be attributable to the fact that the physical therapists were assessing patients beyond 2 days. Thus, an intermediate period that may have shown a difference was unavailable to Snoek.

After commenting on the methodologic shortcomings of clinical epidural trials, Koes states that the benefits of epidural steroid injections, if any, seem to be of short duration only (30).

One noteworthy study has appeared in the literature since the reviews stated in Table 76E-2 were written. Carette et al. performed a randomized, double-blind prospective study on 158 patients who either received three epidural injections of methylprednisolone, 80 mg in 8 mL of isotonic saline, or three injections of isotonic saline, 1 mL (49). All patients had experienced a first or recurrent episode of sciatica that had lasted a minimum of 4 weeks but less than 1 year. *Sciatica* was defined as the presence of constant or intermittent pain below the knee. Signs of nerve root irritation (positive straight-leg test, defined as reproduction of radicular pain by elevation of the leg), nerve root compression (motor, sensory, or reflex deficits), or both had to be present, with computed tomography evidence of a herniated nucleus pulposus at a level corresponding to the symptoms and clinical findings. Functional disability was also assessed, requiring patients to have a score of greater than 20 on the Oswestry Low Back Pain Disability Questionnaire. Differences in improvements between the groups were not significant, except for improvements in the finger-to-floor distance (p = .006) and sensory deficits (p = .03), which were improved in the methylprednisolone group. After 6 weeks, the only significant difference was the improvement in leg pain, which was greater in the methylprednisolone group (p = .03). After 3 months, there was no significant difference between the groups. The Oswestry scores had improved by a mean of –17.3 in the methylprednisolone group and –15.4 in the placebo group. At 12 months, the cumulative probability of back surgery was 25.8% in the methylprednisolone group and 24.8% in the placebo group. In this study, the assumption was made that recurrent and new onset of radicular symptoms in patients with symptoms between 4 weeks and 1 year represent a homogeneous study group. This may be an unwarranted assumption, particularly when one recalls Waddell's data regarding the natural history of low back pain. This study otherwise surpasses all others performed thus far from a methodologic point of view. Patients suffering from radicular symptoms due to nerve root irritation may obtain short-term relief from epidural steroids. As seen in many epidural steroid studies, this author considers that an illusion of “cure” is created when those patients who fail either the epidural steroid or control treatment go on to receive surgery or improve due to the natural history of the disease.

A new approach to epidural steroid injection, termed the *epidural perineural selective nerve root technique*, has been developed and reported by Kraemer et al. (50). This double-needle technique uses an introducer needle to pass through the skin and interspinous ligaments in an oblique interlaminar approach. A 29-gauge spinal needle is passed through the introducer such that the needle tip enters the lateral aspect of the anterior epidural space. An argument is made that, in radiocontrast studies using the conventional posterior approach to the epidural space, fluids flow along the route of least resistance, which is likely away from the area one wishes to inject. Kraemer states that in his radiologic contrast investigations using the conventional posterior approach, only a small amount of injected material reached the affected transversing and exiting nerve root on the side of the anterior epidural space. He argues that the perineural technique also reduces the amount of steroid needed, as the steroid is injected directly on to the affected nerve root, thus avoiding the potential complications posed by larger quantities of steroids. The initial results of this new technique in two prospective controlled studies appear promising (50).

To date, there are no studies comparing the effects of different steroids or different doses or volumes of injectate.

COMPLICATIONS

Complications from epidural steroid injections are rare (51) but can be disastrous when they do occur. Complications can be divided into those attributable to epidural needle placement, to local anesthetic, and to steroid adverse reactions and idiopathic causes (Table 76E-3) (3,37,38,39,40 and 41,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90 and 91).

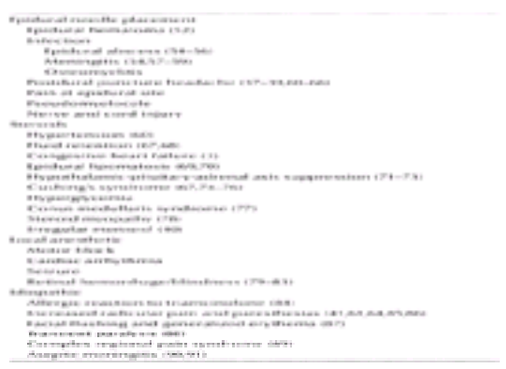

TABLE 76E-3. Complications of epidural steroid injections

Complications secondary to needle placement and local anesthetic injection are well described in the anesthesia literature. The mechanism of retinal hemorrhage is unknown but may well be attributable to a rise in cerebrospinal fluid pressure, which is then transmitted through the optic nerve sheaths to the posterior retinal venous circulation (83).

The role of steroids as a causative agent in arachnoiditis remains controversial. There are reports in the literature of arachnoiditis related to the use of intrathecal steroids (78,92,93,94 and 95). The presence of polyethylene glycol as a preservative agent in methylprednisolone has been implicated in cases of sterile meningitis, arachnoiditis, and pachyarachnoiditis when injected intrathecally (93). Latham et al. examined the histopathologic effects of intrathecally administered betamethasone in sheep and found that evidence of arachnoiditis did not appear until high doses were used and concluded that intrathecal injection of betamethasone in the low

doses used in humans is unlikely to cause arachnoiditis (96). To date there are no reports of arachnoiditis in patients who have received epidural steroid injections.

Less controversial is the observation that frequent epidural steroid injections clearly produce prolonged suppression of the hypothalamic-pituitary-adrenal axis. Jacobs et al. showed that a single dose of 80 mg of epidural methylprednisolone markedly suppressed plasma cortisol levels and the ability of the adrenal glands to secrete cortisol in response to synthetic adrenocorticotrophin for up to 3 weeks (72). Similarly, Kay et al. demonstrated acute and chronic adrenal suppression in patients receiving epidural triamcinolone, 80 mg weekly for 3 weeks. Full recovery of adrenal function occurred in 3 months (73). Cushing's syndrome has been reported with as little as one epidural injection of methylprednisolone, 60 mg. The consequences of systemic effects of steroids should engender caution in advocating the use of repeated epidural injections of steroids. Diabetics can lose good blood sugar control after a single epidural steroid injection.

Finally, as an aside, the author knows of an unreported case of osteomyelitis and pseudomeningocoele formation as a complication of epidural steroids.

CONCLUSION

Given the conflicting results of numerous studies, it is difficult to make broad-based recommendations regarding the role of epidural steroid injections in the treatment of low back pain. The extremes are represented by scientific purists who may never have firsthand experience of the desperation of those in pain and who argue that the literature has not established a role for epidural steroid injections. At the opposite pole are those who sustain a clinical career performing numerous epidural steroid injections on a purely empiric basis. Should one deny a request for an epidural steroid injection from a conservative surgeon who wishes to explore all possible nonsurgical approaches before embarking on a surgical intervention in a patient with a complex medical problem? On the other hand, the author has been approached by an individual who saw his anesthesia income declining and wished to supplement it by performing epidural steroid injections at the end of his ever-shrinking daily operating room responsibilities. His probe into the world of pain medicine was limited to how much steroid and at what level. This practice is mentioned only to be severely condemned and is discussed in Chapter 11.

The author believes that epidural steroid injections are but one tool in the multidimensional approach to the treatment of low back pain. This is truly a complex (26) problem, one that only physicians with a strong understanding of the biopsychosocial influences on pain are capable of assessing and treating effectively.

After a comprehensive assessment of a patient referred for epidural steroids, the pain management physician should determine whether the patient has a condition that may respond to this modality. After a full explanation of the associated risks involved and the probable short-term results that are expected, it may be reasonable to proceed with one epidural injection. A partial response suggests that further epidural steroid injections may have a cumulative benefit. The myth of requiring a series of three injections probably originates in a paper by Brown (97) in 1977, in which he stated, “more than 3 injections do not seem to provide additional benefit.” Somehow this statement has been construed to the common request for “a series of three.” The pain physician should use the opportunity of a request for epidural steroid injections to assess and address any other issues that may be contributing to pain and disability. These issues frequently include depression, inappropriate bed rest and use of medications, work issues, sleep and physical activity habits, and so forth. The initial visit is also an opportune time to explore a patient's understanding of low back pain and to provide education about the natural history of low back pain and the necessary elements of a physical rehabilitation program to restore physical function. After this has been completed and the patient has agreed to proceed, any relief of pain should be regarded as a window of opportunity to improve upon all the issues mentioned above.

Difficulties arise when patients receive short-term relief and continue to request additional epidural steroid injections. The risk of systemic side effects of steroids are real, and the practice of multiple epidural steroid injections is probably unwise. In this situation it is prudent to reassess the clinical problem and look for an appropriate next step in a treatment algorithm. This may tax even the most experienced of pain physicians. The physician with an armamentarium limited to blocks will have little else to offer in this frequently encountered situation. The proper role of epidural steroid injections in the treatment of low back pain and leg pain has not yet been determined. Those who wish to heavily use this interventive technique should design and implement appropriate outcome studies.

CHAPTER 77

Pain of Neurologic Origin in the Hips and Lower Extremities

John D. Loeser

Pain of neurologic origin in the hips and lower extremities, often referred to as *lumbar* and *lumbosacral neuralgia*, includes a broad category of painful conditions localized to the lumbar and first two sacral nerve distributions. Neuralgia restricted to the lumbar area is relatively uncommon; most of these pains also involve sacral segments. These pain syndromes are thought to be caused by pathologic processes that involve the lumbar and sacral segments of the spinal cord, the nerve roots, the lumbosacral plexus, or the peripheral nerves (see Fig. 75-7). The information in this chapter is presented in two major sections: (a) general considerations, including an overview of etiology, symptoms and signs, diagnosis, and treatment, and (b) specific causes of lumbosacral neuralgia. More detailed information can be found elsewhere (1,2 and 3).

GENERAL CONSIDERATIONS

Etiology

Pain of neurologic origin in the hips and lower extremities is a symptom secondary to diseases that most commonly involve the nerve roots or the lumbosacral plexus. Pathology in the spinal cord or peripheral nerves is identified less often. Although sciatica is written about as if it were common, most low back and leg pain originating in the back is not caused by radicular disease at the L- 5 and S-1 levels, and most of what is called “sciatica” is a misnomer. The vast majority of hip and leg pains are of musculoskeletal origin, and their pathophysiology is not well understood. Further discussion of this topic can be found in Chapter 28, Chapter 29, and Chapter 76.

Pain of neurologic origin in the hips and legs can be best considered on the basis of the site of pathology: (a) lesions of the spinal cord and dura, (b) lesions of the spinal nerve roots, (c) lesions of the formed spinal nerves, (d) lesions of the lumbosacral plexus, and (e) lesions of one or more peripheral nerves.

Symptoms and Signs

The characteristics of the pain in these conditions are a function of the location of the offending lesion. Intrinsic lesions of the spinal cord rarely present with pain, but are more likely to be characterized by motor and sensory loss. Bowel and bladder dysfunction is usually an early sign; in the male, sexual dysfunction is common. Lesions of the dorsal roots usually produce a pain syndrome that has a dermatomal pattern and is exacerbated by mechanical factors. Lesions of the formed spinal nerves are uncommon; in addition to dermatomal pain, the motor and sensory changes are a function of the nerve involved. Lumbosacral plexus lesions are relatively rare and cause both local and referred pain, as well as sensory and motor changes. Peripheral nerve lesions are characterized by focal pain at the site of nerve damage and pain referred into the distribution of the nerve. Sensory and motor deficits are determined by the innervation pattern of the involved nerve.

Sensory alterations generally accompany the pain of any lesion involving the nervous system. Variations in the type of sensory loss are not terribly helpful in locating the lesion. Anesthesia, hypesthesia, paresthesia, hyperesthesia, hyperalgesia, and dysesthesia can all be associated with almost any type of nervous system lesion.

Motor deficits are frequently observed. Weakness of the muscles, loss of tone, atrophy, and reflex changes can all be seen. If the ventral root axons are significantly compromised, fasciculations can be observed. Abnormalities of sympathetic nerve function are common when the nerves to the legs are involved, including loss of sweating and piloerection and a cool extremity. A diffuse, deep, aching pain in the hip can also indicate sympathetic involvement.

Local tenderness can help to indicate the site of the lesion. Movements of the lumbar spine and hip that lead to increased mechanical pressure can exacerbate the pain. If a nerve in the leg is mechanically traumatized, movements and local pressure can aggravate the symptoms.

When the lesion has been present for a month or more and the nerve damage has been sufficient to disrupt axons, a *neuroma* sign can be present at the lesion site. Percussion over the nerve in this area produces paresthesias that are perceived in the cutaneous distribution of the nerve. If the lesion has been present long enough for some regeneration to occur distal to the site of the injury, *Tinel's sign* can be elicited: Percussion over the nerve distal to the injury site results in paresthesias in the cutaneous territory of the nerve. Tinel's sign can be used as an indication of the continuity of the nerve and the presence of some regenerating axons.

If the offending lesion is near the body surface it can be palpated, or the overlying skin contours can be altered. Deeper lesions might not be accessible to physical examination. The lesion itself can cause local pain because of tissue damage.

Diagnosis

The diagnosis of the cause of pain of neurologic origin in the hips and legs is based primarily on the history and physical examination. The strategies for obtaining a thorough history and carrying out a detailed physical examination are discussed in Chapter 12. Neurodiagnostic studies such as electromyography, nerve conduction velocity and reflex tests, somatosensory evoked potentials, and thermography are often valuable adjuncts that can help to locate the lesion precisely (see Chapter 13 and Chapter 14).

When the history has been obtained and the general physical examination has been done, the examiner should focus on the region of pain. The back, abdomen, groin, buttocks, and entire lower extremities should be inspected, with the physician searching for a loss of normal contours, muscular atrophy, or other deformities. Rectal or vaginal examination is important when sacral segments are involved in a chronic pain syndrome. Atrophy should be documented by measurement of the thigh and calf circumferences a fixed distance above and below the patella. Painful areas should then be palpated to locate regions of tenderness or of pain reproduction. The effects of movement at the major joints must be ascertained. Limitation of movement usually suggests disease of the joint or of the surrounding muscles, tendons, or ligaments. Most pains in this area are found to be in the low back, buttock, hip, and proximal leg. They are most often of musculoskeletal origin, in spite of the pattern of radiation, which suggests sciatic nerve involvement.

Examination of the lumbar and sacral neural segments is obviously critical in patients with pain symptoms in the lower body and legs. A knowledge of the dermatomes and patterns of muscular innervation is required (see Chapter 8).

Radiographic and imaging studies can be helpful in delineating mass lesions and sites of trauma. Computed tomography (CT) and magnetic resonance imaging (MRI) have helped greatly in locating internal pathologic processes. Magnetic resonance neurography is particularly helpful in localizing a peripheral nerve lesion (4). MRI scanning has largely replaced myelography in the diagnosis of intraspinal lesions.

Paravertebral somatic nerve blocks with a local anesthetic can be helpful in locating a lesion when other studies are not conclusive (see Chapter 102). If myofascial pains are suspected, trigger point injections can be both diagnostic and therapeutic. Indeed, presumptive treatment with physical measures can allow the cause of the pain to abate; vague pain states without specific findings do not need to be studied in great detail the first time that the patient is seen.

SPECIFIC CAUSES OF LUMBOSACRAL NEURALGIA

Lesions of the Spinal Cord

Intrinsic Spinal Cord Lesions (XXVI–4)

Neoplasms or cysts of the thoracolumbar spinal cord can lead to pain in the abdomen, low back, perineum, and lower extremities. Lesions intrinsic to the spinal cord rarely present with pain; neurologic deficits are usually the initial complaint, and profound sensory and motor loss can be found without any pain complaints. Segmental pains can be present and are probably caused by stretching of the dorsal roots by the enlarging intrinsic mass. In the male, sexual dysfunction is a frequent early sign. Because the pain can involve the lower lumbar segments, the patient might be thought to have disk disease; for this reason the conus must be visualized in any imaging study.

The common cause of an intrinsic spinal cord lesion is a tumor (5,6 and 7). Other causes include syringomyelia, congenital or posttraumatic cysts, and vascular malformations. Unrecognized congenital abnormalities of the spinal cord can also produce low back pain and neurologic deficit; CT or MRI scanning and other studies can help to establish the diagnosis. A significant percentage of patients with repaired meningomyelocele or lumbosacral lipomeningomyelocele develop symptoms of a tethered spinal cord; pain and progressive neurologic deficit are the common presentation of such a condition (8). Surgical repair usually alleviates the symptoms and prevents further neurologic loss. Midline cutaneous and subcutaneous abnormalities should alert the physician to the possibility of an underlying congenital abnormality of the spinal cord.

Extramedullary Intradural Lesions

Lesions extrinsic to the spinal cord but within the dura are not common; most occur in the thoracic region and not in the lumbar and sacral segments. Neurofibroma and meningioma are the most common neoplasms, but almost any tumor of neural or glial origin, as well as congenital cysts, can be present (9). Neurofibromas usually start on a root and present relatively early, with radicular pain and neurologic loss. Meningiomas usually start ventral or dorsal to the spinal cord, and radicular signs are often late to develop. Ependymoma of the conus region can begin within the spinal cord but can expand into the subarachnoid space and compress nerve roots, leading to pain and neurologic deficits. Radicular lumbosacral pain is too often assumed to be caused by herniated nucleus pulposus at L-5 or S-1; a tumor at the level of the conus medullaris can also produce radicular pain and neurologic loss. For this reason, every imaging study performed for suspected lumbar disk disease should also include views of the conus.

Diagnosis of intramedullary or extramedullary intradural lesions is established by myelography, CT, or MRI. Electrodiagnostic studies can also be helpful. Treatment is exclusively by surgical removal, because these lesions are almost all benign and are not sensitive to radiation or chemotherapy (Fig. 77-1).

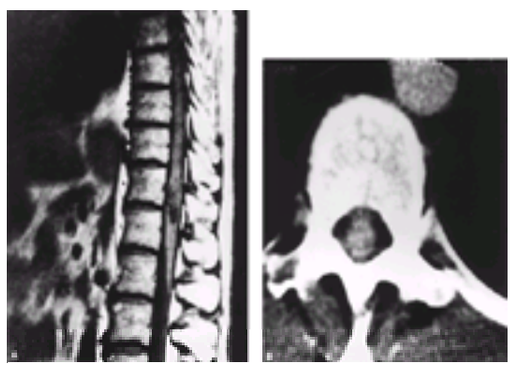

Figure 77-1. **A:** Intramedullary tumor (hemangioblastoma) at T-10 to T-11 as seen on midsagittal projection of magnetic resonance imaging scan. The tumor is the low-signal ovoid region within the higher-signal spinal cord. In this scan, cerebrospinal fluid is dark; fat and bones are white. **B:** Axial computed tomography scan with intravenous enhancement at T-10 to T-11. Swollen spinal cord with enhancing mass is obvious.

Meningeal Carcinomatosis (XXVI–11)

Leptomeningeal metastases from solid tumors elsewhere in the body can produce severe radicular pain and loss of function. The pathology is direct invasion of the nerve roots by tumor cells; a discrete mass might not be present. The most common primary tumors are carcinoma of the lung or breast, malignant melanoma, lymphoma, and leukemia. Both children and adults can suffer from this type of tumor spread. Diffuse spinal pain and headache are common. The diagnosis is confirmed by finding malignant cells in the spinal fluid. Treatment is by radiation or chemotherapy, depending on the primary lesion. Pain relief is sometimes obtained with narcotics; anticonvulsants can also be helpful (10).

Extradural Spinal Lesions (XXVI–4)

Herniated lumbar disk (see below) is probably the most common type of extradural lesion; tumors and abscesses also occur in this space. Extradural neoplasms are probably metastases from a primary lesion elsewhere in the body. Lung, breast, prostate, and thyroid neoplasms are the most common solid tumors. The patient usually has back pain before the development of signs of nerve root or spinal cord compression. The epidural deposit might be the first sign of the malignancy, or it might occur late in the course of the patient's disease. Diagnosis is established by myelography, CT, or MRI. Chemotherapy, radiation therapy, and decompressive laminectomy can all be used; the histology of the lesion determines the most effective therapy.

Epidural abscess is less common in the present antibiotic era than it was 50 years ago. There is often a history of bacteremia after a surgical procedure or of infection in the pelvic area, although epidural abscess can occur without any recognized antecedent infection. The patient almost always has severe back pain; neurologic deficits follow the pain if the lesion is not treated aggressively. The use of surgical decompression and appropriate antibiotics usually yields good results if the decompression is done before devastating neurologic loss has occurred (11).

Lesions of the Nerve Roots

Herniated Nucleus Pulposus (XXVI–1)

Certainly the most popular cause of lumbosacral radiculopathy, herniated nucleus pulposus (“ruptured disk”), is now recognized as a relatively uncommon cause of lumbago and sciatica (3). The pioneering work of Mixter and Barr (12) led to the realization that these common symptoms could be a result of extrusion of a fragment of disk into the spinal canal; formerly, surgeons had observed disk material in the spinal canal but thought it to be a form of neoplasm. Mixter and Barr (12) also described the value of myelography in establishing the diagnosis of ruptured disk.

In the past 20 years it has been recognized that many other structures in the back can produce both low back pain and pain referred to the sciatic nerve distribution. It is also well established that the pathologic changes that have been described in older texts as the basis for chronic pain are, in fact, found in many people who have never had any symptoms. Hence, there is only a loose association between the structural lesions and the patient's symptoms. Nonetheless, compression of the dorsal roots or of the dorsal root ganglion can lead to pain; herniated nucleus pulposus is a common cause of this syndrome (13). The role of herniated nucleus pulposus in

low back pain is discussed in greater depth in Chapter 76.

Etiology. Herniated nucleus pulposus is caused by trauma, the aging process, or both. If workers are compensated for on-the-job injuries, almost all disk disease will be ascribed to some type of minor traumatic event that happened at work. The actual role of trauma is not well understood because ruptured disks can occur in sedentary as well as heavy-labor settings. Degrees of disk disease are seen: degeneration of the disk, bulging of the annulus fibrosis, rupture of the disk through the annulus, and free fragment rupture of the disk into the spinal canal (Fig. 77-2). In general, the severity of symptoms is related to the extent of the pathology. Furthermore, as Spangfort (14) has clearly shown, the results of diskectomy are much better in patients who have free fragment disk ruptures. Disk degeneration and bulging of the annulus are a part of the aging process and occur in everyone to some degree.

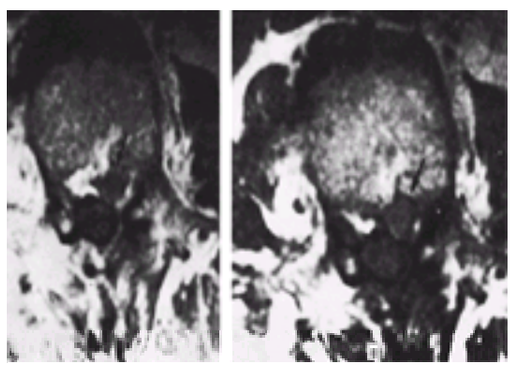

Figure 77-2. Free fragment disk L2-L3 rupture as seen on axial magnetic resonance imaging scan. Scar tissue from prior surgery enhances; disk fragment does not. **A:** Unenhanced scan. **B:** Gadolinium-enhanced scan. Arrow points to free fragment of disk. The patient had severe left L-2 radicular pain and paresthesia.

Symptoms and Signs. The outstanding symptom of herniated nucleus pulposus is pain. Most patients have had several episodes of low back pain before they develop pain that radiates to the buttock and leg in a segmental pattern. A specific episode of lifting, straining, or twisting is identified as the cause by most patients. The exact distribution of the pain depends on the root involved (Fig. 77-3). The S-1 root is most frequently compressed and leads to pain that radiates from the low back to the buttock, posterior thigh, lateral leg, lateral ankle, lateral foot, and fifth toe. The L-5 root is the next most frequently compressed and leads to pain in the low back, posterolateral thigh, dorsal foot, and medial toes. The L-4 root is the third most commonly involved and leads to pain in the low back, anterolateral thigh, and medial leg and foot to the first toe. Only rarely are more rostral nerve roots compressed by a herniated nucleus pulposus, because ruptures of disks above the L-3 to L-4 interspace are uncommon. The pain is aggravated by sitting, twisting, or lifting and is usually relieved by walking or lying down. Coughing, sneezing, and straining on the toilet typically exaggerate the pain.

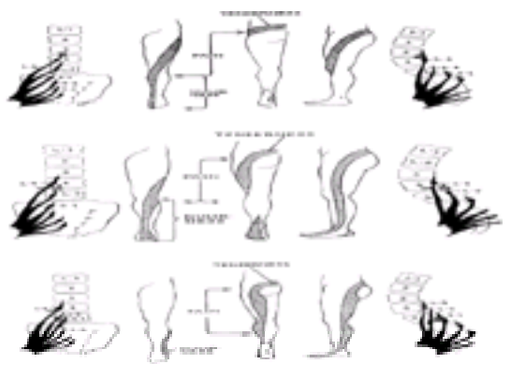

Figure 77-3. Dermatome hypalgesia, pain, and tenderness in the distribution of the lower limb from herniation of intervertebral disks. **A:** Pattern of distribution of the L-4 segment from herniation of the L-3 intervertebral disk. **B:** Dermatome hypalgesia, pain, and tenderness in the distribution of the L-5 segment resulting from herniation of the L-4 intervertebral disk. **C:** Dermatome hyperalgesia, pain, and tenderness in the distribution of the S-1 segment resulting from herniation of the L-5 intervertebral disk. (Modified from Keegan JJ. Dermatome hyperalgesia associated with herniation of the lumbar intervertebral disc. *J Bone Joint Surg* 1944; 26:238–248.)

Paresthesias are often perceived in the distribution of the compressed nerve root. These are of greater localizing value than the pain or sensory or motor deficits. Decreased light touch and pinprick sensations are sometimes noted. Motor changes are usually subtle but can be more pronounced. Weakness, atrophy, fasciculations, and reflex changes can occur (Table 77-1).

	Location		
Symptoms and signs	L4	L5	S1
Pain	In gluteal ("hip") region below iliac crest	In gluteal ("hip") region between sacral tuberosity and femoral trochanter	In medial gluteal ("hip") region over sacral tuberosity
Pain radiation	Anterior thigh and leg	Lateral thigh and leg	Posterior thigh and leg
Tenderness	Over spinous and transverse processes of vertebrae	Over spinous and transverse processes of vertebrae	Over spinous and transverse processes of vertebrae
Subjective numbness	Anterior leg, great toe	Lateral leg, three middle toes	Posterior leg, little toe
Hypalgesia	Over entire segment	Over entire segment	Over entire segment
Reflex changes	Patellar tendon reduced or absent	Usually no alteration	Achilles tendon reduced or absent
Motor weakness	Dorsiflexors of great toe	Dorsiflexors of ankle and toes	Plantar flexors

TABLE 77-1. Single nerve root syndromes of the lower lumbar and upper sacral segments

Mechanical signs of nerve root irritation are also present. These include reproduction of the pain on straight-leg raising, tenderness to percussion over the adjacent spinous processes to the herniated nucleus pulposus, paravertebral muscle spasm, lumbar scoliosis, and loss of lordosis.

A small percentage of patients sustain a massive free fragment rupture of a disk and suffer from a cauda equina syndrome, with multiple nerve root involvement and severe pain. This is the only case in which a herniated nucleus pulposus is a surgical emergency.

Diagnosis. Classic presentations of lumbar disk disease can be diagnosed from the history and physical examination (3). Atypical cases can be more difficult to discriminate from other pathologic processes that involve the back. Careful neurologic examination will usually locate the lesion. Radiculopathy caused by disk disease rarely involves more than one nerve root, and the signs and symptoms are usually unilateral. Low back pain usually precedes the development of leg pain.

Bowel and bladder symptoms are uncommon except in cases of large free fragment rupture, although subtle cystometrographic abnormalities have been well described in many patients with typical single-level disk disease. Intradural and epidural neoplasms, spinal infections and neoplasms, and retroperitoneal neoplasms and infection must be considered in the differential diagnosis. All these are much rarer than herniated nucleus pulposus. In addition, pain syndromes originating from

the joints of the spine, ligaments, or muscles must also be kept in mind. Pain that radiates into the lower extremity is not pathognomonic of herniated nucleus pulposus and nerve root compression.

Treatment

Conservative Therapy. The treatment of herniated nucleus pulposus should always be conservative, except in the case of a massive free fragment rupture with cauda equina compression (15). There is little evidence to show that any form of therapy improves on the natural history (see Chapter 76). The role of steroids is equivocal (16,17). Although some studies have indicated that the use of oral or epidural steroids hastens recovery from radicular pain caused by disk prolapse, others have not been confirmatory. Furthermore, the influence on later symptoms and signs (i.e., Is the natural history of the disease altered?) remains to be determined. As is so often the case, what is lacking is not the results of treatment but, instead, the natural history of the disease being treated. Prolonged bed rest and inactivity are deleterious. Narcotics and sedative-hypnotics can be of value for a few days, but their long-term use adds to the patient's disability. The patient should be told to avoid strenuous activities that stir up the pain but to resume normal activities as soon as possible.

Surgical Therapy. The major problem with lumbar disk disease is pain. The severity of the neurologic deficit rarely mandates surgical therapy. Only when the pain complaints are severe and unremitting should a surgical procedure be considered. If the diagnosis is straightforward, a diagnostic study such as myelography, CT or MRI, or electromyography is warranted only when the decision has been made to operate. Such studies only locate the lesion, and it should be remembered that they play no role in determining who needs surgery. All the myelographic, CT, and MRI changes that characterize lumbar disk disease are often found in people who do not have and might never have had significant low back and leg pain. These diagnostic studies never determine the need for surgery; they only locate the pathology in a patient who has already met the criteria for diskectomy (Fig. 77-4).

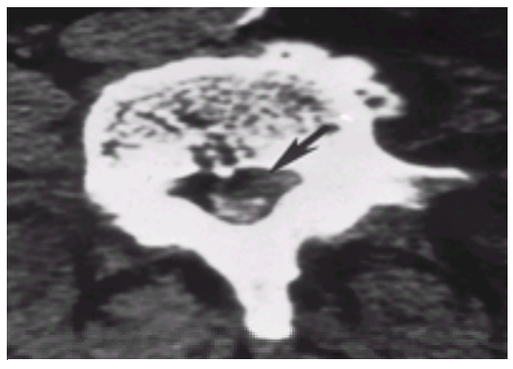

Figure 77-4. Axial computed tomography scan using intrathecal contrast agent showing that the dural sac is displaced posteriorly by a larger, herniated disk fragment (*arrow*). The patient had low back pain radiating to both legs, which was made worse by standing or walking.

The traditional open surgical method of removing a herniated lumbar disk has seen several modifications in the past 20 years. Microdiskectomy has its proponents; a percutaneous technique for mechanically removing the disk has been described (18). Enzymatic degradation of the nucleus pulposus by injection of chymopapain has also been popular. All of these procedures remove the disk, but none has been shown to offer major advantages. Each method carries some risk of complications. No matter how one removes a disk, the key to success is patient selection. Spangfort (14) showed that the relief of both leg and back pain was correlated with the findings at surgery: Free fragment disk ruptures had a 90% likelihood of relief of sciatica; bulging disks had a 60% likelihood of pain relief, and leg pain was more likely to be relieved than low back pain. The lack of randomized prospective allocation trials prohibits comparisons of results of different surgical strategies (19,20 and 21).

Relief of leg or back pain is not synonymous with return to work. Little evidence has shown that fusion of an otherwise normal lumbar spine improves the outcome for patients who have had a herniated nucleus pulposus and a diskectomy. Disk disease is a small component of the problem of low back pain in the modern industrialized state. Chapter 76 contains a more thorough discussion of low back pain and its attendant disability.

Spinal Stenosis (XXVII–3)

Spinal stenosis, also known as *neurogenic claudication*, is a painful syndrome that was first clearly described by Verbiest in 1954 (22). Bilateral lower extremity numbness, weakness, and pain, in association with low back pain, are present in varying degrees after walking or when standing erect. The symptoms are exercise induced and rapidly clear with rest. Vascular claudication occurs after exercise regardless of posture; neurogenic claudication occurs primarily in the erect position (23). The severity of the pain complaint usually exceeds the magnitude of the neurologic deficits (24).

The diagnosis can be confirmed by provocative physical testing and corroborated by myelography, CT, or MRI (Fig. 77-5). The causes of spinal stenosis are multiple, and accurate predictors of outcomes are not yet established (25). Conservative therapy can lead to excellent outcomes, but some patients prefer prompt surgery (26). Decompressive surgery is often effective treatment; stenosis of the spinal canal and of the neural foramina can be present to varying degrees, and surgical therapy must resolve the anatomic problems in each patient. Spinal stenosis and its treatment are also discussed in Chapter 76.

Figure 77-5. Myelogram showing pattern of spinal stenosis. The segmental narrowing is caused by encroachment of the enlarged ligamenta flava.

Arachnoiditis (XXVII–10)

One of the most disastrous complications of disk disease, myelography, trauma, subarachnoid hemorrhage, infection, or spinal surgery is the development of arachnoiditis involving the cauda equina (27). It is not understood why only a small percentage of patients who have one of these inciting causes develop inflammatory changes in the nerve roots and the surrounding arachnoid. Furthermore, not everyone with the histologic findings of arachnoiditis has a pain syndrome.

Etiology. Although any of the causes listed above can precede the development of arachnoiditis, none of them does so with any regularity. In addition to these factors, the following causative influences have been thought to be involved: syphilis; bacterial, fungal, or disk space infection; intrathecal drug therapy; herniated nucleus pulposus; spinal stenosis; radiation therapy; intradural tumor; and spinal anesthesia. It is not known whether patients who develop inflammation in the arachnoid that progresses to fibrosis have an alteration in their immunologic responses. The initial inflammatory process can proceed to severe scarring, both within the arachnoid and within the nerve roots themselves. The process can be restricted to one nerve root or can involve various parts of the cauda equina. Arachnoiditis has become

much less common since myelography has been largely replaced by MRI scanning.

Symptoms and Signs. The major problem with arachnoiditis is severe, unremitting pain in the low back and legs. Varying degrees of motor and sensory loss can be present, and in some patients the scarring process in the arachnoid is associated with progressive, profound neurologic loss, although this is relatively uncommon. The pain is aggravated by movements or positions that stretch the lumbar nerve roots. Most patients say that exercise aggravates their pain and rest relieves it.

Diagnosis. The development of chronic low back and leg pain in a patient who has been exposed to any of the causative factors should lead to the suspicion of arachnoiditis. Patchy neurologic deficits that involve multiple nerve roots are common. Diagnostic studies should reveal the absence of other structural lesions and the presence of nerve root matting or clumping and filling defects in the arachnoid. This is often a diagnosis of exclusion and is sometimes made without any real evidence.

Treatment. No controlled studies have demonstrated effective treatments for arachnoiditis. Some patients have responded to epidural and intrathecal steroids, usually administered with a local anesthetic. Because steroids do not affect collagen that has already been laid down to form a scar, it is difficult to explain their purported efficacy in arachnoiditis (28). Surgical lysing of the scarred nerve roots has also been undertaken, with variable results at best (29,30). Some patients lose neurologic function after this operation. Because arachnoiditis is probably a form of deafferentation pain, ablative surgical procedures are not indicated in most patients. Spinal cord stimulation has led to symptomatic improvement in many but not all patients (31,32).

Fractured Lumbar Spine (XXVI–5)

Fractures of the lumbar spine represent major trauma. They are associated with acute pain that can be expected to abate as the injury heals, but some patients develop a chronic pain syndrome. Persistent pain should raise the suspicion of instability at the site of injury. Trauma to the lumbar and sacral spine can also result in damage to the cauda equina and lead to deafferentation pain. Arachnoiditis and nerve root scarring can also follow trauma, and severe pain can ensue.

Lumbosacral Plexus Avulsion

Avulsion of the lumbosacral plexus or contusion of the roots that form the plexus is less common than major injuries to the brachial plexus. The lumbosacral plexus is more protected than the brachial plexus, and avulsion only occurs with massive trauma (33). These roots originate in the conus medullaris; avulsion can lead to myelopathy because of compromise of the blood vessels that feed the spinal cord and enter the dura in association with the nerve roots. A history of major trauma is almost always present, and the neurologic deficits occur immediately. Pain is present initially, and in some patients a denervation pain develops in the anesthetic areas of the body.

The management of this chronic pain is difficult. It does not respond well to narcotics, but anticonvulsants are sometimes valuable. Ablative surgical procedures are usually not helpful; dorsal root entry zone lesions are probably the most effective (see Chapter 106).

Postherpetic Neuralgia (XXVI–3)

Herpes zoster can involve the lumbar and sacral dermatomes and can lead to severe pain in the acute phase and chronic pain if postherpetic neuralgia develops. This common pain syndrome is discussed in Chapter 22; nothing is unique about its occurrence in the lower extremities. Inflammatory and degenerative changes are found in the peripheral nerves, dorsal roots, and dorsal horn of the spinal cord. Medical and surgical management can be difficult.

Tabes Dorsalis (XXVI–9)

Tabes dorsalis (tabetic neurosyphilis) is the cause of lancinating pains in a radicular pattern that can involve the lumbar and sacral dermatomes (34). It is much less common in the present antibiotic era, occurring predominantly in those of middle age, because it takes several decades for the infection to progress to this stage. Patients describe severe, shocklike pains that are of brief duration but can recur frequently. Both hypesthesia and hyperesthesia can be found in the areas of pain. Signs of spinal cord dysfunction are usually present. This pain syndrome is almost pathognomonic; tests for syphilis are positive.

The lightning pains can be ameliorated by anticonvulsants; diphenylhydantoin, gabapentin, and carbamazepine are most commonly used (see Chapter 23). Cordotomy has been reported to have a high success rate for cases in which medications are not effective (see Chapter 106).

Diabetic Pseudotabes (XXVI–9)

Diabetics can develop various neuropathies and myelopathies, including what is called *diabetic pseudotabes*. The exact cause of the neurologic signs and symptoms is not understood. The patient has signs of posterior column dysfunction (proprioceptive loss), radicular sensory loss, and radicular lancinating pains. Pseudotabes is distinguished from tabes dorsalis by the presence of abnormalities of sugar metabolism and the absence of positive tests for syphilis. Optimal management of diabetes seems to lessen the likelihood of occurrence of this form of neuropathy. Symptomatic relief can sometimes be obtained with anticonvulsants (see Chapter 23).

Lesions of the Lumbosacral Plexus

Lesions of the lumbosacral plexus are rare, because its location protects it from most trauma. Any lesion of the plexus can produce pain that is increased by deep palpation or by exercise that stretches the plexus or involves the psoas muscle. A sudden onset of severe pain and unilateral lumbosacral plexopathy can be a result of rupture of an abdominal aortic aneurysm or of the development of a retroperitoneal hemorrhage in a patient who is taking anticoagulants. Most other causes of plexopathy are of gradual onset.

Neoplasms (XXVI–8/503X4b)

Intrinsic Tumors. Tumors of the lumbosacral plexus present with neurologic deficits and pain that is usually referred to the distribution of the involved nerves. Most of these intrinsic lesions are benign schwannomas or neurofibromas, which can be solitary or part of a more generalized phakomatosis. Malignant degeneration rarely occurs. CT and MRI are of great diagnostic assistance; electromyography localizes the lesion functionally. Treatment involves surgical excision and repair of the plexus with cable grafts, when appropriate. Pain from a tumor of the plexus is sometimes relieved by narcotics; anticonvulsants can also be helpful, because often a component of deafferentation pain is also present.

Extrinsic Tumors. Retroperitoneal neoplasms can invade the lumbosacral plexus and produce severe pain and progressive neurologic deficits. Lymphoma, sarcoma, and uterine carcinoma (in women) are the most common types of tumors that invade the plexus and produce pain. Typically, the pain is perceived both deep in the abdomen and pelvis and in the distribution of the plexus to the groin and lower extremities. Aggressive medical (and sometimes surgical) treatment is needed to alleviate this type of cancer pain (see Chapter 35 and Chapter 36).

Lumbosacral Plexitis

Pain and neurologic deficits can develop rapidly in the lumbosacral plexus without any apparent injury or anatomic lesion and are assumed to be caused by a viral inflammation of the lumbosacral plexus (35). The disease is self-limiting and usually has a favorable prognosis. Symptomatic therapy is indicated; some have advocated the use of steroids (36).

Postradiation Plexopathy

Radiation therapy of the lower abdomen and pelvis can lead to lumbosacral plexopathy secondary to fibrosis. It is sometimes difficult to discriminate between tumor recurrence, surgical scarring, and radiation-induced fibrosis. MRI or CT helps to rule out tumor recurrence and make the diagnosis of plexopathy more likely. Radiation-induced pain rarely develops in less than a year after therapy; the latency period can be several years (1).

Symptoms and Signs. Sensory changes are usually found earliest in those with radiation-induced plexopathy; the amount of sensory and motor loss varies and can be slowly progressive. Radiation-induced skin changes are almost always observed.

Treatment. The treatment of radiation-induced plexopathy is not successful in most patients. The condition is rare, and proven therapies do not exist. Some patients respond favorably to analgesics, and anticonvulsants and antidepressants help others. Ablative surgical procedures are sometimes helpful; neurostimulation of either spinal cord or brain has been reported to be successful.

Contusion or Stretching

The lumbosacral plexus is not often contused or stretched by external trauma because it is well protected. The most common cause of such an injury is childbirth—hence the female preponderance (37). Either the fetal head or the forceps used to deliver the head can contuse or stretch the plexus; the lower segments are more likely to be involved. The pain and neurologic deficits are usually of several months' duration and abate spontaneously. The upper portion of the plexus can be damaged during delivery if the hips are maintained in flexion and abduction for a prolonged period. Pelvic surgery or external trauma can also damage the lumbosacral plexus (38).

Penetrating Trauma

Gunshot wounds or low-velocity penetrating injuries can directly damage the lumbosacral plexus, but this is a rare traumatic injury. Neuromas and scarring around the plexus can follow the acute injury and lead to chronic pain. Proper management requires adequate visualization of the plexus at the time of debridement so that the nature of the injury can be identified and plans for restorative surgery can be developed. Repair of the damaged plexus is the best method of preventing chronic pain. Secondary procedures to lyse the scar from within and around the nerve are sometimes helpful. Some patients respond to pharmacologic management with narcotics, anticonvulsants, or antidepressants. Ablative surgical procedures are rarely indicated. Electrical stimulation of the spinal cord or brain is sometimes helpful.

Lesions of the Peripheral Nerves

Acute Trauma

Any of the nerves of the leg can be injured by blunt or penetrating trauma. The injury itself is painful because of the surrounding tissue damage, and neurapraxia develops immediately. The likelihood of neurologic deficit and of the development of chronic pain is a function of the severity of the nerve injury. Chronic pain can develop if a neuroma is formed at the site of axonal disruption or if the nerve becomes chronically entrapped in a scar.

Prevention of chronic pain is associated with prompt repair of the nerve (39). If surgical exploration does not result in pain relief, local injections of steroids can be helpful for some patients.

Chronic Trauma

The most common cause of chronic nerve trauma is mechanical compression by surrounding structures; these are known as *entrapment syndromes* (40,41). Although it is possible for any nerve at any point in its course to be entrapped, most entrapments occur at specific sites on specific nerves. The more common lower extremity entrapment syndromes are described in Table 77-2.

Nerve	Location of pain	Sensory changes	Weakness	Usual cause
Lateral femoral cutaneous (meralgia paresthetica)	Anterolateral thigh	Anterolateral thigh	None	Entrapment under inguinal ligament
Saphenous	Medial leg, knee	Medial calf	None	Entrapment at adductor canal
Obturator	Proximal medial	Proximal medial	Adduction	Entrapment at obturator canal
Sciatic (piriformis syndrome)	Buttock, lateral and posterior leg, knee	Lateral and posterior leg, knee	Hamstrings, all distal muscles	Entrapment by piriformis muscle
Peroneal	Lateral knee, retro leg, and foot	Lateral leg, dorsum of foot	Foot drop/flexors	Entrapment at fibular head
Deep peroneal (anterior tarsal tunnel)	Dorsum of foot	First dorsal web	None	Entrapment by flexor retinaculum
Posterior tibial (posterior tarsal tunnel)	Plantar foot and toes	Plantar foot and toes	Intrinsic flexors	Entrapment at tarsal tunnel
Interdigital (Morton's neuroma)	Toes (usually third and fourth)	Opposing toes surfaces	None	Entrapment at metatarsal head

TABLE 77-2. Lower extremity entrapment syndromes

Etiology. The pathophysiology of nerve entrapment is almost certainly ischemia of the nerve. A mild degree of pressure for a short period produces a rapidly reversible dysfunction. Variations in the amount of pressure might be responsible for the intermittent symptoms that are so characteristic of these lesions. The lesion is electrophysiologically characterized by slowing of conduction velocities; histologic findings include segmental demyelination and remyelination (42).

Symptoms and Signs. Entrapment neuropathies are responsible for focal neurologic deficits, local and radiating pain, and paresthesias. Any of these three components can predominate, or they can be absent. The lost axons probably cause the motor and sensory loss; the paresthesias and pain of course require functional axons. Thus, the electrophysiologic changes do not correlate well with the pain or paresthesias.

Usually the symptoms of an entrapment neuropathy develop after unusual exercise of the appropriate body part. Once present, the symptoms frequently wax and wane without obvious cause. The neurologic deficits are usually slowly progressive; the pain and paresthesias vary. The pain might not be only local, but can radiate proximally and distally from the site of entrapment.

Diagnosis. Entrapment neuropathies can be diagnosed on the basis of history and physical findings and are corroborated by electrodiagnostic studies (43). Both early and late responses of nerve conduction and electromyography might be required for accurate location (see Chapter 13). Magnetic resonance neurography and the identification on MRI of denervated muscle can also be helpful (4) (Fig. 77-6).

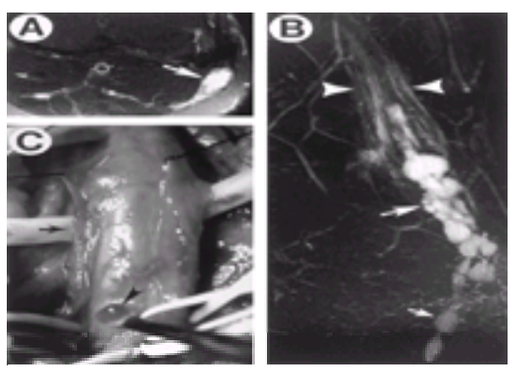

Figure 77-6. Magnetic resonance neurogram of cysts of the peroneal nerve. **A:** Axial T2 fast-spin echo (FSE) image with high spinal cystic lesions (*arrow*) within common peroneal nerve. **B:** Coronal T2 FSE multiplanar reconstruction showing high signal intraneural cysts (*small arrows*) and splayed nerve fascicles (*between arrowheads*). **C:** Intraoperative photograph demonstrating enlargement of peroneal nerve and cyst (*black arrowhead*). (From Kuntz C IV, Blake L, Britz G, et al.

Magnetic resonance neurography of peripheral nerve lesions in the lower extremity. *Neurosurgery* 1996;39:750–756, with permission.)

Treatment. Both nonsurgical and surgical therapies have been effective for entrapment neuropathies. Mild lesions related to repetitive movements can be managed by appropriate changes in occupation or recreation. Splinting or bracing can be effective for some lesions. Local injection of steroids can be beneficial. When these measures fail, surgical decompression is often curative. If major damage to the nerve has already occurred, decompression might not alleviate the loss of function or the pain.

Specific Nerve Entrapment Syndromes

Lateral Femoral Nerve Entrapment (XXX–1)

Entrapment of the lateral femoral cutaneous nerve is known as *meralgia paresthetica*. It was one of the earliest entrapment syndromes to be described. The nerve is derived from the L-2 and L-3 roots and travels across the pelvic side wall to enter the thigh at the lateral end of the inguinal ligament, which is the common site of entrapment. This nerve has no motor fibers; the symptoms are purely sensory.

Etiology. Entrapment usually occurs where the nerve passes underneath or through the inguinal ligament at the origin of the ligament and attaches to the anterior superior iliac spine. Human studies have revealed that in a significant percentage of individuals the nerve passes from the pelvis to the thigh through the fibers of the inguinal ligament rather than below it (43) (Fig. 77-7). Other causes are chronic trauma in those in certain occupations, intrapelvic pathology with compression along the long course of the nerve, and occupations that require standing with the side of the anterior superior spine held against a hard object (e.g., barbers) (44).

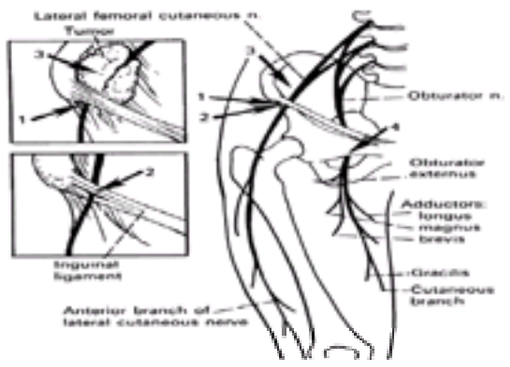

Figure 77-7. Sites of entrapment of the lateral femoral cutaneous and obturator nerves: the most common site of entrapment of the lateral femoral cutaneous nerve as it passes below the inguinal ligament (1); site of entrapment of the lateral femoral cutaneous nerve as it passes within the ligament (2); site of entrapment of the lateral femoral cutaneous nerve in the pelvis by a tumor (3); site of entrapment of the obturator nerve (4). (Developed by JJ Bonica and M Domenowske from data in Kopell HP, Thompson WAL. *Peripheral entrapment neuropathies*. Baltimore: Williams & Wilkins, 1963.)

Signs and Symptoms. The patient usually complains of both pain and paresthesias in the upper lateral thigh. The pain is described as burning or tingling and is localized to the skin and not to deep structures. Light stimulation of the skin is often described as very unpleasant (allesthesia). The pain and paresthesias are aggravated by standing and walking or by extending the hip; sitting or lying with the hip flexed can alleviate the symptoms. Many patients complain of the paresthesias without describing pain in the thigh; others have neither pain nor paresthesias but only sensory loss. The area of sensory loss is usually only in the center of the large territory of this nerve; the region of altered response to stimulation is often greater.

Diagnosis. Sensory action potentials can demonstrate conduction delay, temporal dispersion, or absence of responses (see Chapter 13). Electromyography should not reveal abnormalities of the quadriceps muscle or femoral nerve. No motor or sensory abnormalities should be present elsewhere in the leg. Retroperitoneal mass lesions should be excluded by physical examination or appropriate imaging studies. In fact, the presentation of burning and tingling in the lateral thigh is rarely caused by anything other than entrapment of the lateral femoral cutaneous nerve.

Treatment. Symptoms are usually mild, and reassurance and accurate diagnosis often suffice. Patients should be advised not to wear constricting garments such as corsets or belts. Obese patients should be advised to lose weight. If the onset of symptoms is associated with a new exercise activity, patients should be advised to find another, less stressful exercise.

The role of nerve blocks with or without steroids at the level of the inguinal ligament is unclear, because no controlled studies have been carried out. Whether temporary relief of symptoms alters the long-term prognosis is unknown. Some patients have remission of their complaints without any treatment. Although surgical decompression and nerve resection were once common, they are often not successful. Indeed, the pain complaints usually increase after transection of this or any other peripheral nerve.

Femoral Nerve Entrapment (XXX–3)

The femoral nerve can be compressed by various neoplasms and vascular diseases, but it is not involved in an idiopathic entrapment syndrome. Most of these lesions are intrapelvic and not occult. The nerve can also be damaged by extreme flexion or hyperextension at the hip. The femoral nerve is derived from the L-2, L-3, and L-4 roots and travels across the retroperitoneal space to exit the pelvis at the femoral triangle in close proximity to the femoral artery and vein.

Signs and Symptoms. Pain is not usually a symptom of femoral nerve entrapment. The major findings are quadriceps weakness with severe gait impairment and decreased sensation over the anterior thigh and medial calf. Pain can be at the site of the causative lesion rather than in the distribution of the nerve itself.

Diagnosis. The presence of hip flexor weakness indicates a lesion of the lumbosacral plexus or spinal roots and discriminates femoral nerve entrapment from femoral neuropathy. Electromyography, sensory action potentials, and nerve conduction velocity studies can help to locate the lesion. Imaging studies (CT or MRI) can be helpful in identifying intrapelvic or retroperitoneal pathology.

Treatment. Because entrapment is almost always caused by a pathologic lesion impinging on the nerve, treatment is aimed at that lesion. Explorative surgery to relieve pain is usually fruitless; only if a structural abnormality is present will surgery help.

Saphenous Nerve Entrapment

The saphenous nerve is a sensory branch of the femoral nerve that travels through the adductor canal of the thigh and penetrates the fascia just above the knee to supply the skin of the medial calf and ankle and often the medial portion of the foot dorsum. Idiopathic entrapment occurs where the nerve exits from the adductor canal in the distal thigh (subsartorial tunnel).

Symptoms and Signs. Saphenous nerve entrapment is characterized by burning or aching pain in the medial calf that can radiate into the entire distribution of this nerve. The patient does not have any weakness. Use of the knee can exacerbate the pain or the sensory changes.

Diagnosis. The diagnosis of saphenous nerve entrapment is based on the complaint of pain and sensory changes in the territory of this nerve without involvement of any other branches of the femoral nerve. Sensory action potentials can be helpful; mass lesions in the adductor canal can be seen on CT scan or with MRI. Prior

surgery in the area of the knee can lead to entrapment in the postoperative scar.

Treatment. Severe symptoms have been treated successfully by exploration and decompression of the exit zone of the saphenous nerve from the adductor canal. This is a rare entrapment neuropathy, and few data are available concerning its natural history and treatment outcomes.

Obturator Nerve Entrapment (XXX–3)

Entrapment of the obturator nerve usually occurs at the obturator membrane as this nerve leaves the pelvis and enters the thigh (see Fig. 77-7). Most obturator nerve lesions are traumatic; idiopathic entrapment is rare. Sacroiliac and sacrum pathology can encroach on the obturator nerve as it traverses the pelvis.

Symptoms and Signs. The patient complains of pain in the upper medial thigh, with possible associated sensory loss in the medial thigh and weakness of the adductor muscles. The latter can lead to a wide-based gait with the leg held in an abducted position. Rarely, the pain radiates to the knee or even below it.

Diagnosis. Sensory and motor findings can be confirmed by electromyography and nerve conduction studies. Space-occupying lesions in the retroperitoneal or pelvic regions can be seen with MRI or on CT.

Treatment. Most obturator nerve entrapment is caused by a lesion, and extirpation of the lesion is the goal of therapy. Entrapment at the obturator membrane can be approached surgically.

Sciatic Nerve Entrapment (XXX–4)

The sciatic nerve can be compressed at many sites along its course from the sciatic notch to the point at which it divides into the peroneal and posterior tibial nerves, just above the popliteal fossa. This nerve is derived from the L-4 and L-5 roots and the S-1, S- 2, and S-3 sacral roots. The nerve leaves the pelvis through the sciatic notch, where it immediately underlies the piriformis muscle and is above the obturator internus muscle. This is the most frequent site of sciatic nerve entrapment, where it has been called the *piriformis syndrome* (Fig. 77-8).

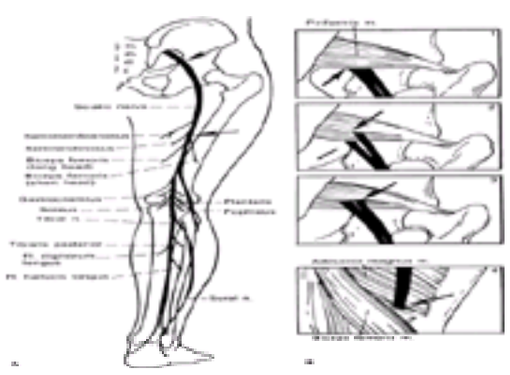

Figure 77-8. Sites of entrapment of the sciatic nerve. **A:** Posterior view of lower limb showing the position of the sciatic nerve and its branches. Arrows indicate sites of sciatic nerve entrapment. **B:** Insets with details. Inset 1. Arrow shows the most frequent site of entrapment. This occurs because of compression by the piriformis muscle, which lies just above the sciatic nerve as it passes from the pelvis through the greater sciatic foramen; beneath the nerve itself is the obturator internus muscle. It has been shown that inward rotation of the thigh causes compression of the sciatic nerve against the tendinous origin of the piriformis muscle. Spasm of the piriformis muscle (inset 1) can also cause compression. In 12% of individuals the nerve passes between parts of the piriformis muscle (insets 2 and 3), the peroneal nerve portion of the sciatic nerve being most frequently involved. Compression can also be caused by a myofascial band in the distal portion of the thigh between the biceps femoris and the adductor magnus muscles trapping the nerve (*arrow,* inset 4). Other causes include muscle fibrosis induced by repeated injections of pentazocine, compression of the nerve in the pelvis during anticoagulant therapy, and compression of the nerve from leakage of acrylic plastic into the region posterior to the hip joint during total hip replacement. (Developed by JJ Bonica and M Domenowske from data in Kopell HP, Thompson WAL. *Peripheral entrapment neuropathies*. Baltimore: Williams & Wilkins, 1963.)

Symptoms and Signs. Sciatic nerve entrapment by the piriformis syndrome can lead to buttock pain and pain that radiates in the distribution of the sciatic nerve to the foot. Motor loss can lead to instability of the foot and a severe gait dysfunction. The pain is usually described as aching and cramping. Paresthesias can be present in the sciatic nerve sensory territory.

Diagnosis. Piriformis syndrome can be diagnosed by determining the site of sciatic nerve compression on clinical, imaging, and electrodiagnostic grounds. The nerves and muscles innervated by the nerve roots before the lumbosacral plexus are spared; electromyography can be helpful in showing no involvement of the paraspinal muscles. Electromyography and nerve conduction velocity studies in the extremity, however, cannot locate the site of the lesion between the plexus and mid- thigh. The physical findings and history so typical of herniated nucleus pulposus are not found in patients with sciatic nerve entrapment (see Chapter 75). Unilateral symptoms and signs are rare in patients with spinal stenosis. Unfortunately, many patients with sciatic nerve entrapment are initially treated as if they had a herniated nucleus pulposus.

Treatment. If the diagnosis of piriformis syndrome is confirmed by diagnostic studies and the patient has significant neuropathic signs, the piriformis muscle should be detached from its origin and any fascial bands constricting the nerve should be transected.

Peroneal Nerve Entrapment

The peroneal nerve is a component of the sciatic nerve; it separates from the posterior tibial nerve approximately 8 cm proximal to the popliteal fossa. The peroneal nerve can be compressed as it courses around the fibular head in the upper calf and passes through a fibrous tunnel between the edge of the peroneus longus muscle and the fibula (Fig. 77-9). Trauma is a more common cause of peroneal neuropathy. Other causes include compression from improperly applied plaster casts, tight stockings, bandages, or garters. Peroneal damage can result from certain practices that produce compression and ischemia of the nerve, such as sitting, squatting, or kneeling when picking strawberries or weeding a garden for long periods, which result in compression by the tendon of the posterior part of the peroneus longus at the level of the head of the fibula. The peroneal nerve can also be compressed by various masses, including tumors of the nerve itself or tumors of the bone or ganglia arising from the superior tibiofibular joint.

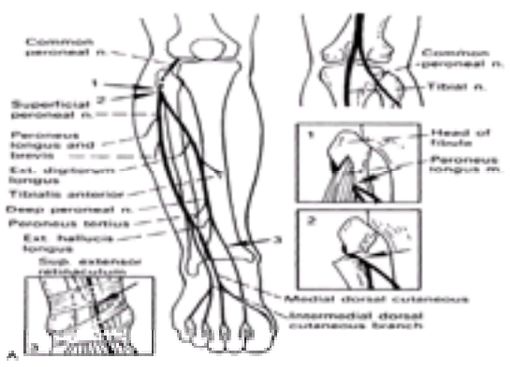

Figure 77-9. Entrapment of the peroneal nerve. **A:** Posterior view of the knee depicting the beginning of the common peroneal nerve as it separates from the tibial nerve and winds around the head of the fibula. **B:** Anterior view of the lower leg showing the common peroneal nerve winding around the head of the fibula and then dividing into superficial and deep branches. Arrows indicate sites of nerve entrapment. Inset 1 shows entrapment as the nerve passes through a fibrous tunnel

between the edge of the peroneus longus muscle and the fibula. Inset 2 shows entrapment caused by fracture of the fibula. Inset 3 shows entrapment of the deep peroneal nerve by the superior extensor retinaculum. (Developed by JJ Bonica and M Domenowske from data in Kopell HP, Thompson WAL. *Peripheral entrapment neuropathies*. Baltimore: Williams & Wilkins, 1963.)

Symptoms and Signs. Entrapment of the peroneal nerve usually presents with a deep, aching pain in the lateral distal knee. Pain can radiate into the foot, especially with pain at the fibular head, and slowly progressive sensory and motor loss is common. The sensory loss can vary from no loss to anesthesia over the lateral calf and dorsolateral surface of the foot. The skin distribution of the peroneal nerve is variable, but hypesthesia is commonly noted in the lateral calf and foot dorsum, including the medial three toes. Weakness of the foot dorsiflexors and everters can be present. Peroneal palsies caused by trauma are usually painless. Electrodiagnostic studies show both motor and sensory changes restricted to the peroneal nerve distribution. If the posterior tibial nerve is spared and both the superficial and deep branches of the peroneal nerve are involved, the lesion is at the fibular head.

Treatment. If entrapment of the peroneal nerve is confirmed, surgical decompression is warranted. Pain can be relieved effectively, and return of peroneal nerve function is commonly seen. Significant peroneal nerve dysfunction mandates a foot brace so that the patient can ambulate effectively.

Entrapment Neuropathies of the Foot (XXX–5)

Three entrapment neuropathies of the nerves of the foot have been well described: The deep peroneal nerve can be compromised in the anterior tarsal tunnel, the posterior tibial nerve can be damaged in the posterior tarsal tunnel (Fig. 77-10), and the interdigital nerves can be damaged by adjacent metatarsal heads (Morton's neuroma). Local anesthetic injections can help to establish the diagnosis; electrodiagnostic studies have not been reported in significant number. Surgical decompression of tarsal tunnel syndrome has been reported to yield good results (38). Morton's neuroma is treated by excision of the common interdigital nerve when conservative measures have failed to relieve the metatarsal pain.

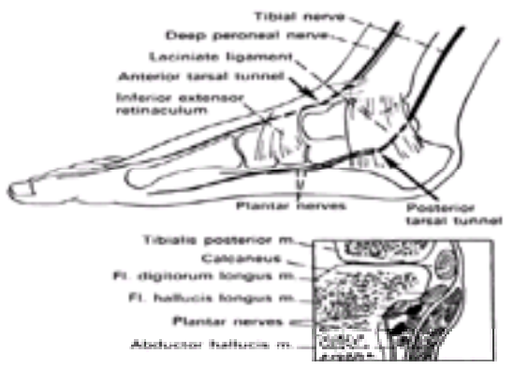

Figure 77-10. Entrapment of the tibial nerve in the posterior tarsal tunnel, which contains the tibial nerve, its posterior tibial artery, and tendons of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus. The syndrome usually has a traumatic basis such as fracture and dislocation of the ankle, but symptoms might not develop until some time after the injury. Nonspecific tenosynovitis or thrombophlebitis can affect other contents of the tarsal tunnel and produce compression of the nerve. The anterior tarsal syndrome is an entrapment of the terminal portion of the deep peroneal nerve as it runs below the dense superficial fascia of the ankle. Inset: Cross-section of the ankle showing the contents of the posterior tarsal tunnel. (Developed by JJ Bonica and M Domenowske from data in Kopell HP, Thompson WAL. *Peripheral entrapment neuropathies*. Baltimore: Williams & Wilkins, 1963.)

Neoplasms

Tumors of the peripheral nerves can present with both local and referred pain and with sensory and motor changes in the distribution of the nerve (45). The typical history is of gradually progressive sensory and motor loss and pain in the region of the tumor. These tumors are usually slow-growing benign lesions, although they can become sarcomatous (46). Ganglion cysts may be found throughout the course of the sciatic nerve, but are most common in the popliteal fossa. They grow slowly and often present with symptoms similar to an entrapment (47). The treatment is surgical excision.

CHAPTER 78

Pain in the Hip

John M. Clark

Many different diseases, either alone or in combination, can cause pain in the region of the hip. Most, but not all, of these diseases are musculoskeletal in origin. Disorders of the lumbosacral spine commonly cause buttock and thigh pain. More rarely, diseases of the urogenital and gastrointestinal systems will present as groin and thigh pain. This chapter covers musculoskeletal conditions other than those originating in the spine (Table 78-1). The purpose is to assist a practitioner confronted with the complaint of hip pain, and for that reason diagnostic features are emphasized. Pediatric hip disease, tumors, and most traumatic conditions are discussed only briefly.

Degenerative arthritis
Nontraumatic necrosis of the femoral head
Septic arthritis/osteomyelitis
Trochanteric bursitis/iliotibial band syndrome
Iliopsoas tendinitis/iliopectineal bursitis
Psoas abscess, tumor, or hematoma
Tear of the acetabular labrum
Painful pubic symphysis
Painful sacroiliac joint
Piriformis syndrome
Stress fractures of the femur and pelvis
Hip pain in pregnancy
Paget's disease

TABLE 78-1. Conditions that cause pain in the hip region

DEFINITIONS OF HIP PAIN

Clinicians and patients use the term “hip pain” differently, and this leads to confusion. Technically, the hip is the synovial joint and the ligaments that give it stability. To the layperson, however, the *hip* is the gluteal region, or buttock. Therefore, many patients who present complaining of hip pain actually suffer from extraarticular conditions, such as sciatica. Once the exact pain pattern is established, the diagnosis may be obvious. Conversely, diseases in the hip joint typically refer pain to the thigh and knee. For these reasons, one should clarify the patient's complaints early in the evaluation process so that further examination and testing can be focused. Use of pain diagrams is particularly helpful in this process.

ANATOMY AND MECHANICS OF THE HIP

The hip is a spherical ball and socket joint that routinely supports loads between three and 10 times the body weight. The joint shape provides a large arc of motion but requires stout ligaments and large, powerful muscles for movement and stabilization.

Muscular Anatomy

Hip muscles are classified by the motion they control (Fig. 78-1, Table 78-2). All of these muscle groups are powerful. The muscles that effect hip abduction are also those that support the pelvis and trunk during one-legged stance. For this reason, deficits in abductor strength cause significant dysfunction. The most important hip flexors are rectus femoris (part of the quadriceps), iliacus, and psoas (Fig. 78-2). The psoas and iliacus converge, forming the large iliopsoas tendon (Fig. 78-3). Complete loss of active flexion, as can occur after a stroke, will usually necessitate the use of crutches for walking. Powerful hip extension is necessary for stair climbing and rising from a chair.

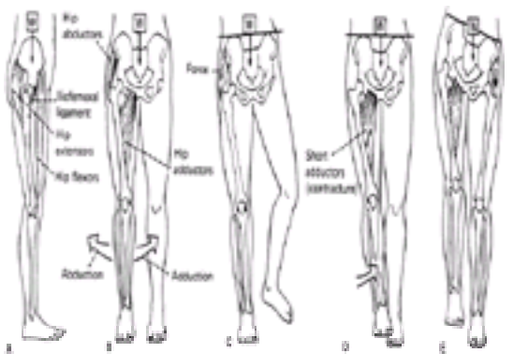

Figure 78-1. Simplified schematic of the pelvis and lower limbs and their relation to the major muscle groups at the hip. **A:** Lateral view showing the flexors and extensors. **B:** Anterior view showing the abductors and adductors. **C:** Abductors of the hip on one side balance the pelvis when the opposite leg is lifted [the force exerted by these muscles; this operates at the hip in addition to the weight of the body (W)]. **D:** Contracture of hip adductors prevents the leg from achieving the neutral (vertical) position in the abduction-adduction plane. **E:** Because walking requires the walking limb to be vertical, an adductor contracture causes the pelvis to be elevated, thus producing a fixed tilt that results in an apparent shortening of the leg. (Modified from Rosse C. The hip region and the lumbosacral plexus. In: Rosse C, Clawson DK, eds. *The musculoskeletal system in health and disease*. Hagerstown, MD: Harper & Row, 1980.)

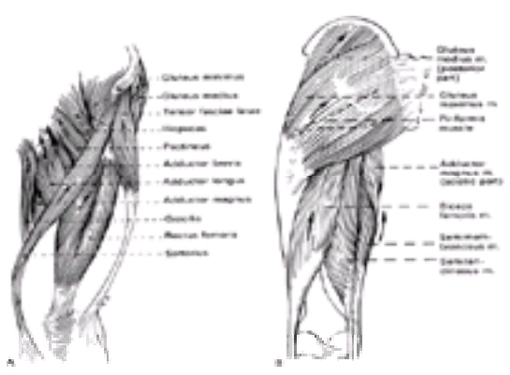

Figure 78-2. Muscles of the hip. **A:** Anterior view showing the flexors and adductors of the hip and extensors of the knee. The iliacus, together with the psoas major, forms a chief flexor. The iliacus originates from the pelvic surface of the ilium and then joins the psoas major, which originates from the last thoracic and all lumbar vertebrae. The common tendon inserts on the lesser trochanter. The rectus femoris, although primarily an extensor of the knee, is an effective hip flexor. The pectineus arises from the pectineal line of the pubis and inserts along the line leading from the lesser trochanter to the linea aspera. The sartorius arises from the anterior superior iliac spine and inserts on the proximal part of the medial surface of the tibia. The abductors also contribute to hip flexion. **B:** Posterior view showing extensors of the hip. The gluteus maximus originates over a wide area of the back of the bony pelvis and inserts into the gluteal tuberosity of the femur. The hamstring muscles, the semimembranosus, the semitendinosus, and the biceps femoris originate in the ischial tuberosity and insert below the knee. Consequently they also act as flexors of the knee joint. (From Hollinshead WH. *Anatomy for surgeons.* Vol 3, The back and limbs. Philadelphia: Harper & Row, 1982, with permission.)

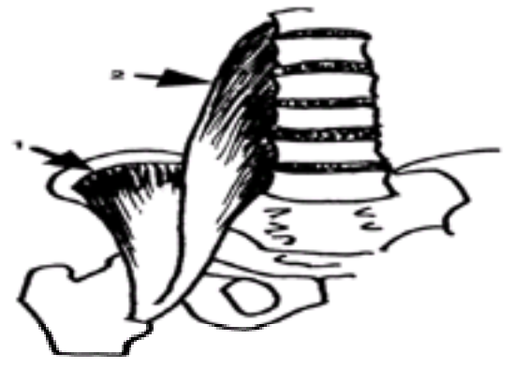

Figure 78-3. Anatomy of the iliacus and psoas muscles and the iliopsoas tendon. The iliacus arises from the entire internal iliac fossa and is joined by the psoas muscles, which arise from the lumbar vertebral bodies. Together they form one large tendon that inserts into the femur at the lesser trochanter. The tendon can snap where it passes over the anterior hip joint or the pubic symphysis (*arrows*). (1, iliacus; 2, psoas.)

Action	Muscles	Innervation	Nerve roots
Abductors	Tensor fascia latae Gluteus minimus and medius	Superior gluteal nerve	L-5–S-1
Extensors	Gluteus maximus Hamstrings	Inferior gluteal nerve Sciatic nerve	L-5–S-1
Flexors	Rectus femoris Iliopsoas	Femoral nerve Segmental nerves	L-2–L-4
Adductors	Adductor magnus Longus and brevis	Obturator nerve Sciatic nerve	L-2–L-4

TABLE 78-2. Major planes of hip motion and muscles controlling them

Capsule

The hip joint capsule is composed of ligaments running from the pelvis to the base of the femoral neck. The most important of these ligaments is the iliofemoral ligament, which is anterior and takes the form of an inverted Y (Fig. 78-4). This ligament normally acts as a passive restraint against hyperextension and permits a person to “lock” the hip in extension. The capsular ligaments spiral medially around the femoral neck as they span between pelvis and femur. For these reasons, the capsule tightens as the hip is extended and internally rotated, effectively reducing the volume of the joint capsule.

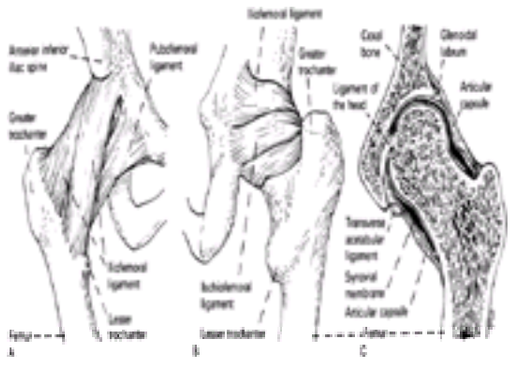

Figure 78-4. Chief ligaments of the capsule of the hip joint. **A:** Anterior view. **B:** Posterior view. **C:** Schematic coronal section through the hip joint showing the synovial membrane, which lines the capsule and covers the femoral head, ligament of the head, and intraarticular fat. (**A** and **B** modified from Clemente CD, ed. *Gray's anatomy of the human body*, 30th Am ed. Philadelphia: Lea & Febiger, 1985; **C** modified from Hollinshead WH. *Anatomy for surgeons.*Vol 3, The back and limbs. Philadelphia: Harper & Row, 1982.)

Skeletal Anatomy

Developmentally, each half of the pelvis is formed from three bones: the ilium, the ischium, and the pubis (Fig. 78-5). These three bones meet at the acetabulum. During growth the bones are separate, and the border between them in the acetabulum is called the *triradiate cartilage*. At approximately 17 years of age, the triradiate cartilage fuses to form a single bone called the *innominate bone*, although the regions of the pelvis are still identified as pubis, ilium, and ischium. Narrow processes of the pubis and ischium, called *rami*, converge anteriorly, forming the obturator ring.

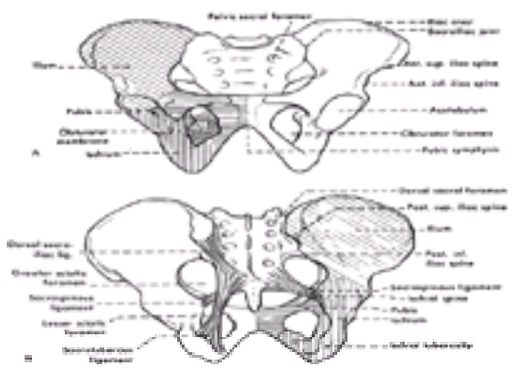

Figure 78-5. The bony pelvis. **A:** Anterior view. **B:** Posterior view. The two hip or coxal bones are separated posteriorly by the sacrum, thus making the pelvic girdle. Each hip bone consists of the ilium, ischium, and pubis, which are shaded differently. The three bones diverge from the acetabulum in different directions, with the winglike ilium projecting upward from the acetabulum. Its iliac crest, palpable along its length, terminates anteriorly in the anterior superior iliac spine and posteriorly in the posterior superior iliac spine. The posterior superior iliac spines are at the level of the S-2 spinous process and indicate the position of the sacroiliac joint, which cannot be palpated. The summit of the iliac crest is at the level of the L-4 spinous process. The ischium projects posteriorly and has two important landmarks, the ischial tuberosity and the ischial spine. Note the sacrospinous and sacrotuberous and other ligaments and the greater and lesser sciatic foramina. The body of the pubic articulates anteriorly with its fellow of the opposite side across the pubic symphysis, which is in the medial plane, while posteriorly the superior ramus fuses with the ischium and ilium in the acetabulum and the inferior ramus fuses with the ramus of the ischium. The two pubic rami embrace the obturator foramen, which is almost completely filled by the obturator membrane. (From Rosse C, Gaddum-Rosse P, eds. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:308, with permission.)

Anteriorly, the two halves of the pelvis are joined by a fibrous joint called the *pubic symphysis*. Posteriorly the iliac wing is attached to the sacrum at an interface called the *sacroiliac joint*. The upper half of the sacroiliac joint is a fibrous joint similar to the pubic symphysis. The lower half contains a synovial space and is a true diarthrodial joint. Under normal circumstances, the pubic symphysis and sacroiliac joint move minimally. Both joints are held together by heavy ligament systems. These ligaments must be altered by disease, trauma, or pregnancy to permit significant displacement.

Surface Anatomy

In most people, the anterior superior iliac spine and the pubic tubercle can be palpated because little subcutaneous fat is deposited anteriorly over these structures, even in obese subjects (Fig. 78-6). The inguinal ligament connects these landmarks, and the center of the hip joint is located at the midpoint between them. The pulse of the femoral artery is palpable 1 cm below the midpoint. The posterior superior iliac spine is usually palpable and can be located by following the iliac crest back from the anterior superior spine. The posterior spine marks the upper extent of the sacroiliac joint—that is, the junction of the sacrum with the ilium. The buttocks are separated by the natal cleft, and the crease forming the inferior limit of each buttock is called the *gluteal fold*. These creases are created by suspensory ligaments between skin and deep fascia, and not by the gluteal musculature. The ischial tuberosity is palpable at the center of the gluteal fold but is more easily felt when the hip is flexed to a right angle.

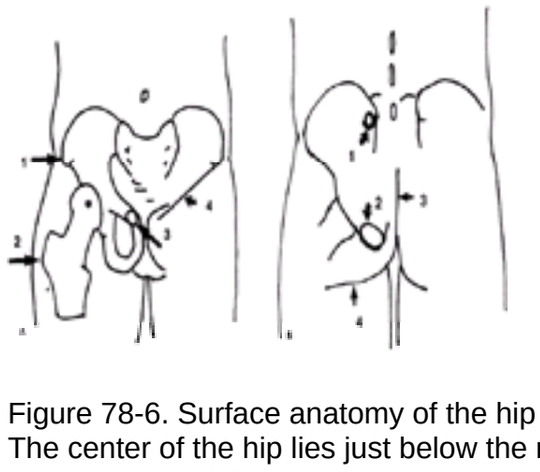

Figure 78-6. Surface anatomy of the hip region. **A:** Anterior view. The iliac crest and the anterior iliac spine (1), and the greater trochanter (2) are usually palpable. The center of the hip lies just below the midpoint of the inguinal ligament (4), connecting the pubic tubercle (3) to the anterior spine. **B:** Posterior view. The posterior superior spine (1) is palpable at the medial aspect of the posterior iliac crest and sometimes is visible as a dimple. This spine marks the upper lateral margin of the sacroiliac joint. The ischial tuberosity (2) is palpable just above the gluteal fold (3) and medial to the natal cleft (4).

Mechanics of the Hip

The center of gravity of the body is located in the sacrum (roughly in the body of the second sacral vertebra) (see Fig. 78-1). When erect, the weight of the upper body passes through the sacrum, across the sacroiliac joint through the ilium, and into the hip joint. Of course, when standing at rest on both feet, body weight is distributed

evenly onto both hips and lower extremities. When a person is walking, running, or climbing, the hip joint is constantly moving, and much of the time the entire body weight is supported by only one extremity. During these periods of one-legged stance, the trunk would tip to the opposite side were the pelvis not fixed by the abductor muscles.

The load on the hip includes both the body weight and the muscle forces. Large muscle forces are required to stabilize and move the hip. The joint load during normal gait or when standing on one foot is 2.8 times the body weight. During running and climbing, this load reaches six times body weight. Because the hip flexor muscles are located close to the axis of rotation, a simple straight-leg raise generates a load of one body weight on the hip. The magnitude of these mechanical forces has an important impact on hip disease and pain patterns.

EXAMINATION OF THE HIP REGION

Examination must be thorough, but is usually simple and logical.

Gait, Posture, and Limps

Normally, when a person stands on one leg, the pelvis on the opposite side tilts up slightly. This can be felt by resting one's index fingers on the iliac crests. If the hip abductor muscles are nonfunctional, the opposite side of the pelvis will drop down. This is called a *positive Trendelenburg sign*, and if the opposite hip and shoulder drop while walking on an affected hip, the result is a *Trendelenburg gait*. Generally, the Trendelenburg sign is not associated with pain.

If the hip hurts, a patient strives to reduce the load on the joint. Because load is greatest when standing on one foot, walking is altered to limit the length of time spent in the stance phase. The result is a hopping pattern, generally known as an *antalgic gait*. The same effect would be caused by a painful knee or a tack in the shoe. Another way to reduce pain is to limit the muscle force required to stand on the hip. This is done by throwing the body center over the affected hip, obviating the need to use the abductor muscles. This pattern is the opposite of the Trendelenburg sign because the opposite side of the pelvis rises up and the trunk tilts to the affected side. This is called an *abductor lurch*, and is specific to the hip joint.

Patients with significant hip or spine symptoms often do not stand erect or cannot lie flat. Atrophy of the thigh and calf can be seen but should be documented by measurement of circumference. The gluteal muscles and buttocks are best examined with the patient standing erect. Because the buttock is formed by fat deposition, the outline of each gluteus maximus must be palpated. All scars must be recorded and explained if possible.

Motion

Normal motion of the hip varies among individuals and with age. Flexion and extension are subtly augmented by motion of the spine. For these reasons, reference guides to normal motion are marginally helpful. The average person should be able to flex one hip to the point that the thigh rests on the chest while the opposite hip is extended fully, keeping the thigh on the examination table. The knee must be flexed because the hamstrings limit hip flexion if the knee is straight. Deficits in extension appear as the angle between the examination table and the thigh when the opposite hip is maximally flexed; this is called the *Thomas test* (Fig. 78-7).

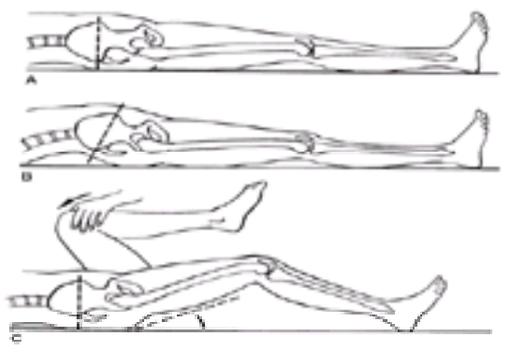

Figure 78-7. Diagnosis of hip flexion contracture using the Thomas test. **A:** The patient lies supine on a hard surface, with the hips and knees extended. If no contracture is present the pelvis remains neutral, with the anterior superior iliac spine lying vertically above the posterior superior iliac spine (*dashed line*). **B:** The patient has a flexion contracture, so the patient must arch the back to keep the legs on the table, thus compensating for the forward tilt of the pelvis. **C:** The Thomas test. To test the right hip, the left thigh is flexed passively until the anterior superior iliac spine lies directly over the posterior superior iliac spine. This places the pelvis in the neutral position and brings the lumbar spine down flat on the table. If a flexion contracture is present the right thigh cannot remain on the table and makes an angle with it that equals the angle of the deformity. (Modified from Rosse C. The hip region and the lumbosacral plexus. In: Rosse C, Clawson DK, eds. *The musculoskeletal system in health and disease*. Hagerstown, MD: Harper & Row, 1980.)

Precise measurements of hip rotation are best done with the subject prone and the hips extended fully and the knees flexed approximately 90 degrees. In this position, the hips can be tested simultaneously, first in maximal internal rotation, then in maximal external rotation. (One knee must be extended slightly to permit one leg to pass the other when testing external rotation.) By this method, asymmetries are apparent, and the angle of motion is clearly visible as the angle between the leg (tibia) and the vertical. When a patient cannot lie prone due to contractures or illness, measurement in the supine position is possible, using the foot axis, rather than the leg, to record the angle of rotation.

Because the spine will move and because the pelvis may tilt while lying, pelvic position must be monitored while testing hip abduction and adduction. One way to accomplish this is to place the thumb and long finger of one hand onto the anterior superior spines while moving the hip with the other hand. This test is best accomplished by asking the subject to abduct and adduct the hip actively. Full adduction or abduction is achieved when the pelvis starts to move.

Particularly at the start of an examination, it is better to ask the patient to demonstrate motion, giving ample time to comply. Guarding of a painful joint cannot be overcome by brute strength. Both hips should be examined, especially because asymmetry may be the best clue to lost movement, masses, or atrophy.

SPECIFIC CONDITIONS

Degenerative Arthritis

Osteoarthritis (OA) (Fig. 78-8) is by far the most common cause of hip pain and dysfunction (1,2 and 3). The incidence and severity of hip arthritis are closely related to age; the incidence increases steeply after the age of 65 years. Approximately 75% of hip replacements are for OA, and the average age at surgery is 70 years. In most cases, the arthritis is idiopathic. Rare heritable disorders of cartilage collagen have now been identified, and afflicted subjects suffer generalized OA as young adults.

Figure 78-8. Degenerative arthritis. This is an example of severe osteoarthritis with lateral migration, joint space destruction, and cysts.

The incidence of hip arthritis is low (1%) in Hong Kong Chinese in comparison with white European populations (7% to 25%). In the knee, obesity is a known risk factor for development of OA, but such a relationship has not been established for the hip. Obesity increases the intensity of pain from hip arthritis, probably because the joint is subjected to proportionately greater loads in heavier people.

Hip OA can complicate trauma or developmental abnormalities that deform the shape of the articular surfaces. Despite appropriate treatment, hip pain is a common sequel of congenital dislocations, slipped femoral epiphysis, and Perthes disease. Late symptoms present any time from the third to sixth decades, depending on the severity of the anatomic anomaly. Oftentimes, patients are unaware of their deformities, and the diagnosis is not made until the painful hip is x-rayed. High-energy trauma, specifically femoral head and neck fractures, acetabular fractures, or fracture dislocations, also leads to secondary OA. Such trauma is rare and the cause is obvious.

The cardinal symptoms of hip OA are pain with use and loss of motion. The pain is most commonly centered in the groin and medial thigh (60% of cases) but can also be in the buttock (17%), the lateral thigh (8%), or the knee (2%). The patient may complain of stiffness and sharp pain early in the day followed by some resolution of these symptoms with activity. The pain returns as the day goes on, depending on the intensity and duration of use. Eventually, arthritic hips cause severe rest pain and sleep disturbance. Stiffness presents in a variety of ways, most commonly as difficulty reaching the foot, crossing the legs, and standing fully erect. In most people, hip arthritis evolves over several years.

The most sensitive physical sign of hip OA is loss of motion. Because a swollen or inflamed hip joint is more comfortable in flexion and external rotation, patients favor that position and gradually lose extension and internal rotation. Forced internal rotation usually elicits pain, even when motion is full. Global stiffness and a limp occur relatively late in the course of the disease. At that point, thigh muscle atrophy will be visible.

The diagnosis of hip OA is confirmed by radiography. The first visible change often occurs in the subchondral plate of the acetabulum. The density of the plate is normally uniform and symmetric in comparison with the opposite hip. Due to pressure concentration in the arthritic hip, the plate will thicken and appear sclerotic in a focal area, usually at the lateral edge of the acetabulum. Osteophytes, joint space narrowing, and lateral migration of the femoral head in the socket also occur early but can be difficult to appreciate. Cysts usually form late, after the loss of articular cartilage. In a rare cystic form of OA, multiple subchondral cysts are observed before loss of joint space and osteophyte formation.

Loss of the joint space due to wear of the articular surfaces is the critical feature of OA. In the hip, this joint narrowing is usually seen at the superior, lateral edge of the joint; this is called a *lateral pattern* because the femoral head migrates laterally. In the somewhat less common central pattern, the head moves medially as the joint space in the center of the hip narrows. When cysts and osteophytes are seen in the absence of joint space narrowing, one should consider a computed tomography (CT) scan to look for narrowing in the posterior aspect of the joint, or evidence of a labral tear anteriorly. Weight-bearing films are not particularly helpful.

At times, the pain of a degenerative hip cannot be differentiated from coexisting radicular low back pain. In this circumstance, diagnostic injection of anesthetic into the hip joint using fluoroscopic guidance is helpful. With bupivacaine, this procedure should ablate any pain originating in the hip joint for at least 4 hours.

The treatment of hip OA depends on severity and the age of the patient. Young patients are best treated symptomatically with antiinflammatory drugs and activity modification. The central intent of the conservative approach is to reduce loads on the damaged joint cartilage. Weight loss can be very effective for the moderately obese. Use of a cane in the opposite hand is the single most useful measure available short of surgery.

Osteotomy—that is, surgical alteration of the bony anatomy around the joint—is sometimes indicated in the treatment of hip OA. In general, this is challenging surgery best suited for relatively young patients in whom definite structural abnormalities are present and the arthritic change is not advanced. For patients older than age 60, hip replacement is a proven treatment for disabling hip OA.

Nontraumatic Necrosis of the Femoral Head

Sometimes a segment of subarticular bone in the femoral head dies (Fig. 78-9) (4,5). The most common known cause of this condition is disruption of blood vessels during fracture of the femoral neck. The bone circulation can also be obstructed by red blood cells in sickle cell anemia and by nitrogen bubbles in decompression illness. High-energy radiation therapy kills the bone directly. The precise mechanism leading to bone necrosis has not been identified in some circumstances. Most of these idiopathic cases are associated with corticosteroid treatment (60%) or alcohol abuse (20%). Patients with hyperlipidemia, diabetes, hyperuricemia, liver disease, vasculitis, and Cushing's disease are at risk as well, but this group represents only a small fraction of idiopathic cases. In some cases no risk factor can be identified. Because the etiology is variable and often unclear, this disease is now referred to as *osteonecrosis* (ON), but the term *avascular necrosis* is still in use.

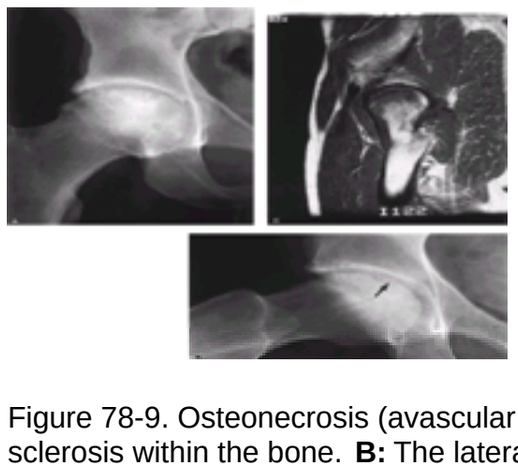

Figure 78-9. Osteonecrosis (avascular necrosis) of the right hip. **A:** The anteroposterior radiograph shows collapse of the femoral head as well as typical cysts and sclerosis within the bone. **B:** The lateral view demonstrates the anterior location of the lesion and a “crescent sign” (*arrow*), caused by fragmentation of the dead subarticular bone. **C:** On magnetic resonance imaging, the low signal in the femoral head is caused by displacement of normal marrow fat. The subarticular fracture is seen as a dark black line.

ON is a particular problem after renal transplantation—it has been reported in 29% of cases. The incidence is related to the total dose of oral corticosteroid given and perhaps for that reason is less common with heart and liver transplant. The precise relationship between steroid dose and incidence is currently unknown.

Idiopathic ON can cause pain in two ways. If the affected area of bone is large enough, it will fracture before it has healed. The fracture usually leads to collapse of

the articular surface and mechanical dysfunction of the hip joint. The symptoms of collapse are similar to severe OA. Occasionally, fragments of loose cartilage or dead bone will cause catching or locking symptoms. Deep, aching rest pain is sometimes present before fracture and collapse. For reasons that are poorly understood, marrow pressure is often elevated in the early stages of the disease. The rest pain is thought to be a symptom of this increased intraosseous pressure.

Diagnosis of ON is relatively straightforward when fracture or collapse has occurred because these conditions are apparent on simple radiographs. Usually, a wedge-shaped area of the superior femoral head is sclerotic or cystic. Before collapse, a thin rim of subchondral bone may fracture free from the head, creating a *crescent sign*. A collapsed segment and the crescent sign are often better seen on a frog-leg lateral view of the hip because the lesions are located anteriorly on the femoral head.

In the absence of visible collapse or fracture, ON lesions may appear as osteopenic or sclerotic areas on radiographs. Often, however, the radiograph is normal. In this circumstance, bone scans can be helpful, but are nonspecific. At present, magnetic resonance imaging (MRI) is the most sensitive method for confirming the diagnosis of ON. The necrotic segment of the femoral head appears as a dark area due to displacement of the normal marrow fat. The area of abnormality will be larger early in the course of the disease, probably because of edema in the surrounding living bone.

The time course of the MRI changes after renal transplants suggests that most cases of ON do not progress to fracture or collapse. In one study, 29% of transplant patients exhibited changes, but only 6% required hip replacement (6). The lesions probably stabilize within a year after the initial corticosteroid exposure.

For purposes of determining prognosis, staging systems based on radiographs and bone scans have now given way to simpler systems based on MRI scans. The risk of segmental collapse and subsequent destruction of the hip joint depends on the size and location of the lesion. Lesions that occupy more than approximately 25% of the head have a poor prognosis, especially if located in the classic superior-lateral position in the weight-bearing region. Lesions of 20% or less demonstrate a remarkably good prognosis, despite ongoing steroid exposure. In some cases, the symptoms and MRI changes resolve completely. When coupled with pain and visible osteopenia, this syndrome has been called *transient osteoporosis*.

No one knows the precise relationship between corticosteroid (or alcohol) exposure and ON. Apparently, the patients at greatest risk are those who receive large doses of oral steroids for immunosuppression or for treatment of diseases such as asthma or polymyalgia rheumatica. Some investigators believe that the presence of a vasculitis, as in systemic lupus erythematosus, is a critical risk factor. Because ON is relatively rare, MRI cannot be used as a screening test, especially as a substitute for radiography. The primary indication for MRI would be hip pain in a patient with a clear risk factor such as sickle cell anemia, exposure to steroids, chronic alcoholism, lupus, local radiation treatment, and so forth who does not have a clear-cut diagnosis after radiologic study.

The pain of ON can sometimes be relieved temporarily by *core decompression*, a surgical procedure in which a drill is passed into the femoral head. This procedure is still done with the hope that it might improve the prognosis of the disease. Unfortunately, the effectiveness of decompression has not been confirmed by prospective studies that also consider the size of the lesion (7).

Currently, the most promising therapy for larger lesions is placement of impacted bone graft and a vascularized fibular strut into the lesion. Lipid-clearing agents and biphosphonates may play a role in prophylaxis against collapse, but strong clinical evidence for a pharmacologic approach is absent.

Trochanteric Bursitis (Iliotibial Band Syndrome)

The lateral thigh is enclosed by a sheet of specialized fascia extending from the iliac crest to the lateral tibial plateau. The fascia is known as the *iliotibial band* or the *fascia lata*. Where it runs over the greater trochanter the fascia is separated from the bone by a large bursa. Both the gluteus maximus and the tensor fascia latae insert into the fascia lata and exert great tensile forces there during gait. Therefore, pressure between the fascia and underlying bone can be great.

Inflammation of the greater trochanteric bursa (trochanteric bursitis) is a common cause of pain in the hip region, and the pain can be surprisingly severe (8,9). Afflicted patients usually cannot lie on the affected side or sit comfortably due to tenderness. Usually, this tenderness is accompanied by pain with activity. The pain may be local, directly over the trochanter, but often radiates along the entire course of the fascia. Some subjects will complain of pain in the iliac crest, and others will experience pain to the knee. The tight iliotibial band may also snap over bony prominences at the knee.

The common feature of trochanteric bursitis is tenderness over the bursa itself. Anatomically, the bursa covers the posterior half of the greater trochanter, and the tenderness is localized there. Sometimes, patients will have a contracture of the fascia lata. In this circumstance, adduction is restricted when the hip is fully extended. The Ober test for this contracture is performed with the subject lying with the affected side up. The hip is passively extended and abducted, then adducted while held in extension. This maneuver brings the iliotibial band into line with the greater trochanter, where it will restrict adduction if tight. When the hip is then permitted to flex, a tight band will often snap as it slips anteriorly off of the trochanter.

When the pelvis tilts, the fascia lata is stretched tightly over the trochanter on the higher side. Therefore, trochanteric bursitis can be caused by a long limb or by weakness of the abductor muscles (which allows the pelvis to drop on the opposite side) or even by walking in a cast. For this reason, the examination should include a test for abductor strength and leg length.

Trochanteric bursitis and a contracture of the iliotibial band often accompany other conditions such as degenerative arthritis of the hip or a lumbosacral radiculopathy. Whenever the diagnosis is unclear, injection of the bursa with local anesthetic is helpful. The injection usually can be performed in clinic with a 1.5-inch needle and should immediately relieve the symptoms of bursitis. MRI can demonstrate enlargement of the bursa, but this test is probably not necessary unless other coexisting conditions are suspected.

The primary treatment of trochanteric bursitis is correction of all inciting causes. Physical therapy can strengthen the abductor muscles and stretch the fascia/iliotibial band and should also include passive modalities such as ultrasound and local heat. A shoe lift under the short limb can help immediately. Corticosteroid injection is effective when physical therapy fails to eradicate the symptoms. Surgical lengthening of the iliotibial band or excision of the bursa may be indicated in the most resistant cases.

Neuralgia of the Lateral Femoral Cutaneous Nerve (Meralgia Paresthetica)

The lateral femoral cutaneous nerve arises from the lumbosacral plexus and follows a retroperitoneal course over the iliacus muscle before entering the thigh. The nerve exits the pelvis by passing under or through the attachment of the inguinal ligament on the medial aspect of the anterior superior iliac spine and is subject to injury at this exit point.

The symptoms of injury to the lateral cutaneous nerve are numbness, hyperesthesia, and dysesthesias in the distribution of the nerve. The surgical options include transection and decompression, with transection providing more reliable relief (10,11 and 12). Tumors within the iliacus and psoas can present as meralgia paresthetica, but are rare. They should be considered when symptoms are persistent, however. The condition is discussed in greater detail in Chapter 77.

Space-Occupying Lesions of the Iliopsoas Compartment

The iliopsoas compartment contains the iliacus, psoas major and psoas minor muscles, as well as the femoral and lateral femoral cutaneous nerves. Hematomas, abscesses, and malignancies within this compartment cause lower abdominal pain and hip pain (13,14,15 and 16). The hip pain will present as irritation of the iliopsoas—that is, pain with passive extension and active flexion. Dysfunction of the femoral nerve may also be present.

Abscesses within the iliacus and psoas muscles can be caused by direct extension from infections of the spine or peritoneal cavity. This is a recognized complication of Crohn's disease and appendicitis, and right-sided abscesses are more common because the cecum overlies the right iliacus muscle. Pyomyositis of the iliacus may develop without an obvious local source, however. The abscess can track along the iliopsoas tendon into the perirectal space and medial thigh, where it is visible as a mass effacing the gluteal fold. Due to communication among the iliopectineal bursa, the iliopsoas tendon sheath, and the hip joint, an iliopsoas abscess and septic hip can coexist.

Hematomas have been described in patients with bleeding disorders or anticoagulation and with athletic injuries. The most devastating consequence of a large

hematoma is irreversible femoral neuropathy.

Diagnosis depends largely on a thorough history and awareness of a risk of retroperitoneal abscesses or poor coagulation. MRI and CT greatly facilitate recognition of these conditions but cannot differentiate among them. CT-guided aspiration or biopsy of this region is now technically straightforward. Treatment, of course, depends on the underlying problem.

Hip Pain in Pregnancy

Pain in the region of the hip may develop late during pregnancy (17,18). Due to increased body weight and the general relaxation of ligaments supporting the pelvis, the sacroiliac joints and pubic symphysis can become unstable. Although painful, these conditions are benign and usually reverse in the months after delivery. The symptoms are pain in the joints themselves and a sensation of movement where before there was none. The corsets used to treat low back pain in pregnancy are sometimes helpful.

Transient osteoporosis is a rare cause of groin or anterior thigh pain that typically appears in the third trimester of pregnancy. The patients tend to be older, first-time mothers. The condition derives its name from the loss of bone density seen on radiographs of the hips and spine. The precise etiology of the bone loss in unknown, although some subjects have preexisting risks for osteoporosis. One or both hips can be painful; for some reason, the left hip is preferentially involved.

The hip pain increases with time and may require use of crutches. The femoral neck can fracture spontaneously in this disease, although the incidence of this complication is unknown and evidently small. MRI is probably the optimal method of diagnosis. The changes are those of nonspecific marrow edema and could be confused with osteonecrosis.

Painful Symphysis Pubis

Chronic inflammation of the pubic symphysis occurs spontaneously, during pregnancy, after trauma, or after urogenital surgery (19). The precise etiology of the condition is often unknown and probably varies. Like sacroiliiitis, it can be a manifestation of a systemic inflammatory illness, specifically ankylosing spondylitis. Cases of idiopathic inflammation are sometimes called*osteitis pubis*(Fig. 78-10). Some cases are clearly related to instability caused by trauma or pregnancy. Runners and other athletes develop the condition from overuse. Some cases clearly are infectious, although the incidence of this is thought to be low. Inflammation of the symphysis is clearly related to surgical procedures that violate the joint, such as bladder suspension and placement of a suprapubic catheter.

Figure 78-10. Osteitis pubis. **A:** This is a typical case showing cysts, sclerosis, and irregularity of the joint margins. **B:** A case of septic arthritis after placement of a suprapubic catheter. The joint and adjacent bone are eroded.

Pain in the pubic symphysis presents as medial groin pain radiating down the medial thigh on one or both sides. The pain is activity related and can be severe. The abdominal muscles and hip adductor muscles attach to the pubic symphysis; thus, pain can be elicited by use of these muscles. The symphysis is tender to palpation and, when unstable, can be felt to move slightly or click when stressed.

Lysis and sclerosis of the bone adjacent to the symphysis appear on radiographs within weeks of the onset of symptoms. In the presence of a suggestive history and examination, these findings are diagnostic. When symptoms persist despite rest and antiinflammatory drugs, biopsy or suppressive treatment for osteomyelitis may be considered. Refractory cases have responded to excision of the symphysis, but this is a rarely performed operation.

Painful Sacroiliac Joint

The sacroiliac joint is subject to degenerative arthritis, chronic inflammatory disease, and traumatic instability (Fig. 78-11) (20). Sacroiliitis is a feature of ankylosing spondylitis and other systemic inflammatory conditions associated with the HLA-B27 antigen. The joint may also develop an isolated inflammatory disease called *osteitis condensans ilium*. This unusual condition is named for the x-ray appearance of sclerosis in the adjacent iliac crest.

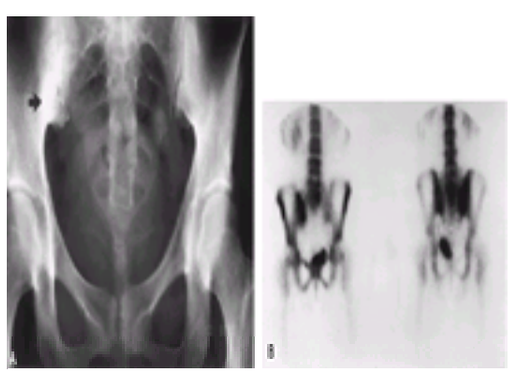

Figure 78-11. Osteoarthritis of the sacroiliac joint. **A:** The right sacroiliac joint (*arrow*) appears irregular due to formation of large cysts in the adjacent ilium. **B:** This technetium bone scan demonstrates increased uptake on both sides of the right joint.

Mechanical dysfunction of the joint, as occurs during pregnancy, is difficult to distinguish from low back pain. Primary degenerative arthritis of the sacroiliac joint is rare and usually the result of major pelvic trauma. Years ago, fusion of the joint was a common treatment for low back pain, but the incidence of this procedure declined as the mechanisms of radicular spinal disease were recognized. Now, fusion is recommended only after the more common causes of medial buttock pain are excluded.

Mechanical pain in the sacroiliac joint can be reproduced with Patrick's test, in which the hip is forced into external rotation by placing the ankle on the opposite thigh and pushing down on the knee. A positive test produces pain in the joint. The x-ray appearance of the sacroiliac joints is sometimes difficult to interpret because normal joints can be irregular and asymmetric. Bone scans will show increased bone turnover around arthritic joints. Currently, the most definitive test for pain originating in the sacroiliac joint is local anesthetic block. The presentation of infection in the sacroiliac joint is discussed in the next section.

Septic Arthritis/Osteomyelitis

Any joint or bone can become infected. Usually, organisms are carried into the synovial space and bone through the bloodstream or by a foreign object entering the joint. For example, the hip can be violated during attempts to catheterize the femoral artery or vein. Rarely, osteomyelitis of an adjacent bone will break through into a joint. After the knee, the hip is the second most common site of joint infection.

The risk factors for septic arthritis (Fig. 78-12) and osteomyelitis include advanced age, skin infections, intravenous drug abuse, surgery (joint replacement), and immunosuppression (14,21,22,23 and 24). Patients with inflammatory arthritis are particularly susceptible to the complications of joint sepsis because their arthritic joints contain excessive fluid and avascular debris and because they often are immunosuppressed. Gonococcal arthritis of the hip is rare.

Figure 78-12. Septic arthritis. **A:** The radiograph shows complete loss of the joint space and some irregularity of the femoral head. **B:** The bone scan (posteroanterior view) shows markedly increased uptake of technetium on both sides of the joint.

In immunocompetent patients, septic arthritis of the hip causes severe pain, particularly with motion. To reduce intracapsular pressure, the hip will characteristically be held in a flexed, externally rotated position. Sepsis of the sacroiliac joint in adults is usually apparent as tender, erythematous swelling posteriorly over the joint. The presentation of infection in the pubic symphysis is discussed under the heading Painful Pubic Symphysis. Septic arthritis of the hip is an emergency. The infection flourishes in the avascular environment of the joint space and will rapidly destroy the articular surfaces unless the joint is drained surgically. In contrast to most other joints, surgical drainage is usually the preferred option for treatment of hip infections because infections there do not reliably respond to aspiration alone and because the vascularity of the femoral head is endangered by intracapsular pressure elevation.

In general, infection should be considered in any adult with spontaneous, acute hip pain, but especially in those with specific risks. Often, systemic symptoms of infection are present, and the peripheral white cell count, erythrocyte sedimentation rate, and C-reactive protein level are elevated. The definitive diagnostic test for a septic joint is aspiration, with examination of the fluid for white cells and organisms. Bone scan and MRI will demonstrate abscesses in bone, and the diagnosis is made by biopsy. Aspiration of the hip and sacroiliac joints is difficult and benefits from radiographic control of needle placement. If fluid cannot be withdrawn, arthrography or irrigation is needed to ensure that the needle is in the joint space.

Tears of the Acetabular Labrum

With the advent of hip arthroscopy and MRI, pathology of the fibrocartilaginous labrum has been identified as a cause of hip pain and snapping (25,26,27 and 28). Symptomatic tears of the labrum can occur during traumatic dislocations of the hip, but most cases of hip pain ascribed to the labrum are spontaneous or related to relatively modest twisting injuries. The pain usually is located anteriorly. More than half of the time, a click is described, with associated pain radiating toward the knee.

On examination, pain and a clunk can be evoked by passive extension and internal rotation from a flexed, abducted position. This maneuver helps distinguish a torn labrum from a snapping iliopsoas tendon. A minority of patients will have an extension deficit. The current choices for diagnosis are CT-arthrography or MRI-arthrography. Because asymptomatic individuals can have MRI abnormalities of the labrum, false-positive scans will occur. Arthroscopy of the hip is now used for diagnosis and treatment of loose bodies in the hip, and labral tears have been effectively treated by this technique.

Stress Fractures

Stress fractures (Fig. 78-13 and Fig. 78-14) occur in the absence of overt trauma and are caused by fatigue of the bone during a repetitive or unusually strenuous activity (29,30 and 31). A classic example of this is the “march fracture” of the metatarsal in new military recruits. Poor bone quality is now recognized as an important risk factor. For example, stress fractures occur in amenorrheic female athletes due to their diminished bone density. Stress fractures are classified as incomplete, complete but nondisplaced, and displaced. Especially because incomplete fractures are often invisible on radiographs, these injuries can be difficult to recognize.

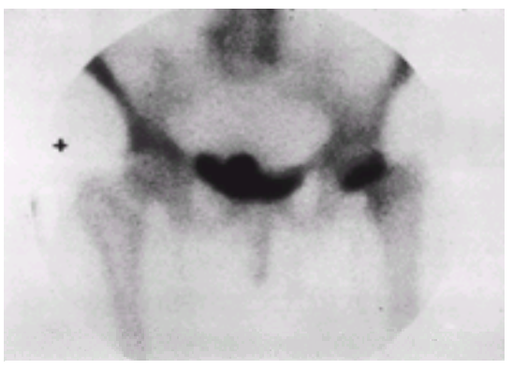

Figure 78-13. Osteoporotic stress fracture. Bone scan of a 72-year-old woman with normal hip radiographs and left groin pain. The scan reveals increased uptake of technetium in the left femur, evidence of a stress fracture at the junction of head and neck (+, right).

Figure 78-14. Overuse stress fracture in a 27-year-old runner. **A:** The radiographs shows sclerosis and widening of the cortex of the medial femoral neck (*arrow*). **B:**

On bone scan, the area immediately adjacent to the fracture has the greatest uptake of tracer, but the entire femoral neck is abnormal. **C:** Magnetic resonance imaging is useful because the exact location of the injury is delineated and other possible conditions, such as tumor, infection, and bursitis, are eliminated.

Stress fractures of the proximal femur generally occur in two groups: runners and the osteoporotic elderly. The most common site is the femoral neck. Early recognition of these injuries is important because the prognosis for uneventful healing is far better when the fracture has not displaced.

Femoral stress fractures in running athletes are rare but due to the serious nature of the injury should be considered in any athlete who spontaneously develops pain in the hip region. The symptoms are pain with weight bearing, stiffness, and a limp. Patients may complain of a “groin muscle pull” because the pain commonly radiates down the medial thigh.

The incidence of stress fractures of the femur in the elderly is unclear because fractures of the osteoporotic hip can occur with minimal trauma. One study has suggested that some patients fall because the femoral neck fractures spontaneously and many of these events are preceded by pain (32). In any case, elderly people sometimes can walk on a nondisplaced hip fracture, and these fractures often are not apparent on x-ray. As in the younger runner, the cardinal symptom is pain with activity.

The physical diagnosis of proximal femoral stress fractures is difficult because the severity of symptoms is related to the inherent stability of the fracture. Minimally displaced or incomplete fractures may be painful only when standing. Usually, straight-leg raising is painful or impossible. Most femoral stress fractures are located within the capsule of the hip joint and will cause pain when the hip is forcefully rotated internally.

The pubic and ischial rami also may fracture spontaneously or with minimal trauma, such as kicking or a fall onto the side. In athletes, the injury can be confused with a groin muscle strain because the adductor muscles originate on the obturator ring.

The first diagnostic test should be high-quality radiographs. With time, the fracture lines become visible due to subtle resorption or callus formation. Fractures of the femoral neck often cannot be seen on oblique views. To place the femoral neck parallel to the plane of the film, the anteroposterior view must be made, with the hip internally rotated 15 degrees (toes touching). Because this can be painful, films often do not meet this standard.

In the presence of normal, inadequate, or equivocal films, a bone scan or MRI is needed to confirm or rule out a fracture. MRI is the most accurate study available, but it is relatively expensive. Bone scans are not reliable in the first 24 to 48 hours after fracture and can give false-positive readings when periarticular inflammation is present.

Stress fracture should be considered in all cases of acute, activity-related hip pain. Association with a period of increased physical activity, suspected or documented osteopenia, incidental trauma, or a past history of stress fractures should lower the threshold for obtaining an MRI scan. All of these patients should cease painful activities and possibly use crutches until the diagnosis is clarified.

Iliopsoas Tendinitis/Iliopectineal Bursitis/Snapping Iliopsoas Tendon

The iliopsoas tendon passes anteriorly over the hip joint and the pubic ramus. In that region, the tendon is surrounded by a synovial sheath and separated from the bone and capsule by a bursa. The bursa is sometimes called the *iliopectineal bursa*. Pain in the groin has been attributed to inflammation of both the iliopsoas tendon sheath and the iliopectineal bursa (33, 34 and 35). These conditions are rare, and anatomic differentiation between them is difficult.

The iliopectineal bursa enlarges when inflamed (Fig. 78-15). Enlargement has been observed in rheumatoid arthritis and septic arthritis. An enlarged bursa can be palpated and has been observed to occlude the femoral vein. Because the bursa sometimes communicates with the hip joint synovial space, diseases of the hip can present as iliopectineal bursitis.

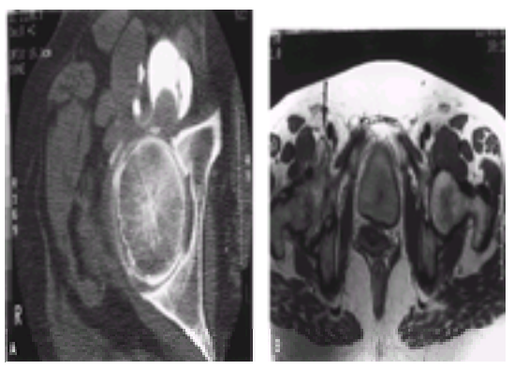

Figure 78-15. Iliopectineal bursitis/iliopsoas tendinitis. **A:** This computed tomography arthrogram demonstrates communication between the hip joint and an anterior bursa (*arrow*). The bursa surrounds the psoas tendon. **B:** On a magnetic resonance imaging scan the bursa appears as a mass extending anteriorly beneath the femoral artery. Such a mass (*arrow*) can be palpated and may compress the femoral vein.

Tendinitis of the iliopsoas tendon is also associated with a fluid collection over the anterior aspect of the hip. This tendinitis occurs in running or kicking athletes and causes groin pain with active flexion.

One form of iliopsoas tendinitis is associated with painful snapping. The assumed mechanism is snapping of the tendon over the iliopectineal eminence, a prominence on the pubic ramus (see Fig. 78-3). Unlike snapping of the iliotibial band over the trochanter, this snap is felt deep in the groin. It occurs with stretch or contraction of the iliopsoas, but a discrete evocative maneuver has not been elucidated.

Diagnosis of abnormalities of the iliopsoas appear as peritendinous or intratendinous fluid on MRI scans of the hip. No one knows how often such changes are present in asymptomatic patients. Because of potential communication with the hip synovial space, hip pathology should be excluded by plane films. Abnormal lateral excursion of the iliopsoas tendon can be seen under fluoroscopy when contrast is injected into the tendon sheath. Ultrasound is used to identify the fluid collection and abnormal tendon motion.

Piriformis Syndrome

As it exits the pelvis, the sciatic nerve passes under or through the belly of the piriformis muscle. Some clinicians have attributed a specific form of sciatica to entrapment of the nerve by the muscle (36). In this syndrome, sciatica and deep pain in the buttock are elicited by positions or activities that stretch the piriformis muscle. Specifically, flexion, adduction, and internal rotation of the hip or flexion and abduction against resistance are used as evocative maneuvers. Case reports have described electromyographic and MRI abnormalities. Some patients respond to stretching exercises, and surgical release of the tendon is sometimes recommended.

The prevalence of piriformis syndrome is unknown. To date, nerve compression by the piriformis muscle has not been reliably verified by anatomic studies.

Paget's Disease of Bone

Paget's disease causes progressive, sometimes painful deformities of bone (Fig. 78-16) (37). The etiology is unclear, although a viral origin is suspected. The disease is focal and axial, affecting the skull, spine, femur, and tibia preferentially. Within the affected areas, bone turnover and blood flow are elevated. Prevalence of the disease in the United States is estimated at 3%, but not all of these subjects are symptomatic.

Figure 78-16. Paget's disease of the right hemipelvis. Enlargement of the bone and coarse, distorted trabecular patterns are typical of the disease. The hip joint is severely arthritic due to deformation of the acetabulum.

Paget's disease can cause aching pain in the region of the diseased bone or bones. Complications of the disease are also painful and require specific attention. When Paget's disease deforms the pelvis, the hip joint can become severely arthritic. Stress fractures occur in affected bones, particularly in the upper femur. A small proportion of long-standing cases will undergo sarcomatous degeneration.

The diagnosis is usually made from radiographs. After an early osteolytic phase, the characteristic bony changes of thickened trabeculae and generalized hypertrophy are readily visible. Serum alkaline phosphatase and urinary hydroxyproline levels are elevated. Hip arthritis, fractures, and tumors should be considered whenever the pain of Paget's disease is severe or changing. Fractures and arthritis are usually visible on directed x-rays. Sarcomas can be difficult to see in badly diseased bones, but rapid changes in appearance, cortical erosions, and soft tissue invasion should arouse suspicion.

Tumors

Primary tumors are a rare cause of hip pain. Symptoms depend on size and location. Tumors should be considered especially when the pain is chronic or when rest or night pain is predominant (38). The majority of malignant bony tumors are metastatic and therefore are more common in older patients.

Pigmented villonodular synovitis (Fig. 78-17) and synovial chondromatosis are aggressive but benign synovial tumors. Both conditions are rare and will destroy the hip over time. The major symptom is hip pain with use, and restricted motion worsening as the tumor grows. Chondromatosis can be recognized on radiographs due to the presence of calcifications in the periarticular soft tissues. Pigmented villonodular synovitis is best seen on MRI, where the presence of iron creates a characteristic stippling of the tissue.

Figure 78-17. Pigmented villonodular synovitis. This synovial tumor was not apparent on radiographs but is seen here as a synovial mass on magnetic resonance imaging scan. Anteriorly, the mass, which has dark stippling, displaces the joint capsule (*arrow*).

CHILDREN

Hip pain in children is often the associated with serious and acute conditions requiring immediate specialty care. The spectrum of causes and presentation are different from adults. Each of the diseases causing pediatric hip pain is complex, controversial, and subject to swift changes in the approach to diagnosis and therapy (39). For these reasons, the following discussion is relatively brief.

Infections

Osteomyelitis and septic arthritis (of the hip and sacroiliac joints) are more common in children than in adults. Unlike in adults, septic arthritis of the hip and sacroiliac joints often occurs in the absence of an identifiable source or associated disease process. Risk is greatest in the first 6 years of life. The mechanism is believed to be hematogenous seeding. Similarly, osteomyelitis is usually caused by blood- borne organisms. The end vessels penetrating growth plates seem to trap organisms, especially after nondisplaced fractures. Perhaps for this reason, the onset of pain is often traced to an injury, and infection is sometimes discounted for that reason. Osteomyelitis and septic arthritis of the hip can coexist because the bone infection can penetrate this joint.

Depending on the age of the child, a limp or refusal to move the hip may be the only sign of infection. Hip pain frequently refers to the knee in children. Except for the limp, the examination in osteomyelitis may be benign. Infections of the hip joint cause escalating pain on motion, and the child holds the hip in flexion/external rotation. Warmth, tenderness, and a mass over the sacroiliac joint usually accompany infections there. Laboratory tests are essential for diagnosis. Sedimentation rate, c-reactive protein, and white cell count are usually abnormal, and radiographs are not. As in the adult, successful aspiration of the joint is necessary when septic arthritis is suspected. Inability to obtain fluid is not equivalent to a negative aspiration, and confirmation of needle placement is necessary in that circumstance. Bone scan and MRI will locate osteomyelitic areas.

As in adults, the treatment is timely surgical drainage of a septic hip. Antibiotic therapy is sometimes adequate for osteomyelitis and sepsis of the sacroiliac joint.

Toxic or Transient Synovitis

Toxic or transient synovitis is a benign, acute inflammatory condition afflicting the hip in younger children. The presentation is identical to septic arthritis. The child may have recently recovered from the flu. Generally, the sedimentation rate is moderately elevated. Aspiration reveals sterile fluid with lymphocytes rather than polymorphonuclear white cells. Treatment is rest and observation.

Fractures

Until growth ceases, fractures through the growth plates are possible. The most commonly involved sites are the proximal femoral epiphysis, the anterior inferior iliac spine, and the ischial tuberosity. Slip of the proximal femoral epiphysis is the most serious of these conditions. Although this is a fracture, the injury usually cannot be traced to a specific traumatic event. The known risk factors are male sex, obesity, rapid growth, and collagen abnormalities, specifically Marfan's disease. The peak age range is 11 to 14 years. Injury to the proximal epiphysis must be considered in any older child or growing young adult with a limp and irritable hip. Limited internal rotation is the cardinal physical sign, and laboratory studies will be normal. Diagnosis can be made from carefully positioned anteroposterior and frog lateral radiographs, in which the femoral head is displaced posteriorly and inferiorly. Because the disease can be silent and bilateral, symmetric abnormalities are possible. Treatment of a slip is usually surgical pinning.

Avulsions of the ischial tuberosity and anterior inferior spine are traumatic injuries usually incurred in sports. The inferior spine is the origin of the rectus femoris muscle, and forceful hip flexion can pull the spine off. Similarly, the ischial tuberosity is the origin of the hamstrings, and forceful extension, such as blocking in football, is the primary mechanism for injury. Pain during resisted hip flexion or extension is the key physical finding and presenting complaint. The radiograph will show separation of the ossified muscle origin. Because these injuries are sometimes chronic, the radiograph may reveal apparent enlargement of the spine or tuberosity, leading to concern about infection or tumor. Usually, careful history and a typical appearance are sufficient to clarify the diagnosis.

Perthes Disease

Perthes disease is a relatively rare condition unique to children and most common in boys aged 4 to 10. Although unproved, the commonly accepted etiology is vascular insufficiency leading to softening, fragmentation, overgrowth, and deformity of the femoral head. As in most other acute conditions, the symptoms may be a limp, knee pain, or painfully restricted motion of the hip. Enough cases are preceded remotely by an episode of toxic synovitis that a causal relationship is suspected. The presentation of Perthes disease usually is not acutely painful. The diagnosis is made when characteristic abnormalities of the femoral head are seen on radiographs. The prognosis of the condition is determined by the radiographic size and location of the affected lesion as well as the age of the child. Treatment options are numerous and vary with severity of the deformity.

CHAPTER 79

Painful Disorders of the Thigh and Knee

Michael H. Metcalf and Roger V. Larson

The thigh and the knee joint provide an enormous amount of function. The bony architecture, combined with the surrounding soft tissue envelope, allows stability in three planes while maintaining a stable, weight-bearing platform. Essential to the changing motions and forces around the knee are the muscles of the thigh and soft tissues such as the capsule, ligaments, menisci, and articular cartilage. These provide the shock-absorbing and restraining qualities that keep the bony architecture in proper alignment.

Everyday actions of walking, climbing stairs, and raising from a chair, as well as athletic tasks of jumping, running, and side-to-side motion, depend on the integrity of this vital area. Any disease process or trauma to the bones or soft tissue envelope can significantly impair the ability to perform basic tasks. The thigh and knee are most commonly involved in musculoskeletal disorders because they must function under the extremes of physiologic stresses that, over time, result in degenerative changes. In addition, the thigh and knee are frequently involved in traumatic insults from sports participation, vehicular accidents, and falls from height. Infections, inflammation, and primary and metastatic neoplasms can also affect the knee and thigh. All of these conditions may result in chronic pain, suffering, and disability.

Proper diagnosis and treatment of disorders of the knee joint and thigh are essential for a successful return to full function. Proper diagnosis requires a thorough knowledge of the anatomy and biomechanics of all of the structures, as well as the pathophysiology and mechanism of injury and disease.

This chapter is divided into four major sections: Basic Considerations, including a classification of painful disorders and a discussion of the anatomy, biomechanics, and function of these structures; Clinical Evaluation of the Patient; Painful Disorders of the Thigh; and Painful Disorders of the Knee. More detailed information can be found elsewhere (1,2,3,4,5,6,7,8 and 9).

BASIC CONSIDERATIONS

Classification of Disorders

Almost all conditions causing pain around the thigh and knee result from traumatic, degenerative, vascular, congenital/developmental, neoplastic, or infectious processes. Table 79-1 and Table 79-2 classify various painful conditions of the thigh and knee primarily according to cause and pathophysiology. Pains caused by peripheral vascular diseases, neurologic disorders, reflex sympathetic dystrophy, and myofascial syndromes are discussed elsewhere. The remainder of those conditions listed in Table 79-1 and Table 79-2 are discussed in the last two sections of this chapter.

Type of disorder	Examples
Traumatic	Fracture; rupture of the quadratus femoris; muscle contusion; reflex muscle spasm; myofascial pain syndromes
Infectious	Acute osteomyelitis; chronic osteomyelitis; other bone infections
Metabolic or endocrine	Paget's disease; osteomalacia; osteoporosis
Neoplasic	Benign tumors: osteoma, chondroma; malignant primary tumors: giant cell tumor, osteosarcoma, Ewing's tumor, multiple myeloma; metastatic cancer

TABLE 79-1. Classification of painful disorders of the thigh

Type of disorder	Examples
Traumatic	Fracture; dislocation; meniscal tear; capsular or ligamentous tear; rupture of the quadriceps tendon
Inflammatory or degenerative	Arthritic gyogenic arthritis, rheumatoid arthritis, osteoarthritis, tuberculous arthritis, brucellic arthritis, neuropathic arthritis; syncitic acute traumatic synovitis, pigmented villonodular synovitis, osteochondromatosis, chronic synovitis, recurrent synovitis; bursitis: prepatellar bursitis, deep patellar bursitis, pesanserine bursitis, Baker's cyst
Avascular or necrotic	Osteonecrosis; embolism; circulatory insufficiency
Congenital	"Laxity" syndromes; Ehlers-Danlos syndrome; Blount's disease; varus-valgus deformities
Developmental	Patellar alignment; Osgood-Schlatter disease
Neoplastic	Primary benign tumors: osteoid osteoma, primary malignant tumors: osteosarcoma, chondrosarcoma, fibrosarcoma, giant cell tumor, Ewing's tumor, multiple myeloma
Miscellaneous	Osteochondritis dissecans, loose bodies in the knee, Pellegrini-Stieda disease
Referred pain	Diseases of the hip, spinal stenosis, other lumbosacral spinal disorders

TABLE 79-2. Classification of painful disorders of the knee

TABLE 79-2. Classification of painful intraarticular disorders of the knee joint

Anatomy, Biomechanics, and Function of the Thigh and Knee

Anatomy of the Thigh

Bony Anatomy. Figure 79-1 illustrates the anatomy of the femur, the largest of the long bones, with the corresponding origins and insertions. The anatomy of the proximal femur is described in Chapter 78. The femoral shaft is slightly anteriorly bowed beginning distal to the lesser trochanter. It maintains a relative tubular shape until the distal flaring of the medial and lateral condyles (5). In the normal standing position, the femoral shaft inclines medially to allow the knee to be centered under the femoral head and over the center of the ankle, thus creating the mechanical axis of the lower extremity. This angle of obliquity varies from 3 to 15 degrees (average, 10 degrees) when measured along the femoral shaft compared to a line drawn perpendicular to the joint line (5).

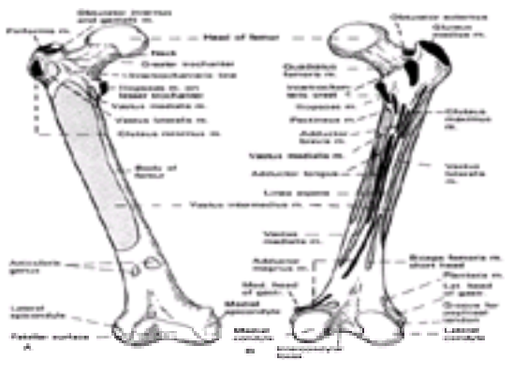

Figure 79-1. Anatomy of the femur and its muscular attachments. **A:** Anterior view. **B:** Posterior view. The body or shaft of the femur is almost cylindric but is a little broader proximally than in the center and is broadest and flattest distally. It is slightly arched, convex anteriorly, and concave posteriorly, where it is strengthened by a prominent longitudinal ridge, the linea aspera. This forms the prominent posterior border of the shaft and projects as an elevated longitudinal ridge or crest along the posterior aspect of the middle third of the bone. This crest consists of medial and lateral lips and a narrow rough intervening band. The distal extremity of the bone is greatly expanded in all directions to form the medial and lateral condyles, which are joined together anteriorly but separated posteriorly by the intercondylar fossa. The black areas are muscle insertions, and the stippled areas are sites of origin of muscles. The upper three-fourths of the anterior surface gives rise to the vastus intermedius, and the lower fourth of the bone surface is separated from the muscle by the intervention of the synovial membrane from the knee joint and by the suprapatellar bursa. The articularis genus muscle arises above the bursa. **B:** On the posterior surface the medial lip of the linea aspera gives rise to the vastus medialis, and the lateral lip and its prolongation give rise to the vastus lateralis. The adductor magnus is inserted into the linea aspera. Two muscles are attached between the vastus lateralis and adductor magnus, the gluteus maximus above and the short head of the biceps femoris below. Four muscles are inserted between the adductor magnus and vastus medialis, the iliacus and pectineus proximally and the adductor brevis and adductor longus distally. (Modified from Hollinshead WH. *Anatomy for surgeons,* 3rd ed. Vol 3. Philadelphia: Harper & Row, 1982:631, 633.)

The distal end of the femur consists of the medial and lateral condyles, which articulate with the tibia and patella to form the knee joint. The medial condyle projects approximately 0.5 cm below the level of the lateral condyle when the femur is held vertically. This difference allows the obliquity of the femoral shaft. Both condyles project more posteriorly than anteriorly to allow flexion of the knee joint.

Compartments. Figure 79-2 demonstrates the division of the musculature of the thigh into compartments and indicates the positions of the various muscle groups, nerves, and blood vessels. In contrast to the upper extremity, where intermuscular septa clearly separate the flexor and extensor compartments, the extensor muscles in the thigh almost completely surround the femur at their origins, leaving only the linea aspera for the attachment of other muscles. With the exception of the short head of the biceps femoris, the knee flexors of the thigh do not arise from the femur, instead taking origin from the ischium. The adductors occupy a large medial compartment that inserts to the femur as far distal as the adductor tubercle. Other relationships are demonstrated in Figure 79-5.

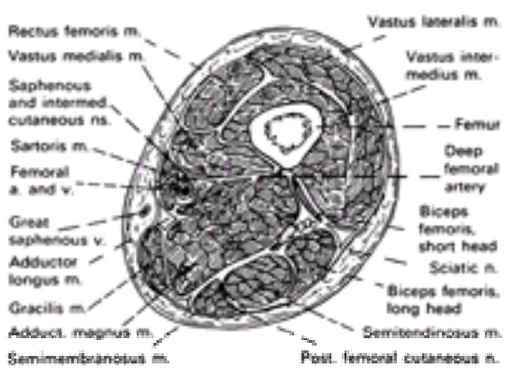

Figure 79-2. Transverse section through the middle third of the right thigh showing the division of the musculature into compartments and the position of the arteries and vessels. The vastus intermedius covers almost the entire circumference of the femur, except for the linea aspera posteriorly. The sciatic nerve is located deep in the posterior compartment that underlies the biceps femoris and semitendinosus muscles. At this level, the branches of the femoral nerves include the saphenous and intermedius cutaneous nerves, which are on the medial aspect of the thigh. (Modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985:561.)

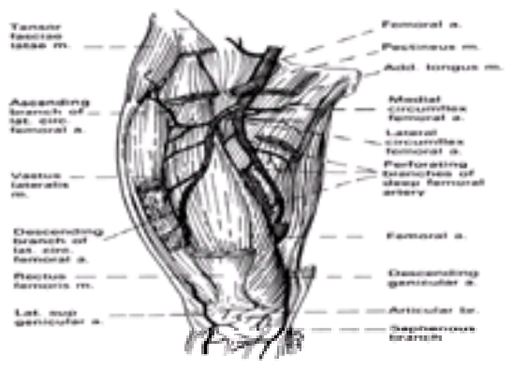

Figure 79-5. Anatomy of the femoral artery and its branches. The femoral artery, a continuation of the external iliac artery, enters the femoral triangle midway between the symphysis pubis and anterior superior iliac spine as its emerges from underneath the inguinal ligament, which forms the base of the triangle. In the femoral triangle, the artery is medial to the femoral nerve before it breaks up into its many branches. At the lower end of the femoral triangle, the femoral artery is cut to show the takeoff of the deep femoral artery, which is the chief source of blood for the thigh and its musculature. The lateral and medial circumflex arteries are branches of the deep femoral artery and encircle the proximal end of the femur to supply the hip joint. The deep femoral artery then descends posteriorly to the floor of the

adductor canal; as it descends, it gives off muscular branches and perforating arteries, which arise throughout its course. These perforate the adductor magnus and distribute blood to muscles in the posterior compartment.

The fascia lata (deep fascia of the thigh) forms a strong fibrous sheath around the thigh. It attaches superiorly along the iliac crest, inguinal ligament, conjoint ramus, ischial tuberosity, sacrotuberous ligament, and sacrum and inferiorly to Gerdy's tubercle on the tibia (7). Just below the inguinal ligament, the fascia lata covers the femoral triangle, where the femoral artery, vein, and lymphatics pass through the saphenous opening—an aperture in the fascia lata. At the back of the knee, the fascia lata covers the popliteal fascia, which covers the popliteal fossa.

Muscles. Table 79-3 lists the most important muscles that control motion of the knee and leg and their nerve supply. The prime movers of the knee joint are the bulk of the thigh muscles, which are important dynamic stabilizers of the knee joint; they also provide power for flexion and extension. A number of the muscles that move the knee also cross the hip and therefore provide dual functions for coordinated movements across two joints. Through postural reflexes they can recruit appropriate muscles for stabilizing the joints and balancing the trunk at the hip and knee. In addition, these muscles provide the power for active rotation of the tibia.

Region/muscle group/ function	Peripheral nerve supply	Segmental nerve supply*
Extension		
Rectus femoris	femoral	L-2, L-3, L-4
Vastus medialis, intermedius, and lateralis	femoral	L-2, L-3, L-4
Sartorius	femoral	L-2, L-3, L-4
Leg flexion		
Semitendinosus	Sciatic (tibial)	L-5, S-1, S-2
Semimembranosus	Sciatic (tibial)	L-5, S-1
Biceps femoris (long head)	Sciatic (tibial)	L-5, S-1, S-2
Gracilis	Obturator	L-2, L-3
Biceps femoris (short head)	Sciatic (peroneal)	S-1, S-2, S-3
Gastrocnemius	Sciatic (tibial)	S-1, S-2
Medial rotators		
Semitendinosus	Sciatic (tibial)	L-5, S-1, S-2
Semimembranosus	Sciatic (tibial)	L-5, S-1
Sartorius	Femoral	L-2, L-3, L-4
Gracilis	Obturator	L-2, L-3, L-4, L-5
Lateral rotators		
Biceps femoris		
Popliteus	Tibial	L-4, L-5, S-1, S-2, S-3

*Underlined vertebrae indicate the primary roots supplying the muscles.

TABLE 79-3. Function and nerve supply of muscles responsible for movement of the knee and leg

Extensors. The major muscle of the extensor group (Fig. 79-3) is the quadriceps femoris (rectus femoris, vastus medialis, vastus intermedius, vastus lateralis). The sartorius muscle also helps to extend the knee. Acting in unison, these muscles extend the knee. They also serve as secondary stabilizers of the knee (with the posterior cruciate ligament) to resist posterior tibial translation. The bony anatomy allows the quadriceps to relax when standing with the knee fully extended; however, if the foot is elevated off the ground in the same position, the muscle is tonically contracted (7).

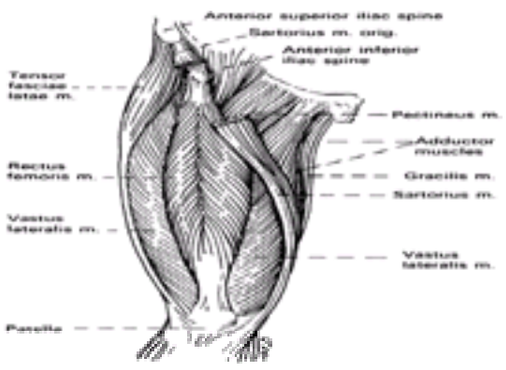

Figure 79-3. Extensor muscles of the knee. The rectus femoris originates from the anterior inferior iliac spine, whereas the vasti arise from the shaft of the femur. All four muscles converge onto a common tendon that crosses the knee joint and attaches to the tibial tuberosity by way of the patella. The common tendon of the quadriceps femoris comprises three lamina: the superficial layer from the rectus, the middle layer from the tendons of the vastus lateralis and medialis, and the deep layer from the vastus intermedius. The sartorius, a ribbonlike muscle, passes across the length of the thigh superficial to the quadriceps. It arises at the anterior superior iliac spine and inserts into the anterosuperior medial portion of the tibia. See Figure 79-1 for sites of origin and Figure 80-1 for sites of insertion of these muscles. (Modified from Hollinshead WH. *Anatomy for surgeons,* 3rd ed. Vol 3. Philadelphia: Harper & Row, 1982.)

Flexors. The chief flexors of the knee (Fig. 79-4) are the hamstrings (biceps femoris, semitendinosus, semimembranosus). These muscles also serve as secondary stabilizers (with the anterior cruciate ligament) to resist anterior tibial translation. The gracilis muscle also flexes the knee in addition to adducting the thigh and medially rotating the leg. The gastrocnemius also helps to flex the leg, in addition to plantar flexing of the foot.

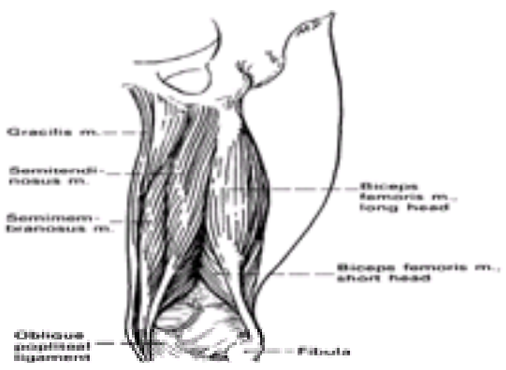

Figure 79-4. Flexor muscles of the knee. All three hamstring muscles arise from the ischial tuberosity and insert into the following structures. The semitendinosus muscle inserts into the medial aspect of the body of the tibia just posterior to the insertion of the gracilis and sartorius. These three muscles form a tendon complex sometimes called the *pes anserinus,* to which the anserina bursa is associated. The semimembranosus muscle inserts into the back of the medial tibial condyle, with the straight part of the tendon attaching to the medial meniscus as it crosses it. As it goes through its insertion, it gives off an expansion that runs obliquely, superiorly, and laterally across the posterior aspect of the knee joint to form the oblique popliteal ligament. The long head of the biceps femoris wraps around the lateral posterior medial side of the attachment of the fibular collateral ligament to the fibula, whereas the short head is attached to the tibia and to the fibular collateral ligament. The gracilis muscle is a long straplike structure located on the medial side of the thigh that arises from the lower part of the body of the pubis close to the symphysis and inserts into the medial surface at the upper end of the tibia below the medial condyle. See Figure 79-1 for sites of origin and Figure 80-1 for sites of insertion of these muscles. (Modified from Hollinshead WH. *Anatomy for surgeons,* 3rd ed. Vol 3. Philadelphia: Harper & Row, 1982.)

Rotators. Medial rotation of the tibia is produced by the semimembranosus, semitendinosus, sartorius, and gracilis muscles, whereas lateral rotation is produced by

the biceps femoris and popliteus muscles.

Blood and Nerve Supply. The blood vessels of the thigh are shown in Figure 79-5. The segmental and peripheral nerve supplies to the skin, muscles, and bones are described in detail in Chapter 8,Chapter 12, and Chapter 75. As is true for other long bones, the femoral shaft has dual circulation, with both small periosteal vessels as well as larger nutrient arteries providing blood supply. The nutrient arteries enter the upper half of the femur and give off long descending branches.

The nerves that supply the periosteum of the femoral shaft consist of filaments derived from the nerves that supply the muscles surrounding the bone. More distal innervation is from the corresponding nerves that supply the knee joint (see Nerves, later in this chapter).

Anatomy of the Knee

Bony Anatomy. The knee is the largest joint in the body. Although structurally it resembles a simple hinge joint, its movements are much more complex. In addition to flexion and extension, rotation and gliding movements occur at the knee. The bony architecture provides little inherent stability, which makes the knee vulnerable to injury. Stability is maintained by ligaments, muscles, and tendons as well as the menisci and joint capsule.

The knee joint consists of the articulations of three bones (femur, tibia, and patella) within a common cavity. The knee joint contains three compartments. The medial compartment consists of the articulation of the medial femoral condyle with the medial tibial plateau. The lateral compartment consists of the articulation of the lateral femoral condyle with the lateral tibial plateau. The patellofemoral compartment consists of the articulation of the retropatellar surface with the femoral trochlea. Disease processes may affect one or all three compartments of the knee. The articulating surfaces are covered with articular cartilage. In addition, the medial and lateral compartments have a fibrocartilaginous meniscus interposed between the articulation's surfaces.

Articular Surfaces. Figure 79-6 illustrates the articular surfaces of the knee joint. Note that the two rounded condyles are eccentrically curved, having a smaller radius of curvature posteriorly than anteriorly. Moreover, the curve of the lateral condyle is slightly greater, but shorter, than the medial condyle. The difference in curvature produces a difference in the movement of the two condyles and accounts for the medial rotation of the femur on the tibia that occurs with full extension of the knee (screw-home phenomenon) (7). The two femoral articular surfaces are confluent anteriorly through the articular surface of the patella but are widely separated posteroinferiorly and posteriorly by the intercondylar notch. The two epicondyles are two roughened convex prominences that surround the condyles proximally. The medial epicondyle receives the attachment of the medial collateral ligament of the knee joint, and the lateral epicondyle receives the attachment of the lateral collateral ligament and popliteus tendon.

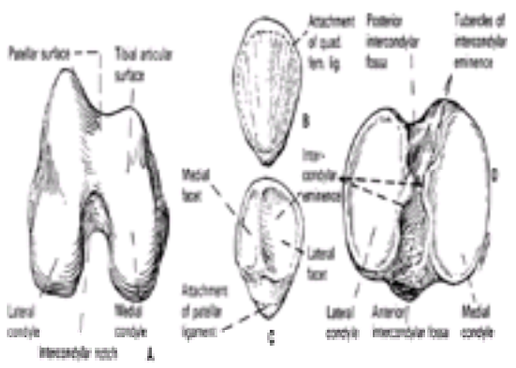

Figure 79-6. Articular surfaces of the knee joint. **A:** The articular surfaces of both condyles of the femur participate in the formation of the articular surface of the patella, which is larger on the lateral than on the medial condyle. Posteriorly, they are separated from each other below the intercondylar line by a deep intercondylar fossa. The articular surface of the lateral condyle is wide, whereas that of the medial condyle is longer and more highly curved posteriorly. **B:** The quadratus femoral ligament is attached to the periphery of the anterior surface of the patella. **C:** The posterior surface of the patella presents a smooth articular area covered with cartilage and divided into two facets by a vertical ridge, which lies adjacent to the groove on the anterior surface of the femur. The lateral patellar facet is broader and deeper than the medial facet. **D:** The upper surface of each tibial condyle is an articular surface that is almost ovoid and slightly concave. The two condyles and their articular surfaces are separated anteriorly by a slight depression of the anterior intercondylar fossa (or notch), which runs from the anterior to superior surface of the bone, and posteriorly by a more marked depression, the posterior intercondylar fossa (or notch). Between the anterior and posterior intercondylar fossae, the condyles and their articular surfaces are separated by a raised area, the intercondylar eminence, which has medial and lateral tubercles. Posteriorly, the articular cartilage extends over the smooth lip of the lateral condyle, but otherwise the articular surfaces are confined to the tibial plateau.

The tibial plateaus also consist of medial and lateral divisions. The surface of the medial plateau is slightly concave, whereas the surface of the lateral plateau is slightly convex. The lateral plateau is slightly higher than the medial plateau, secondary to the increased size of the medial femoral condyle compared to the lateral. Between the femoral condyles and the tibial plateau are the menisci, which are attached to the tibia by meniscotibial ligaments and to the femur by the meniscofemoral ligaments. The medial meniscus accounts for approximately 50% of the articulating surface in the medial compartment and the lateral meniscus approximately 70% of the articulating surface in the lateral compartment between the tibia and femur.

The patella is a roughly triangular bone (see Fig. 79-6). The quadriceps attaches to the superior pole through the quadriceps tendon, whereas the patellar ligament arises from the inferior pole and attaches to the tibia at the tibial tubercle. Anterior to the patella is a large prepatellar bursa, and the posterior surface is covered by articular cartilage with two main smooth facets to allow smooth gliding motion within the femoral trochlea.

Joint Capsule. The articular capsule of the knee is a complex structure that does not form a complete fibrous sleeve around the joint. Instead, the fibrous capsule consists of muscle, tendons, and ligaments between which a few capsule fibers that interconnect the articulating bones are found (5). Its inner surface is lined by synovial membrane, but this lining is often separated from the fibrous-ligamentous layer by other structures within the joint, such as fat pads and menisci.

The articular capsule is shown in Figure 79-7. In the anterior view, the fibrous layers of the capsule are seen to be completely lacking above the patella and deep to the tendon of the quadriceps femoris muscle. The fibrous capsule blends with the tendons of the vasti medialis and lateralis, the fascia lata, and its iliotibial band, which constitutes the medial and lateral patellar retinacula. *Anteriorly,* the capsule is reinforced by the patellar ligament, which is the central portion of the common tendon of the quadriceps femoris that continues from the patella to the tuberosity of the tibia. *Posteriorly,* the capsule consists of vertical fibers that arise above from the margins of the femoral condyles and the borders of the intercondylar fossa of the femur and descend to attach to the posterior margin of the tibial condyles. The capsule is reinforced from a tendinous expansion of the semimembranosus and oblique popliteal ligament. *Laterally,* capsule fibers stretch from the border of the lateral femoral condyle above to the aspect of the tibial condyle and head of the fibula below. The lateral collateral and popliteofibular ligaments reinforce the lateral capsule. *Medially,* the capsule attaches above to the margin of the medial femoral condyle and below to the corresponding margin of the tibial condyle. The medial collateral ligament reinforces the medial capsule.

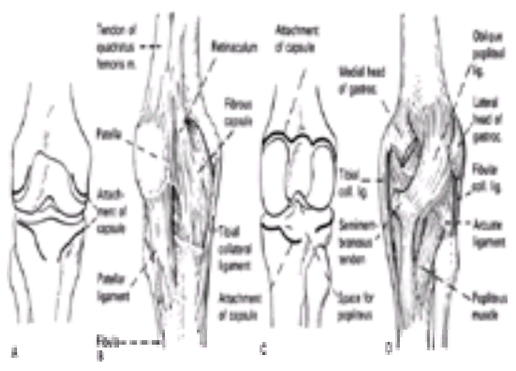

Figure 79-7. Articular capsule and some external ligaments of the knee joint. **A:** Anterior view. As shown by the thicker lines, the fibrous layers of the capsule are completely lacking above the patella. The synovial membrane is found deep to the tendon of the quadriceps. **B:** Anterior view. At the level of and inferior to the patella, the anteromedial and anterolateral aspects of the fibrous capsule blend with the expansion of the tendons of the vastus medialis and vastus lateralis muscles, as well as with the fascia lata and its iliotibial band. These structures constitute the medial and lateral patellar retinacula, which fill the intervals between the patellar and collateral ligaments and descend to attach to the anterior rim of the tibial condyle. The patellar ligament is the central portion of the common tendon of the quadriceps femoris that is continued from the patella to the tuberosity of the tibia. The ligament is a strong flat band approximately 8 cm long that is attached above to the apex and adjoining margins of the patella and the rough depression, on its anterior surface and below to the tuberosity of the tibia. Superficial fibers are continuous over the front of the patella with those of the tendon of the quadriceps, whereas the medial and lateral portions of the tendon pass from each side to the patella to be inserted into the proximal extremity of the tibia along the side of its tuberosity. These portions merge into the capsule to form the medial and lateral patellar retinacula. **C:** Lines of attachment of the capsule on the side and posterior to the cruciate ligaments. The gap in the tibial attachment of the capsule provides a hiatus for the exit of the popliteus muscle from the joint. **D:** Posterior view. The capsule consists of vertical fibers that arise above from the margins of the femoral condyles and from the border of the intercondylar fossa of the femur and descend to attach to the posterior margin of the tibial condyles. Blending with the capsule fibers posteriorly and above are the tendons of origin of the two heads of the gastrocnemius muscle. The popliteus muscle arises by a strong tendon approximately 2.5 cm long from a depression at the anterior part of the groove on the lateral condyle of the femur. The edge of the capsule, which arches over the muscle, is known as the *arcuate ligament*.

Accessory Ligaments. The major ligaments of the knee are independent of its capsule (Fig. 79-8). One pair, the medial and lateral collateral ligaments, is extraarticular; another pair, the anterior and posterior cruciate ligaments, is intraarticular (2,7).

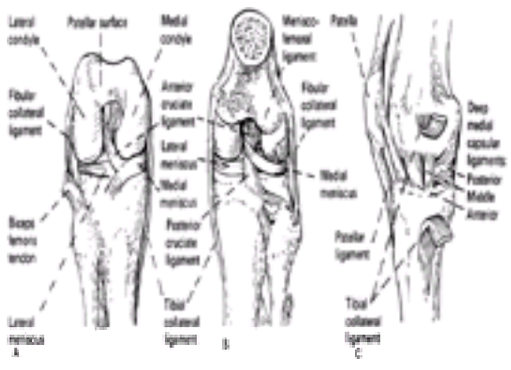

Figure 79-8. Accessory ligaments and menisci of the knee joint. **A:** Anterior view. **B:** Posterior view. **C:** Medial view. The two collateral ligaments, the anterior and posterior cruciate ligaments, and the medial and lateral menisci are interposed between the two bones. The superficial portion of the medial collateral ligament has been cut **(C)** and the ends reflected to show the deep section, which is composed of anterior, middle, and posterior ligaments. The anterior portion consists of parallel fibers that cover the anterior aspect of the joint, extend anteriorly into the extension mechanism, and attach loosely to the medial meniscus. These fibers are slightly relaxed during knee extension but tighten during flexion. The middle portion has distinct fibers and is composed of superior and inferior divisions. The superior (meniscofemoral) segment is thicker and fixes the medial meniscus to the femur, whereas the inferior (meniscotibial) segment is looser and permits the tibia to move on the meniscus. The posterior ligament consists of thin, indistinct, and fan-shaped fibers that pass posteriorly to aid in the formation of the posterior popliteal capsule. They are attached to the posterior aspects of the medial meniscus and blend with the semimembranosus muscle. (**A** and **B** modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985. **C** modified from Cailliet R. *Knee pain and disability,* 2nd ed. Philadelphia: FA Davis, 1983.)

The medial collateral ligament is composed of a superficial and a deep section. The superficial section is a broad flat band that extends from the medial femoral epicondyle to the proximal tibial metaphysis. Along its posterior edge, the superficial ligament fuses with the deep section, which is adherent to the joint capsule. The medial meniscus is attached to the deep section, along with the joint capsule (7). The medial collateral ligament is the primary restraint to valgus rotation.

The lateral collateral ligament is a cordlike structure that runs between the lateral femoral epicondyle and the tip of the fibula. It has no connections with either the deep capsule or the lateral meniscus. The lateral collateral ligament receives fibers from the popliteofibular ligament, which is a static portion of the popliteus tendon that arises from the posterior fibular head.

The anterior cruciate ligament runs from the intracondylar notch of the lateral femoral condyle to the anterior tibial plateau in front of the posterior cruciate ligament (Fig. 79-9). Its main function is to prevent anterior translation of the tibia in respect to the femur (Fig. 79-10). It is nearly isometric, in that it maintains tension throughout the range of motion of the knee.

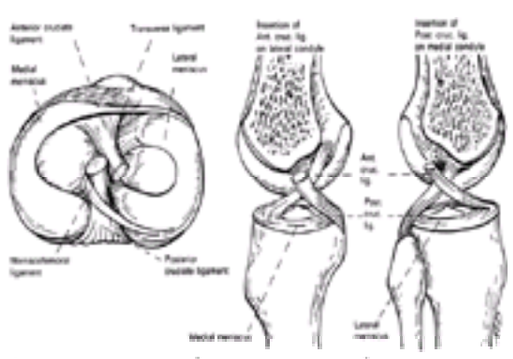

Figure 79-9. Menisci and cruciate ligaments. **A:** Superior view of the top of the right tibia. The medial meniscus is approximately 10 mm wide, with its posterior horn wider than the middle portion and its curve wider than that of the lateral meniscus. The anterior horn of the medial meniscus connects to the anterior ridge of the tibia, the anterior intercondylar eminence, and the anterior cruciate ligament by fibrous ligamentous tissue and, by way of the transverse ligament, connects to the anterior horn of the lateral meniscus. The lateral meniscus is 12 to 13 mm wide, and its curvature is greater than the medial meniscus, causing it to resemble a closed ring. Both its anterior and posterior horns insert directly into the intercondylar eminence and connect to the posterior cruciate ligament by fibrous tissue. Most of the posterior horn inserts into the femoral intercondylar fossa by way of the meniscofemoral ligament (of Wrisberg), which proceeds superiorly and medially and blends with the posterior cruciate ligament. **B,C:** Medial and posterior views of the cruciate ligaments. The anterior cruciate ligament is attached to the anterior part of the intercondylar eminence and passes posteriorly into the intercondylar fossa to attach to the medial side of the lateral condyle of the femur. The posterior cruciate ligament is attached to the posterior part of the intercondylar eminence and passes anteriorly in the intercondylar fossa to attach to the medial aspect of the medial condyle of the femur.

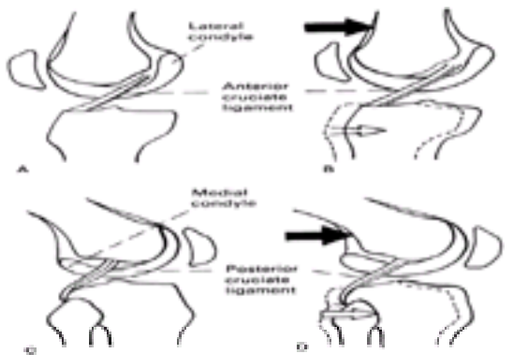

Figure 79-10. Function and restriction imposed by the cruciate ligament. **A:** A medial view of the right knee shows the attachment of the anterior cruciate ligament. **B:** Pressure on the lower part of the femur (*black arrow*), which tends to produce hyperextension, is prevented by the ligament. **C:** A lateral view of the right knee shows the attachment of the posterior cruciate ligament. **D:** Pressure posterior to the femur (*black arrow*), which would tend to displace the femur anteriorly, is prevented by the cruciate ligament. It also aids in normal knee flexion by acting as a drag force. (Modified from Cailliet R. *Knee pain and disability,* 2nd ed. Philadelphia: FA Davis, 1983.)

The posterior cruciate ligament runs from the intracondylar notch of the medial femoral condyle to the posterior tibial plateau behind the anterior cruciate ligament. It is the primary restraint to posterior translation of the tibia on the femur. It is composed of several bands that are tensioned at differing degrees of knee flexion.

Menisci. The menisci are two fibrocartilaginous semilunar wedges that partially divide the joint cavity and deepen the shallow articular facets of the tibia. Their concave inner margins are markedly thinner than their convex peripheral rims, which fuse with the capsule. Both menisci are anchored by their anterior and posterior horns to the intercondylar eminence. The upper and lower surfaces of the menisci are in contact with the articular cartilage of the femoral and tibial condyles, respectively, and both surfaces are moistened by synovial fluid.

The lateral meniscus becomes attached posteriorly to the medial condyle of the femur by the posterior meniscofemoral ligament (of Wrisberg), the anterior meniscofemoral ligament (of Humphrey), or both. The lateral meniscus is not rigidly attached. Its movements are guided by the movements of the femur, and its mobility is enhanced by the popliteus muscle, which can retract the meniscus over the smooth edge of the lateral tibial condyle. The medial meniscus is less mobile than the lateral meniscus, partly because of its attachment to the medial collateral ligament (7).

The menisci are penetrated by nerves derived from the capsular plexus but are avascular except for their most peripheral zone. The lack of blood supply to the rim of the menisci result in decreased ability to heal (4).

Synovial Membrane. The synovial membrane lines the inner surface of the capsule and covers all intraarticular structures except the menisci. Its attachment closely follows the articular margins (Fig. 79-11). The cruciate ligaments, popliteus tendon, and a large fat pad behind the patellar ligament are therefore intracapsular, but are extrasynovial. The synovial membrane projects from both medial and lateral borders of the articular surfaces of the patella as two fringelike folds to the interior of the joint. These alar folds converge and continue as a single band, the infrapatellar synovial fold (or ligamentum mucosa), attaching to the anterior aspect of the intercondylar fossa of the femur. At the upper posterior aspect of the joint, the synovial membrane forms true pouches, or bursae, which lie deep to the origin of the gastrocnemius muscle (Fig. 79-12).

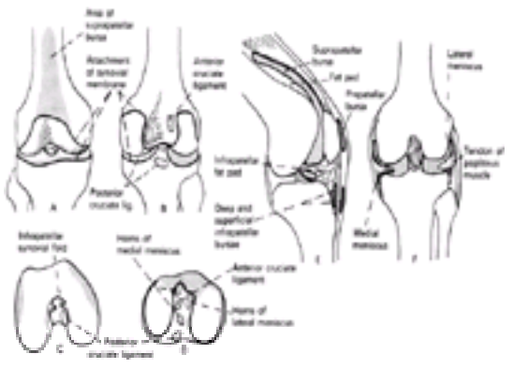

Figure 79-11. Attachment of the synovial membrane and its reflection on the surface of the bone. **A:** Anterior view of the knee joint. **B:** Posterior view of the knee joint. **C:** Articular surface of the femur. **D:** Articular surface of the tibia. The thick black lines show the boundary of the synovial membrane; the gray areas indicate its reflection on the surface of the bones. **E:** Sagittal section. **F:** A frontal section shows the boundaries of the synovial membrane (*thick black lines*) and some of the bursae around the joint. (Modified from Hollinshead WH. *Anatomy for surgeons,* 3rd ed. Vol 3. Philadelphia: Harper & Row, 1982.)

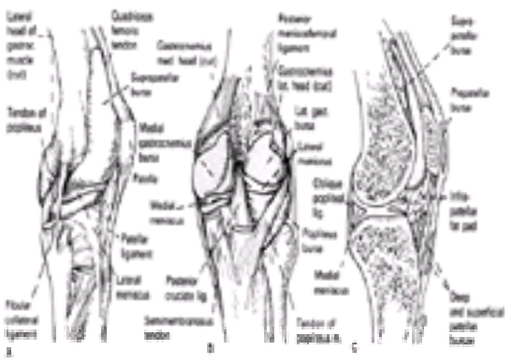

Figure 79-12. Synovial membrane of the right knee joint. **A:** Lateral view. **B:** A posterior view shows the distended synovial membrane (*indicated in gray*). Posteriorly, a smaller extension of the synovial cavity is interposed in the form of bursae between the popliteus muscle and the tibia as that muscle exits from the joint. The lateral gastrocnemius bursa lies between the lateral head of the gastrocnemius muscle and the capsule; the medial gastrocnemius bursa lies between the medial tendon of the gastrocnemius and the capsule. **C:** A sagittal section of the knee joint shows the synovial membrane and some of the bursae of the knee joint. As the membrane is draped over the fat, it is raised up into an infrapatellar fold and forms a ridge over which the two limbs of the U-shaped synovial cavity communicate with each other. The anterior conjoined portion of the cavity of the synovial membrane sweeps upward from its femoral attachment to cover the anterior surface of the femur; then, 7 to 8 cm above the patella, it reflects anteriorly onto the quadriceps tendon and attaches to the superior margin of the patella, thus producing the suprapatellar bursa or pouch. (**A** and **B** modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985. **C** modified from Rosse C, Clawson DK. *The musculoskeletal system in health and disease.* Hagerstown, MD: Harper & Row, 1980.)

The synovial membrane passes downward from the femur on both sides of the joint, lining the capsule at its points of attachment to the menisci. It then passes downward over the proximal surface of the menisci to their free borders, which are not covered by synovial membrane, and then along their distal surfaces. At the posterior part of the lateral meniscus, the synovial membrane forms a small sac, the popliteal recess, between the groove on the surface of the meniscus and the

tendon of the popliteus muscle. The membrane is then reflected across the cruciate ligaments.

Bursae. A number of bursae are related to the knee joint (see Fig. 79-12). Anterior to the knee are four bursae: (a) the large subcutaneous prepatellar bursa, which is interposed between the patella and the skin; (b) the small deep infrapatellar bursa, which lies between the upper part of the tibia and the patellar ligament; (c) the superficial infrapatellar bursa, which is between the lower part of the tuberosity of the tibia and the skin; and (d) the suprapatellar bursa, which lies between the anterior surface of the of the distal femur and the deep surface of the quadriceps that usually communicates with the knee joint.

Lateral to the knee joint are also four bursae: (a) the lateral gastrocnemius bursa, which sometimes communicates with the joint between the lateral head of the gastrocnemius muscle and the capsule; (b) the inferior biceps femoral bursa, which is between the lateral collateral ligament and the biceps femoris tendon; (c) the popliteus bursa, which lies between the popliteal tendon and the lateral condyle of the femur and is usually an extension from the synovial membrane of the joint; and (d) a bursa between the fibular collateral ligament and the tendon of the popliteus muscle.

Medial to the knee joint are five bursae: (a) the medial gastrocnemius bursa, which is between the medial head of the gastrocnemius and the capsule, sends a prolongation between the tendon of the medial head of the gastrocnemius and the tendon of the semimembranosus, and communicates with the joint; (b) the anserine bursa, superficial to the medial collateral ligament and deep to the tendons of the sartorius, gracilis and semitendinosus; (c) a bursa deep to the medial collateral ligament, which is between it and the tendon of the semimembranosus; (d) a bursa between the tendon of the semimembranosus and the medial tibial plateau; and (e) a bursa that is occasionally found between the tendons of the semitendinosus muscle.

Nerves. The knee joint is supplied by a large number of articular fibers from muscular branches of the femoral, obturator, tibial, and common peroneal nerves (Fig. 79-13). The articular branches of the femoral nerve to the knee joint arise from the saphenous nerve and from the nerves to the three vasti muscles. The branch from the saphenous nerve, which can contain some fibers from the anterior division of the obturator nerve, is distributed to the anteromedial part of the knee joint, and a branch from the nerve to the vastus medialis is distributed to the medial part of the joint. A branch from the nerve to the vastus intermedius is distributed to the suprapatellar part of the knee joint, and a branch from the nerve to the vastus lateralis is distributed to the anterolateral part of the joint. The amount of overlap is significant, and anastomoses among these branches are often seen (10).

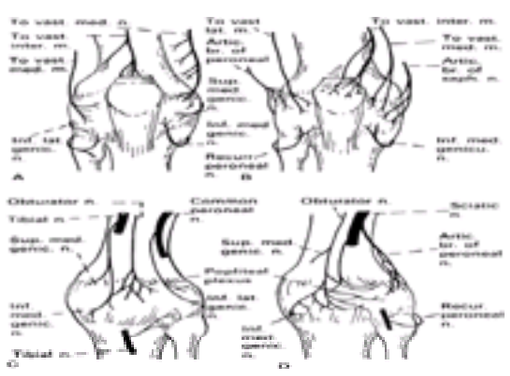

Figure 79-13. Nerves that supply the knee joint. **A,B:** Anterior views. **C,D:** Posterior views. See text for details. (Modified from Gardner E. The innervation of the knee joint. *Anat Rec* 1948;101:109–130.)

The branch from the obturator nerve is usually derived from its posterior division, follows the femoral and popliteal arteries to the knee joint, and is distributed especially to the posteromedial part of the capsule. The tibial nerve provides a single large branch that breaks up into subsidiary branches, which accompany various genicular vessels or run directly to the capsule to supply its posterior part. A single branch from the common peroneal nerve is distributed to the anterolateral part of the capsule.

The recurrent branch of the peroneal nerve arises at the point of division of the common peroneal nerve into its superficial and deep branches and is mainly distributed to the periosteum of the anterolateral surfaces of the tibia and the tibiofibular joint. In addition, some of the subsidiary branches follow blood vessels to the knee joint and supply the infrapatellar fat pad and adjacent capsule. The horns of the menisci, but not the body, are well innervated, as is the posterior meniscofemoral ligament of Wrisberg (7).

Blood Vessels. The arteries of the knee joint are branches of the vessels that enter into the anastomosis around the joint that receives contributions from the femoral, profunda femoral, and popliteal arteries (Fig. 79-14).

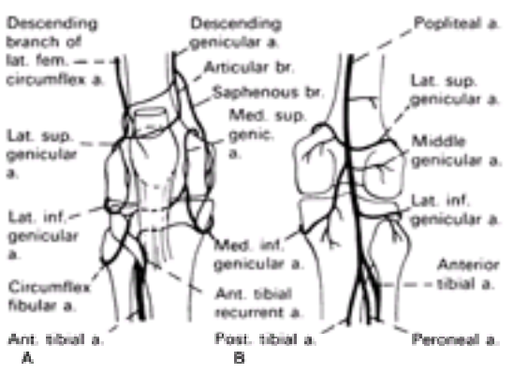

Figure 79-14. Blood supply of the knee joint. **A:** The arteries that supply the knee joint include the descending genicular branch of the femoral artery, which gives off saphenous and articular branches that supply the joint; the descending branch of the lateral femoral circumflex artery, which is a branch of the deep femoral artery; the lateral and medial superior genicular arteries and the lateral and medial inferior genicular arteries, which are branches of the popliteal artery; and the recurrent branch of the anterior tibial artery. Occasionally, a posterior tibial recurrent artery is present, which helps to supply the joint. **B:** The fibrous capsule is perforated posteriorly by the middle genicular artery, which supplies particularly the tissue of the intercondylar region—that is, the cruciate ligaments and attachments of the menisci. The menisci have minimal vascularity at their extremities, whereas the rest of the menisci are avascular. (Modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985.)

Movement and Stability of the Knee Joint

Movement. The tibiofemoral joint range of motion is greatest in the sagittal plane, where the range from full extension to full flexion is from approximately 0 to 140 degrees (11). Knee flexion and extension are accompanied by a gliding motion of the tibia on the femur with simultaneous rotation: External rotation of the tibia on the femur occurs during knee extension, and internal rotation occurs during knee flexion.

In the transverse plane, the range of motion of the knee increases from full extension of the knee up to 90 degrees of flexion. In full extension, almost no rotation is possible because of the interlocking of the femoral condyles and the tibial plateau. At 90 degrees of flexion, external rotation of the knee ranges from 0 to approximately 45 degrees and internal rotation ranges from 0 to approximately 30 degrees. Beyond 90 degrees of flexion, the range of motion in the transverse plane decreases, primarily because of restriction by the ligaments and other soft tissues.

In the frontal plane (abduction/adduction), much less motion secondary to the ligamentous restraints is seen. The maximal motion in this plane is obtained with the

knee flexed to 30 degrees, but even here it is limited to a few degrees (11).

The range of motion of the knee in the sagittal plane during level walking has been measured at approximately 5 degrees of flexion at the beginning of stance, at heel strike, and at the end of stance phase just before toe-off, whereas 75 degrees of flexion were observed during the middle of the swing phase (12). During normal gait, the knee is never fully extended. The range of motion required to do various other activities is varied: 0 to 83 degrees during stair climbing, 0 to 90 degrees during descending stairs, 0 to 93 degrees sitting, 0 to 106 degrees tying a shoe, and 0 to 117 degrees lifting an object (13,14).

Stability. Stability of the knee joint is crucial to proper function of the knee. Because the bony surfaces have a negligible influence on stability, the integrity of the ligaments and muscles is essential (2,7). In relaxed standing, the knee depends on its ligaments for stability, with the reinforced part of the capsule and the cruciate ligaments being the chief factors in preventing hyperextension. Once the weight-bearing knee is flexed, muscle force is essential to maintain stability. Even a few degrees of flexion are accompanied by contraction of the quadriceps, whose power can maintain stability in the knee despite considerable laxity of the ligaments. The quadriceps is important in stabilizing the patella. Because the femoral shaft articulates with the tibia at an angle, the pull of the quadriceps tends to displace the patella laterally. This is prevented by the prominent trochlea of the lateral femoral condyle and by the attachment of the vastus medialis into the medial border of the patella.

In the flexed position of the weight-bearing knee, the femoral condyles have a tendency to slip anteriorly on the tibial plateau, but this is prevented by the anterior cruciate ligament. The iliotibial tract is also important in knee function, particularly when weight is borne by the flexed knee. Because it is attached to the anterior surface of the lateral tibial condyle, the iliotibial tract can transmit forces to the knee from the gluteus maximus and tensor fasciae lata. The pelvis, with the femur, is balanced on the sloping tibial plateau by the gluteus maximus and tensor fasciae lata by way of the iliotibial tract.

Kinetics. Kinetic analysis is used in any situation, static or dynamic, to determine the magnitude of the forces on a joint that are produced by muscle, body weight, connective tissue, or externally applied loads. By kinetic analysis those situations that produce excessively high forces can be identified.

During walking, just after heel strike, the joint reaction force ranges from two to three times body weight and is associated with contraction of the hamstring muscles (11). During knee flexion, at the beginning of the stance phase, the joint reaction force is approximately two times body weight and is associated with contraction of the quadriceps muscle, which acts to prevent buckling of the knee. The peak joint reaction force occurs during the late stance phase, just before toe-off, when it ranges from two to four times body weight and is associated with contraction of the gastrocnemius muscle.

During the gait cycle, the joint reaction force shifts from the lateral to the medial tibial plateau, which sustains the peak force in the stance phase. In the swing phase, when the force is minimal, it is sustained primarily on the lateral plateau. The larger size and greater thickness of the medial plateau allow it to sustain the higher forces imposed on it during walking and other activities. Although the tibial plateaus are the main load-bearing structures in the knee, the cartilage, menisci, and ligaments also bear loads. The menisci help to distribute the stresses imposed on the tibial plateau.

CLINICAL EVALUATION OF THE PATIENT

The thigh and knee are frequent sites of painful disorders. In addition to the many mechanical injuries it can sustain, the knee is prone to almost every type of inflammatory and degenerative joint disease. Moreover, the metaphyseal regions of the femur and tibia are common sites of osteomyelitis and neoplasia. To make a correct diagnosis and carry out the appropriate therapeutic strategy, the patient must be evaluated thoroughly (Table 79-4).

TABLE 79-4. Evaluation of the patient with knee pain

History

As with all aspects of medicine, a proper diagnosis begins with a careful history. If a history of trauma is elicited, the mechanism of injury can provide important clues about destructive damage. The amount of force absorbed and the direction of force help to define injury.

A history of pain must be carefully characterized. Knowledge of the onset, distribution, intensity, quality, and aggravating and relieving factors assists in narrowing the differential diagnosis. Pain can arise from bone, muscle, or joint tissue. In addition to local trauma and overuse syndromes, pain may result from degenerative, congenital, infectious, vascular, neurologic, neoplastic, and systemic diseases. It may also be a referred phenomenon from the hip joint or spine. Weakness, stiffness, swelling, deformity, restricted movement, and clicking or locking of the knee joint are all important factors to define.

Physical Examination

A systematic approach to the physical examination of the thigh and knee is essential to confirm the history. The painful extremity should always be compared to the uninvolved (if unilateral symptoms) side to better establish “normal” for the particular patient. Inspection, palpation, range of motion, strength testing, sensory examination, ligament stability, and associated joints are all important components of the physical examination (see Table 79-4).

Inspection

Exposure of the extremity is essential for an adequate examination. The color and texture of the skin, with notation of any bruising or scars, can provide information not initially obtained in the history. The alignment of the femur, tibia, and patella should be noted. Mild degrees of genu valgum and genu varum are common in children, and normal growth usually corrects the deformity, unless it is excessive, in which case congenital disease of the bone should be considered. Hyperextension (genu recurvatum) results from muscle imbalance, a growth abnormality, or an unhealed ligamentous injury, all of which may distort the mechanics of the joint. The levels of the two patellae should be compared while the patient is in the relaxed standing position. Foot alignment should be noted. The contour of the soft tissues in the thigh and around the knee, with comparison of the muscles in both relaxed and isometric contraction, should be noted. Finally, the patient's gait should be closely observed for alterations in the normal pattern.

Palpation

All anatomic structures should be palpated, being especially gentle over painful and swollen joints. Abnormalities in skin temperature or texture and local tenderness or swelling can provide clues to underlying pathology.

With the quadriceps relaxed, the relatively flat patellofemoral articular surfaces should permit manual side-to-side displacement of the patella. The medial and lateral joint lines should not be tender. Insertions of muscles and ligaments, as well as bursae, should be palpated. Roughness of the articular surface can be evaluated by passively flexing and extending the knee with a hand over the patella. A grating sensation (crepitus) may signify underlying pathology. The crepitus can be magnified

by having the patient extend the knee against gentle resistance.

Generalized swelling is nonspecific and has several basic causes, including thickening or enlargement of the bone, fluid within the joint, and thickening of the synovial membrane. A hot, diffuse, tender swelling may suggest underlying osteomyelitis or a malignant primary tumor. Swelling around the knee joint should be differentiated from an intraarticular effusion. A large effusion will elevate the patella and obliterate the normal medial and lateral contour of the patella. The ballottement test (Fig. 79-15) is helpful in diagnosis of an effusion. Aspiration and examination of the intraarticular fluid can differentiate between traumatic (blood), inflammatory (serous), and infectious (pus) etiologies of effusions. Palpation of the soft tissues may demonstrate thickening of the synovial membrane, especially in the suprapatellar pouch.

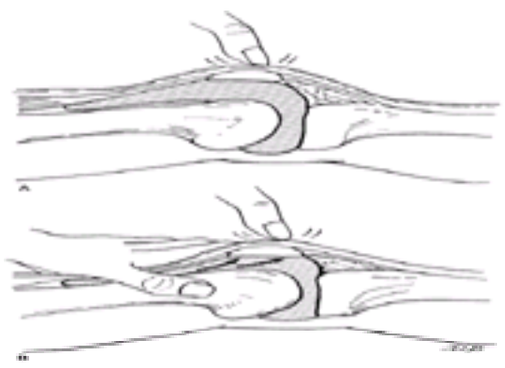

Figure 79-15. Technique of ballottement of the patella and of testing for the presence of a large effusion into the joint. **A:** With a large effusion (*shaded area*), the patella is greatly elevated, enabling ballottement of the patella against the femoral condyle with the second finger. **B:** With moderate effusion (*shaded area*), the patella may not be elevated. Thus, fluid must be displaced from the suprapatellar pouch and the site of the joint cavity by compressing the region with the left hand. When the patella is elevated, ballottement can be carried out with the second finger of the right hand. (Modified from Rosse C. The thigh and the knee. In: Rosse C, Clawson DK, eds. *The musculoskeletal system in health and disease.* Hagerstown, MD: Harper & Row, 1980.)

Range of Motion

Accurate assessment of the range of motion is an important part of the physical examination. The unaffected extremity is used as the control, as both the passive and active range of motion are evaluated. Any pain or crepitus with motion should be noted. Normally, the range of motion is from full extension with flexion being limited by the posterior soft tissues of the buttocks, thigh, and calf.

Muscle Strength

Motor strength is graded on a scale of 0 (no active muscle twitch) to 5 (full strength over a complete range of motion). Resistive testing of extension is easier to test with the patient sitting, whereas testing of flexion is easier with the patient prone (Fig. 79-16). In general, the knee flexors and extensors of a patient are considerably stronger than the arms of even the most robust examiner. Therefore, relative strength should always be compared to the opposite side. In addition, observation of ability to perform a deep knee bend and to toe and heel walk can provide additional information.

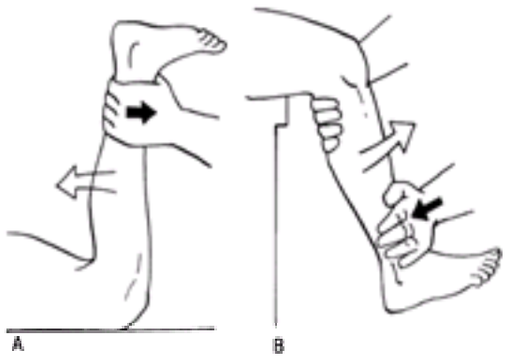

Figure 79-16. Testing the strength of the muscles of the knee. **A:** The flexor muscles are tested with the patient lying prone and the leg partly flexed. The patient attempts to further flex the lower leg toward the thigh against the resistance offered by the examiner. **B:** The extensor muscles are tested with the patient sitting at the edge of the examining table. The patient attempts to extend the knee against the resistance of the examiner.

Muscle atrophy can be assessed by measuring the thigh circumference. A mark made on the anterior thigh, 10 cm proximal to the superior pole of the patella, provides a repeatable assessment of muscle bulk. Both right and left sides should be measured.

Sensation

Decreases in light touch, temperature, and vibration at the thigh and in the lower leg and foot can help identify peripheral and central neurologic pathology. Reflex testing of the patellar tendon and Achilles tendon should be symmetric. Achilles reflexes typically are decreased or absent in the elderly. An abnormal Babinski test should be identified.

Stability

Patient relaxation is the key to obtaining a good assessment of ligamentous stability. Wide variation among the population is seen in the “tightness” of the knee ligaments, and therefore, both knees must be compared. Medial and lateral collateral ligament testing is performed with the knee at 30 degrees of flexion (Fig. 79-17). Anterior and posterior drawer tests are performed with the knee at 90 degrees of flexion and the foot anchored on the table (Fig. 79-18). A Lachman test, performed with the free leg at 30 degrees, has been shown to be more sensitive than the anterior drawer test in diagnosing anterior cruciate insufficiency (15).

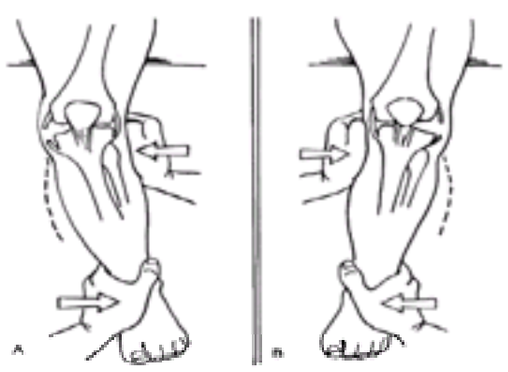

Figure 79-17. Testing the collateral ligaments of the knee. **A:** With the left knee slightly flexed to eliminate the stabilizing effect of the cruciate ligament on the extended knee, the tibial collateral ligament is tested by grasping the patient's ankle with one hand and using the other hand as a fulcrum at the knee. Abduction force

is then applied at the ankle in an attempt to produce a valgus deformity of the knee. **B:** The examiner tests the lateral collateral ligament by attempting to produce a varus deformity. (Modified from Rosse C. The thigh and the knee. In: Rosse C, Clawson DK, eds. *The musculoskeletal system in health and disease.* Hagerstown, MD: Harper & Row, 1980.)

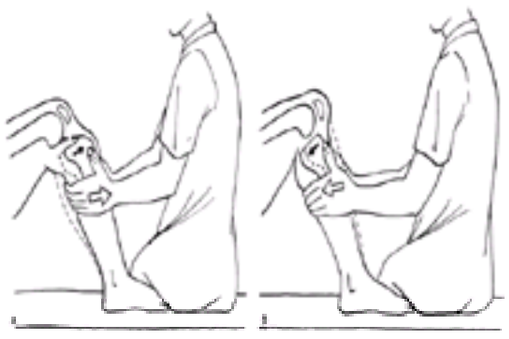

Figure 79-18. Testing the cruciate ligaments of the knee. **A:** With the patient lying supine on the examining table, the knee flexed to approximately 120 degrees, and the foot stabilized, the examiner grasps the upper end of the tibia with both hands, with the fingers interlocked behind and the tip of each thumb placed on each tibial condyle. The examiner tests the anterior cruciate ligament by attempting to displace the tibia anteriorly on the femur. If the ligament is torn, a forward displacement of the tibia occurs (anterior drawer sign). **B:** The integrity of the posterior cruciate ligament is tested in the same manner by attempting to produce posterior displacement of the tibia.

Other Areas

Because the knee is a common site of referred pain, the spine, hips, ankles, and feet must be carefully evaluated when assessing knee pathology.

Imaging

Anteroposterior and lateral radiographs of the thigh or knee provide a good general screening. Tangential views of the patella (sunrise view) can assist with patellofemoral symptoms. Oblique views (45 degrees) can help diagnose osteochondritis dissecans or fractures. Weight-bearing anteroposterior views are helpful when looking at compartmental involvement of osteoarthritis. A 45- degree flexion, weight-bearing posteroanterior view helps delineate lesions of the true posterior femoral condyles.

Depending on clinical suspicion after history and physical examination, additional imaging studies may be needed. Radioisotope bone scanning provides a sensitive but nonspecific assessment. Magnetic resonance imaging (MRI) can assist with soft tissue abnormalities, including ligaments, menisci, infection, and neoplastic processes. Computed tomography provides more detailed assessment of complex intraarticular fractures. Imaging studies of hips, spine, and feet may be necessary to diagnose pathology.

Arthroscopy

Arthroscopy has developed into both an adjunctive tool for diagnosis and an instrument for therapeutic intervention. Although arthroscopy has traditionally been performed in the operating room with regional or general anesthesia, experience is growing with office use with local anesthesia (16).

PAINFUL DISORDERS OF THE THIGH

Traumatic Disorders

Fractures

Etiology. Femoral shaft fractures are generally secondary to high-energy mechanisms. Pathologic fracture should be suspected when a femoral shaft fracture is seen after minimal trauma. Frequently, patients have additional injuries secondary to the high energy absorbed. Life-threatening causes of hypovolemic shock must be ruled out before assuming that the femur fracture is an isolated injury. However, even isolated femur fractures may result in hypovolemic shock and fat embolism syndrome.

Diagnosis. A careful assessment of the skin must be performed to ensure that the fracture is not an open injury, with an associated higher infection risk. Appropriate antibiotics followed by careful irrigation of the wound are key to decreasing infection risk.

Treatment. Definitive treatment of femoral shaft fractures depends on patient, fracture, and surgeon variables (17). Younger children are usually treated with external immobilization in a hip spica cast. Older, skeletally immature children usually require a period of traction followed by immobilization or operative stabilization. Skeletally mature patients are almost uniformly treated with operative fixation. Closed, percutaneous intramedullary nailing has had excellent results for several decades (18) (Fig. 79-19). Open plating and external fixation are additional methods that can be used depending on the particular fracture pattern and the surrounding soft tissue. Regardless of the technique, early fixation allows early mobilization and decreases the rate of problems associated with long bed rest.

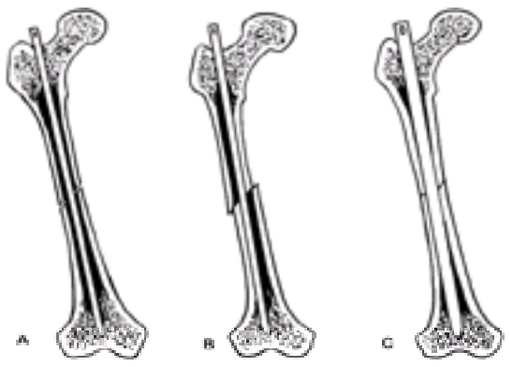

Figure 79-19. Internal splinting of the shaft fracture with a narrow intramedullary rod **(A)** often results in displacement and shortening **(B)**. Intramedullary reaming and nailing with a large rod allows better cortical contact and stability, thus minimizing this complication **(C)**. (Modified from Bucholz RW, Mooney V. Fractures of the femoral shaft. In: Evarts CM, ed. *Surgery of the musculoskeletal system.* Vol 3. New York: Churchill Livingstone, 1983.)

Pain Control. The intensity and duration of pain vary with the type of fracture and the associated soft tissue damage. A nondisplaced fracture produces moderate pain, whereas displaced fractures produce continuous, severe, deep pain and sharp, well- localized, superficial pain. The key to pain control is immobilization of the

fracture. Immobilization can be initially performed with external splinting; however, it is best accomplished with longitudinal traction, either skin or skeletal.

Initial pain control is provided systematically during transport and evaluation of the patient. Once the patient has been immobilized, effective pain relief can be attempted with opioid infusion. Patient-controlled analgesia is an excellent method of delivering pain control. When available, a continuous epidural analgesia produced by an opioid combined with a dilute solution of a local anesthetic, given in sufficient amounts to produce analgesia of the site of injury (T-10 to S-5 for the femur and knee joint) can provide pre- and postoperative analgesia. The need for ongoing assessments of compartments may preclude the use of epidural anesthesia.

Operative anesthesia is most commonly general; however, a regional anesthetic obviates the risk of vomiting or regurgitating gastric contents into the lungs. It also prevents massive nociceptive input and the neuroendocrine stress response. An alternative method of anesthesia is a sciatic-femoral-obturator nerve block.

Postoperatively, either patient-controlled anesthesia or continuous analgesia with a dilute solution of a local anesthetic and an opioid should be continued to provide effective pain relief, prevent the neuroendocrine stress response, and permit early motion and rehabilitation (19).

Contusions

Etiology. Contusions are the most common injury sustained to a muscle. They usually occur during an athletic event resulting from a direct blow to the muscle.

Diagnosis. A mild contusion of the quadriceps is associated with localized tenderness and pain with active contraction or passive stretching of the involved muscle. A moderate contusion is associated with increasing local edema in addition to pain. A severe contusion is associated with continuous pain, gross swelling, and disability.

Treatment. Initially, the goal is to minimize hemorrhage with rest, ice packs, compression, and elevation. This regimen is continued for 24 to 48 hours, during which no exercises beyond isometric quadriceps contractions are performed. After the phase of inflammation is passed, the goal is restoration of range of motion. Depending on the severity of the contusion, weight bearing may need to be limited with crutches. Active range of motion exercises are continued until full extension and flexion and a normal gait are obtained. The final phase is progressive resistance exercises until full strength is regained.

Muscle Strain

Etiology. Muscle strain is a common injury occurring when a muscle is forcibly contracted. It can occur passively, but muscle strain more commonly occurs with the active, eccentric loading of muscles. Muscles that cross two joints seem to be at particularly high risk (rectus femoris and hamstrings in the thigh). Myotendinous junctions are frequently involved (20).

Diagnosis. Patients typically complain of pain while participating in athletics. They may describe a popping sensation and have difficulty ambulating. Tenderness to palpation is found usually at the distal or proximal end of the muscle. Pain with passive stretch, swelling, and ecchymosis are often present. The degree of symptoms correlates with the degree of injury.

Treatment. Prevention of the injury with proper warm-up and stretching is best. As with contusions, rest, ice, compression, and elevation are the mainstays of early treatment. Gradual stretching exercises are continued until full range of motion is obtained, and return to activity with proper preparticipation warm-up is advised. Antiinflammatory medications are useful during the initial period.

Tendon and Muscle Ruptures

Etiology. Quadriceps and patellar tendon ruptures occur when the muscle rapidly contracts with the knee flexed. Rupture usually occurs through an area of weakened tendon secondary to age-related disorders (20). Direct trauma can also result in rupture.

Diagnosis. Patients complain of immediate pain and inability to ambulate. On physical examination, extensive swelling and a palpable gap are noted. Radiographs of the knee often demonstrate an abnormal position of the patella.

Treatment. Complete ruptures must be repaired surgically. Repairs are more effective if done early, as chronic ruptures contract and make an end-to-end repair more difficult. Patients are usually immobilized for 6 to 8 weeks postoperatively and then gradually allowed to return to activities once full range of motion is obtained. Partial ruptures are best repaired if diagnosed in the acute phase; chronic partial ruptures may respond to nonoperative rehabilitation.

Reflex Spasm of the Quadriceps

Etiology. Various injuries and a few disease states can provoke bouts of reflex spasm of the quadriceps or hamstrings that can cause transient severe pain. The reflex spasm can be a result of impact injuries to the muscles or can be associated with acute or chronic diseases of the hip and occasionally of the knee joint. Postoperative spasm can be excruciating and may occur on the second, third, or fourth postoperative day.

It has long been recognized that acute tissue damage caused by injury of muscle often provokes reflex spasm of the muscles that are supplied by the same and adjacent spinal cord segments as the site of injury. Until recently, these reflexes were believed to be produced as a result of continuous nociceptive input from the site of injury, stimulating interneurons in the dorsal horn and motor neurons in the anterior horn, with a consequent increase in skeletal muscle tension and spasm. It has been shown that massive nociceptive input not only stimulates various spinal cord neurons, the axons of which pass to the brain, but also sensitizes dorsal horn neurons, interneurons, and motor neurons, persisting for days and even weeks (21). The increased sensitivity decreases the threshold of these cells, and as a result, they can be activated by innocuous sensory stimulation such as light touch or proprioception (movement), which under normal conditions has no effect.

Diagnosis. Reflex spasm is probably one of the factors responsible for the production of hyperalgesia and allodynia in complex regional pain syndromes and for the abnormal motor response. It explains why such spasm occurs days after the pain from the surgical wound has diminished.

Treatment. The usual doses of potent opioids are ineffective in preventing or relieving the intense reflex muscle spasm and the associated severe pain. Even patient-controlled intravenous opiate analgesia may not provide sufficient relief. Intraspinal opioids dampen the reflex spasm, but only interruption of the afferent and efferent limbs or the reflexes with local anesthetic can adequately relieve the spasm and prevent or eliminate the pain. This is usually best achieved with administration of continuous epidural analgesia that extends from T-10 to the S-2 segments, either through repeated boluses or by continuous infusion. This blocks all nociceptive input from the hip joint, the area of the surgical incision, and the efferent somatomotor and sympathetic fibers to the thigh. This method of postoperative pain relief not only completely relieves pain and prevents the reflex spasm but also permits earlier mobilization and reduces the length of hospitalization (19).

Infections

Acute pyogenic osteomyelitis frequently involves the metaphyseal regions of the femur. The infection can enter either through an open wound (open fracture) or, more commonly, through the bloodstream (hematogenous osteomyelitis) (1,9). The distal femoral metaphysis is more prone to osteomyelitis than the proximal metaphysis. Children are more susceptible than adults, secondary to the large area of enchondral ossification. Chronic osteomyelitis is almost always a sequel to an acute infection that has been neglected or has been refractory to treatment.

Both acute and chronic osteomyelitis produce moderate to severe pain, fever and malaise, lethargy, and other constitutional symptoms. Local pain, draining sinuses, heat, swelling, tenderness, and erythema over the involved area are diagnostic hallmarks. Laboratory tests including white blood cell count, sedimentation rate, and C-reactive protein (CRP) may be elevated. Blood cultures typically fail to identify the causative organism. Radiographs may reveal a lytic bone lesion late in the course. Bone scanning reveals increased uptake in the lesion.

Antibiotics and surgical debridement are the usual treatment regimen for most pyogenic osteomyelitis.

Metabolic and Endocrine Disorders

The femur can be affected by various metabolic bone diseases, including osteoporosis, osteomalacia, osteitis fibrosa, and osteosclerosis. Nonmetabolic diseases including Paget's disease may also affect the femur. These conditions are discussed in Chapter 95.

Neoplasms

The knee and thigh represent one of the most common sites in the body for bone and soft tissue neoplasms. Benign and malignant bone and soft tissue tumors, as well as metastatic lesions, must be considered in the differential diagnosis of all patients with new onset of pain. Neoplasms of both the thigh and the knee are discussed in this section. As with most diseases, the diagnosis of neoplasia requires a through history and physical examination. Although the majority of patients present with pain, the presentation varies from an incidental finding on radiographs to severe constitutional symptoms. A complete description of all bone and soft tissue tumors is beyond the scope of this text (22,23); however, a brief description of diagnosis and treatment of some of the more common tumors follows.

Benign Bone Tumors

A simple bone cyst presents as a well-demarcated lytic lesion in the metaphysis of long bones, primarily in children. Many respond to a single injection of corticosteroids, with multiple injections or bone grafting occasionally required.

An aneurysmal bone cyst presents as an eccentric, lytic, expansile lesion in the metaphysis, primarily of adolescents. Treatment is careful curettage and bone grafting. Local recurrence is as high as 25%.

A nonossifying fibroma presents as an eccentric lytic metaphyseal lesion with a well-demarcated sclerotic rim. These lesions typically resolve without treatment. Curettage and bone grafting have been recommended for lesions greater than 50% of the bone diameter to prevent fracture.

Osteochondromas arise as an aberrant focus of cartilage near an epiphyseal center. They appear as a surface lesion with continuous cortex involvement of the underlying bone. They have a low rate of malignant degeneration (less than 1% if isolated, 10% if multiple). Symptomatic lesions should be excised.

Enchondroma typically appear as well-circumscribed lesions with calcifications within the medullary canal. Treatment is curettage and bone grafting, with wide resection for the small percentage with malignant transformation.

Chondroblastomas typically present as a lytic lesion of the epiphysis with occasional spread to the metaphysis. Most respond to curettage and bone grafting, with a small percentage of local recurrence and distant metastasis.

Osteoid osteomas are small diaphyseal lesions with a sclerotic border surrounding a zone of translucency. They are classically painful but respond to nonsteroidal antiinflammatory drugs (NSAIDs; particularly aspirin). Definitive treatment is *en bloc* resection.

Fibrous dysplasia is not a true neoplasm but tends to be locally aggressive. Typically, it presents as a ground-glass-appearing lesion, but there is a broad range of appearance. Thirty percent of the cases have involvement at multiple sites. Observation is most common with resection and bone grafting for more aggressive lesions.

Giant cell tumors are commonly an aggressive, expansile lytic lesion, without a sclerotic margin, of the epiphysis of skeletally mature bones. Curettage and bone grafting have led to recurrence rates as high as 50%, and therefore *en bloc* resection is often required.

Eosinophilic granulomas are vary widely in appearance. Typically, they do not require treatment unless there is impending fracture or they are close to an articular surface.

Paget's disease represents abnormal bone remodeling that presents in the fifth decade of life. These lesions are blastic appearance on radiographs. Less than 1% develop malignant degeneration. Paget's disease is treated with diphosphonates, calcitonin, and methotrexate.

Benign Soft Tissue Tumors

Pellegrini-Stieda disease is ossification of a subligamentous hematoma after injury to the medial collateral ligament, primarily at the insertion on the medial condyle of the femur. Medial pain and tenderness with thickening at the medial epicondyle are usually present. Radiographs reveal calcified deposits within the ligament. Rehabilitative stretching and strengthening are typically successful. Persistent pain may respond to aspiration, with surgical removal of the ossified tissue reserved for cases unresponsive to conservative measures (1).

Myositis ossificans represents calcifications within the soft tissue, typically after a traumatic episode. It most commonly occurs within the quadriceps after a contusion with hematoma formation. It must be differentiated from osteosarcoma. Resection of myositis ossificans is usually not needed.

Ganglia present as an outpouching of the synovial lining of an adjacent joint. Treatment is initially with aspiration and cortisone injection, but this is often unsuccessful; the lesion then requires surgical resection.

Pigmented villonodular synovitis is a proliferation of the synovium in middle-aged adults. It usually presents as recurrent monoarticular effusions. Limited resection is associated with high local recurrence. Complete synovectomy is considered the standard of care and can usually be done by arthroscopic means.

Synovial chondromatosis usually presents with pain and catching symptoms within the knee of young adults. Radiographs reveal multiple calcified loose bodies. Treatment consists of complete synovectomy. This condition must be differentiated from chondrosarcoma, which requires resection.

Malignant Bone Tumors

After multiple myeloma, osteosarcoma is the most common primary malignant bone tumor. It affects patients in the second decade of life, with 60% occurring during the adolescent growth spurt. Wide variation is seen in the radiographic appearance, but these tumors typically have areas of osteolysis, ossification, and periosteal reaction. Osteosarcoma is currently treated with chemotherapy and wide resection, with limb salvage when possible. Treatment and response depend on subtype.

Chondrosarcoma is the third most common primary malignant bone tumor. It occurs primarily in the fourth, fifth, and sixth decades of life. It appears as a destructive lesion with central areas of calcification. Most are resistant to chemotherapy and radiation, but they rarely metastasize. Radical resection is the treatment of choice. Adjuvant chemotherapy is also used for high-grade lesions.

Fibrosarcomas are lesions occurring in the third through fifth decades of life. They appear as lytic lesions, without calcification or periosteal reaction. This lesion is resistant to radiation. Amputation has been the definitive treatment, but wide resection, limb salvage, and chemotherapy have been tried.

Ewing's sarcoma is a round cell tumor classically affecting males younger than 20. Constitutional symptoms are frequent. It appears as a permeative, destructive lesion with ill-defined margins. Treatment involves neoadjuvant chemotherapy, radiation, and surgical resection.

Multiple myeloma is the most common malignant bone tumor. It typically affects elderly patients who present with pain or pathologic fracture. It classically appears as a punched-out lesion radiographically. Treatment is with multiagent chemotherapy and surgical stabilization.

Lymphoma is a painful lesion that affects a broad age range. Bone destruction and soft tissue involvement are common. Radiation and chemotherapy are mainstays

of treatment; surgery is needed for selected lesions.

Malignant Soft Tissue Tumors

Malignant fibrous histiocytoma is a poorly differentiated bone and soft tissue tumor. Thirty percent arise within benign conditions. The distribution of this lesion is bimodal with primary lesions occurring in young adults and secondary lesions found typically in the sixth and seventh decades. They appear as highly destructive lesions with soft tissue expansion. Treatment is with chemotherapy and resection.

Synovial sarcoma presents as a painful swelling around a joint in young adults. Lesions are rarely found within the joint. Radiographs reveal spotty calcifications within a paraarticular mass. Treatment is with wide resection. The benefit from chemotherapy is unclear.

Multiple types of fibrosarcomas are known. They present as soft tissue masses in the adult population. Treatment consists of surgical resection and chemotherapy.

Metastatic Neoplasms

Primary tumors that readily metastasize to bone include lung, breast, prostate, kidney, thyroid, and gastrointestinal lesions (24). The metastasis typically creates a lytic lesion on plain radiograph, although many are found on routine bone scans for follow-up of primary lesions. Severe local pain and pathologic fracture are the main concerns. Radiotherapy is often effective for a time and can promote union of the pathologic fracture. Metastasis from the thyroid can respond to radioactive iodine, whereas breast and prostate metastasis may respond to hormone therapy and other modalities.

Pathologic fractures are extremely painful and have a high incidence of morbidity. Prophylactic stabilization with a full-length reconstruction nail decreases pain and facilitates nursing care.

PAINFUL DISORDERS OF THE KNEE JOINT

Fractures

Etiology

Fractures around the knee can lead to prolonged disability. The normal range of motion requires smooth surfaces for painless gliding motion and weight-bearing. Displaced intraarticular fractures rapidly progress to premature degenerative arthritis. In addition, displaced extraarticular fractures can lead to joint malalignment with subsequent alterations of normal joint mechanics. Appropriate diagnosis and treatment are critical for the long-term outcome of these fractures.

Fractures around the knee are classified by location and involvement of the intraarticular surface. Distal femur fractures include supracondylar, intercondylar, and condylar fractures. The degree of comminution within the fracture is an important consideration. Proximal tibial fractures may involve the medial plateau, lateral plateau, both plateaus, or proximal metaphysis without extension into either plateau (Fig. 79-20). Patellar fractures can be transverse, vertical, or comminuted.

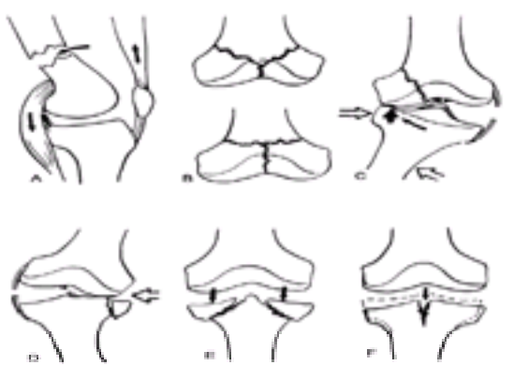

Figure 79-20. Various types of fractures of the bones of the knee joint. **A:** Supracondylar fracture with the gastrocnemius pulling the distal fragments posteriorly into the popliteal fossa and the hamstring and quadriceps pulling to shorten the femur. **B:** Intercondylar fracture of the distal femur: Y fracture (*top*); T fracture (*bottom*). **C:** Condylar fracture from severe valgus (varus) stress. Force applied to the knee joint or laterally to the tibia (*arrows*) can cause fracture of the femoral condyle, tearing of the opposite collateral ligament, and tearing of either or both of the cruciate ligaments, with compression of the meniscus. **D:** Fracture of one tibial plateau. Direct trauma to the tibial plateau, such as a fall on extended legs, can cause a Y fracture **(E)** or a T fracture **(F)** of the plateau. (Modified from Cailliet R. *Knee pain and disability,* 2nd ed. Philadelphia: FA Davis, 1983.)

Diagnosis

Pain after a traumatic event is the predominant symptom. It is generally limited to the knee region but can spread to the lower thigh and leg. Swelling and inability to bear weight are frequently encountered. Tenderness, crepitus, and edema are seen on physical examination. A careful neurovascular examination should be performed, because nerve and vessels are in close proximity to fractures within this area.

Anteroposterior and lateral radiographs are usually diagnostic. Computed tomography scans provide additional information of the extent of intraarticular involvement. MRI is better for assessment of soft tissue abnormalities.

Treatment

Basic principles of pain control and immobilization have been previously discussed. Longitudinal traction is typically not required; however, proper splinting to avoid painful movement across the fracture site is paramount while obtaining additional studies typically needed for these complex fractures.

Fracture fixation requires adequate exposure to judge the reduction of the intraarticular fragments. Anatomic reduction, stable fixation, and early motion are keys to improved outcome. Multiple methods of fixation including internal plates and screws, intramedullary rods, and external constructs are available for fixation. The best construct depends on the fracture pattern and individual surgical experience.

Postoperative care is focused on early mobilization. Careful examination of postoperative swelling within the compartments of the leg is crucial to avoid compartment syndrome. As described, adequate pain control assists in early mobilization.

Dislocations

Etiology

Complete dislocation of the knee joint is a rare, high-energy event. Ligamentous structures must be torn to allow complete dislocation. Direction of the tibia in relation to the femur describes the type of dislocation as posterior, anterior, and less commonly medial or lateral. These injuries are associated with a high incidence of neurovascular injury. Proper identification of the dislocation is important to preventing further injury.

Patellofemoral dislocations are much more frequent than complete knee dislocations. The patella is typically laterally dislocated. Diagnosis is occasionally difficult

because many relocate spontaneously before presentation. Proximal tibiofibular joint dislocation is a frequently overlooked injury that may lead to chronic symptoms.

Diagnosis

A high index of suspicion is required to properly diagnose dislocations. Often, the dislocations have been reduced. Careful isolation of each ligament will define the injury. Radiographs remain the proper screening tool, although they may not reveal fractures in purely ligamentous injuries. Patellofemoral dislocations are diagnosed with history and tenderness, primarily medial to the patella. Careful examination of neurovascular structures must be performed. Ankle-arm blood pressures should be obtained, with angiography reserved for injuries suspicious for vascular insult. MRI is useful in identifying soft tissue pathology.

Treatment

Preservation of blood supply to the lower leg and foot is the primary concern. Dislocations should be reduced and immobilized as soon as possible. Patellofemoral dislocations are immobilized with the knee in extension for 2 weeks and then started on a motion and strengthening program. Knee dislocations are highly unstable. During the course of treatment, diligent monitoring of the neurovascular structures is essential. Fractures are treated as described under Treatment, in the section on Fractures. Ligamentous injuries are dealt with as described in the next section.

Ligamentous Injuries

Etiology

Ligamentous injury commonly occurs after both contact and noncontact injuries to the knee. Injuries include a spectrum of minor sprains from tearing of a few fibers to complete tears of the ligament. Children typically present with avulsion injuries, whereas adults sustain midsubstance injuries. The direction of the force is helpful in predicting the ligaments injured. Often, multiple ligaments are injured with increasing force (Fig. 79-21).

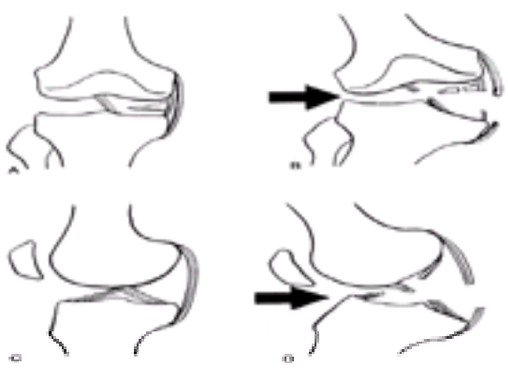

Figure 79-21. Severe ligamentous sprain. **A:** Anterior view of a normal joint. **B:** Severe lateral stress disrupts the medial collateral ligaments, medial meniscus, and anterior cruciate ligament—this is known as the *unhappy triad*. **C:** Lateral view of normal joint. **D:** Severe anterior stress. This can produce hyperextension of the joint and disrupt both the anterior and posterior cruciate ligaments and the posterior capsule. Examination reveals a positive drawer sign. (Modified from Cailliet R. *Knee pain and disability,* 2nd ed. Philadelphia: FA Davis, 1983.)

Diagnosis

Pain and a feeling of instability of the knee are common after ligament disruption. A “popping” sensation, as well as an audible pop, may be present. An immediate effusion is highly suggestive of an intraarticular ligament tear, and aspiration typically demonstrates a hemarthrosis. Tenderness over the medial or lateral aspect of the knee suggests involvement of the medial or lateral collateral ligament. Stability testing reveals laxity compared to the uninjured extremity; however, it is often difficult secondary to pain, especially in the presence of a tense effusion. Radiographs may reveal an avulsion injury in younger patients or may reveal medial or lateral joint space widening. MRI is a helpful diagnostic adjuvant. Examination under anesthesia provides additional information about the degree of injury (15).

Treatment

Isolated medial collateral ligament injuries are treated with protective weight-bearing with relative immobilization in a hinged knee brace to allow 30 to 60 degrees of active/passive motion for the first 3 weeks. Return to activity is limited until a full range of pain-free motion is obtained (15). Care must be taken to identify more severe injuries that include injury to the anterior collateral ligament.

Mild injuries to the lateral collateral ligament are treated with bracing and progressive exercises. More severe injuries can result in posterolateral rotatory instability, which should be repaired or reconstructed surgically.

Treatment of isolated injuries to the anterior cruciate ligament depends on multiple patient variables, including patient age, future demand to return to high-risk activities, associated injuries, and general laxity and alignment of the knee. Surgical reconstruction is required for patients with associated injuries (multiple ligament tears, meniscal tears) or those who desire to return to high-risk cutting and jumping sports. Proper positioning of the graft and postoperative rehabilitation are essential. Nonoperative treatment consists of bracing, strengthening exercises, and activity modification (15).

Isolated injuries to the posterior cruciate ligament are usually treated nonsurgically. Bracing and rehabilitation are usually successful. Reconstruction should be performed in patients with instability recalcitrant to conservative measures as well as patients with multiple ligament involvement (typically posterolateral).

Meniscal Injuries

Etiology

Meniscal injuries are encountered frequently in active adults. Classically occurring with a combination weight-bearing with rotatory stress, these injuries can occur secondary to both contact and noncontact injuries. Peripheral lesions occur in response to tension forces, whereas lesions to the body occur with compression (15).

Diagnosis

Pain localized to the joint line with or without mechanical symptoms of catching or locking suggests a meniscal tear. Joint line tenderness, effusion, and catching sensations may be reproduced on physical examination. Radiographs are typically normal. MRI results are technique-dependent but have been shown to be helpful. Diagnostic arthroscopy allows direct visualization of the pathology, including assessment of the stability of the meniscus.

Treatment

Studies suggest that as much of the meniscus as possible should be preserved at surgery to prevent premature degenerative disease. In general, partial-thickness tears, small tears in the vascular periphery, and stable tears should be left alone. Larger tears within the vascular periphery should be repaired, and large unstable tears out of the vascular periphery should be resected. Repairable tears with an associated anterior cruciate deficiency will fare better if the ligament is reconstructed (15).

Arthritides

Pyogenic Arthritis

The knee joint is prone to infectious involvement secondary to direct trauma or surgical intervention or from hematogenous spread from the distal femoral metaphysis, a site of frequent osteomyelitis. Systemic symptoms of fever with a recent infection elsewhere may be present. Typically, the knee is warm, swollen, tender to palpation and painful with range of motion. White blood cell count, erythrocyte sedimentation rate, and CRP are helpful in making the diagnosis but are not always elevated. Plain radiographs are typically normal. Bone scan may reveal increased uptake. Aspiration for culture before initiating antibiotics is mandatory. Younger children can be managed with serial aspirations. Adults who have had a prior total knee arthroplasty require open debridement with possible removal of components. Directed antibiotic therapy is usually curative.

Rheumatoid Arthritis

Rheumatoid arthritis is felt to be an autoimmune reaction to synovium (see Chapter 27). As such, it commonly leads to knee symptoms. Pain, stiffness, and swelling may be mild to debilitating. Mechanical deformities of alignment can occur. The goal of treatment is to reduce pain and enhance function. NSAIDs with modest doses of narcotics are usually successful; however, arthroscopic synovectomy or total knee arthroplasty may be necessary for progressive dysfunction.

Hemophilic Arthritis

Nontraumatic or minimally traumatic hemarthrosis is the common presentation with hemophilia. The knee is frequently involved. Frequent episodes can lead to synovial thickening and chronic knee symptoms. Aspiration of the hemarthrosis once the coagulation levels are corrected decreases symptoms. Improved control of the underlying coagulopathy helps prevent recurrence.

Other

Tuberculosis, human immunodeficiency virus, fungal infection, and Lyme disease are other infectious causes of acute arthritis of the knee. Systemic lupus, spondyloarthropathies, crystal deposition diseases, and sickle cell disease are all systemic diseases that may affect the knee. These also affect other joints and are discussed in more detail in Chapter 27.

Osteoarthritis

Etiology

Although degenerative joint disease is the most common cause of arthritis in the knee, the underlying etiology remains unclear. Generally, osteoarthritis is grouped into two categories: (a) primary (secondary to intrinsic mechanical, immune, vascular, or cartilage defect) and (b) secondary (secondary to trauma, infection, or congenital disorders). Primary osteoarthritis progresses more slowly, has an older age of onset, and is usually polyarticular when compared to secondary osteoarthritis. Deterioration and loss of the articular surface are followed by development of sclerosis, osteophytes, subchondral cysts, and narrowing of the joint space.

The pain associated with degenerative arthritis is secondary to inflammatory changes, synovitis, and mechanical pain from distortion of the capsule secondary to osteophytes. Pain is usually dull and aching, usually worse in the morning and after periods of rest, and usually improves with 30 to 60 minutes of activity.

Diagnosis

The diagnosis of degenerative joint disease is made from the history and radiographic signs. The classic radiographic signs are sclerosis of the joint line, osteophyte formation, subchondral cyst formation, and loss of the joint line. Radiographs do not always correlate with the severity of the symptoms. Computed tomography and MRI are useful to rule out other pathologic processes.

Treatment

The goal of treatment is pain control, with an accompanying increase in the ability to perform daily activities secondary to decreased pain. NSAIDs and salicylates remain the mainstay of medicinal therapy. Longer-lasting NSAIDs that allow once- or twice-a-day dosing have not proved to be more effective than traditional aspirin or ibuprofen. Some do have a lower incidence of gastrointestinal upset and offer a simplified dosing regimen. Thermal therapy has been shown to be effective for some patients. Overweight patients benefit from weight reduction.

Operative measures are reserved for patients who have failed conservative measures. Arthroscopic debridement and removal of loose bodies temporarily relieves symptoms. Younger patients who have unicompartmental disease and wish to remain active have benefited from high tibial osteotomy to alter the weight-bearing area of the joint. Total knee arthroplasty is effective at reducing pain and has a greater than 95% survivorship after 10 years (25).

Bursitis

Etiology

As noted, many bursae surround the knee, any one of which can become inflamed and cause pain. The pain may be acute and secondary to trauma, or it may be chronic and secondary to prolonged microtrauma. Pain is secondary to local inflammation and can be reproduced by pressure on the overlying soft tissues.

Diagnosis

The key differential diagnosis in patients with classic symptoms is between bursitis and an intraarticular process. Prepatellar bursitis is characterized as tenderness over the patella and a fluid mass that do not change in characteristics with range of motion. Inflammations in other bursae are not as easily diagnosed. A high index of suspicion must be held when there is a history of symptoms that are worse with motion and reproducible tenderness to palpation is found over the suspected bursae.

Treatment

Typically, conservative treatment will resolve symptoms. Rest, NSAIDs, and compressive dressings should be tried. Aspiration is reserved for more severe cases and should be followed with a compressive dressing in an attempt to oppose inflamed surfaces. In chronic bursitis, however, fibrosis, synovial thickening, and the formation of painful nodules may cause pain unresponsive to conservative measures. Surgical excision of the entire bursae may be required (9).

Synovitis

Etiology

Like bursitis, synovitis can be acute or chronic. Acute synovitis is most often caused by trauma, although foreign bodies, gout, and pseudogout are other common etiologies. Chronic synovitis lasts months and sometimes years and can be associated with rheumatoid arthritis, infection, ankylosing spondylitis, and other systemic disorders. It may also occur postoperatively (15).

Diagnosis

Synovitis produces a painful effusion and invariably causes decreased range of motion. Chronic synovitis may cause muscle atrophy secondary to disuse. A careful history of recent trauma, associated medical problems, and symptoms at other joints will help identify the cause. Radiographs help rule out foreign debris. MRI is not necessary, but diagnostic arthroscopy can readily identify the presence of synovial inflammation.

Treatment

Rest, NSAIDs, compression dressings, and occasionally aspiration are conservative treatment measures that are typically effective. Isometric quadriceps exercises should be performed to prevent atrophy. For chronic synovitis that is unresponsive to conservative measures, complete synovectomy has been performed, usually by arthroscopic means. Open mechanical procedures are often complicated by pain and hemarthrosis; however, arthroscopic laser or thermal ablation has shown promise (16).

Osteochondritis Dissecans

Etiology

Osteochondritis dissecans involves the subchondral bone and overlying cartilage. The origin is unclear but is thought to be traumatic. It typically involves the lateral aspect of the medial femoral condyle, with less than 1 to 2 cm of involvement. Early stages reveal subchondral injury without interruption of the articular surface. In late stages, the entire osteoarticular fragment may separate and create a loose body within the knee. The condition is most common in adolescence and occurs less frequently with increasing age. Males are more often affected than females (26,27).

Diagnosis

Pain and recurrent swelling are the most common symptoms. Catching and locking occur as the fragment separates. Standard radiographs may not visualize the fragment, and therefore oblique views are helpful. MRI can better demonstrate the lesion.

Treatment

Symptomatic lesions in adolescence are treated with immobilization for up to 3 months. Fixation of large fragments is recommended. Smaller loose bodies can be removed arthroscopically. Subchondral drilling and bone grafting are newer modalities (28).

Loose Bodies

Etiology

A loose body is any free-floating debris within the knee. The multiple etiologies include trauma, osteoarthritis, meniscal tears, osteochondritis dissecans, synovial chondromatosis, and tuberculosis.

Diagnosis

Loose bodies often cause a history of recurrent catching and locking of the knee. Patients can frequently disengage the loose body with manipulation of the knee. Physical examination is frequently normal except for a slight effusion. Radiographs may identify the loose body if it is osseus, but they represent the location of the body only at the time the radiograph was taken.

Treatment

Treatment is directed at symptoms. If symptoms are mild and infrequent, observation may be warranted. Removal of the loose bodies is typically performed via an arthroscope. Careful examination of the entire joint is necessary to avoid missing any fragments (28).

Baker's Cyst

Etiology

Popliteal cysts can be produced either by herniation of the synovial membrane through the capsule or by communication of fluid with the bursa around the knee. They may arise in children or adults and may be associated with an underlying disease such as rheumatoid arthritis.

Diagnosis

Popliteal cysts typically present as a tender, swollen area in the posterior knee. Although they are frequently found on routine examination, they must be differentiated from a vascular thrombosis or soft tissue tumor. Cysts are typically translucent. Radiographs are not usually helpful, and ultrasound and MRI provide more information.

Treatment

Small cysts in children frequently resolve. Treatment for chronic or symptomatic cysts should be directed at the underlying cause. When the cyst is associated with a significant effusion, correction of intraarticular pathology (i.e., meniscectomy for posterior horn meniscal tears) is usually sufficient. If the cyst does not appear to communicate, an open resection is needed (29).

Patellofemoral Pain

Etiology

Patellofemoral pain is a difficult condition to diagnose and treat, owing to the wide variety of symptoms. Generally thought of as an overuse injury, maltracking of the patella within the femoral trochlea and medial quadriceps muscle weakness are currently viewed as significant factors. Abnormal tracking increases the proportion of force absorbed by the patella and may lead to degenerative changes within the patellofemoral compartment.

Diagnosis

This condition is classically described as anterior knee pain. The onset of symptoms may be acute, but patients more frequently present with chronic pain. Difficulty with stair climbing and descending, kneeling, prolonged sitting, or squatting is a frequent complaint. Physical examination may demonstrate tenderness of the peripatellar tissues, crepitus with knee range of motion, and malalignment of the patella. A tangential view of the patella (sunrise view) should be obtained, although it is often nonspecific. An MRI can rule out other internal knee abnormalities but is not specific for patellofemoral pain.

Treatment

The majority of patients respond to rehabilitation. Strengthening of the medial quadriceps musculature is emphasized. Gradual return to athletic participation is essential. Some success has been reported with special taping procedures. Gross malalignment may need surgical correction. Lateral retinacular release, tibial tubercle medializations, and even patellectomy have been performed.

Tendinitis

Etiology

Patellar tendinitis is the most common tendinitis affecting the thigh and knee. As with other areas of the body, tendinitis is an overuse injury that occurs with repetitive motions, such as running, jumping, and climbing. It is common in repetitive motion sports such as basketball, tennis, soccer, and weightlifting. It is felt to be secondary to eccentric loading of the myotendinous junction.

Diagnosis

Diagnosis is confirmed by a history of pain with repetitive motions. Tenderness may not be reproducible if the tendinitis is in an early stage. Radiographs are not necessary initially but are useful for patients who do not respond to initial treatment.

Treatment

Initial treatment consists of rest, ice, compression, and NSAIDs. Ultimate improvement depends on the strengthening and stretching of the involved muscle. Returning to sports participation too soon leads to recurrent symptoms. Conditioning is essential to prevention of recurrence.

Apophysitis

Etiology

Apophysitis is similar to tendinitis but occurs in skeletally immature children. Repetitive loading through the unfused apophysis results in a traction injury. The tibial tubercle is the most common site (Osgood-Schlatter disease), but it can also occur at the distal pole of the patella (Sinding-Larsen-Johansson syndrome) and other apophysis in the body.

Diagnosis

History of infrapatellar knee pain and tenderness to palpation of the involved apophysis are diagnostic. Radiographs occasionally demonstrate enlargement of the tibial tubercle and assist with ruling out other pathology.

Treatment

Apophysitis is usually self-limiting as the child reaches skeletal maturity. Proper stretching and warm-up before activities, with ice and compression after participation, may decrease symptoms. Neoprene sleeves and NSAIDs may provide additional relief. Rarely, long leg casting may be required for severe symptoms.

Congenital Diseases

Multiple congenital and developmental abnormalities affect the growing child. Gait abnormalities can be the result of hip, thigh, knee, leg, or foot abnormalities. A complete discussion of the many abnormalities is beyond the scope of this chapter. A careful history (including pregnancy and family diseases), physical examination (with close observation of gait and leg length discrepancies), and basic screening radiographs often assist in the appropriate diagnosis. Any pain with ambulation is abnormal in a child and warrants further investigation.

CHAPTER 80

Pain in the Leg, Ankle, and Foot

Alastair S. E. Younger and Bruce J. Sangeorzan

Leg, ankle, and foot pains are common reasons for physician consultation. Only backache and headache result in more frequent visits to primary physicians (1,2). Foot and ankle pain is the second most common complaint seen by orthopedic surgeons after back pain (3). Orthopaedic conditions cause the largest number of chronic conditions in the U.S. population, with 14% of patients having an orthopaedic complaint (4). Flat feet cause activity limitation in 1.5% of the population. Comparatively, orthopaedic impairment of the lower extremity (all conditions) causes limitation in 5.0% of the population (4). Hereditary problems, poor posture, poor footwear, trauma, infections, and arthritis are common underlying causes of foot pain. This broad number of etiologies and the complex anatomy of the leg, ankle, and foot make diagnosis and treatment of foot and ankle conditions a challenge. A thorough knowledge of the anatomy, biomechanics, and function of this area is required for effective treatment.

The material in this chapter is presented in five major sections: Basic Considerations, including classification and epidemiology of foot and ankle pain and a review of local anatomy, function, and biomechanics; Evaluation of the Patient, expanding the information in Chapter 12; Painful Disorders of the Leg; Painful Disorders of the Ankle and Heel; and Painful Conditions of the Foot.

BASIC CONSIDERATIONS

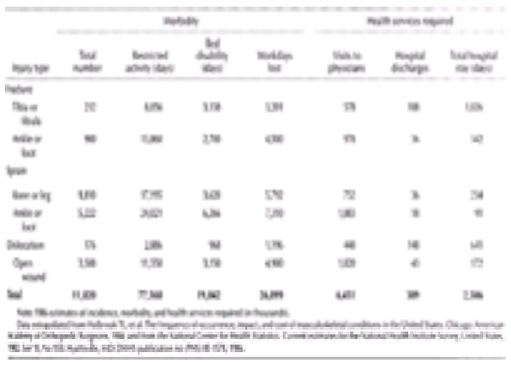
Etiology

Table 80-1 lists the most important painful disorders that affect the leg, ankle, and foot. Those listed in the first three major categories are discussed in this chapter. Those in the fourth and fifth categories are covered in Chapter 19, Chapter 20, Chapter 21, Chapter 22 and Chapter 23, Chapter 28, Chapter 29 and Chapter 30, Chapter 33, and Chapter 77.

TABLE 80-1. Classification of painful disorders in the leg, ankle, and foot

Epidemiology

The National Ambulatory Medical Care Survey 1980–1981 (1) estimated that in 1986 acute pain in the knee, leg, ankle, and foot resulted in approximately 5 million visits to physicians in the United States. This is second only to the number of physician visits caused by ear pain. Chronic painful conditions in the foot and ankle result in nearly 4 million visits to physicians, representing 10% of all visits for chronic painful conditions (2). Estimates have been made for the type, number, morbidity, and health services required by various musculoskeletal disorders and injuries of the leg, ankle, and foot (Table 80-2).



Injury type	Morbidity: Total number	Morbidity: Restricted activity (days)	Morbidity: Bed disability (days)	Morbidity: Workdays lost	Health services required: Visits to physicians	Health services required: Hospital discharges	Health services required: Total hospital stay (days)
Fracture							
Tibia or fibula	212	6,876	3,118	1,334	578	108	1,026
Ankle or foot	900	11,860	2,750	4,500	970	74	542
Sprain							
Knee or leg	5,810	57,195	3,420	5,792	752	36	234
Ankle or foot	5,222	24,021	6,264	7,210	1,082	58	911
Dislocation	176	2,886	960	1,776	448	148	640
Open wound	2,500	11,750	3,750	4,900	1,020	40	172
Total	11,820	77,568	19,842	26,099	4,451	389	2,586

Note: Title estimates of incidence, morbidity, and health services required (in thousands).

Data extrapolated from Holbrook TL, et al. The frequency of occurrence, impact, and cost of musculoskeletal conditions in the United States. Chicago: American Academy of Orthopaedic Surgeons, 1984, and from the National Center for Health Statistics. Current estimates from the National Health Interview Survey, United States, 1983. Jan'll, No.155. Hyattsville, MD: DHHS publication no (PHS) 85-1571, 1984.

TABLE 80-2. Musculoskeletal injuries involving the leg, ankle, and foot

Table 80-2 also lists the incidence of musculoskeletal injuries involving bones, joints, and soft tissues of the leg, ankle, and foot (1,2). These injuries, together with arthritis and other conditions affecting the leg, ankle, and foot, are among the most frequent causes of pain and disability in the United States. Similar trends are expected in other industrialized nations. The economic impact is significant and, taking into account the 1984 cost for workdays lost, visits to physicians, and hospital stays for acute injuries and pain, amounts to approximately $2.4 billion (3). This number does not take into account the economic impact of arthritis, infections, tumors, and other chronic painful conditions. The estimated cost for all conditions probably exceeds $8.5 billion (5).

Anatomy and Function of the Leg, Ankle, and Foot

Although the anatomy of the lower and upper extremities shares similarities, the functions are very different (6). The distal part of the upper limb is structured for versatility of movement, whereas the lower limb is built for weight-bearing and locomotion. Evolution and embryologic development demonstrate rotation and extension of the lower limb that position the foot for erect stance. Therefore, the flexor aspect of the leg faces posteriorly and the extensor aspect, anteriorly. In the anatomic position, the thumb is on the hand's lateral margin, whereas the great toe is on the foot's medial margin (6). The sole of the foot faces backward, and the palm of the hand faces forward. The foot is positioned at right angles to the leg. Flexion of the foot is described as *plantar flexion* and extension is called *dorsiflexion* (6).

The total body weight during weight-bearing is transmitted though the ankle and foot. Thick heel and toe pads act as shock absorbers during walking and running, and the joints are capable of making adjustments necessary for fine balance on various terrain (7). In some forms of strenuous physical activity, the ground reaction force is five times body weight. Because of the mechanics of the foot and ankle, the forces in the ankle are two to three times larger than the ground reaction force. Peak ankle joint forces may exceed 15 to 20 times body weight (7).

Anatomy

Tibia and Fibula. The tibia and fibula, two parallel bones, constitute the skeleton of the leg corresponding to the radius and ulna. However, unlike the radius and ulna, little motion occurs between the lower limb bones at the proximal and distal articulation (6). The fibula does not articulate at the knee as the radius does at the elbow. The fibula acts mainly as an origin for muscles and has little weight-bearing role (8) (Fig. 80-1).

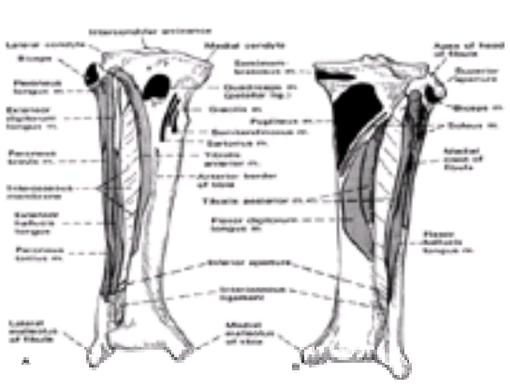


Figure 80-1. Anatomy of the tibia and fibula showing the sites of origin (*gray areas*) and insertion (*black areas*) of the muscles that move the ankle and foot. **A:** Anterior view. **B:** Posterior view. The lateral condyle has a raised area into which most of the iliotibial tract inserts. The facet for articulation with the head of the fibula is on the curved inferior surface of the lateral condyle. The semimembranosus muscle inserts on the medial condyle into a posteriorly placed deep transverse groove. The anterior border and medial surface of the tibia are largely subcutaneous. The posterior surface gives origin to most of the soleus, tibialis posterior, and flexor digitorum longus muscles. The posterior tibia receives the insertion of the popliteus and two of the hamstring muscles. The medial border of the tibia extends into the medial malleolus. This has an articular surface on the medial side continuous with the distal tibia. These articular surfaces, with the lateral malleolus formed by the distal fibula, form the ankle mortise articulating with the dome of the talus. The fibula articulates with the lateral border of the distal tibia at the fibular notch. The proximal head of the fibula is subcutaneous and rises laterally to its apex; the facet for its articulation with the tibia is on its medial crest. The lateral malleolus is the expanded lower end of the fibula and is also subcutaneous. Its medial articular surface forms the lateral part of the ankle mortise. (Modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985.)

The tibia and fibula articulate at proximal and distal tibiofibular joints and are joined together by the capsules of both joints as well as the intraosseous membrane. The superior tibiofibular joint is a synovial joint between the head of the fibula and a posterolateral part of the lower surface of the lateral tibial condyle. The anterior and posterior ligaments of the head of the fibula run upward and medial to the tibia and strengthen its capsule (see Fig. 80-1). This joint is innervated by the common peroneal nerve and the nerve to the popliteus muscle, a branch of the tibial nerve.

The interosseous membrane consists of thin but strong fibers passing downward and laterally joining the interosseous margin of the tibia to the sharp medial border of the fibula (see Fig. 80-1). The membrane separates the muscles of the anterior compartment from the posterior compartment and forms a large surface for the origin of muscles in both compartments. Above the proximal end of the membrane, just below the superior tibiofibular joint, is a large oval aperture for passage of the anterior tibial vessels to the anterior compartment. Close to its distal end (approximately 5 cm above the lateral malleolus) is a smaller aperture for the perforating branch of the peroneal artery. Between the adjacent distal ends of the tibia and fibula, the membrane is continuous with the crural tibiofibular interosseous ligament.

The tibiofibular interosseous ligament is composed of thick, short, strong fibers that run from the tibia to the fibula ending short of the articular margin of the ankle joint (6,8). The interosseous ligament is much stronger than the interosseous membrane. It prevents separation of the distal tibia and fibula and stabilizes the ankle joint. Rosse (9) has pointed out that the ligament is so strong that, when these forces are excessive (e.g., in an eversion injury), the fibula fractures distal to the ligament rather than the ligament rupturing. These injury patterns depend on the ratio of the strength of the ligaments and bones. Very old and very young patients will fracture bone, whereas the patients between these ages are more likely to tear ligaments. The tibiofibular interosseous ligament allows rotational displacement of the malleolus, with greater motion occurring at the proximal tibiofibular joint (see Fig. 80-1) (7).

The inferior tibiofibular joint is a fibrous joint stabilizing the distal end of the fibula in a groove on the lateral aspect of the tibia. It is essential for the integrity of the ankle joint. The inferior tibiofibular joint is stabilized by the interosseous ligament and the thinner, weaker anterior and posterior inferior tibiofibular ligaments, placed superficially on the front and back of the joint. The joint is innervated by the tibial and peroneal nerves as outlined in Hilton's law (6).

Muscles of the Leg and Foot

Muscular Compartments of the Leg. Figure 80-2 illustrates the compartments of the leg at midcalf level (10). The muscles within these compartments provide movement at the ankle, tarsus, and toes and flexion at the knee (gastrocnemius). The muscles are arranged in a manner similar to that of the prime movers of the wrist and carpus. The anterior compartment contains the extensors; the deep posterior compartment contains the flexors of the toes and tarsus. The superficial posterior compartment contains the flexors of the ankle, the triceps surae (6). A third compartment containing the peroneal muscles is present laterally for which there is no counterpart in the forearm. Each compartment is supplied by a nerve. The tibial nerve supplies the flexor compartment, the deep peroneal nerve supplies the extensors, and the superficial peroneal nerve supplies the peroneal compartment. Table 80-3 lists the muscles of the leg and foot, their function, and their nerve supply.

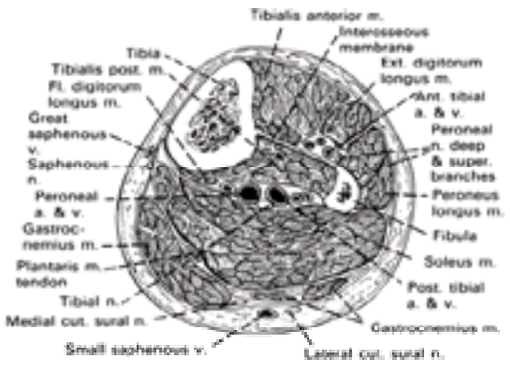

Figure 80-2. Transverse section of the leg at midcalf showing the three major compartments covered by the deep fascia of the leg, which is also known as the *crural fascia*. The anterior and posterior compartments are separated by the interosseous membrane. The anterior and posterior crural intermuscular septa enclose the peroneus longus and brevis, which separate the peroneal compartment from the anterior and posterior compartments. Note the location of the major vessels and nerves. (Modified from Eycleshymer AC, Schoemaker DM. *A cross-sectional anatomy.* New York: Appleton- Century-Crofts, 1911:96.)

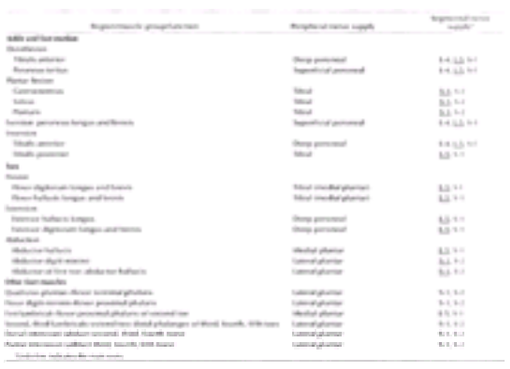

TABLE 80-3. Muscles of the leg, ankle, and foot and their nerve supply

Prime Movers of the Ankle

FLEXOR COMPARTMENT (PLANTAR FLEXORS). Figure 80-3 shows the muscles of the back of the leg (11). The gastrocnemius, soleus, and plantaris act together as the triceps surae within the superficial posterior compartment. These three muscle bellies are the most powerful plantar flexors of the foot (6,8). Other muscles pass behind the axis of the ankle but, because they are smaller and have a less efficient lever arm, they are less powerful plantar flexors of the ankle (6,8). These muscles include the tibialis posterior, peroneus longus and brevis, flexor hallucis longus, and flexor digitorum longus.

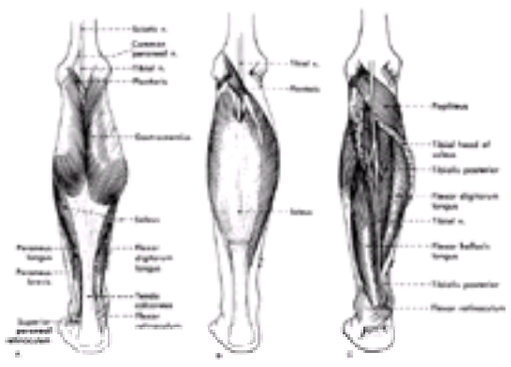

Figure 80-3. Posterior muscles of the left leg. All are plantar flexors, although some also act to flex and invert the foot or toes. **A:** The gastrocnemius muscle is superficial, with heads originating from the posterior aspect of the medial and lateral femoral condyles. Each head inserts onto the soleus, together forming the Achilles tendon, which inserts into the posterior surface of the calcaneus. **B:** The second layer consists of the soleus and plantaris muscles. The soleus arises from two heads, one on the tibia and the other on the fibula and interosseus membrane. A tendinous arch unites the two heads from which additional fibers arise. Under the fibrous arch runs the tibial nerve. Its muscular fibers end in a broad aponeurosis into which the gastrocnemius muscle inserts. The plantaris arises from the lateral condyle of the femur, passes obliquely medially, and forms a thin tendon that inserts just medial to the tendo calcaneus on the calcaneus. **C:** The deep muscles of the calf showing the tibial nerve. The soleus, gastrocnemius, and plantaris form the superficial posterior compartment. The tibial nerve is superficial to the muscles of the deep posterior compartment. The tibialis posterior arises from the interosseous membrane and from the adjoining parts of the posterior surfaces of the tibia and fibula (see Fig. 80-1B). The tendon lies deep to the flexor digitorum longus and lies beside it in a tendon sheath on a groove on the medial malleolus. The tendon passes deep to the flexor retinaculum and superficial to the deltoid ligament. It inserts into the tuberosity of the navicular bone with fibers going to other bones in the midfoot (see Fig. 80-15). This muscle (with the tibialis anterior) inverts the foot. The flexor digitorum longus arises from the tibia and the flexor hallucis arises from the fibula. Both tendons enter the sole of the foot behind the medial malleolus, and both are invested in tendon sheaths. The common tendon of the flexor digitorum longus splits into four tendons with their own sheaths to insert into the base of the distal phalanges of the second, third, fourth, and fifth toes, and the flexor hallucis inserts into the base of the distal phalanx of the great toe. These muscles flex the toes (see Fig. 80-15 for insertions of these muscles). (Reprinted from Rosse C. *Hollinshead's textbook of anatomy,* 5th ed. Philadelphia: Lippincott–Raven Publishers, 1997:371, 372, with permission.)

EXTENSOR COMPARTMENT (DORSIFLEXORS). The tibialis anterior and peroneus tertius are the two main dorsiflexors of the ankle and also act on the midtarsal joint. The extensor hallucis longus and extensor digitorum longus act primarily to extend the great toe and lesser toes, respectively. They also weakly dorsiflex the ankle and midtarsal joints (Fig. 80-4) (7). The tibialis anterior is the bulkiest muscle in the anterior compartment and acts to dorsiflex and invert the foot. The peroneus tertius arises with the muscle belly of the digital extensor but, because its tendon inserts into the base of the fifth metatarsal, dorsiflexes the ankle (Fig. 80-5).

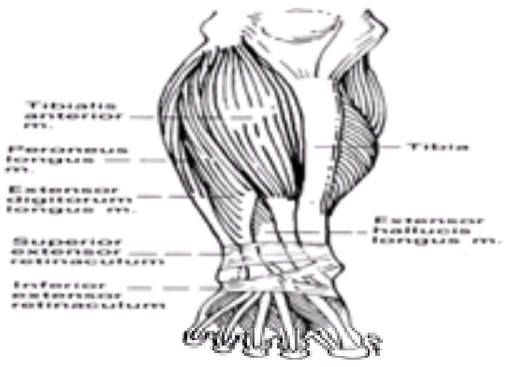

Figure 80-4. Anterior muscles of the leg. The tibialis anterior arises from the inferior surface of the lateral condyle of the tibia and the adjacent interosseous membrane. It inserts into the medial cuneiform after passing under the extensor retinaculum. It is the largest anterior compartment muscle. The extensor digitorum longus and extensor hallucis longus arise from the anterior surface of the tibia and pass under the superior and inferior extensor retinacula. The extensor digitorum longus divides into four separate tendons that split around the four smaller toes and insert into the volar plate of the proximal interphalangeal joints. These tendons therefore act to extend the toes at the metatarsophalangeal joint but not at the interphalangeal joints. The extensor hallucis longus inserts into the distal phalanx of the great toe. The peroneus tertius arises from a small area on the anterior tibia and adjacent interosseous membrane. The tendon passes under the extensor retinaculum lateral to the extensor digitorum brevis and inserts into the fifth metatarsal base. The tibialis anterior acts as an ankle dorsiflexor and inverter, whereas the peroneus tertius acts as a dorsiflexor and everter (see Fig. 80-15 and Fig. 80-16 for insertions of these muscles). (Modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985.)

Figure 80-5. Lateral muscles of the left leg. The two anterolateral compartment muscles are the peroneus longus and peroneus brevis arising from the head and upper two-thirds of the lateral surface of the tibia (see Fig. 80-1A). The two tendons pass behind the lateral malleolus, lateral to the axis of the subtalar joint. The brevis inserts into the base of the fifth metatarsal. The longus enters the sole of the foot in a groove of the cuboid bone and crosses the sole before inserting into the base of the first metatarsal and the bones around it (see Fig. 80-16 for the insertions of these muscles). The brevis muscle everts the foot, and the longus acts to plantar flex the great ray and everts the ankle. (Reprinted from Rosse C. *Hollinshead's textbook of anatomy,* 5th ed. Philadelphia: Lippincott–Raven Publishers, 1997:377, with permission.)

Extrinsic Flexors and Extensors of the Toes. The superficial flexor of the arm is analogous to the soleus. The soleus muscle belly forms a tendon inserting onto the calcaneus. The tendon insertion continues distal to the heel, forming in the same plane the flexor digitorum brevis, which inserts into the middle phalanx of the toes similar to the profundus in the hand. Therefore, only one common extrinsic digital flexor is found in the calf, the flexor digitorum longus (see Fig. 80-3C), analogous to the flexor digitorum profundus in the forearm (6) (see Fig. 80-4). The flexor hallucis longus corresponds to the flexor pollicis longus. The flexor digitorum longus arises from the tibia, and the flexor hallucis arises from the fibula (see Fig. 80-1B); the tendons pass on the medial side of the heel and enter the sole of the foot through the tarsal tunnel behind the malleolus (Fig. 80-6). Also contained in the tarsal tunnel are, from medial to lateral, the tibialis posterior tendon, the digitorum longus, the blood vessels, the tibial nerve, and the hallucis longus. The tendons are invested in synovial sheaths and are kept in place by the flexor retinaculum, which is much thinner than the corresponding structure in the wrist (6,10) (see Fig. 80-6). The flexor tendons insert into the distal phalanges. The anatomic arrangement of synovial and fibrous flexor sheaths in the toes through which the tendons pass is similar to that of the fingers.

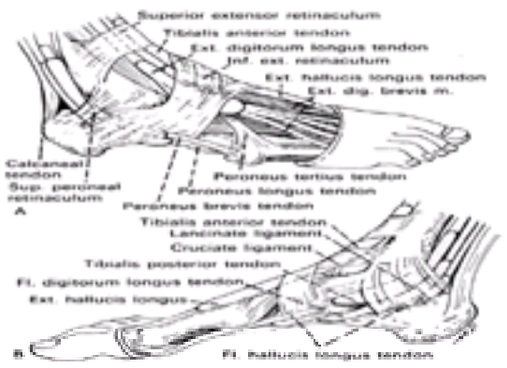

Figure 80-6. Synovial sheaths of the tendons around the ankle. **A:** Anterolateral aspect showing the tendons and synovial sheaths of the tibialis anterior and extensor digitorum longus passing under the superior and inferior extensor retinacula. Beyond the sheath, the extensor digitorum longus divides into four tendons. The extensor hallucis longus inserts into the base of the distal phalanx of the great toe. Note the insertion of the peroneus tertius onto the bases of the fifth metatarsal (see Fig. 80-16B). The peroneus longus and brevis have individual synovial sheaths that pass under the peroneal retinaculum. **B:** Medial aspect showing the synovial sheaths of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus passing behind the medial malleolus. These tendons are covered by the flexor retinaculum covering the end of the tibial nerve and the beginning of two plantar nerves. This is a site for entrapment of these nerves. (Modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985.)

The extensor hallucis longus and extensor digitorum longus are located in the anterior compartment (see Fig. 80-4). Both originate from the fibula and insert into the toes through the dorsal digital expansions, analogous to those in the fingers, and act mainly to extend the metatarsophalangeal (MP) joints (see Fig. 80-16). The tendons are held in place in front of the ankle by the superior and inferior extensor retinacula and are enclosed in a synovial membrane (see Fig. 80-4). Unlike the hand, an additional short extensor muscle exists on the dorsum of the foot extending all of the toes.

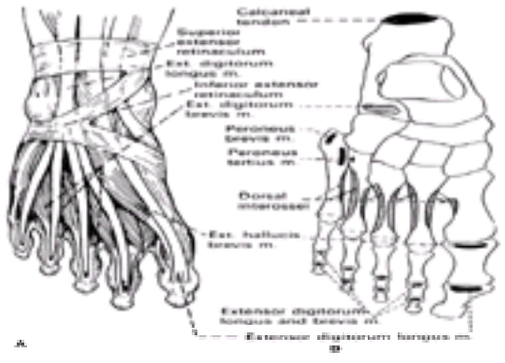

Figure 80-16. **A:** Muscles of the dorsal surface of the right foot. **B:** Dorsal view of the bones of the foot showing the origins of the intrinsic muscles (*striped*) and the insertions of the intrinsic and extrinsic muscles (*black*). (Modified from Hollinshead WH. *Anatomy for surgeons,* 3rd ed. Vol 3. Philadelphia: Harper & Row, 1982.)

Inverters and Everters. The peroneus brevis is the primary everter of the foot (see Fig. 80-5). The peroneus longus inserts mainly into the base of the first metatarsal on the plantar aspect having passed around the lateral border of the cuboid. It acts primarily to plantar flex the great ray and everts the ankle as a secondary function. Both peroneal muscles arise from the fibula and pass behind the lateral malleolus. The brevis inserts into the base of the fifth metatarsal.

The tibialis posterior, the deepest muscle in the flexor compartment, is the principal inverter of the foot (see Fig. 80-3). In this function it is substantially assisted by the tibialis anterior (see Fig. 80-4).

Many other muscles act to invert and evert the foot at the subtalar and midtarsal joints. Even the tendo Achilles can act to both invert or evert the foot in severe cavus deformity and flatfoot, respectively. As a flatfoot deformity progresses, the muscles acting to invert the foot have less mechanical advantage and those acting to evert the foot have greater mechanical advantage, explaining the rapidly progressive nature of severe flatfoot.

Figure 80-6 illustrates the synovial sheaths of the tendons and retinacula around the ankle joint.

Nerve and Blood Supply of the Leg. Figure 80-7 depicts the major arteries and nerves of the leg (6,8). The anatomy and distribution of the tibial and peroneal nerves are described in detail in Chapter 77. The leg and foot receive their arterial blood supply from the lower portion of the popliteal artery and its two terminal branches, the anterior tibial and posterior tibial arteries. The popliteal artery has two lower branches, the lateral and medial inferior genicular arteries. Both of these vessels terminate in the circumpatellar anastomosis and contribute to the blood supply of the knee and the surrounding ligaments. The anterior tibial artery arises from the posterior tibial artery and passes anteriorly through the superior aperture of the interosseous membrane. It descends to the ankle sitting on the interosseus membrane in the anterior compartment and has the dorsalis pedis artery as its terminal branch.

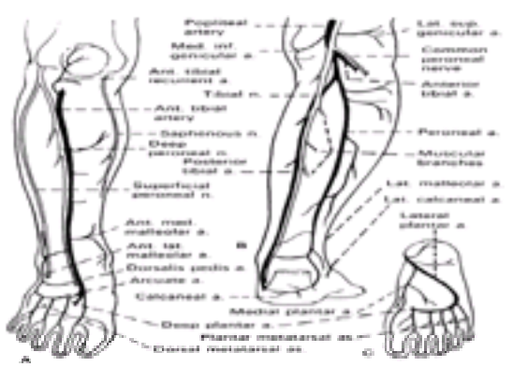

Figure 80-7. Nerve and blood supply of the leg. **A:** Anterior view.**B:** Posterior view. **C:** Plantar surface of the foot. The anatomy of the nerves is described in Chapter 70. (Modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985.)

The anterior tibial artery gives off (a) the fibular artery before it passes through the interosseus membrane, which supplies the soleus and peroneus longus muscles; (b) the anterior tibial recurrent artery, which terminates in the patellar plexus; (c) numerous muscular branches that supply the muscles of anterior compartment; and (d) the anterior medial and lateral malleolar arteries, which supply the ankle joint. The terminal branch, the dorsalis pedis artery, gives off the lateral and medial tarsal arteries and the arcuate arteries (see Fig. 80-7).

The posterior tibial artery descends in back of the leg as far as the ankle, where it divides into the medial and lateral plantar arteries. It lies between the deep and superficial posterior compartments alongside the tibial nerve. Along its course it gives off (a) the large peroneal artery, which gives off numerous muscular branches, nutrient arteries to the tibia and fibula, and perforating and communicating branches; (b) a large nutrient artery to the tibia; (c) muscular branches to the soleus and deep muscles in the back of the leg; (d) the posterior medial malleolar artery, which contributes to the malleolar arterial network and blood supply to the talus, and several large medial calcaneal arteries.

Anatomy of the Ankle and Foot

Skeleton. The foot is an intricate structure composed of 28 articulating bones similar to the bones of the hand and modified for weight-bearing (Fig. 80-8). The bones of the ankle and foot are the tarsals, metatarsals, and phalanges. The tarsal bones differ from the carpal bones of the wrist, but the metatarsals and phalanges are similar to the metacarpals and phalanges of the hand (6,11). The bony skeleton of the foot is divided into the forefoot, the midfoot, and the hindfoot. The metatarsals and phalanges form the forefoot; the navicular, cuboid, and cuneiforms form the midfoot; and the talus and calcaneus form the hindfoot.

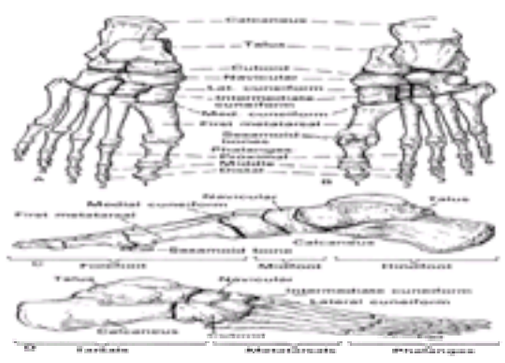

Figure 80-8. Bones of the ankle and foot. **A:** Superior surface. **B:** Plantar surface. **C:** Medial view. **D:** Lateral view. The seven bones of the hindfoot and midfoot, which constitute the tarsus, are arranged in two rows, with one bone between them. In the posterior row the talus sits on the calcaneus, and in the distal row the cuneiform bones and cuboid lie side by side. The navicular bridges the two rows on the medial side. The talus articulates with tibia and fibula so all force within the foot must pass through the talus. Normally the calcaneus and the heads of the five metatarsals are the weight- bearing points of the foot **(C,D)**. The skeleton of the foot has an arch between the calcaneus and metatarsal heads, with the arch being much higher on the medial side **(C)** than on the lateral side **(D)**. The calcaneus, the largest bone of the foot, forms the contour of the heel. The calcaneus supports the talus and transmits the ground reaction force applied to the heel. The calcaneus

forms a lever arm for the insertion of the Achilles tendon. The tubercle of the navicular is palpable 3.5 cm anterior to the medial malleolus. Its posterior concave surface articulates with the head of the talus, and its anterior or distal convex surface articulates with the three cuneiform bones. The cuboid articulates with the fourth and fifth metatarsals anteriorly, the lateral cuneiform and navicular bones medially, and the calcaneus posteriorly. The three cuneiforms, together with the cuboid forming the distal row of tarsal bones, are in line with the three medial rays of the foot and articulate with the corresponding metatarsals. The arrangement of the metatarsals and phalanges is similar to the corresponding segments of the hand. (Modified from Hollinshead WH. *Anatomy for surgeons,* 3rd ed. Vol 3. Philadelphia: Harper & Row, 1982.)

The talus has a body, neck, and head (Fig. 80-9) (8,12). Most of the body, the large trochlea, articulates with the tibia and fibula, together forming the ankle joint. The talus is hard to palpate. The calcaneus is the largest tarsal bone and forms the heel. It supports the talus and articulates with the cuboid laterally. Various parts of the calcaneus are palpable. The sustentaculum tali, a finger's breadth below the tip of the medial malleolus, supports the talus and can be identified as a buttress projecting medially from the calcaneus. Both the medial and lateral walls as well as the tuberosity can be clearly felt. The sinus tarsi is a depression between the body of the talus, the neck of the talus, and the calcaneus opening laterally just anterior and inferior to the lateral malleolus (13).

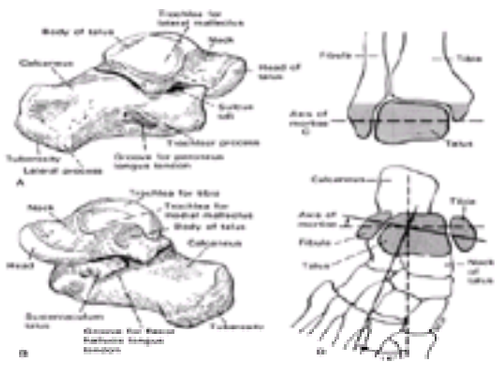

Figure 80-9. Anatomy of the right talus and calcaneus showing their relationship to the tibia and fibula, to other bones of the tarsus, and to the proximal ends of the metatarsals. **A:** Lateral view.**B:** Medial view. The talus has a body, a neck, and a head. **C:** The superior aspect of the large trochlea tali and both sides of the body articulate with the tibia and fibula, together forming the ankle mortise. The tibia contacts the entire superior aspect of the talus, with the medial malleolus extending one-third of the way down the medial aspect of the talus. The lateral malleolus covers the lateral aspect of the body of the talus. The rounded head of the talus fits into the concavity of the navicular bone. The inferior surface of the neck forms the roof of the tarsal canal, the floor being formed by the calcaneus. The tarsal canal separates the nonarticular portions of the talus and calcaneus. The talar neck is situated between the head and trochlea and fits closely between the two malleoli. The axis of rotation of the ankle is oblique to both the long axis of the foot and tibia. **D:** From above, the talus is wedge shaped, with the anterior portion wider than the posterior portion. The longitudinal axis of the joint is perpendicular to the axis of the mortise and forms an external “toe-out” of 16 degrees. (**A** and **B** modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985, with permission. **C** and **D** modified from Cailliet R. *Foot and ankle pain,* 2nd ed. Philadelphia: FA Davis, 1983.)

The navicular is a disk-shaped bone, identifiable by a tubercle that is 3.5 cm anterior to the medial malleolus, level with the sustentaculum tali. It can be identified by following the tibialis posterior tendon distally. It articulates with the talus proximally and the medial and middle cuneiforms distally. The three cuneiforms articulate with the medial three metatarsals. The cuboid articulates with the lateral two metatarsals and is palpable just proximal to the prominent tuberosity of the fifth metatarsal.

Joints

ANKLE JOINT. The ankle joint is a hinge, uniaxial, or ginglymus joint (6,12). It is formed above by the lower end of the tibia and the medial malleolus and the lateral malleolus of the fibula. The mortise articulates with the talus on its convex proximal surface and the flat medial and lateral facets. A cast of the ankle mortise duplicates all contours of the articular surface of the talar body, and hence is one of the most constrained joints of the body (6). A good fit is maintained throughout the whole range of plantar flexion and dorsiflexion. No lateral play or accessory motion occurs in any position. The distance between the malleoli does not change in dorsiflexion, although a small amount of lateral rotation of the fibular malleolus is permitted by the obliquity of the tibiofibular interosseous ligament, accommodating the wider anterior talus during full dorsiflexion (7).

The bones are connected loosely by the articular capsule. The medial deltoid ligament complex and lateral collateral ligament complex provide stability to the ankle joint (Fig. 80-10) (8). Part of the medial deltoid ligament and the lateral calcaneofibular ligament stabilizes the subtalar joint (14). The deltoid ligament inserts into the spring ligament stabilizing the talonavicular joint.

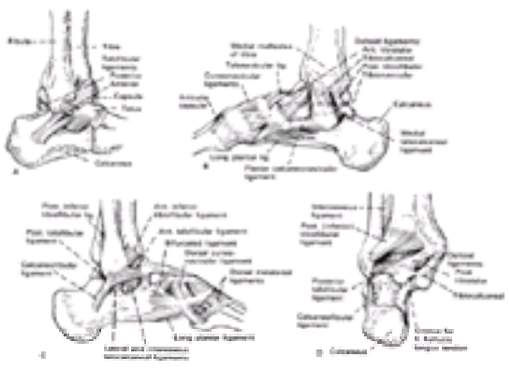

Figure 80-10. Anatomy of the capsule and ligaments of the right ankle joint. **A:** Lateral view: The articular capsule surrounds the joint, attaching above to the borders of the articular surface of the tibia and malleoli and below to the talus around its articular surface. **B:** Medial view: The medial collateral “deltoid” ligament fans out in a triangular shape from medial malleolus, attaching into the navicular anteriorly and the calcaneus and talus posteriorly. The deltoid ligament has superficial and deep portions. The superficial anterior portion is the tibionavicular ligament. The superficial posterior portion is the tibiocalcaneal ligament inserting into the sustentaculum tali. The anterior and posterior tibiotalar ligament inserts into the talus and forms the deep portion of the deltoid ligament. The deltoid ligament is covered by the tendons of the tibialis posterior and flexor digitorum longus. **C:** Lateral view: The lateral collateral ligament consists of three discrete bands. The short anterior talofibular ligament arises from the anterior margin of the lateral malleolus and inserts onto the lateral aspect of the talar neck. The posterior talofibular ligament, stronger and deeper than the anterior ligament, runs almost horizontally from the posteromedial aspect of the lateral malleolus to insert in a prominent tubercle on the posterior surface of the talus, lateral to the flexor hallucis longus tendon. The calcaneofibular ligament, the strongest of the three, is a narrow rounded cord passing from the apex of the lateral malleolus to a tubercle on the lateral surface of the calcaneus. **D:** This posterior view of the ankle joint showing the posterior inferior tibiofibular, posterior talofibular, posterior tibiotalar, and tibiocalcaneal ligaments. (Modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985.)

The articular capsule surrounds the joint. It inserts superiorly on the articular border of the tibia and malleoli and inserts inferiorly on the talar articular surface (see Fig. 80-10A). The anterior and posterior capsule is thin.

The collateral ligaments provide side-to-side stability to the ankle (see Fig. 80-10B,Fig. 80-10C). Inversion and eversion injuries may rupture the lateral or medial

collateral ligaments or fracture the malleoli. In a young adult, fracture dislocation includes rupture of the deltoid ligament, disruption of the distal tibiofibular syndesmosis, and fracture of the fibula just above the joint (15). Occasionally, the medial malleolus may be avulsed without injury to the deltoid ligament. The lateral ligaments rupture during an inversion sprain, the most common form of ankle sprain. The anterior talofibular ligament is ruptured first in the plantar flexed position. The interosseous ligament running between the talus and the calcaneus aids the stability of the subtalar joint (see Fig. 80-10C). The posterior fibers of the deltoid ligament prevent excessive dorsiflexion, whereas the anterior talofibular ligament prevents excessive plantar flexion (see Fig. 80-10B,Fig. 80-10D).

INTERTARSAL JOINTS. Movements at the ankle joint are limited mainly to plantar flexion and dorsiflexion. Inversion, eversion, forefoot abduction and adduction, and the combined movements of supination (inversion and abduction) and pronation (eversion and adduction) occur at the other joints (8,10). Most of this motion occurs throughout the subtalar joint, the talonavicular joint, and the calcaneocuboid joint. The motions of these joints are closely tied, with the talonavicular joint allowing the most combined motion. Because three of the arches of the foot involve these joints, they are under particular strain during weight-bearing. The plantar ligaments of these joints are particularly strong (8). The plantar surface of the foot has strong intertarsal ligaments that bind the bones together and help to prevent collapse of the arch. The arch is further maintained by the short muscles of the foot, the plantar aponeurosis, and the long tendons passing into the sole of the foot from the leg (Fig. 80-11C) (7). The posterior tibial tendon and the peroneus longus muscle have particular roles in maintaining the arch of the foot.

Figure 80-11. Ligaments of the ankle and foot. **A:** This coronal section through the right ankle and subtalar joints shows the talocalcaneal interosseous ligament, the deep portion of the deltoid ligament, the tendons and muscles in back of the heel, and the structures coursing beneath the malleoli. **B:** Oblique view of the ankle, subtalar, and transverse talar joints and the tarsometatarsal joints. **C:** Ligaments of the sole of the foot illustrated with the peroneus longus and both tibialis tendons. The long plantar ligament arises from the plantar aspect of the calcaneus and passes anteriorly in a fan-wise fashion. The deep fibers stretch to the plantar tuberosity of the cuboid bone. The most superficial fibers insert into the bases of the second, third, fourth, and fifth metatarsal bones. The plantar calcaneocuboid (short plantar ligament) is a strong ligament lying deep to the long plantar ligament. It extends from the plantar aspect of the anterior tubercle of the calcaneus to the plantar surface of the cuboid behind the peroneal groove. The plantar calcaneonavicular, or spring ligament, is a broad band of fibers that connects the calcaneus and navicular. (Modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985.)

The subtalar joint allows inversion and eversion of the heel and lies between the calcaneus and talus with two or three facets within the joint. The transverse tarsal joint links the hindfoot and midfoot. This joint allows inversion and eversion of the forefoot, forefoot adduction and abduction, and a small amount of forefoot flexion and extension (6). The talonavicular and calcaneocuboid joints together form the transverse tarsal joint. Independent movements are not possible in any of these joints (8). The subtalar joint and the lateral and medial components of the transverse tarsal joint are enclosed by an independent fibrous capsule lined by synovial membrane (Fig. 80-11).

Multiple ligaments stabilize the midtarsal joints (see Fig. 80-11B). The cervical ligament is located in the sinus tarsi and is attached to the neck of the talus and the upper surface of the calcaneus (8). One limb of the bifurcate ligament, the dorsal calcaneonavicular ligament, arises anterior in the sinus and connects the calcaneus and navicular. The other limb, the dorsal calcaneocuboid ligament, connects the calcaneus and cuboid bones. The plantar calcaneocuboid ligament (the short plantar ligament) maintains the calcaneocuboid joint during weight-bearing.

The long plantar ligament (see Fig. 80-11C) arises from the plantar surface of the calcaneus anterior to the calcaneal tuberosity. Its deep fibers insert on the plantar surface of the cuboid wall, and the superficial fibers continue to the bases of the second, third, fourth, and fifth metatarsal bones. These fibers form the roof on the groove on the plantar surface of the cuboid, making a tunnel for the tendon of the peroneus longus muscle. This ligament reinforces the lateral longitudinal arch (4,5,8).

Other intertarsal joints are found between the navicular and cuneiform bones, the cuboid and cuneiform bones, and among the cuneiforms (6). These can all form one continuous joint cavity, although the navicular cuneiform and cuboid to lateral cuneiform joints can be separate. These joints are supported by weaker dorsal interosseous ligaments and stronger plantar interosseous ligaments. The cuneiforms are supported by the weak transverse dorsal intercuneiform ligaments and by the stronger plantar intercuneiform ligaments.

JOINTS OF THE MIDFOOT AND FOREFOOT. The tarsometatarsal joints lie between the three cuneiforms and cuboid bones proximally and the bases of the five metatarsal bones distally. These joints are strengthened by the dorsal and plantar tarsometatarsal ligaments and by interosseous ligaments between the metatarsals and between the cuneiforms (see Fig. 80-11B).

The bases of the metatarsal bones are connected by the dorsal plantar and interosseous intermetatarsal ligaments. These help stabilize the midfoot and are ruptured in a Lisfranc midfoot fracture dislocation. The heads of the metatarsal bones are interconnected on their plantar aspects by the deep transverse metatarsal ligament. Some fibers of this ligament attach to the base of the proximal phalanx and the metatarsal heads. The range of extension is greater in these joints than the range of flexion, although movement is fairly minimal.

The MP joints are strengthened by the plantar and collateral ligaments. The anatomy of the interphalangeal (IP) joint corresponds to that in the hand (5,8).

Nerve and Blood Supply of the Joints of the Ankle and Foot. Figure 80-12 shows the nerve supply of the foot and ankle. The ankle joint is supplied by the deep peroneal, tibial, and saphenous nerves (5,14). The intertarsal joints are supplied by the superficial and deep peroneal nerves (15). The saphenous nerve supplies the joints on the medial border of the foot. The lateral and medial plantar nerves have branches to the plantar aspects of the joints.

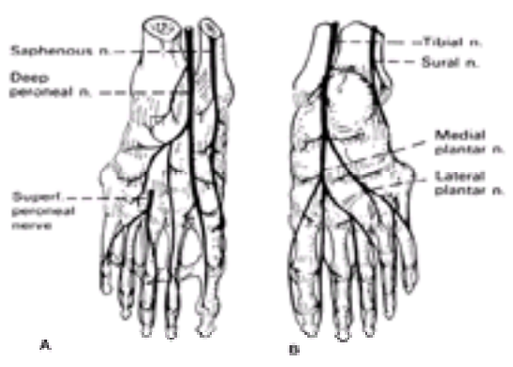

Figure 80-12. Nerve supply of the ankle joints and joints of the foot. **A:** Dorsal view.**B:** Plantar view. Many fibers supply the ankle. See text for details.

The blood vessels supplying the ankle joint are the malleolar branches of the anterior tibial and peroneal arteries. The other joints of the foot are supplied by the dorsalis pedis artery and its branches, the medial and lateral plantar arteries, and the plantar arch.

Fascia and Intrinsic Muscles of the Foot

Plantar Aponeurosis and Plantar Fascia. The superficial fascia forms a tough thick padding over the sole of the foot. The fascia is thin on the dorsum of the foot (4,5,8). The plantar aponeurosis is attached posteriorly to the calcaneus and fans out anteriorly toward the toes (Fig. 80-13). It sends fibers to the skin forming septa within the sole of the foot (4,5,8). The sides of the aponeurosis continue with intermuscular septa that separate the intrinsic muscles of the first and fifth digits from a central compartment containing the flexor tendons and the lumbricals. Additional sagittal septa over the metatarsal heads distally connect the plantar aponeurosis to the deep transverse metatarsal ligament. The tunnels formed between the septa, the plantar fascia, and the metatarsal heads alternately contain the flexor tendons or the lumbricals and digital vessels and nerves. The lumbricals, digital vessels, and nerves are protected from compression by the metatarsal heads.

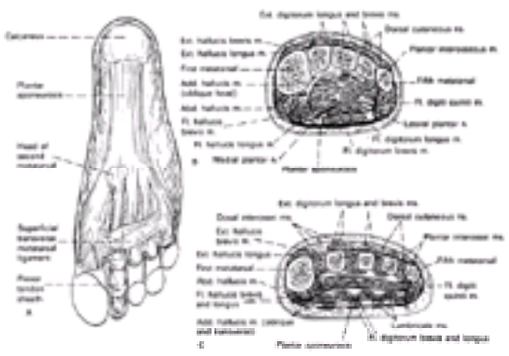

Figure 80-13. The plantar aponeurosis and bones and muscles of the right foot. **A:** Inferior view: The plantar aponeurosis arises from the posterior calcaneus and divides at the midfoot into bands inserting around the five toes. **B:** This cross section through the posterior metatarsal arch shows the fascial compartments and relationships between the bones, supporting ligaments, and muscles. The plantar aponeurosis and associated fascia are shown in black. The aponeurosis is thick on the plantar surface and thin on the lateral and dorsal aspects of the foot. **C:** Cross section at the anterior metatarsal arch. (**A** modified from Hollinshead WH. *Anatomy for surgeons,* 3rd ed. Vol 3. Philadelphia: Harper & Row, 1982. **B** and **C** modified from Eycleshymer AC, Schoemaker DM. *A cross-sectional anatomy.* New York: Appleton-Century-Crofts, 1911:159.)

Intrinsic Muscles. Figure 80-14 depicts the intrinsic muscles of the plantar aspect of the foot. Figure 80-15 shows the origins of the intrinsic muscles and the insertions of the intrinsic and extrinsic muscles. Figure 80-16 illustrates the muscles of the dorsum of the foot and the origins of the intrinsic muscles. The flexor digitorum brevis and extensor digitorum brevis act to flex and extend the toes when the long flexors are ineffective at extremes of plantar flexion and dorsiflexion. The lumbricals act to flex the MP joints and extend the IP joints and are weak in claw toe deformity. The interossei assist the lumbricals and have a minimal role in moving the toes in abduction and adduction.

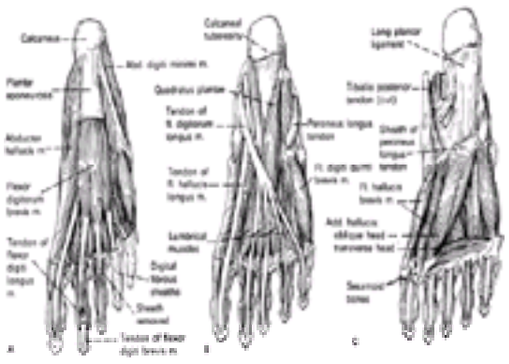

Figure 80-14. Plantar muscles of the right foot. **A:** The first layer consists of the abductor hallucis, flexor digitorum brevis, and abductor digiti minimi. **B:** The quadratus plantae and lumbrical muscles form the second layer. The tendons of the flexor digitorum longus and flexor hallucis longus lie over these muscles. **C:** The third layer consists of the flexor hallucis brevis, adductor hallucis (oblique and transverse heads), and flexor digitorum brevis. The fourth layer consists of the plantar and dorsal interossei (not shown). (Modified from Clemente CD, ed. *Gray's anatomy of the human body,* 30th Am ed. Philadelphia: Lea & Febiger, 1985.)

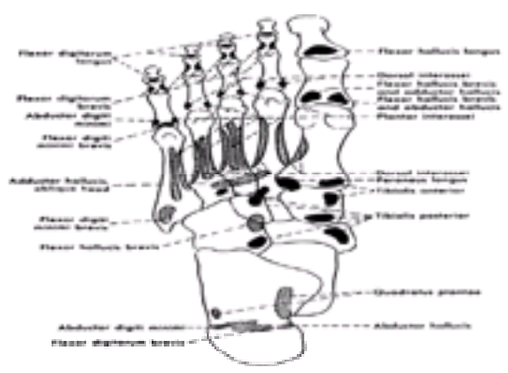

Figure 80-15. This plantar view of the bones of the right foot shows the origins of the intrinsic muscles (*striped*) and the insertions of the extrinsic and intrinsic muscles (*black*). (Reprinted from Hollinshead WH. *Anatomy for surgeons,* 3rd ed. Vol 3. Philadelphia: Harper & Row, 1982, with permission.)

Nerve and Blood Supply of the Foot. Figure 80-17 depicts the nerve supply of the foot. Cutaneous sensation of the sole is supplied by the medial and lateral plantar nerves and by the medial calcaneal branch of the tibial nerve. A strip of the lateral side of the foot is supplied by the lateral dorsal cutaneous branch of the sural nerve, itself a branch of the tibial nerve. The saphenous nerve supplies a thin part of the skin and fascia on the medial aspect of the midfoot. Motor innervation of the intrinsic muscles is primarily from the L-5 and S-1 segments through the medial and lateral plantar nerves (see Table 80-3). Most of the cutaneous innervation of the dorsum of the foot lies within the distribution of the superficial peroneal nerve medial and lateral branches. A twig from the deep peroneal nerve supplies adjacent sides of the first interdigital cleft. The saphenous nerve supplies the skin along the medial side of the foot, and the sural nerve supplies the skin along the lateral edge of the foot. (The segmental nerve supply to the skin, muscles, and bones of the foot is depicted in Fig. 75-20, and the peripheral nerve supply is shown in Fig. 75-21.)

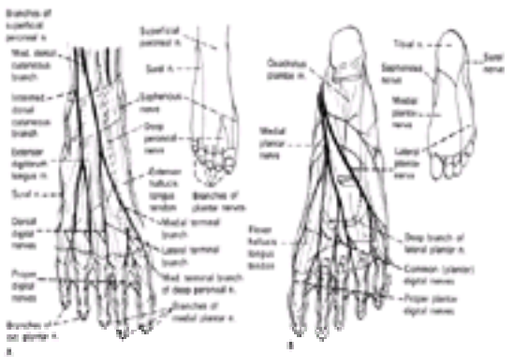

Figure 80-17. Nerves of the foot. **A:** Dorsal view.**B:** Plantar view. See text for details. (Modified from Goss CM, ed. *Gray's anatomy of the human body,* 29th Am ed. Philadelphia: Lea & Febiger, 1959.)

Blood reaches the foot by terminal branches of the anterior and posterior tibial arteries. Many anastomoses exist between these vessels (see Fig. 80-7). The dorsalis pedis artery and its branches supply the dorsum of the foot as the terminal branch of the anterior tibial artery. The plantar surface is supplied by the medial and lateral plantar arteries arising from the posterior tibial artery. The dorsalis pedis artery gives off medial and lateral metatarsal arteries, supplying the front part of the ankle joint. It anastomoses with the first tarsal and deep plantar arteries, the arcuate artery, and the plantar arch (see Fig. 80-7). These in turn give off vessels to the first through fifth plantar metatarsals. Each plantar metatarsal artery gives off two digital arteries, which supply the dorsal and plantar aspects of the joints of adjacent toes.

Arches of the Foot. The foot has four arches, two longitudinal and two transverse. The medial and lateral longitudinal arches are formed by the wedge-shaped bones, which together with their ligamentous support form the arches (Fig. 80-18). The plantar aponeurosis acts as a bowstring or tie rod, as do the long and short plantar and spring ligaments. The medial arch is dome shaped and is higher than the lateral arch (see Fig. 80-8). The posterior transverse or midtarsal arch is formed by the navicular, the three cuneiforms, the cuboid, and the bases of the metatarsal bones. This arch is maintained by ligaments and tendons binding the metatarsal bases. The integrity of these plantar ligaments maintains the arch (16). The anterior metatarsal arch formed by the metatarsal heads is maintained by the deep transverse metatarsal ligaments.

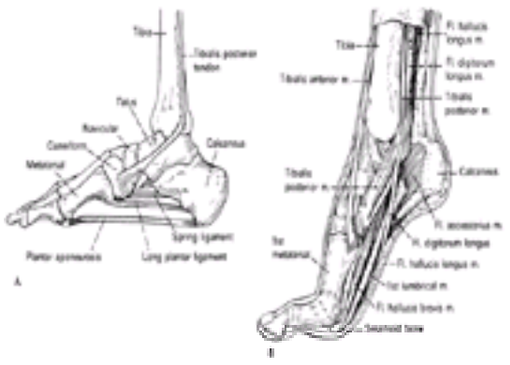

Figure 80-18. **A:** The structures maintaining the longitudinal arches of the foot. All ligaments are shown in the same sagittal plane from the same side. **B:** Dynamic stabilization of the medial arch. With the foot plantar flexed, as in walking, the heel is raised and the toes remain on the ground. The sesamoid bones and the flexor hallucis brevis tendons act to support the first metatarsal. The quadratus plantae lines the hollow between the flexor hallucis longus tendon and the heel. The tibialis posterior provides dynamic support in stance by inverting the hindfoot and locking the subtalar joint. This transforms the foot into a rigid lever for toe-off.

Movement and Biomechanics of the Foot

Movement. In the neutral or anatomic position, the foot forms a 90-degree angle with the tibia (6). Plantar flexion increases and dorsiflexion decreases this angle. This motion occurs mainly at the ankle joint and partially at the midtarsal joint. The total range of motion of the ankle joint in the sagittal plane is approximately 45 degrees but varies widely (17). Ten to 20 degrees of this range of motion are in dorsiflexion, and the remaining 25 to 35 degrees are in plantar flexion. The dorsiflexion range is increased with knee flexion as the gastrocnemius muscle passes behind both the knee and hip. The axis of the ankle joint slopes posteriorly and inferiorly on the lateral side (6,8,16,17). As a result, the foot adducts during plantar flexion and abducts during dorsiflexion. Toeing in and out can also be produced by tibial rotation (9,18).

Inversion and eversion turn the sole of the foot medially and laterally, respectively (6,13) (Fig. 80-19). This side-to-side rotation of the foot occurs at the subtalar and transverse tarsal joints around an anterior posterior axis deviating from the sagittal plane. During inversion the heel deviates medially; during eversion it deviates laterally (see Fig. 80-19A). In addition, this motion involves the forefoot, and its deviation is gauged by the line of the second metatarsal in relation to the tibia (see Fig. 80-19B). Because the axis of inversion and eversion is not strictly in the sagittal plane, the foot adducts during inversion and abducts during eversion through the transverse tarsal joint.

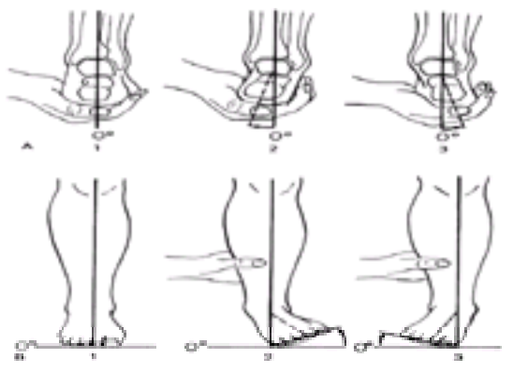

Figure 80-19. Inversion and eversion. **A:** In the neutral position, the vertical axis of the heel is aligned with the longitudinal axis of the tibia (1). By grasping the calcaneus with the hand, the entire heel can be moved inward (inversion) 20 degrees (2) or outward (eversion) 10 degrees (3). Excessive inversion may indicate laxity or tear of the calcaneofibular ligament and excessive eversion indicates tear or laxity of the deltoid ligament. **B:** Inversion and eversion of the forefoot. In the neutral position, the line of the second metatarsal is aligned with the midline of the tibia (1). Inversion is associated with adduction (2), and eversion is associated with abduction of the forefoot (3). (Modified from the American Academy of Orthopedic Surgeons. *Joint motion: method of measuring and recording.* Chicago: American Academy of Orthopedic Surgeons, 1965.)

These movements displace the metatarsals in relation to one another and involve the transverse tarsal joint and the joints distal to it (16,17). The foot cannot be adducted without inverting, nor can it abduct independent of eversion. In the neutral position, the heads of the metatarsals are in the same horizontal plane. Adduction associated with inversion elevates the head of the first metatarsal and depresses the head of the fifth metatarsal, whereas abduction associated with eversion has the

opposite effect (Fig. 80-20).

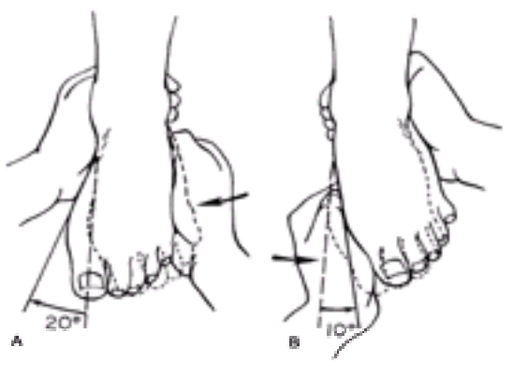

Figure 80-20. Testing for adduction **(A)** and abduction **(B)** of the forefoot. This takes place primarily at the transverse tarsal joint. The patient's foot is held at the calcaneus. The forefoot is moved medially and laterally. Under normal circumstances, adduction accompanies inversion and abduction accompanies eversion. (Modified from Hoppenfeld S. *Physical examination of the spine and extremities.* New York: Apple-Century-Crofts, 1976.)

Biomechanics. The foot adapts to uneven ground and allows the center of gravity of the body to be positioned over the center of support. The fit and construction of shoes affect shock absorption and the support of the foot. Footwear available today is designed specifically for such activities as sports, aerobics, walking, running, and dancing and provides the support, fit, control, shock absorption, and in some cases, splinting necessary for the specific activity. Wearing a shoe that is not designed for a vigorous form of activity can be a source of pain.

Foot biomechanics analyzes the alignment and magnitude of forces acting on the foot. The foot has 26 bones, 19 muscles, and 107 ligaments forming four arches (medial and lateral longitudinal and posterior and anterior transverse) (14). The shape of the foot relates to the supporting ligaments, muscle forces, and loading environment. Foot alignment during weight-bearing determines the loading environment to which the foot is subjected. The alignment of the foot is determined by the shape of bony structures, ligamentous tension, coordination of the musculotendinous units, and alignment of the leg in general.

The foot can be thought of as a tripod, with the os calcis providing one point of support and the heads of the fifth to first metatarsals providing the other two points of support (Fig. 80-21). The weight-bearing line normally passes through the ankle joint into this tripod area. If the weight-bearing line passes outside the area, problems arise. For example, in a pronated foot, the weight-bearing line falls medial to the foot and the hindfoot goes into eversion. Structures on the medial side of the foot are placed in tension. When the weight- bearing line falls laterally in a supinated foot, the ankle becomes inverted and overloads the lateral ligaments and the lateral border of the foot. Medial knee pain can occur in a supinated (or cavus) foot by causing overload of the medial side of the knee. Thus, abnormal foot biomechanics in an active individual can eventually lead to local or more widespread discomfort (6,16,18,19).

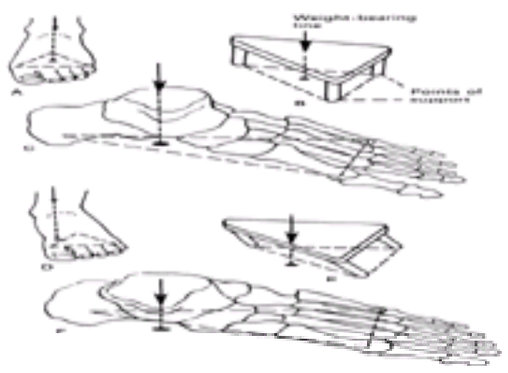

Figure 80-21. Weight-bearing alignment of the foot. A tripod is formed by the heads of the first to fifth metatarsals anteriorly and the calcaneus posteriorly. **A–C:** The normal weight-bearing line falls within the base of the tripod. **D,E:** In pronation, the weight-bearing line falls medial to the foot. **F:** The structures on the medial side of the foot are placed under tension.

EVALUATION OF THE PATIENT

A large segment of the population seeks health care because of pain in the distal lower limb (4). Comfortable feet are usually taken for granted. A small foot problem can dominate a person's perception of health. Feet vary in size, shape, posture, and soft tissue tension, thus changing the presentation of the pain. Problems are exacerbated as modern shoes are often designed more for fashion than for fit, support, or comfort.

For some patients and conditions, some minor therapeutic measures can greatly relieve pain in the foot. A patient with a painful ingrown nail is as grateful for the relief provided by cotton placed between the nail and the nail fold as the arthritic undergoing successful total hip arthroplasty. Physicians can do a great service to a patient by being aware of and using the general principles for treating pain described in this chapter.

Evaluation of the patient with pain in the lower extremity should be carried out using the principles in Chapter 12 and Chapter 75. Table 80-4 summarizes the major points of the history and clinical examination. The proximity of most of the structures in the foot and ankle to the skin facilitates diagnosis (6,13,20). Pain in the leg and foot can be caused by systemic disease. Radiating pain may result from disorders of the low back or deficient arterial supply (13). As a result, a general history and physical examination should be carried out. The following discussion presents a method for routine evaluation of the foot and ankle. Gait is examined as the foot and ankle form part of the locomotor system (16).

History

The clinical evaluation requires a detailed history of the pain. The patient should ideally be given a questionnaire before examination because this will help the patient communicate the complaint.

The patient is asked to describe the pain as it presently affects him or her. The location, intensity, quality, temporal profile, and aggravating and relieving factors should be elicited. The patient is asked to point exactly to the location of the pain and to trace the distribution of any radiation. Pain aggravated by walking or running and relieved by rest is often arthritic in nature if present for more than a couple of months. Occasionally, the pain may be caused by circulatory insufficiency, tumor, infection, or stress fracture. Some measure of the intensity of the pain should be used, such as the 1 to 10 intensity scale (0 being no pain and 10 being the most severe pain imaginable). Any relation of the pain to weather (e.g., arthritis), other joint involvement (e.g., systemic disease), or a general illness should be ascertained.

The quality of the pain helps in the diagnosis. Local pathology has sharp, well-localized discomfort. More diffuse aching about the leg or whole foot can be caused by systemic disease. The temporal profile of the pain is elicited (i.e., intermittent or continuous). Is the overall trend one of improvement, worsening, or no change? If the symptoms are deteriorating, therapeutic intervention should be earlier and more aggressive.

The functional disability should be assessed. The effect of pain on activities of daily living, work-related activities, and recreational activities is recorded. In each category, the physician should ask enough questions to develop a clear picture of the type of loading environment and degree of physical stress that the foot, ankle,

and leg must absorb during a typical day and the duration of exposure before symptoms appear. This is particularly important in patients suspected of having calf pain caused by peripheral vascular disease and in patients with pain in the ankle and foot caused by bone or joint pathology.

The patient is asked about the initiation and time course of the pain. Pain of acute onset is often related to specific events, such as trauma or overuse. A sedentary person beginning an aerobic dance course can be expected to have pain in the leg, ankle, and foot. Gradual development of pain without a precipitating event might reflect a systemic problem or structural abnormality that the person has had for many years that is just becoming symptomatic.

The treatment so far is recorded. Treatments benefiting the patient and those not assisting will aid diagnosis and further management. Many patients with foot and ankle problems have selected footwear to alleviate their problems. Others require education as to appropriate footwear. The physician should examine the shoes worn for recreational, day to day, and work use.

Physical Examination

Both legs should be exposed from the knee down. I use a nine-point physical examination checklist: exposure, gait, standing, inspection sitting, palpation, range of motion, special tests, joints above, and distal neurovascular examination.

Exposure

Both limbs should be visible from the knee down for the physical examination. Patients with loose clothing can roll up their trouser legs. Patients otherwise should be examined in a gown. Both socks and shoes should be removed after the patient has been observed walking with shoes and orthoses, if used.

Gait

While the patient walks, note any effects of pain on gait and observe the timing of the three phases of gait: foot-flat, toe-off, and swing phase. Observe the progression of weight-bearing and any asymmetry of motion between the left and right. Toes that lie in a normal position during stance can assume a claw toe or hammertoe configuration during swing-through or push-off. The patient is asked to walk on tiptoes and on the heels. Pain in the forefoot will prevent tiptoe walking. Muscle weakness or dislocation within the midfoot region will also prevent toe walking. Heel walking is prevented by equinus contractures at the ankle, often caused by arthritis or a tight Achilles tendon. Painful conditions of the forefoot or hindfoot may restrict both heel or toe walking, and such restrictions will assist the examiner in assessing the severity of the patient's disability.

Standing

With the patient standing, the position of the hindfoot and forefoot is observed. Excessive abduction of the forefoot occurs in symptomatic adult flatfoot (16). The degree of splaying or spreading of the forefoot is compared with the shoe size. Excessive supination, cavus or high arch pattern, and the presence of excessive pronation are noted. The posture of the foot should be recorded with the patient standing because the arch is usually restored once the patient is non-weight-bearing and the dynamic deformity no longer apparent.

Inspection

The patient sits on the edge of a high examination table in a well-lit room. The examiner should sit on a low stool with the patient's feet at waist level so they can be comfortably viewed. The position of the foot with respect to the knee is examined. The patella should be in vertical alignment with the first interosseous or interdigital space. External rotation of the forefoot is the more common disorder secondary either to forefoot adduction or external rotation of the tibia, a common postfracture malunion (13,17). Significant variation occurs between patients, and the pathologic side thus should be compared to the normal side. Internal rotation of the forefoot occurs in cavus foot disorders and clubfoot. The normal relaxed foot will hang in slight plantar flexion. Abnormal signs include local areas of increased or decreased temperature, loss of hair, abnormal coloration (e.g., blanching, blotching, or cyanosis, as seen in peripheral vascular disease), or localized areas of redness from shoe pressure. The skin texture should be examined, especially for excessive or diminished sweating. These skin changes are altered by peripheral vascular disease, complex regional pain syndromes, and peripheral neuropathies. The nails are inspected for evidence of infection within the nail or nail bed.

The heel and sole of the foot are examined. Subtle differences, such as swelling about the origin of the plantar fascia, are best appreciated by comparing one side to the other (20). Inspection of the foot for callosities, corns, areas of redness, and increased skin thickening will indicate areas of excessive load.

The shoes are inspected for excessive wear. Normal wear at the heel is slightly lateral to the midline. Excessive wear at the heel or sole associated with medial or lateral drift of the upper surface of the shoe indicates abnormal foot posture and dynamics. The interior of the shoe, particularly the toe box, should be inspected for signs of toe pressure. Foot orthotics and braces should also be examined. The shoes are inspected for their appropriate fit. Patients will present in everything from high-fashion high heels to custom-made orthopedic shoes.

Palpation

Palpation begins in the heel region (see Table 80-4). The Achilles tendon and bony landmarks are palpated. Bursitis and insertional tendonitis cause pain at the calcaneal level (Fig. 80-22B). Sometimes the defect in a ruptured Achilles tendon can be palpated. Plantar fascitis causes pain on the plantar aspect of the calcaneus (Fig. 80-22C). Each of the tendons passing around the heel on the medial and lateral side is palpated along its course during resisted active contraction.

TABLE 80-4. Evaluation of the patient with pain in the leg, ankle, and foot

Figure 80-22. Pain in isolated regions of the sole may indicate a specific diagnosis. **A:** Palpation of the Achilles tendon. **B:** Palpation of the calcaneal bursa. **C:** Palpation of the calcaneus at the origin of the plantar fascia can elicit pain caused by plantar fasciitis. **D:** Palpation of the heads of the metatarsals for metatarsalgia. **E:** Shooting pain between the metatarsal heads may indicate a Morton's neuroma.

Examination of the sole of the foot includes palpation of the arch (Fig. 80-22D). Tenderness immediately proximal to the tuberosity of the navicular suggests a sprained spring ligament. Tenderness elicited by pressure on the metatarsal heads suggests neuroma, metatarsalgia, or calluses (Fig. 80-22E). Usually the head of the second metatarsal is the most painful in metatarsalgia. Synovitis of the associated MP joint may also be palpable.

Range of Motion

In examining the active and passive ranges of motion, side-to-side comparisons are made because large variations in normal exist between patients. The presence of pain or crepitus during passive range should be recorded. Arthritis in any joint will cause restricted range of motion. Movement should be separately tested at the ankle, subtalar, midtarsal, and MP joints. In claw toe deformity the IP joints are examined to determine if the contracture is flexible or fixed. Excessive laxity at the first tarsometatarsal joint can decrease the weight borne by the hallux and transfer more weight to the second metatarsal head (21).

A tight gastrocnemius muscle occurs with many foot pathologies, including flatfoot and diabetes. A tight gastrocnemius muscle causes a difference in dorsiflexion at the ankle with the knee flexed and extended. The subtalar joint should be locked for this examination by inverting the hindfoot. An excessively tight gastrocnemius muscle prevents dorsiflexion above neutral with the knee extended.

Figure 80-23 depicts the method of examining movement at the ankle and midtarsal joints and toe movements. To test the range of plantar flexion and dorsiflexion, the examiner grasps the heel with one hand and stabilizes the foot with the other. Although considerable variation exists, at least 15 to 20 degrees should be in dorsiflexion and 20 to 25 degrees in plantar flexion (17). The two sides should be compared.

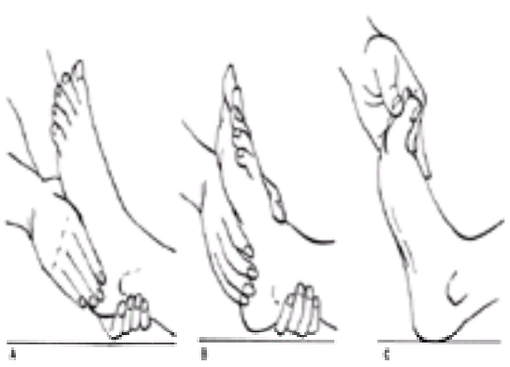

Figure 80-23. Examination of motion at the ankle, midtarsal, and metatarsophalangeal joints. **A:** Examination of ankle movement. The examiner's hand grips the hindfoot and calcaneus rather than the forefoot so that the movements of the subtalar and metatarsal joints are eliminated. The normal range of ankle movement varies, but in the average normal foot it is 20 to 25 degrees for dorsal flexion and 25 to 35 degrees for plantar flexion. **B:** Examination of metatarsal movement. The examiner grasps the Achilles tendon firmly so that the subtalar movement is eliminated. The other hand lightly grasps the midfoot near the bases of the metatarsals and the patient is asked to twist the foot alternately inward and outward into inversion and eversion. Normal rotation should be 15 to 20 degrees on each side of neutral. **C:** Examination of the normal range of motion at the metatarsophalangeal joint of the big toe. This should be nearly 90 degrees; less than 60 degrees of dorsal flexion is considered abnormal. (Modified from Adams JC. *Outline of orthopedics,* 10th ed. Edinburgh, UK: Churchill Livingstone, 1986.)

Tests for active range of motion and strength are shown in Figure 80-24. The results of these tests also provide an indication of the muscle power in the various functional units.

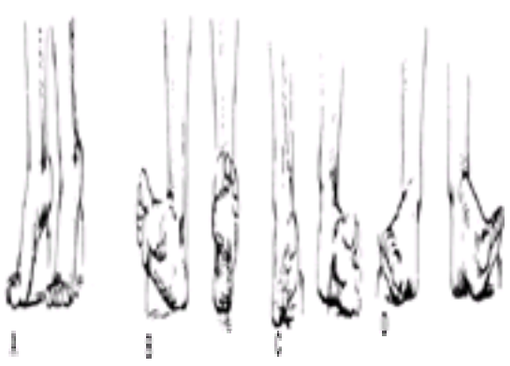

Figure 80-24. Rapid method of testing active range of motion and the strength of muscles controlling movement of the ankle and foot. **A:** Test of plantar flexion and toe motion: The patient is asked to walk on the toes. **B:** Test of dorsiflexion: The patient is asked to walk on the heel. **C:** Test of inversion: The patient is asked to walk on the lateral borders of the feet. **D:** Test of eversion: The patient is asked to walk on the medial borders of the feet. (Reprinted from Hoppenfeld S. *Physical examination of the spine and extremities.* Upper Saddle River, NJ: Prentice Hall, Inc, 1976, with permission.)

Special Tests

Coleman Block Test. The Coleman block test determines the origin of hindfoot varus in a cavus foot. The patient initially stands on the floor, and the hindfoot position is recorded. The patient then stands with the lateral border of the foot and heel supported on a block. If the deformity is fixed or secondary to loss of motion in the subtalar joint, the hindfoot position will not correct. In some cases, the hindfoot varus is secondary to a plantar-flexed rigid first ray with a flexible hindfoot, at which point the heel will correct to normal.

Single Heel Raise. The single heel raise test assesses the function of the posterior tibial tendon. The patient stands on one leg and places both hands on a table or bench for support. Upon standing on tiptoes the hindfoot should invert. If the hindfoot remains in valgus, either the tendon is ruptured or the muscle is too weak to invert the heel because of pain or a severe flatfoot deformity (16).

Thomas Sign. After rupture of the Achilles tendon, the soleus and gastrocnemius are no longer connected to the calcaneus. When the muscle is squeezed midcalf it will shorten. When the tendon is intact the foot will plantar flex. No plantar flexion is seen if the tendon is ruptured (17).

Inversion Stress Test and Anterior Drawer. To test the stability of the ankle, the leg is grasped with one hand and the heel moved anteriorly. Excessive anterior motion of the talus suggests that the anterior talofibular is torn (see Fig. 80-10). Figure 80-19 illustrates measurement of eversion and inversion. Excessive inversion, the more common disorder, indicates a tear in the calcaneofibular ligament or tear of the lateral stabilizers of the subtalar joint. Excessive eversion indicates disruption of

the deltoid ligament (17). Figure 80-20 illustrates measurement of adduction and abduction.

Joints Above. Pain and deformity in the knee and spine can be referred to the calf and ankle. Furthermore, foot disorders can cause problems at the knee. An equinus contracture of the ankle results in recurvatum of the knee and a stretched out capsule. A cavus-adducted foot results in the patient walking with the hip externally rotated, increasing the pressure on the medial aspect of the knee (17).

Distal Neurovascular Examination. Determining the state of the peripheral circulation is an essential part of the examination that is often forgotten (7). A palpable posterior tibial or dorsalis pedis pulse indicates adequate vascularity in most patients. Occasionally, vasculitis may cause skin ischemia with normal pulses in patients with diabetes, rheumatoid arthritis, or pyoderma gangrenosum. In the absence of pulses, capillary refill may crudely estimate the degree of insufficiency. A reasonably accurate assessment can be made by checking the skin temperature and texture. Severe arterial insufficiency of the leg and foot causes loss of hair, coarse nails, painful ulcers of the toe tips, and thin shiny inelastic skin (Chapter 33). If ulcers are present and painless, diabetes should be suspected.

If a peripheral vascular disease is suspected, special studies should be carried out, including ankle pressure recordings, Doppler ultrasound analysis, and other tests (Chapter 33).

Neurologic Examination

Although having the patient walk on the toes, heels, and lateral and medial edges of the foot provides a rough estimation of muscle strength, the strength of each muscle should be tested individually. The power of the triceps surae can be tested by opposing plantar flexion or by observing elevation of the heel while the patient attempts to stand on tiptoe. The ankle jerk test objectively reveals the integrity of the muscle and the nerve pathway. The dorsiflexors of the ankle can be tested by opposing dorsiflexion. Similarly, the power of the extrinsic flexors and extensors of the toes can be evaluated by opposing their action. Tone and clonus should be examined, particularly in the rheumatoid patient, as cervical cord compression may occur.

Sensory examination begins with light touch, comparing side to side and proximal to distal. If this is normal, further examination is unnecessary. The distribution of the sensory nerves and lumbar dermatomes is examined. The deep branch of the peroneal nerve passes through the anterior compartment and supplies the first web space. Intact sensation on the dorsum of the foot confirms an intact L-4 root and intact superficial branch of the peroneal nerve passing through the peroneal compartment. The tibial nerve passes through the deep posterior compartment and divides into the medial and lateral plantar nerves supplying the respective borders of the sole of the foot and the dorsum of the toes. The sural nerve and the saphenous nerve supply respective borders of the medial side and lateral side of the foot.

If light touch is abnormal, a more detailed examination including pinprick, proprioception, temperature, vibration sense, and possibly monofilament testing is performed (Chapter 76). Painful areas should be evaluated for the presence of neuroma by gentle tapping (Tinel's test). Foot trauma often produces injury to the sensory nerves, either by contusion or stretching. The superficial branch of the peroneal nerve can be seen in thin patients by inversion and plantar flexion of the foot.

The calf circumference should be measured. Any decrease of more than 2 cm is objective evidence of muscle atrophy, which is most often a sign of disease atrophy resulting from pain or, less often, peripheral neuropathy. Focal areas of increased warmth, swelling, and tenderness indicate inflammation, which then must be localized to a particular joint, tendon, or tendon sheath complex. Crepitation over a tendon sheath during active motion is pathognomonic of acute tenosynovitis.

Radiographic Examination

The radiographic examination includes routine radiographs and special views. Stress radiographs of the ankle are occasionally indicated. When possible, weight-bearing radiographs are desirable, including anteroposterior and lateral views. An oblique view of the foot or a mortise view of the ankle should also be obtained. Care should be taken to note abnormalities in the structural alignment of the foot, condition of the joints, mineralization, and any overlying soft tissue abnormalities. Special views show the sesamoids (Fig. 80-25), calcaneus (calcaneal axial view), subtalar joint (Broden view), Lisfranc joint (lateral oblique view of the foot), and views of tarsal coalitions (internal oblique view) (16).

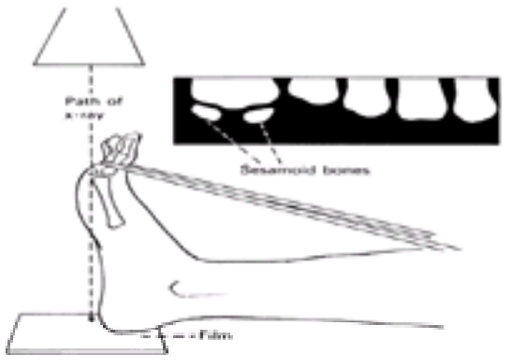

Figure 80-25. The sesamoid bones and joints can be assessed using a sesamoid view.

Stress radiographs are occasionally indicated. Anteroposterior and lateral stress radiographs of the ankle should be taken on both the affected and normal sides. The views are then compared to note any joint subluxation. Stress views can also be performed to visualize the subtalar joint using a 40-degree internal rotation Broden view. Finally, stress views may be performed on the midfoot to assess an occult Lisfranc joint injury (16).

Footwear Trial

When strain, overuse, or overload syndromes are suspected, a trial of supportive footwear provides a good diagnostic test. The patient's feedback helps to determine the best shoe orthotic correction and prescription (22) (Fig. 80-26 and Fig. 80-27).

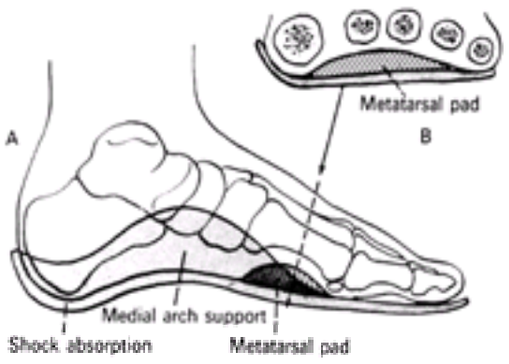

Figure 80-26. Two commonly used orthotics. **A:** Medial arch support. **B:** A metatarsal pad reduces forces under the metatarsal heads.

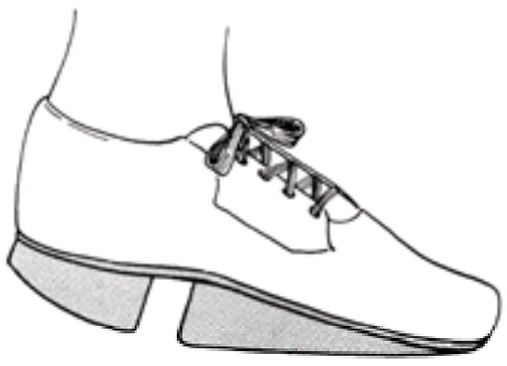

Figure 80-27. Wearing a shoe with rocker-bottom heel and sole helps to reduce the motion of the forefoot during toe-off.

Special Examinations

Bone Scan, Computed Tomography, Ultrasound, and Magnetic Resonance Imaging

Bone scans are useful in the investigation of a persistently painful foot when no abnormality is seen on plain radiographs. They help the physician to identify any underlying problem and to identify the site on which further investigation should be focused. Problems visualized include stress fractures, infection, or fractures not seen on plain radiographs, such as Lisfranc injuries or lateral talar process injuries. Midfoot arthritis can also be difficult to examine and see on plain radiographs; bone scans may assist in the diagnosis. If the bone scan is abnormal and the diagnosis still not certain, computed tomographic (CT) scans will allow the precise anatomy to be outlined. Tomograms may occasionally give more information than a CT scan. CT scans are of use in outlining the anatomy of malunions and nonunions, osteochondral defects, and the extent and degree of necrosis associated with osteomyelitis. Arthrography and tomograms have been largely replaced by CT scans. Arthrography is still of value during the aspiration of joints for sepsis or during local anesthetic blocks to confirm correct positioning of the needle.

If the bone scan is negative and symptoms are significant, magnetic resonance imaging (MRI) is of benefit. MRI is the best method of viewing soft tissue lesions. MRI is particularly valuable in the assessment of soft tissue tumors, both in assisting the diagnosis and outlining the anatomy. Almost all tumors should be imaged this way, as clinical examination does not differentiate a ganglion from a cystic malignant synovial cell sarcoma (23,24 and 25). Apart from soft tissue tumors, MRI is of value in assessing tendons, tendon sheaths, and joint capsules. Smaller lesions, such as a Morton's neuroma or the capsule of the IP joints, may not be seen by the resolution of scans used today. MRI is very sensitive and may find changes of doubtful clinical significance. Any finding should correlate with the history and physical examination. Cartilage lesions are often poorly visualized.

Ultrasound is of value in localizing abscesses, and these can be drained under ultrasound control. Although the resolution of ultrasound is not as good as that of MRI, the test can be performed in more centers and can be done faster and is more accessible on an emergency basis. Tendons and tendon sheaths can be assessed by ultrasound, with less clarity than MRI.

Arthroscopy

Arthroscopy of the ankle may be performed as a diagnostic procedure. Subtalar and first metatarsophalangeal (MTP) joint arthroscopy is being performed in some centers (26). Diagnostic arthroscopy of the ankle is indicated for patients having mechanical symptoms and recurrent effusions with normal investigations. Loose bodies can be missed by both CT and MRI, and the resolution of MRI is not clear enough to assess the chondral surface or impingement of the joint capsule. Excision of capsular lesions such as an anterolateral band seems to provide symptomatic relief. Removal of loose bodies and smoothing of raised chondral defects provide clinical relief (26). Anterior osteophytes and osteochondral defects can also be treated during arthroscopy.

Electromyography

Electromyography and nerve conduction velocity testing, particularly across the tarsal canal, help to evaluate the tarsal tunnel for entrapment (27). Doppler testing provides useful information about the adequacy of circulation at the digit level. In some cases, more proximal lesions, such as entrapment of the peroneal nerve at the level of the fibular head, can have a profound effect on foot and ankle function. Electromyography will help diagnose the cause of weakness and level of injury. Complex regional pain syndromes and compartment syndrome may cause similar disorders.

Diagnostic Blocks

If two or more joints are abnormal or the integrity of an old fusion site is questioned, injection of a low concentration of a local anesthetic (e.g., 0.5% lidocaine or 0.25% bupivacaine) into the joint or fusion site can help to localize the source of pain. For example, an injection into the talonavicular joint may differentiate between talonavicular and ankle joint arthritis. When the pain follows peripheral nerve patterns, a localized entrapment neuropathy should be suspected.

Laboratory Tests

Rheumatoid factor and sedimentation rates are of value in assessing patients with symptoms suggestive of an arthropathy or arthritis (25). If infection is suspected in an otherwise healthy patient, erythrocyte sedimentation rate and C-reactive protein are sensitive and specific tests assisting in the diagnosis (28). Plantar fascitis may be caused by a rheumatologic disorder and should be assessed by serology (16).

Joint fluid analysis and joint biopsy may also be performed. Joint aspiration, particularly of the MP joints, ankle, and subtalar joints, is easily performed. If infection is suspected, at least three separate specimens should be sent to a laboratory for culture. The correct position of the needle should be confirmed by arthrography. Joint fluid is sent for cell count, culture, and sensitivity and for crystal analysis looking for uric acid (gout) or calcium pyrophosphate (pseudogout) crystals. When osteomyelitis is suspected, needle or open biopsy of the small joints can be done for pathologic analysis. Table 80-5 summarizes the physical findings and diagnostic tests for painful foot and ankle conditions.

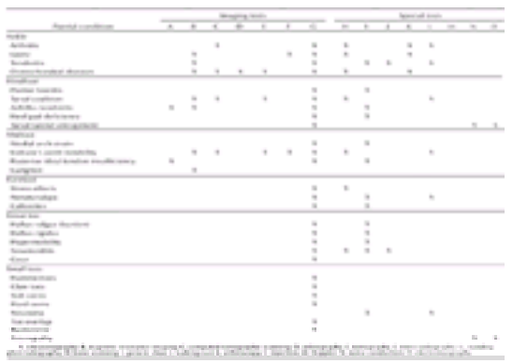

TABLE 80-5. Diagnostic tests for ankle and foot pain

PAINFUL DISORDERS OF THE LEG

Fractures

The tibia and fibula are two of the most frequently fractured long bones in the body. In younger patients, considerable energy is required to fracture these two bones, resulting in significant soft tissue damage. Fractures may be secondary to motorcycle, car, and pedestrian accidents. Falls from heights and sporting injuries account for most of the other injuries. The tibia has little soft tissue coverage and a poor blood supply (15). As a result, soft tissue coverage can be difficult to achieve and the bone may be devascularized by the trauma of the injury. For all open tibia fractures, chronic infection occurs in 10%, nonunion in 15%, and amputation in 5% (15) (Fig. 80-28). For tibial fractures requiring secondary plastic surgical procedures to close the wound, amputation rates approach 50%.

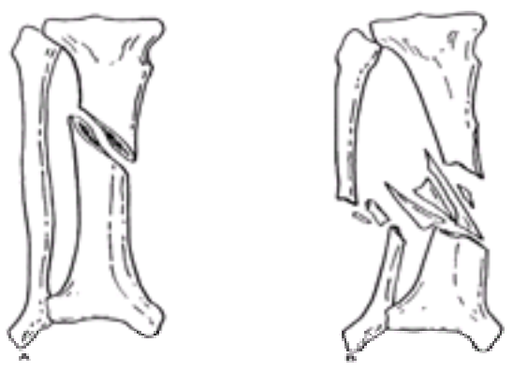

Figure 80-28. Fracture of the tibia. **A:** Long spiral fracture is typical of a low-energy torsion injury such as those occurring during a ski injury. **B:** Comminuted fracture of the tibia with wide displacement of the tibia from the fibula and associated fibula fracture is characteristic of a high-energy fracture commonly associated with motor vehicle accidents and indicates severe soft tissue injury. (Modified from Chapman MW. Fractures of the tibial and fibular shafts. In: Evarts CW, ed. *Surgery of the musculoskeletal system.* New York: Churchill Livingstone, 1983.)

Symptoms and Signs

Pain is the predominant symptom of fracture of the leg. Depending on whether the fracture is open or closed, associated signs such as swelling and bleeding are noted. Associated injuries should be ruled out. Plain radiographs of the splinted leg in two planes should include the ankle and knee.

Treatment

The treatment of the pain of fracture is discussed in Chapter 43. Immobilization of the limb in the emergency department, using a plaster splint before radiography, is the most effective method of early pain control. A small dose of intravenous short-acting benzodiazepine and narcotic will allow comfort for clinical examination and application of the splint.

These fractures require early stabilization by intramedullary nailing or plate fixation. The occasional stable or minimally displaced fracture may be managed in a cast. Postoperative management may be with intramuscular opioids or patient-controlled analgesia (see Chapter 41). An alternative is the use of intraspinal opioids or continuous epidural analgesia, which can be started before radiography and orthopedic therapy (closed or open). A compartment syndrome can occur preoperatively or postoperatively. The distal neurologic function needs to be observed closely, and excessive pain with increasing analgesia requirements is a warning sign of this complication (15).

Acute Compartment Syndrome

If the pressure within a soft tissue compartment exceeds the tissue perfusion pressure, cellular ischemia will result, and if ignored, cell death will follow. The tissues most sensitive to pressure are muscle and nerve. The intracompartmental pressure above which cellular perfusion will decrease is 30 to 40 mm Hg. Compartment syndromes occur after closed fractures, crush injuries without fracture, elective surgery, electrocution, and burns. Some occur after tissue ischemia and reperfusion after more proximal arterial injury or drug overdose, loss of consciousness, and prolonged immobility. Injection of irritants such as industrial agents or secondary to drug abuse can also result in compartment syndrome (15).

Compartment syndromes may occur after excessive elevation of a limb, particularly in patients with low blood pressure. When the leg is lowered, the reperfusion can cause a compartment syndrome. Patients with regional blocks are at particular risk because the insensate limb may be excessively elevated or one compartment may be crushed by positioning. In general, a limb should not be elevated more than 10 cm above the level of the heart.

Symptoms and Signs

Severe pain in the awake patient is characteristic of compartment syndrome. No amount of sedation will control the pain. Patients often undergo a “character change” and can be very abusive, hence the missed diagnosis in some cases. Nerves passing through the compartment lose their function, resulting in loss of skin sensation in that nerve's distribution. Passive stretch of the muscles in the compartment increases pain. Later, loss of muscle function occurs. Distal pulses and distal capillary refill are normal, as the compartment pressure will never reach the arterial perfusion pressure and blood from vessels passing through other compartments ensure distal perfusion through anastomoses in the foot. The diagnosis is clinical in the awake patient because pressure measurements may be unreliable. Comatose or intubated patients require pressure measurements to assist in the diagnosis.

Treatment

Immediate compartment release is required, and compartment syndrome is one of the few immediate orthopedic emergencies. All occlusive dressings must be released to the level of skin, and this may effect adequate treatment. Delay will result in further cell death and potential long-term disability. Prevention includes the careful positioning and monitoring of patients with peripheral nerve blocks.

Analgesia may be given once the diagnosis has been made. Once the compartment has been released, the patient may be difficult to rouse because of the loss of stimulation and the residual narcotic.

Stress Fracture

Tibial stress fracture occurs at the level of the mid- to proximal shaft in patients with no previous surgery (15). Military recruits, the elderly, and endurance sports participants are at risk. Patients with pantalar fusions are at risk for stress fracture at the distal tibia. Patients with previous hardware are at risk for stress fracture through old pin sites.

Diagnosis

Patients may have an underlying history of osteoporosis, previous inactivity, or change in activity level. The pain is often poorly localized and diffuse in nature. Clinical and radiographic examinations may be normal. Increased activity in the region is visualized by a bone scan, narrowing the diagnosis to tumor, infection, or stress fracture. A CT scan will rule out tumor and may confirm the stress fracture. Immobilization of the limb may also be diagnostic. MRI is of additional benefit if the

diagnosis is still in question.

Treatment

Stress fractures should become relatively pain-free once the limb is immobilized. Nonsteroidal antiinflammatory drugs (NSAIDs) can assist with pain control. Strong narcotics should not be required. Once the diagnosis has been made, cast immobilization usually allows bony healing in 6 to 10 weeks.

Rupture of the Calcaneal Tendon

Rupture of the calcaneal (Achilles) tendon is often overlooked (16), because the initial physician may dismiss the symptoms as those of a sprain.

Etiology and Pathophysiology

Rupture of the tendon is usually caused by excessive stress of the muscle while running or jumping. It can also occur as a result of external trauma. The rupture is nearly always complete and is usually found approximately 5 cm above the insertion of the tendon. If left untreated, the tendon may unite spontaneously but in a lengthened and dysfunctional position (29,30).

Symptoms and Signs

The patient is often an aging athlete in the 40- to 50-year-old age group. At the time of injury, there is sudden severe pain in the midcalf. Many report “being hit” in the back of the leg, but on turning around find no one there. The patient usually can walk, but with a limp (30). On examination, tenderness is noted at the site of rupture, with general thickening from effusion of blood and edema, and a gap may be palpated in the course of the tendon. The power of plantar flexion at the ankle is greatly decreased, but some strength remains through the action of the tibialis posterior, the peronei, and the toe flexors (6). Patients with late presentation report loss of strength going up and down stairs and being unable to run owing to the weakness.

Diagnosis

The retention of some power of plantar flexion can cause the unwary physician to make an incorrect diagnosis (17). The Thomas sign is the most efficient diagnostic test. The patient kneels on a chair, and the belly of the gastrocnemius is squeezed. On the affected side the foot does not move, whereas on the normal side the foot plantar flexes. In the chronic condition, the patient is unable to lift up the heel on the affected side during single leg stance (16,29). If the diagnosis is still in doubt, ultrasound can be used to rule out the injury.

Treatment

Immediately after the injury, the pain may be moderate in severity and nonopioid analgesics are sufficient. In some patients, however, the pain is severe and it is necessary to use strong opioid analgesics. Patient-controlled analgesia, intraspinal opioids, and epidural analgesia can be used (see Chapter 43).

Rupture of the Achilles tendon can be treated by immobilization in plaster for 5 weeks with the foot in slight equinus to relax the tendon and help prevent lengthening (29). Surgery entails repair of the tendon. Surgery is indicated for younger and more athletic patients or in cases of delayed diagnosis. Tension on the suture line is reduced by immobilizing the ankle in plantar flexion for 2 weeks followed by a below-knee plaster with the ankle at a 90-degree angle for 4 weeks (29). The operation should be done with continuous epidural anesthesia to prevent the neuroendocrine stress response, and the anesthesia should be continued for 24 to 48 hours to provide postoperative pain relief.

Rupture of the Anterior Tibialis Tendon

Acute and chronic rupture of the anterior tibialis tendon is rare. The rupture occurs between the extensor retinaculum and the insertion of the tendon (31). The patient experiences limitation of dorsal flexion and has a footdrop gait. Operative repair is the procedure of choice (31).

Posterior Tibial Tendonitis and Rupture

Etiology and Pathophysiology. Rupture of the posterior tibialis tendon can occur acutely as a result of an injury, either penetrating or nonpenetrating in nature. A secondary flatfoot deformity can result. More often, the tendon is dysfunctional because of severe flatfoot deformity. The resulting wear on the tendon may cause pain, synovitis, and in some cases, rupture. Rheumatoid arthritis affects the tendon owing to loss of the bony support to the arch as well as direct involvement of the tendon. Pigmented villonodular synovitis may affect the tendon sheath.

Symptoms and Signs. Acute rupture is associated with sudden pain on the medial aspect of the ankle and valgus instability. A painful flatfoot may develop (16). Examination reveals tenderness behind the medial malleolus.

Diagnosis and Treatment. The diagnosis is suspected from the history and physical examination. Early surgical repair is advocated by some (32,33). Nonsurgical treatment with an arch support and a medial heel wedge should be attempted but may not be effective (34). If the posterior tibial tendon is irreparable, a tendon transfer of flexor digitorum longus and some form of arch stabilization procedure such as a triple arthrodesis might be necessary (32). While awaiting surgery, pain is controlled by NSAIDs alone or in combination with opioids, or continuous epidural analgesia is initiated and used for the operation and for postoperative pain relief (see Chapter 41 and Chapter 43).

Shin Splints

Shin splint is a lay term used to describe pain along the anterior or posterior part of the tibia. The pain can be caused by a tibial stress fracture (15). More frequently a strain of the anterior or posterior tibial muscles resulting from overuse of the lower extremities is the cause. Exertional compartment syndrome may cause similar symptoms. The condition is described in Chapter 33.

Infections of Bone

The tibia is one of the most common sites of hematogenous osteomyelitis in pediatric patients. In adults, osteomyelitis occurs occasionally from hematogenous spread and usually occurs secondary to compound fractures or other forms of direct contamination (e.g., drug abuse). The fibula is less often affected. Once established, chronic osteomyelitis requires complete debridement and a full course of antibiotics.

Syphilitic infection of bone is now rare in Western countries. When it does occur, however, the tibia is often the bone affected (35). The infection can take the form of localized gumma or diffuse periostitis and is characterized by gradually enlarging swelling and moderate to severe pain. Adams (35) has noted that the possibility of syphilis should be borne in mind because the swelling is easily mistaken for tumor.

Bone Tumors

Musculoskeletal tumors often occur in metaphyseal bone. Within the tibia, tumors are more likely to occur at the proximal end. Tumors are divided into benign, benign aggressive, and malignant categories (36).

Benign lesions affecting the tibia include enchondromas, adamantinoma, fibrous dysplasia, aneurysmal bone cysts, and unicameral or solitary bone cysts. Most do not require surgery. Some may require biopsy for diagnosis, and some may require surgery for complications such as fracture.

Benign aggressive lesions are characterized by giant cell tumor. Giant cell tumors affect patients in the 20- to 40-year age group and occur right next to a joint

surface. Although the tumor rarely metastasizes, local recurrence is common. Initial treatment involves local excision with adjuvant treatment such as cold cryotherapy and possibly radiation. Occasionally, more radical surgery is required, particularly after recurrence or fracture. Knee fusion or arthroplasty is sometimes required.

The tibia is a site for sarcomas and primary malignant lesions affecting young adults. Ewing's sarcoma, osteogenic sarcoma, malignant fibrous histiocytoma of bone, and occasionally chondrosarcoma affect the tibia (36). The proximal tibia is more often involved than the distal tibia. The prognosis is fortunately better for these more distal lesions, in part owing to earlier diagnosis. Metastatic disease to the tibia is relatively rare. The treatment of cancer pain is discussed in Chapter 35, Chapter 36 and Chapter 37. Modern treatment of these tumors, including Ewing's sarcoma, includes radical resection (36). Usually the limb can be salvaged, particularly with the use of preoperative radiation. Reconstruction can be achieved with allograft and fusion or prosthetic joint replacement. A combination of surgery, local radiation, and chemotherapy is used for these sarcomas.

Acute Rupture of the Gastrocnemius Muscle

Rupture of the gastrocnemius muscle is usually the result of a vigorous contracture while the knee is extended and the foot forcefully dorsiflexed such as can occur during tennis (tennis leg) (30). Occasionally, the rupture is caused by a direct blow. The rupture usually occurs in the substance of the medial head of the gastrocnemius or at the musculoaponeurotic junction.

Signs and Symptoms

The rupture is characterized by sudden pain and a popping sensation. The medial aspect of the muscle is tender. The patient cannot walk without a limp or crutches. Examination reveals a palpable gap in the muscle. In some cases, a posterior compartment syndrome may result secondary to the hematoma. The condition should not be confused with a deep vein thrombosis, because anticoagulants will only increase the symptoms.

Diagnosis and Treatment

The diagnosis is made through the history and physical examination. The control of pain is similar to that for rupture of the Achilles tendon. Nonsurgical treatment using a cast in equinus is the treatment of choice. Compartment syndrome should be managed surgically as soon as diagnosed.

Other Painful Disorders

Other painful disorders of the leg (see Table 80-1) are discussed elsewhere. Intermittent claudication pain in the calf caused by arterial insufficiency in the lower limb as a result of peripheral vascular disease is discussed in Chapter 33. Myofascial pain syndromes with trigger areas frequently involve the calf or anterior leg muscles and cause pain (Chapter 29 and Chapter 79).

PAINFUL DISORDERS OF THE ANKLE AND HEEL

Posttraumatic Pain

Pain caused by acute injuries can result from fracture or dislocation of the bones of the ankle joint or from tear or actual rupture of the surrounding ligaments. In all these conditions, the pain is acute, usually moderate to severe, and requires management with a combination of NSAIDs and strong opioids (Chapter 43) (see Table 31-3).

Ankle Sprains

Ankle sprains are one of the most common presenting complaints to emergency departments and constitute a frequent cause of pain and disability. Many injuries are secondary to sport. Basketball and volleyball players are at particular risk. High-friction surfaces predispose to lower extremity injuries.

Lateral Collateral Ligament Injuries. Most ankle sprains involve the lateral collateral ligaments, and almost all are treated nonsurgically (15). Although isolated ligamentous injuries are common, they are occasionally associated with fractures. A lateral ligament tear may be associated with a medial malleolar fracture.

Symptoms and Signs. Ankle sprains are characterized by sudden, sharp pain. After the injury, the patient may be unable to walk or run. Swelling becomes marked within 6 to 12 hours of injury; the patient cannot bear full weight on the injured leg. Examination reveals the swelling as well as tenderness to palpation of the injured ligament. Ecchymosis is present in the foot and the lower leg. Care should be taken to correctly locate the source of pain, because other injuries, such as a Lisfranc joint injury, may be misdiagnosed owing to incomplete physical examination.

Diagnosis and Treatment. The diagnosis and treatment of ankle sprains are discussed in Chapter 43.

Deltoid (Medial) Ligament Tears

Medial injuries are more severe and associated with greater trauma than lateral injuries, because the deltoid ligament is much stronger than the lateral collateral ligaments. Deltoid ligament injuries can occur in isolation, but they are more commonly associated with lateral malleolar fractures, disruption of the distal tibial-fibular syndesmosis, or both (15). Occasionally, a subtalar dislocation can be associated with a deltoid ligament injury. A subtalar dislocation may be associated with a lateral talar process fracture.

Diagnosis. Pain is localized to the medial side of the ankle. Swelling and ecchymosis in the medial malleolar region can be seen. Complete examination should be performed to exclude associated injuries.

Treatment. The pain can be managed by antiinflammatories, although occasionally stronger narcotics are required. Isolated deltoid ligament injuries are managed nonsurgically, but the associated fractures usually require surgical intervention.

Distal Tibiofibular Syndesmosis Injuries

Occasionally, injuries occur in isolation to the distal tibiofibular joint. This is associated with a feeling of ankle instability and giving way. The diagnosis is often made late.

Symptoms and Signs. Patients complain of localized pain in the region of the distal tibia. Often, an internal rotation twisting injury on a stable foot causes the disruption. Early radiologic examination may show widening of the ankle mortise and talar shift. Late presentation can be diagnosed with a careful history and physical examination.

Treatment. In both early and late cases, the pain outside activity is not severe. However, the syndesmosis needs to be stabilized using a screw to prevent late talar shift and subsequent development of ankle arthritis.

Subtalar Instability

Occasionally, subluxation or dislocation occurs through the subtalar joint. Late instability may be misdiagnosed as ankle instability (16).

Symptoms and Signs. The signs and symptoms of subtalar instability are very similar to those of lateral collateral ligament injuries. The acute subtalar dislocation may spontaneously reduce, and only a careful history will indicate the joint of instability. Late cases may present with recurrent instability, and an inversion stress view of the subtalar joint may assist in the diagnosis.

Treatment. Acute treatment of pain may be achieved similar to lateral collateral ligament injuries. Subtalar joint stabilization by ligament reconstruction may be required.

Recurrent Ankle Instability

Recurrent ankle instability results in apprehension and persistent discomfort. Initial treatment consists of ankle-strengthening exercises and ankle braces. Many cases resolve with time. On occasion, surgical reconstruction is indicated (15).

Ankle Fractures

Etiology and Pathophysiology. Ankle fractures vary in severity from undisplaced lateral malleolus fractures to severely comminuted intraarticular injuries of the distal tibia (15). Isolated malleolar fractures involve less energy than fractures of the tibial midshaft. These injuries often occur as a result rotation of the body on a fixed foot. Distal tibial plafond injuries involving the metaphyseal region may or may not involve the joint. These injuries are associated with significant trauma in younger patients and have a potentially poor prognosis. Figure 80-29 shows several variations of ankle fractures involving the malleoli or the lower part of the fibula (37). Medial injuries are either bony (through the medial malleolus) or ligamentous (through the deltoid ligament).

Figure 80-29. Types of ankle fractures as outlined by Launge-Hansen. This allows the treating physician to understand the nature of the injury creating the fracture pattern. **A:** Supination-eversion injury. **B:** Supination-adduction injury. **C:** Pronation-eversion fracture. **D:** Pronation-abduction fracture. (Modified from Yablon IG, Segal D. Ankle fractures. In: Evarts CW, ed. *Surgery of the musculoskeletal system.* New York: Churchill Livingstone, 1983.)

Treatment. Fractures involving the ankle joint require anatomic reduction so that late degenerative changes are prevented. For displaced fractures, open reduction internal fixation is usually required because any residual displacement or instability results in late degenerative changes.

Undisplaced fractures require cast immobilization. Operative intervention can be performed under regional anesthesia allowing postoperative pain relief. Alternatively, a general anesthetic with postoperative nerve block is used. Intraarticular distal tibial fractures are complex cases requiring up to 4 hours of surgery, and they require prolonged postoperative analgesia and elevation. In contrast, patients with isolated lateral malleolar injuries are usually discharged within 24 hours after the procedure. More detailed discussion of the management of pain caused by these fractures is contained in Chapter 43.

Ankle Arthritis

Various arthritic conditions can affect the ankle joint (see Table 80-1). Osteoarthritis is the most common degenerative condition of the ankle. Many cases occur after trauma in young patients. Spontaneous pyogenic arthritis with subsequent degeneration is uncommon and may be caused by tuberculosis. Rheumatoid arthritis is the most common generalized rheumatologic disorder affecting the ankle joints (25). Seronegative arthritis such as ankylosing spondylitis, psoriatic arthritis, and systemic lupus erythematosus may also affect the ankle joint. Gouty arthritis, pigmented villonodular synovitis, and synovial chondromatosis may affect the ankle in isolation. Hemophilic arthropathy and neuropathic arthritis are common enough to merit investigation in patients with unusual presentation. Diabetic neuroarthropathy can affect the ankle and is often associated with pain. The diabetes may as yet be undiagnosed at the time of presentation. Chapter 27 includes a more in-depth discussion of arthritis.

Osteoarthritis of the Ankle Joint

Degenerative destruction of articular cartilage is less common in the ankle than the knee and hip. Pain is the usual presenting symptom localized over the joint. Swelling is associated with the pain. The pain is mechanical in nature, aggravated by activity, and relieved by rest. On examination the joint is found to be slightly thickened from marginal bony hypertrophy and synovitis. Motion is often limited secondary to the development of osteophytes and a thickened capsule. Radiography reveals the typical features of osteoarthritis including joint space narrowing, sclerosis of the bone adjacent to the joint, hypertrophy or osteophyte formation at the joint margins, and cyst formation.

Treatment of osteoarthritis is discussed in Chapter 27.

Dislocation of the Peroneal Tendons

Etiology and Pathophysiology. Dislocation of the peroneal tendons is a condition resembling a severe lateral collateral ligament sprain (16). The injury can occur in snowboarders owing to a forceful contraction of the tendons while the ankle is dorsiflexed and everted. The peroneal tendon passes behind the lateral malleolus and is held by an overlying retinaculum. Forceful dorsiflexion with simultaneous peroneal contraction can rupture the retinaculum and dislocate the tendon.

Symptoms and Signs. The patient may present immediately after the initial injury. The tendons may be dislocated or relocated. Often, the patient presents late with a history of lateral ankle discomfort and a feeling of snapping or popping over the lateral side of the joint. Peroneal tendon subluxation occurs with the foot dorsiflexed and everted, unlike recurrent lateral collateral ligament injuries in which the foot is plantar flexed and inverted.

Diagnosis and Treatment. Occasionally, the retinaculum requires repair after acute injury. More often the tendons stabilize with cast immobilization. The pain is managed with NSAIDs alone or in combination with a mild or strong opioid. Delayed surgical repair may be indicated for recurrent subluxation.

Posterior Heel Pain

Etiology and Pathophysiology. Inflammation of the bursa under the Achilles tendon may occur with ill-fitting shoes (38). Some patients have an abnormally shaped calcaneus and have trouble finding comfortable shoes. In other cases, spontaneous degeneration of the Achilles tendon insertion occurs. Similar degenerative change may affect the Achilles tendon more proximally and is associated with tenosynovitis.

Symptoms and Signs. Exquisite pain and tenderness over the posterior aspect of the heel and under the skin are common features. This pain is aggravated by direct palpation and pressure (see Fig. 80-22B). The bursa may be visibly inflamed and is often distended with fluid. With chronic bursitis, the walls of the bursa and the overlying skin are thickened. Patients complain of pain on resisted dorsiflexion of the foot, such as getting up from a squat or climbing stairs.

Diagnosis and Treatment. Diagnosis is made by the history and physical examination, including careful evaluation of the shoe fit. Treatment begins with proper-fitting shoes with moderately low heels. The moderate to severe pain of acute bursitis is relieved by the application of ice and NSAIDs. In acute bursitis associated with severe pain, the swollen bursa is drained by needle aspiration followed by injection of a local anesthetic and steroid. Moleskin placed over the thickened skin prevents

further friction. In some cases it is necessary to cut out the back of the shoe or raise the heel inside the shoe. Surgical excision of the bursa is rarely indicated. In contrast, insertional tendonitis may require surgical debridement. Steroids should not be injected into the tendon itself because rupture may occur.

Osteochondritis Dissecans

Etiology and Pathophysiology. Osteochondritis dissecans is an osteochondral defect of traumatic or developmental origin. It involves the talar dome anterolaterally or posteromedially (15). Although a talar lesion can occur at any age, it most often affects adolescents and young adults, with a peak influence in the third decade. Although this condition occasionally develops spontaneously, trauma is often seen in association with the symptoms. Berndt and Harty (39) produced impressive experimental evidence of the traumatic origin of this condition, which they termed *transchondral talar fracture* and classified according to severity (Fig. 80-30).

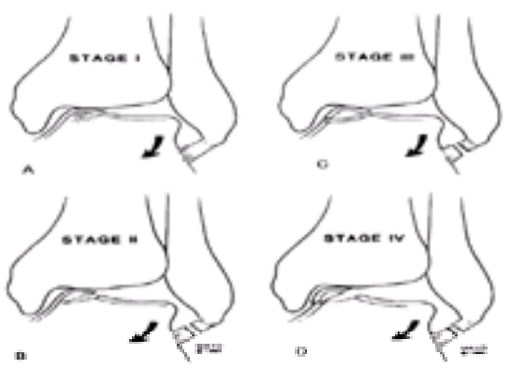

Figure 80-30. Classification of osteochondral fracture of the talus as outlined by Berndt and Harty. **A:** Stage I: A cyclic compression fracture of the medial talar dome with intact lateral ligaments. The articular cartilage remains intact while underlying trabecular bone becomes necrotic. **B:** Stage II: Incomplete fracture of the bone and cartilage with associated rupture of lateral ligaments. **C:** Stage III: Complete osteochondral fracture with an undisplaced fragment. **D:** Stage IV: Complete osteochondral fracture with displacement of fragment within the ankle joint. (Reprinted from Stauffer RN. Intra-articular ankle problems. In: Evarts CW, ed. *Surgery of the musculoskeletal system.* New York: Churchill Livingstone, 1983, with permission.)

Symptoms and Signs. Initially the patient can experience mild to moderate ankle pain, with some “catching” with motion that the patient frequently attributes to “mild ankle sprain” (15). If the bone lesion loosens, intermittent locking, chronic pain, and swelling occur.

Diagnosis. Many osteochondral talar fractures are missed at first presentation, either because radiographs of a routine ankle sprain are not taken or because the talar fracture is overlooked. Tomographs or CT of the talus demonstrates the location and extent of the lesion.

Treatment. If the condition is diagnosed early a conservative or nonsurgical approach can be considered. Patients in the later stages of the disease require surgical treatment. Curettage of the lesion removes all loose cartilage, and drilling of the subchondral bone promotes ingrowth of new fibrocartilage. Even though a large area might be affected, the new surface created by the fibrocartilage appears to hold up well. Pain is usually relieved, allowing full activities to be resumed.

PAINFUL CONDITIONS OF THE FOOT

Arthritis

The joints of the foot can be affected by pyogenic arthritis, rheumatoid arthritis, gouty arthritis, and osteoarthritis or degenerative joint disease. Although gouty arthritis is most common in the joint of the great toe, it can also occur in other joints. The two most common types of arthritis that affect the joints of the foot are considered here: degenerative arthritis and inflammatory rheumatoid arthritis.

Degenerative Arthritis

Symptoms and Signs. Degenerative arthritis causes pain localized to the involved joint persisting both day and night. The pain is aggravated by weight-bearing and worsens as the day progresses. The pain is relieved by rest. Signs include joint synovitis, decreased range of motion, deformity (including subluxation), and crepitation with motion. Radiography reveals hypertrophic changes about the articular margins such as beaking, osteophytes, sclerosis, and cysts.

Treatment. Osteoarthritis or degenerative joint disease of the foot is initially treated nonsurgically by splinting of affected joints, soft orthotics, and well-made running shoes. Alternatively, the foot can be splinted by wearing a shoe with a stiff shank and a rocker- bottom sole (see Fig. 80-27). Push-off is limited. Foam, leather, and other materials are used to make removable shoe inserts, which increase shock absorption. An NSAID can reduce inflammation and pain. The standard dose of ibuprofen is 600 mg t.i.d. with meals for 2 to 3 weeks. If the pain persists, another NSAID is worth trying. If still unsuccessful, additional NSAIDs are probably going to be ineffective. Other medical therapies are discussed elsewhere (Chapter 27, Chapter 83, and Chapter 84).

When pain persists despite conservative treatment, several operative options are available. Bony osteophytes, which decrease motion and cause impingement pain at the ankle and the MP joint of the big toe, can be excised. Diffuse involvement of those joints not responding to conservative treatment requires arthrodesis (16). If the joint is fused in a plantigrade position, pain can be relieved and function restored. Fusing joints in the foot may cause arthritic changes in adjacent joints, which must compensate for the loss of motion.

Inflammatory Arthritis

Symptoms and Signs. Inflammatory arthritis is characterized by exquisite pain localized to involved joints. It is accompanied by stiffness after sitting or rest and is aggravated by inactivity. Some relief is achieved with heat, splinting, and limitation of the range of motion. Associated signs include increased warmth, joint effusion, capsular thickening about the joint, increased laxity, and progressive subluxation, particularly about the ankle, subtalar, and MP joints. Motion is progressively lost.

Inflammatory joint disease of the foot produces joint laxity and osteoporosis. Specific deformity includes hindfoot valgus, pronation of the midfoot, supination of the forefoot, and clawing of the small toes, leading to metatarsalgia.

Treatment. In addition to medical treatment of the underlying inflammatory disease, comfort and function can be improved by accommodative shoes providing support and extra room for the toes (see Chapter 27). Surgery relieves deformities predisposing to pressure problems and can be used to restore the foot to a plantigrade position. Ankle fusion, triple arthrodeses, and midfoot fusion are all helpful, with few complications. Prominent metatarsal heads cause intractable keratoses and metatarsalgia.

Pes Cavus

In pes cavus, the longitudinal arch of the foot is accentuated (Fig. 80-31). The deformity may be congenital or secondary to a neurologic disorder. The metatarsal heads are lowered in relation to the hind part of the foot, with consequent exaggeration of the longitudinal arch. The soft tissues in the sole are abnormally short and eventually the bones themselves alter their shape, perpetuating the deformity. Clawing of the toes, hyperextended at the MP joints and flexed at IP joints, is often seen. The toes become functionless and cannot bear their share of weight-bearing. The metatarsal heads have increased load because of distal migration of the plantar pad, loss of contact of the toes on the ground, and pressure on the IP joints of the toes from the shoe forcing the metatarsal heads down.

Figure 80-31. Pes cavus: The high arched foot is rigid. This limits shock absorption so that weight-bearing forces become concentrated on the metatarsal heads and the heel. Underlying neurologic disease should be considered in such patients.

In many patients, specific treatment is not required. Mild symptoms can often be relieved using a sponge rubber pad beneath the metatarsal heads to distribute load. A wide–toe box shoe will prevent rubbing of the toes and prevent overload of the metatarsal heads. If symptoms are severe, surgery is required.

Pain in the Hindfoot

Plantar Fasciitis

Etiology and Pathophysiology. Pain under the heel is often caused by a plantar fasciitis. Plantar fasciitis is secondary to pain at the insertion of the plantar fascia into the calcaneus. The pain is increased by weight-bearing and relieved by rest. Typically, the pain is worse after the first few steps in the morning or after rest (16). The condition can be part of a more widespread inflammatory condition, such as Reiter's disease (25). It is common in occupations entailing excessive standing or walking, especially when the individual is unaccustomed to such activity. It is more common in pronated feet. Men are more susceptible than are women. A bony prominence or spur can develop at the attachment of the plantar fascia to the calcaneus, although this is often found on radiographs of normal feet.

Symptoms and Signs. Moderate to severe pain and tenderness beneath the anterior portion of the heel, often radiating into the sole of the foot, is the presenting complaint. Although trauma may be the cause, in most cases the onset is insidious. Examination reveals a point of exquisite deep tenderness at the anteromedial area of the calcaneus, the point of attachment of the plantar fascia (see Fig. 80-22C).

Diagnosis and Treatment. Diagnosis is made through the history and physical examination. Radiographs are often normal. Other conditions or theories as to the etiology of plantar fasciitis include infracalcaneal bursitis under the fascial attachment, atraumatic periostitis, and entrapment of the calcaneal branch of the tibial nerve.

Initial treatment consists of preventing hyperpronation by well-constructed shoes with a medial arch support. Alternatively, a sponge rubber cushion with its center removed can be used under the heel. Pain is usually effectively relieved by NSAIDs. Ice and stretching exercises will also benefit the patient. Night splints are used in more resistant cases or when night pain is a significant feature. If the pain is persistent and severe, injection of a mixture of a local anesthetic and steroid can be considered. The injection can be made through the pedal pad or from the medial or lateral approach into the site of maximum tenderness. No more than three injections are used, because injection of steroids can cause secondary rupture of the plantar fascia, complicated often by flatfoot deformity and increased lateral foot pain due to overload of the calcaneo cuboid joint.

If these treatments are ineffective, a walking cast is necessary for 6 weeks. Release of the plantar fascia is sometimes necessary for chronic cases, but generally this condition responds to nonsurgical treatment (40).

Tarsal Coalition

Pathophysiology and Symptoms and Signs. Congenital fibrous union is a fusion between the bones of the hindfoot. In teenagers, the coalition can become painful as the coalition ossifies and forms a nonunion. If the coalition completely ossifies or if it never ossifies, it will not be painful. Later, the coalition can lead to arthritis of the surrounding joints. Overall, tarsal coalition is a relatively rare cause of subtalar pain.

Diagnosis and Treatment. History of pain and lack of subtalar motion in a young patient is diagnostic. Treatment consists of diminishing subtalar motion by the use of supportive shoes and a medial arch insert to provide increased shock absorption. This treatment alone may allow the partial fusion to unite like a fracture. Most patients usually respond to these measures (41,42). Surgery involves fusing the area of fibrous coalition or taking down the coalition when the joint surfaces are compatible with normal movement.

Heel Pad Deficiency

Etiology and Pathophysiology

Generalized pain over the entire calcaneal fat pad (painful heel pad) occurs when the heel pad is deficient or subjected to unusual stress. The heel pad is made of fat and elastic fibrous tissue contained within fibrous septa. Normally this tissue acts as a shock absorber. Its elasticity decreases with age, causing increased contact pressure and pain.

Symptoms and Signs

The pain of a deficient heel pad is localized over the entire calcaneal pad. If untreated, secondary scar formation and calcification will result. Acute stress on the pad can rupture or strain the compartments and cause temporary loss of compressibility and cause symptoms.

Diagnosis and Treatment

Diagnosis is made through the history, physical examination, and results of imaging (see Table 80-5). The pain is effectively controlled by NSAIDs; if severe, however, infiltration of 5 mL of a dilute solution of a long-acting local anesthetic (e.g., 0.25% bupivacaine) relieves pain for 8 to 10 hours. Steroids should not be injected because they will result in further atrophy of the pad. Definitive treatment of the condition involves addition of a shock-absorbing insert to the shoe and ensuring that the heel is supported by a firm center.

Tarsal Tunnel Syndrome

Etiology and Pathophysiology

Entrapment of the medial and lateral plantar nerves within the tarsal tunnel can cause pain, paresthesia, and weakness of the intrinsic flexors of the foot (27). The posterior tibial nerve passes deep to soleus and ends by dividing into the medial and lateral plantar deep to the flexor retinaculum behind the medial malleolus. The flexor retinaculum is a strong fibrous band extending from the medial malleolus to the calcaneus. It forms the roof of the tarsal tunnel, the walls being formed by the posterior margin of the tibia and the lateral side of the calcaneus and talus. The tibial nerve can become trapped within the tunnel. Any space-occupying lesion, such as tumor or synovial hypertrophy, can compress the nerve within the tunnel. Subsequent edema and scar formation will limit blood supply to the nerve and inhibit the full elongation (uncoiling) of the nerve between joint movements. Stretching of the nerve by flatfoot deformity can cause tension within the nerve at the tarsal tunnel. In

late cases, axonal or wallerian degeneration may ensue (see Chapter 19 and Chapter 77 for details).

Symptoms and Signs

The pain is nocturnal and paresthetic or burning in nature and may be associated with numbness (27). The symptoms can be felt when the patient is standing or reclining. If both plantar nerves are involved, the symptoms extend over the plantar surface of the foot and the dorsum of the distal part of the toes. Sometimes the medial calcaneal branch of the tibia becomes entrapped as it perforates the flexor retinaculum. Numbness is distributed to the heel and medial side of the sole of the foot. Tenderness can usually be elicited over the nerve behind the medial malleolus, and a positive Tinel's sign can be elicited by tapping the nerve at that site.

Diagnosis and Treatment

Entrapment is a diagnostic challenge. Because the condition can coexist with peripheral neuropathies it is necessary to decide whether the pain and other symptoms and signs are caused by the neuropathy itself or by tarsal tunnel compression. Electromyographic and nerve conduction velocity studies can be helpful.

An attempt should be made to treat the condition conservatively. Injection of local anesthetic and steroids into the tarsal tunnel can be helpful, as can NSAIDs. Transcutaneous electrical nerve stimulation should also be tried. If the patient experiences lancinating pain, tricyclic antidepressants or anticonvulsants should be tried (see Chapter 85 and Chapter 86).

If the symptoms persist after a few weeks of conservative management, surgical decompression is justified. In severe flatfoot, the symptoms may more relate to stretching of the nerve around the medial malleolus rather than compression itself. In this scenario, augmentation of the arch may be more appropriate than nerve release. The proximal ridge of the abductor hallucis, often a site of compression, is divided to release the tunnel. Varicose veins and ganglions are frequent sources of compression within the tunnel. These patients should be checked to see that their foot is not hyperpronating, because this increases tension on the plantar nerves and aggravates symptoms.

Painful Conditions of the Midfoot

Medial Arch Strain

Medial arch strain can occur in normal feet from prolonged standing on hard surfaces, particularly when the foot is not well supported. Treatment consists of activity modification and wearing of shoes supporting the heel and arch and providing shock absorption. Flatfoot should be supported by arch supports or orthotics to decrease the medial arch strain.

Lisfranc's Joint Instability

Etiology and Symptoms and Signs. A twisting midfoot injury, such as a severe inversion or a forefoot plantar flexion, can lead to injury of Lisfranc's (metatarsal cuneiform) joint. Excessive pain and swelling in the midfoot suggest the diagnosis. Palpation reveals tenderness of the affected joints.

Diagnosis. The history and findings of the physical examination lead to the diagnosis. Whereas Lisfranc's fractures are detectable by radiography, joint subluxations and sprains are difficult to demonstrate by this method. Stress radiographs taken with the foot plantar flexed and inverted may be required.

Treatment. When recognized early, support of the foot either by a cast or a well-fitted shoe promotes healing of the ligaments. If seen 3 to 4 months later, a chronic condition can have developed that might require selective fusion of the painful joints, particularly the metatarsal cuneiform joints. Overweight patients usually have the poorest results, particularly with conservative treatment (15).

Posterior Tibial Tendon Insufficiency

Etiology and Pathophysiology. The posterior tibial tendon is the main dynamic support of the medial arch. If the tendon is disrupted such as occurs with fracture of an accessory navicular, or injured, the arch eventually collapses. A tight heel cord aggravates the situation by holding the heel in valgus when sufficient subtalar motion exists. The tendon can be torn, sprained, or stretched with eversion-type injuries (32). Over time, the foot assumes a pronated posture that is asymmetric to the opposite foot. The patient cannot rise up on that foot or invert the heel. Rheumatoid arthritis can lead to silent rupture.

Symptoms and Signs. Posterior tibial tendon insufficiency causes progressive flatfoot deformity with overload of the midfoot. The patient experiences persistent dull aching pain associated with tenderness, and occasionally swelling is present. Eventually the patient experiences difficulty in standing and walking.

Diagnosis and Treatment. Diagnosis is made through the history and physical examination and by the results of special tests (see Table 80-5), including ultrasound and standing plain radiography. Early treatment consists of wearing supportive shoes to correct and control pronation. Later, when the condition has been established and collapse has already started, augmentation of the posterior tibial tendon helps to restore dynamic support of the arch. As a flatfoot results in posterior tibial tendon overload some form of augmentation of the arch may be required to reduce the stress on the repaired tendon. Procedures such as calcaneal osteotomy, lateral column lengthening, talonavicular fusion, or subtalar fusion may be performed. Augmentation or repair is accomplished using the flexor digitorum longus or extensor hallucis longus. In cases of severe deformity or when degenerative changes have occurred in the midfoot, a triple arthrodesis may be required.

Ganglion

Etiology and Symptoms and Signs. A ganglion is a mucus-filled cyst that usually arises from a joint or tendon sheath. The condition is particularly uncomfortable in the foot because of shoe pressure. Motion of the foot during weight-bearing tends to pump fluid into the ganglion. The condition causes mild tenderness on palpation that is aggravated by pressure and ambulating.

Treatment. Painless ganglions can be left alone. Nonsurgical treatment is often unsuccessful for painful ganglions. Aspiration and installation of steroids sometimes help, but in Lippert's experience (22) these are rarely successful. Definitive treatment requires excision of the ganglion down to its origin. The neck of the ganglion can be tied off or excised completely so that the ball valve effect is eliminated. Patients should be protected in a walking cast for 10 to 14 days to allow the soft tissues to heal and the source of the ganglion to be obliterated by scar.

Painful Disorders of the Forefoot

Stress Fracture

Sedentary individuals and those who begin a new activity that requires running or prolonged walking may develop a stress fracture (march fracture) in the neck of the metatarsal bones. Although any bone of the foot can be involved, stress fracture of the second metatarsal occurs as a consequence of running or dancing on hard surfaces. Sometimes bone scans are necessary for the diagnosis, although radiographic changes are usually evident approximately 10 to 14 days after fracture. Treatment consists of the use of a walking cast until healing occurs, which may require 4 to 6 weeks. If the cast is removed too soon, the stress fracture tends to become chronic and more difficult to treat. In some patients, stress fractures may occur because of abnormal loading of the forefoot. In these cases, when conservative treatment fails, procedures to reconstruct the forefoot may be considered.

Metatarsalgia. Metatarsalgia refers to pain under the heads of the metatarsals owing to excessive load. Metatarsalgia is common in rheumatoid arthritis. In this case, excessive mobility in the medial column leads to loss of support of the first ray. Dislocation of the MP joints displaces the plantar pad distally, prevents the toes from reaching the ground, and causes the toe box of the shoe to increase pressure on the metatarsal heads. Usually, the first metatarsal carries two-sixths of the body weight and the others one-sixth each (7). If the first metatarsal fails to carry weight, the second metatarsal carries three-sixths, or one-half, of the body weight. Excessive load leads to stress fracture, dislocation of the plantar plate, and claw toe deformity.

Etiology and Pathophysiology. In a pronated or splayed foot, the balance of weight-bearing is upset. The transverse arch is depressed, and greater weight is borne on

the second, third, and fourth metatarsal heads. The interosseous ligaments that support the arch are stretched, permitting the forefoot to broaden and splay out (7).

The condition is more common in cavus and rheumatoid feet, in which claw toes have pushed the metatarsal heads downward and displaced the protective padding distally. Women who wear high-heeled shoes are more prone to metatarsalgia as a result of the position of the foot, which concentrates the weight-bearing forces on the metatarsal heads. Congenital traits, such as a long first metatarsal or hypermobile first ray, may increase the risk of metatarsalgia.

Symptoms and Signs. Initially patients experience tenderness of the metatarsal head, which has been described as “walking with a pebble in the shoe.” A callus may be found under the second or third metatarsal head, which itself is painful and causes further irritation by increasing the weight-bearing on the metatarsal head. The tenderness is aggravated when the examiner squeezes the metatarsal head between the thumb and index finger. The examiner should compress each metatarsal head individually and must not compress the tissues between the heads (ligaments and interdigital nerves), because this could cause pain and tenderness and confuse the diagnosis.

In some cases, excessive load occurs under the first metatarsal head. This can occur in patients with a cavus foot or after fracture and malunion of a metatarsal. Excessive load may occur if the second metatarsal is too dorsiflexed, or the first is too plantarflexed.

Diagnosis and Treatment. The diagnosis is made through the history and careful physical examination and by the results of plain radiography and bone scanning (see Table 80-5). Most individuals obtain relief with the use of a metatarsal pad placed in the shoe or as a removable insert (see Fig. 80-26). These devices redistribute the weight-bearing forces away from the metatarsal heads into the arch region. Occasionally, patients present with metatarsalgia under one or two heads secondary to a previous fracture or to some other structural abnormality. Selective padding is usually effective. When an intractable keratosis occurs under one of the metatarsal heads and does not respond to padding, shaving of the callus may effect relief. If these measures do not work, pressure can be reduced by performing an osteotomy of the metatarsal shaft or by excising the condyles of the metatarsal head. The goal of surgery is to equalize weight-bearing under the metatarsal heads. Failure to accomplish this results in a painful transfer keratosis (16).

Painful Conditions of the Great Toe

Hallux Valgus

Etiology and Pathophysiology. Hallux valgus describes the lateral deviation of the great toe at the MP joint. Patients often notice the medial prominence of the first metatarsal head, known as a *bunion*. Hallux valgus is more common in women, especially those past middle age. Although the underlying cause can be congenital (metatarsus primus varus), ill-fitting shoes with a narrow toe may cause progression (43).

Lateral deviation of the big toe is the most obvious feature of the deformity. On standing plain radiographs, the gap between the head of the first and second metatarsals is unduly wide. Secondary and associated changes are numerous. These include the development of a bursa over the medial aspect of the great toe, which can be painful. Some patients also develop secondary arthritic changes at the MP joint (Fig. 80-32). The sesamoids are laterally displaced from under the metatarsal heads and can cause painful sesamoiditis. In other patients, second metatarsal overload and second metatarsalgia may be the primary complaint, and secondary claw toe deformity may develop. Other patients have symptoms more related to the associated flatfoot deformity causing arch and lateral column pain and posterior tibial tendonitis.

Figure 80-32. Hallux valgus. See text for details.

Symptoms and Signs. Early symptoms may arise from tenderness over the bunion from pressure against the shoe, and the patient encounters difficulty in obtaining comfortable footwear. Additional symptoms later arise from osteoarthritis of the MP joint and from flattening of the transverse arch (anterior flatfoot), which is a common associated deformity. On examination, the deformity is obvious and the skin over the prominent joint is hard, red, and tender. In late stages, the forefoot is often flat and splayed and the toes can be severely clawed.

Treatment. Nonsurgical treatment consists of wearing extra-wide shoes and arch supports to prevent pronation. Walking with the foot pronated causes an increased valgus stress on the toe, stretching out the medial capsule. Surgery is performed when nonsurgical measures fail. Surgery is tailored to address the symptoms. Subluxed painful sesamoids with a low intermetatarsal angle can be addressed by a distal osteotomy. The deformity must be flexible, because a distal soft tissue release cannot be performed during a distal osteotomy procedure as the blood supply to the bone will be disrupted. More severe deformities can be addressed by a proximal metatarsal osteotomy or first tarsometatarsal fusion. Occasionally, a first MP joint fusion is required. Contractures around the metatarsal head must be released to reposition the first metatarsal head close to its neighbor. Treatment is usually successful in relieving the pain and deformity provided that the first metatarsal is not excessively shortened or elevated. Some recurrence of the deformity is typical but is not associated with recurrence of pain.

Hallux Rigidus

Etiology and Pathophysiology. Hallux rigidus is osteoarthritis of the first MP joint characterized by lack of joint motion and pain, particularly at push-off (Fig. 80-33). The cause may be multifactorial and include congenital factors, improper shoes (especially those causing hyperextension of the joint), abnormal gait, obesity, and trauma as contributing factors (44).

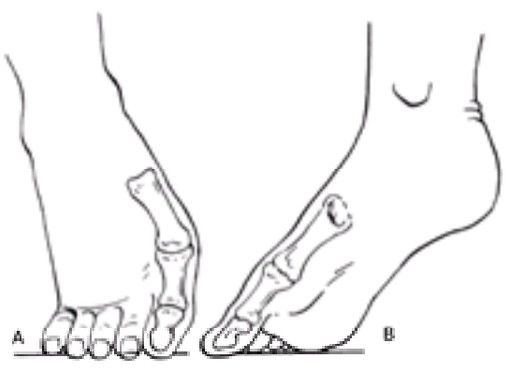

Figure 80-33. Hallux rigidus. **A:** Anterior view. **B:** Medial view. Arthritis of the metatarsophalangeal joint reduces motion, especially in dorsiflexion. Push-off is painful.

Symptoms and Signs. Almost all patients present with symptoms of pain and restriction of motion in the first MP joint. These are usually of gradual onset and patients often give a history that indicates no obvious cause (30). During the initial phase, the motion most severely restricted is dorsiflexion while plantar flexion can be unaffected. Later, more global restriction of motion occurs. Palpation usually elicits considerable tenderness, and any forceful motion, especially dorsiflexion, causes pain. These patients have a particularly difficult time finding any shoe that allows more comfortable walking.

Diagnosis and Treatment. The diagnosis is made through the history and physical and radiographic examination (see Table 80-5). Nonsurgical treatment consists of splinting the joint through the use of a stiff-soled shoe with a rocker-bottom sole (see Fig. 80-27). Frequently, these measures and the use of NSAIDs are all that is required. Operative treatment consists of improving the range of motion by excising osteophytes and freeing up the sesamoid complex. At least 30 to 40 degrees of dorsiflexion at surgery are required for pain relief. Advanced changes in the joint require MP fusion with the toe in 20 to 30 degrees of dorsiflexion. The best position is determined by having patients stand in their shoes and then taking a lateral radiograph. Silastic spacers are no longer indicated.

Hypermobility of the First Ray

Hypermobility of the first ray leads to diminished weight-bearing on the first ray, resulting in pain and intractable keratosis under the head of the second metatarsal (45). Treatment consists of transferring more weight to the first ray. This can be accomplished by having the patient use a shoe insert that is built up selectively under the first metatarsal head. In some cases, fusing the first MP joint is required to increase the weight-bearing capability of the first ray.

Intractable Keratosis

Intractable keratosis refers to hard calluses located under one or more of the metatarsal heads and often associated with aching pain. These are a skin response to excessive weight-bearing on the metatarsal heads. Despite conscientious attempts of the patient to reduce the thickness of these lesions by paring and grinding, daily weight-bearing forces encourage the formation of deeply penetrating indurated lesions. When local measures fail, the pressure on the metatarsal head must be reduced surgically. These options are described above; care must be taken to avoid uneven weight-bearing forces that could transfer the keratoses to adjacent metatarsal heads (46).

Sesamoiditis

Sesamoiditis, which must be distinguished from metatarsalgia, is an inflammation involving the sesamoid–metatarsal head complex. The presenting picture is one of localized swelling and pain aggravated by dorsiflexion of the MP joint. Sesamoiditis can be confused with first metatarsal overload, particularly in patients with cavus feet.

Treatment consists of eliminating weight from the area until the inflammatory reaction subsides. A walking cast is often necessary in addition to the use of NSAIDs. Because sesamoids are weight-bearing bones, they should be preserved unless all other treatment options have been unsuccessful.

Gout

Acute gouty arthritis of the first MP joint causes severe pain. Antiinflammatories help to control the overall reaction, and splinting the toe in a bunion shoe allows the patient to walk. The diagnosis is established by aspirating the joint to test for uric acid crystals and by determining the serum uric acid level. The condition usually responds to treatment measures within 24 hours. Surgery is rarely indicated unless advanced degenerative changes have taken place, in which case the treatment for hallux rigidus applies.

Painful Disorders of the Small Toes

Interdigital Neuroma

Interdigital neuroma, also known as *Morton's neuroma* and *Morton's metatarsalgia*, is characterized typically by metatarsal pain combined with radiating and lancinating pain in the third and fourth toes (47). Morton's neuroma can be hard to distinguish from metatarsalgia.

Etiology and Pathophysiology. The pain and characteristic neurologic symptoms and signs are caused by the neuroma, which is a fibrous thickening of the digital nerve of the cleft between the third and fourth metatarsals just proximal to where the nerve divides into its terminal digital branches. The neuroma takes the form of a fusiform swelling, usually approximately 1 cm long, that surrounds the nerve as it lies in the space between the heads of the third and fourth metatarsals. The cause of the fibrous thickening is uncertain.

Symptoms and Signs. This condition involves middle-aged women more often than younger women and men. The condition is characterized by pain in the forefoot on standing or walking. The pain starts in the metatarsal region and radiates forward into the contiguous side of the second and third or third and fourth toes or to the fourth toe alone. Like neuralgia in general, the pain is sharp, burning, and piercing in character and is often associated with bouts of lancinating pain. Patients often state that they can relieve the pain by taking the shoe off and squeezing or manipulating the forefoot (47). Moving the metatarsal head from side to side and applying pressure to the sole of the foot between the third and fourth metatarsal heads or second and third metatarsal heads elicits pain and is often associated with a clicking sound.

Diagnosis and Treatment. Interdigital neuroma is often diagnosed but inadequately resected. Patients should be followed to ensure that the symptoms are consistent and also that any conservative measures used are not related to discomfort.

Conservative measures include wearing shoes with extra-wide toe boxes, pads between the metatarsal heads to separate the involved toes, and metatarsal pads to relieve pressure on the metatarsal heads. Steroids injected into the web space are sometimes helpful, but injury to the affected digital nerve from the injection can aggravate the condition. If the patient does not respond to nonsurgical measures, surgical excision may be performed. Failure rate of surgery is approximately 20% and may relate to inaccurate diagnosis (16,47).

Hammertoes and Claw Toes

Hammertoes and claw toes are deformities caused by a combination of neurologic imbalance, anatomic predisposition, activity level, and shoe wear. They cause painful corns and callosities and interfere with their shared weight-bearing distribution on the metatarsal heads (Fig. 80-34). Often, the pain is localized in the metatarsal head region on the plantar aspect. Metatarsal overload and plantar plate rupture may be the cause of the deformity. Distal migration of the plantar pad is often seen, exposing the metatarsal head to greater peak forces. The shoe forces the toe and metatarsal head down, increasing the metatarsalgia. Conservative treatment includes the use of metatarsal pads and shoes with extra depth boxes to relieve pressure toe points. An intractable keratosis may develop underneath the metatarsal head of the involved toe.

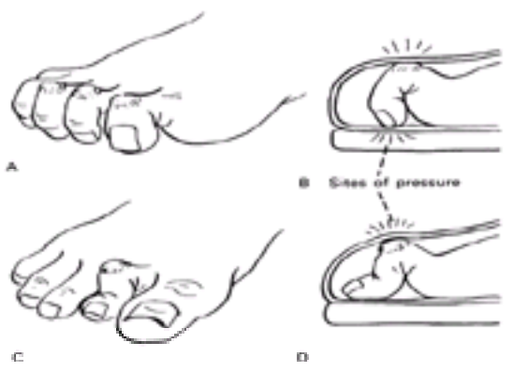

Figure 80-34. Typical small toe deformities. Claw toe **(A,B)** and hammertoe **(C,D)** deformities often cause corns and calluses with standard footwear. Extra deep shoes avoid these problems.

If conservative treatment fails, surgery may benefit the patient. The toe is straightened and held reduced. This may require flexor to extensor tendon transfer, IP joint excisions or IP joint fusion, extensor tendon release, and for dislocated toes, MP joint exploration. The toe is stabilized with an intramedullary pin for approximately 3 weeks while tissue healing takes place. The toe is straight, and the calluses resolve. The plantar pad is reduced under the metatarsal head, reducing the metatarsalgia.

Soft Corns

Soft corns occur between toes. *Soft* refers to a tendency to macerate in the moist interdigital environment. Soft corns are a result of poor foot hygiene and should be managed conservatively.

Hard Corns

Hard corns occur over the IP joints of hammertoes and claw toes, or on the dorsum of the fifth toe. The underlying deformity is treated.

Overlapping Toes

Overlapping toes cause intractable corns, either from floor contact or impingement against the shoe. Whereas conservative measures described for hammertoes and claw toes should be considered, this condition often requires surgical correction of the deformity. The approach is the same as that used for hammertoes and claw toes.

Ingrown Toenails

An ingrown toenail can be exquisitely painful, particularly when aggravated by pressure from the shoe (Fig. 80-35). Causes include improper nail trimming (cutting the nails back at the nail margins), or abnormal nail growth. Preventive measures consist of proper nail trimming and wearing shoes with an adequate toe box.

Figure 80-35. Ingrown toenail is often caused by improper nail cutting techniques or by wearing ill-fitting footwear that creates pressure against the lateral nail fold producing exquisite pain and tenderness.

Later stages may require cotton packing underneath the nail. This pushes the nail fold away and prevents the tip of the nail from irritating the nail fold. Once chronic, surgery may be required. A simple medial or lateral border nail plate resection decompresses the area of inflammation and allows the tissues to heal. Often a new nail grows in without problems in the absence of nail bed deformity. In some cases, a complete nail bed excision and matrixectomy are required (48).

CHAPTER 81

Nonspecific Treatment Effects

Judith A. Turner

An understanding of the role of nonspecific effects in patient-provider interactions can help clinicians improve the outcomes and satisfaction of their patients. This chapter summarizes the findings from studies of placebo or nonspecific treatment effects that are relevant for clinicians who treat patients with pain problems. Knowledge of this literature may also help clinicians to evaluate critically the literature on various pain treatments to make informed decisions in treatment planning.

A number of factors may influence patient outcomes after any treatment for pain (Table 81-1). These factors fall into three general categories. The first category includes *specific effects of the treatment*, attributable solely to the characteristic content or process of the therapy. The second category includes *natural history and regression to the mean*. Most acute and some chronic pain problems improve or even resolve completely, regardless of treatment. Headache and low back pain are two examples of conditions that for many individuals recur episodically with periods of no or mild pain between episodes. Patients with chronic conditions typically have fluctuating symptoms and seek medical care (and enroll in research studies) when symptoms are at their worst. Thus, the next change is likely to be an improvement. When a group of patients with extreme scores on symptom measures is selected for study or treatment, over time the average scores in the group will decrease due to fluctuations toward more typical values. This tendency is known as *regression to the mean* (1). Apparent improvement may also reflect measurement error or random variation in patient symptoms over time (1). Clinicians and patients alike may mistakenly attribute a decrease in a patient's symptoms to a treatment when, in fact, the change is simply a fluctuation in a cycle of waxing and waning symptoms. The third category includes *nonspecific effects of treatment*—that is, change due to factors not specific to the particular drug or therapy. These include physician attention, interest, and concern in a healing setting; patient and physician expectations of treatment effects; the reputation, expense, and impressiveness of the treatment; and characteristics of the setting that influence patients to report improvement. The term *placebo effect* is often used synonymously with *nonspecific effects*.

1. Specific treatment effects
2. Natural history, regression to the mean
3. Nonspecific treatment effects (placebo effects)

TABLE 81-1. Factors that influence patient outcomes

The word *placebo* was first used in the English language in the fourteenth century as the name given to vespers sung for the dead (2). The first line of these vespers was the Latin version of a psalm (translated, “I shall walk before the Lord in the land of the living”). Apparently because of a translation error, “I shall walk” became *placebo* (“I shall please”) (2). Because these vespers were sung for a substantial fee, the term “placebo” had a negative connotation. The word appeared in Hooper's *Medical Dictionary* in 1811, defined as “any medicine adopted to please rather than to benefit the patient” (3). In the past 30 years, many definitions of placebo have been advanced. A useful definition was proposed by Brody (4): an intervention designed to simulate medical therapy but that is not believed to be a specific therapy for the target condition, or an inefficacious treatment believed efficacious at the time of use. Brody (4) further defines *placebo effect* as a change in a patient's illness attributable to the symbolic import of a treatment rather than a specific pharmacologic or physiologic property. Thus, a placebo effect can occur with any treatment, not just with a placebo. A *placebo response*, in contrast, refers to any change in a patient's behavior or condition after the administration of a placebo (5). These distinctions are not always made in the literature, however.

The following sections summarize what is currently known concerning placebo response rates, the pharmacologic and other characteristics of placebo responses (including magnitude and duration), nocebo effects, factors that influence nonspecific effects, and explanations that have been proposed for placebo effects. Finally, the implications of this literature for researchers and clinicians are discussed.

PLACEBO RESPONSE RATES

A common misconception is that approximately one-third of patients will show a placebo response in any clinical trial. This figure is based on Beecher's (6) classic article, a review of 15 studies (seven of which were Beecher's) of patients with a variety of conditions (postoperative pain, cough, angina pectoris, headache, drug-induced mood changes, seasickness, anxiety and tension, and the common cold). Beecher (6) reported that symptoms were “satisfactorily relieved” by a placebo in 35% of patients on average across these studies. However, it is important to note that the placebo response rate ranged from 15% to 58% across the studies. Since Beecher's review, placebo response rates have been observed to vary widely, often greatly exceeding 35%. Since Beecher's review, placebo responses have been observed in other settings and for other conditions [e.g., acute postoperative pain (7), peptic ulcers (8), angina pectoris (9,10), temporomandibular disorders (11)]. Roberts et al. (12) reviewed uncontrolled studies of medical and surgical treatments that were originally believed efficacious but later abandoned because they were found to be no better than placebo. On average, 70% of 7,000 patients included in the studies reviewed had excellent or good outcomes (12). Some studies reported success rates of 100%. Another review of 31 randomized trials found that, on average, 48% of patients showed healing of peptic ulcers, based on endoscopy, after treatment with only a placebo (8). In some of these studies, the rate was as high as 90%.

Even patients with a long history of chronic pain show clinically and statistically significant improvement with placebo. For example, Deyo et al. (13,14) found that, despite the chronicity of their pain (average duration of 4 years), back pain patients' scores on measures of pain severity, pain frequency, and functional status improved on average 20% to 40% after sham transcutaneous electrical nerve stimulation plus hot packs.

NONSPECIFIC EFFECTS OF SURGERY

Beecher (15) emphasized that surgery could evoke a placebo effect and urged caution in interpreting the results of new operations. Two classic studies (9,10) conducted in the 1950s demonstrated substantial and sustained improvement in angina pectoris after sham surgery (skin incision alone). These double-blind randomized trials compared a procedure believed at the time to help angina pectoris (internal mammary artery ligation) with skin incision alone (with vessel exposure but no ligation). In one study, 6 months after the operation, 63% of the ligated patients and 56% of the patients who had skin incision only were substantially improved (9). In the other study, all patients who had skin incision only reported greater than 50% improvement during the subsequent year (10). Benefits were not limited to decreased pain; they also included reduction in nitroglycerin use and increased exercise tolerance.

Improvement in pain after spine surgery may be due in part to some combination of natural history and nonspecific effects. A review of long-term outcomes for 2,504 patients undergoing diskectomies for lumbar disk disease found that, among patients who had no disk herniation (negative surgical exploration), 37% had complete relief of sciatica and 43% had complete relief of back pain (16). Given the lack of known therapeutic effects of surgical exploration of the spine, these outcomes appear to be due to nonspecific effects and/or natural history. The success rates that have been reported for operations for painful lumbar spine disorders are similar to success rates reported for discredited therapies for other conditions. Across 74 studies of surgery for lumbar spinal stenosis, an average of 64% of patients had good or excellent outcomes at long-term follow-ups (17). Similarly, across 47 studies of lumbar spinal fusion, 68% of patients had good or excellent results at long-term follow-ups (18). The lack of randomized controlled trials makes it impossible to draw conclusions concerning the extent to which the outcomes of these operations are due to specific surgery effects, nonspecific effects, or natural history. The weak association between radiologic findings and symptoms (19,20,21,22,23 and 24), and between technical success of surgery (e.g., solid fusion) and symptom improvement (25,26), also suggests the possibility that improvement after back surgery may to some extent be attributable to factors such as natural history and patients' and surgeons' expectations of improvement.

In sum, rates of good patient outcomes after medical and surgical treatments that have no specific therapeutic effects for painful conditions vary considerably across studies but, on average, are strikingly high. This makes obvious the need for studies that compare the short- and long-term clinical outcomes of treatments and procedures believed to relieve pain with those of placebo or control therapies. Although case series reports may provide some useful information, such as rates of specific complications, they cannot provide information concerning whether the outcomes are due to natural history, specific therapy effects, or nonspecific effects.

CHARACTERISTICS OF PLACEBO RESPONSES

Placebos have been demonstrated to have in common with active medications time-effect curves and peak effects, cumulative effects (greater effects with repeated administrations), and carryover effects after cessation of treatment (27). Furthermore, when a placebo is administered to people with pain after they have received an analgesic drug, the pain-relieving effect of the placebo is proportional to that of the drug that preceded it (28). Dose-response effects have also been demonstrated—for example, one study found that two placebo capsules produced more pronounced effects than one (29).

Nonspecific effects of treatments are not always positive; adverse effects have been demonstrated to occur after the administration of inactive pills or procedures. It is well known that placebos are associated with side effects. The most common are drowsiness, headaches, nervousness, insomnia, nausea, and constipation (30). A review of 109 double-blind drug trials found that, overall, 19% of healthy volunteers reported adverse events during placebo administration (31). Complaints were most frequent after repeated dosing and in elderly subjects. The type of side effect varied according to the therapeutic drug it was being compared with in the drug trial. Sham treatments can also worsen preexisting symptoms. For example, in a double-blind study of a magnetic device purported to relieve pain, 13 of 58 patients with pain discontinued treatment after one or two treatments because their pain was worse (32). Six months later, three of these patients believed the treatment made their pain permanently worse.

The duration of response to placebos has not been well studied. Fedele et al. (33) found a gradual decrease in the effectiveness of placebo treatment of dysmenorrhea over three consecutive menstrual cycles. However, patients with angina pectoris in the placebo arm of a double-blind randomized trial had a 77% reduction in anginal attacks after 6 months on placebo (34), and some patients with rheumatoid arthritis who were given placebos reported moderate to marked improvement for as long as 20 months (35). Patients with painful diabetic neuropathy reported a decrease in pain intensity over the first 3 weeks they received a placebo but then showed a partial return toward baseline levels during weeks 4 to 6 (36). In one of the studies of sham surgery for angina pectoris, clinically significant improvement in angina symptoms was maintained for up to 1 year (10). Of course, the extent to which these responses reflected natural history/regression to the mean versus placebo effects cannot be determined. It is likely that the magnitude and duration of placebo responses will vary with varying characteristics of patients, conditions, treatments, providers, measures, and settings. These are discussed in later sections of this chapter.

NOCEBO EFFECTS

The nocebo effect has been defined as the causation of sickness (or death) by expectations of sickness (or death) and by associated emotional states (37). For example, pain can be produced in normal subjects by the power of suggestion. Headaches were reported by 70% of college students told that a (nonexistent) electric current was passing through their heads (38). This study was later replicated by a different group of researchers, who also found that the subjects' pain ratings increased when they believed the electrical current had been increased (39). Hahn (37) distinguishes nocebo effects from placebo side effects, which occur when expectations of healing produce symptoms. Hahn (37) also points out that the act of giving a patient a diagnosis may have a placebo or a nocebo effect, and that failure to give the patient a diagnosis may have a nocebo effect.

One general practitioner randomly assigned his patients with symptoms but no abnormal signs, in whom no definite diagnosis could be made, to a positive or a negative encounter with him (40). In the positive encounter, patients were given a diagnosis and told they would be better in a few days. In the negative encounter, the doctor told patients he was not certain what was the matter with them. Two weeks later, 64% of the positive encounter group, but only 39% of the negative encounter group, reported that they had gotten better (a statistically significant difference). The author speculated that these minor illnesses would be expected to resolve spontaneously by 2 weeks in the majority of patients and that the 61% nonimprovement rate in the negative encounter group reflected adverse effects of the encounter. Another study also suggests that diagnostic testing may have a placebo effect and/or that not testing may have a nocebo effect. Patients thought to have noncardiac chest pain of unclear etiology were assigned randomly to diagnostic testing or no testing (41). Patients not tested were more than twice as likely to report short-term disability. Other examples of nocebo effects are presented in the next section of this chapter.

FACTORS THAT INFLUENCE NONSPECIFIC EFFECTS

Patient Factors

No personality, demographic, or other patient characteristics have been shown consistently to predict placebo responses (42). Specifically, placebo effects have not been found to relate consistently to age, gender, ethnicity, educational level, intelligence, locus of control, extraversion, introversion, neuroticism, or suggestibility (42). In fact, individuals who have a placebo response in one situation may not show a placebo response in a different situation (43,44). For example, one study found that positive responses to a placebo given for labor pain were not correlated significantly with the responses to a placebo given to the same women in the postpartum period (44).

The patient factors that have been shown to influence nonspecific effects are listed in Table 81-2. Patients' positive attitudes toward the provider and toward the treatment have been shown to predict improvement in studies of psychiatric outpatients treated with placebo, psychotropic drugs, or psychotherapy (42). There is also some evidence that highly anxious subjects may show the greatest placebo responses (42).

1. Positive attitudes toward provider, treatment
2. Anxiety
3. Expectations of effects
4. Treatment adherence

TABLE 81-2. Patient factors that influence nonspecific effects

Patient expectations of treatment effects have been shown to influence their responses, at least in some situations. For example, when subjects in one study were given a pill containing only a magnet to measure stomach contractions, the contractions increased, decreased, or did not change according to the effects they were told the pill would cause (45). In a study of asthmatic patients, isotonic saline produced increases or decreases in airway resistance according to what patients were told to expect (46). Furthermore, when patients were given a true bronchodilator, its effects were about twice as great if patients were told it would produce this effect than if they were told it would produce the opposite effect. A later study (47) also demonstrated both nocebo and placebo responses in asthmatic patients, according to their expectations. When patients believed they were inhaling an irritant chemical, which was in fact water, they showed a bronchoconstrictive response. This nocebo effect was shown in the same study to be *abolished* by a placebo. When subjects inhaled an inactive substance they thought was a powerful new drug *before* inhaling the water solution they thought was an irritant, they had no bronchoconstriction in response to the irritant. In yet another study (48), after subjects drank a beverage they believed was caffeinated coffee but in fact was decaffeinated, motor skill task performance was either enhanced or impaired according to what effects they were told the beverage would have.

Expectations of adverse events have been shown repeatedly to be associated with the subsequent occurrence of such adverse events. An extreme example of this is voodoo death, death that can occur in some cultures by unknown mechanisms, believed to be due to the belief of the victim that death is imminent (49). In Western culture today, the belief that one is susceptible to heart attacks has been shown to be a risk factor itself for coronary death. Analysis of the Framingham study data (50) revealed that among middle- aged female homemakers free of coronary disease, those who believed they were more likely than others to develop heart disease were 3.7 times more likely to have a myocardial infarction (MI) in the next 20 years, even after controlling for commonly recognized cardiac risk factors.

Symptoms may also occur when an individual becomes aware of symptoms in others and believes that he or she may also be vulnerable to the condition. A well-recognized form of this phenomenon is *mass hysteria*. Kerckhoff and Back (51) carefully examined the spread of such a sociogenic illness, the 1962 “June Bug” outbreak in a Montana mill. Sixty-two of 965 workers were affected, fainting or complaining of pain, nausea, or disorientation. All of those affected worked in dressmaking departments. Persons affected were 62% more likely to have worked overtime at least two or three times a week, 2.2 times more likely to be sole breadwinners, 5.6 times more likely to be divorced, and 30% more likely to have a child younger than age 6. These facts strongly implicate the role of physical and emotional stress in such conditions.

Other studies have also demonstrated the ability of expectations to produce symptoms. After being told that a medicine administered through a skin patch would induce seizures within 30 seconds, 77% of psychogenic seizure patients showed seizure behavior when the patch, which actually contained only alcohol, was applied (52). Symptoms included nonresponsiveness, generalized violent thrashing, and uncoordinated movements. Nineteen percent of the patients reported auras and 44% showed postictal confusion or sleepiness, or both. A double-blind study designed to evaluate a controversial method of food allergy testing compared the effect of injecting the food substances with the effect of injecting a saline solution (53). Twenty-seven percent of patients given the food substance injection and 24% of those given saline experienced symptoms of nose itching, watering or burning eyes, plugged ears, tight or scratchy throat, nausea, dizziness, sleepiness, and depression.

Another factor demonstrated to be associated with nonspecific treatment effects is treatment adherence. Patients who adhere closely to a prescribed regimen may have better outcomes than those who do not, even when taking a placebo. This observation was first made in a double-blind randomized trial that compared the efficacy of a lipid-lowering drug with placebo on mortality in men who had survived an acute MI (54). Although the lipid-lowering drug was no better than placebo in reducing 5-year mortality, men who adhered closely to the prescribed regimen (i.e., who took 80% or more of the capsules) had a marked reduction in mortality compared with poor adherers (i.e., who took less than 80% of the capsules). Surprisingly, this reduction in mortality was similar in the placebo and lipid-lowering drug groups. Even after controlling for 40 known or suspected coronary risk factors, the placebo noncompliers had a 5-year mortality rate 57% higher than that of the placebo compliers.

The effects of adherence on mortality after MI were further explored in data from the Beta Blocker Heart Attack trial (55). This multicenter randomized double-blind trial compared propranolol with placebo in men surviving an acute MI. Men with poor adherence—that is, who took 75% or less of the placebo or active medication—were 2.6 times more likely to have died within a year after their MI. As in the Coronary Drug Project, poor adherers had an increased risk of death whether they were on placebo or active medication. The association between poor adherence and mortality was not accounted for by measures of the severity of MI, sociodemographic features, smoking, or psychological characteristics.

Yet another study (56) found that the association between medication adherence and mortality after MI is also present in women. In this study, 602 women were assigned randomly to propranolol or placebo 5 to 21 days after an MI. Fourteen percent of the poor adherers but only 6% of the good adherers to placebo or propranolol died within the next 2 years. The effect of adherence on mortality remained undiminished after adjustment for treatment group (placebo versus propranolol), age, severity of MI, and other clinical and sociodemographic variables. The mortality rate was approximately twice as great for poor adherers as for good adherers in the propranolol group and approximately three times as great for poor adherers in the placebo group.

Adherence has also been shown to be associated with clinical outcomes in conditions other than heart disease. For example, a randomized clinical trial (57) of oral antibiotic prophylaxis in patients with cancer receiving chemotherapy showed that fever or infection occurred in 22% of patients who received oral antibiotics and 27% of patients on placebo, but those with excellent adherence had a lower incidence of fever and infections, regardless of whether they received antibiotics or placebo.

What explains this association between adherence and outcome? Gallagher et al. (56) suggest several possibilities. First, adherence to a medical regimen, whether active medication or placebo, may be associated with other favorable health practices or social circumstances related to outcomes but not measured in these studies. Second, baseline health status that is better in some ways not measured in these studies may facilitate both better outcomes and better adherence. Finally, adherence may be one manifestation of prognostically favorable patient characteristics, reflecting an individual's ability to make lifestyle changes that limit disease progression.

Provider Factors

Table 81-3 lists provider factors that have been found to influence nonspecific effects. The provider's warmth, friendliness, interest, sympathy, empathy, prestige, and positive attitude toward the patient and toward the treatment are associated with positive effects of placebos as well as of active treatments (42). The importance of provider expectations was illustrated in a study of a new antihypertensive drug believed at the time to be more effective than existing drugs (58). In the middle of this double-blind study, partners of the enthusiastic physician administering the drug broke the code. Without telling him which pills were the placebo and which were the drug, they told him that the drug, although effective, appeared similar to existing drugs. Although less enthusiastic, they decided to complete the study. The difference between the drug and placebo was maintained, but there was an immediate, marked increase in the blood pressures of patients in both groups.

1. Warmth, friendliness, interest, sympathy, empathy, positive attitude toward patient
2. Prestige
3. Expectations of treatment effectiveness

TABLE 81-3. Provider factors that influence nonspecific effects

In a double-blind study of dental extractions (59), placebo responses were compared for patients in two groups. In the first group, the clinicians knew they would administer either a narcotic analgesic, a placebo, or a narcotic antagonist. In the other group, the clinicians knew they would administer only a placebo or a narcotic antagonist. Placebo patients in the first group reported significantly less pain associated with the dental extraction than did placebo patients in the second group. Because the two placebo groups differed only in the clinicians' knowledge of the range of possible treatments, this knowledge appears to have resulted in subtle behaviors that influenced patient responses.

A study of patients undergoing a procedure for the treatment of chronic pain found that the treating physicians' expectations of pain relief from the procedure, but not the patients', predicted actual pain relief from the procedure (60). These findings indicate that patient expectations of pain relief do not always predict actual pain relief. It is likely that the physicians could predict patient pain relief in this study because of their prior experience with the procedure, and it is also possible the physicians somehow subtly communicated their expectations to patients during the procedure and this influenced patient response.

HOW ARE PLACEBO EFFECTS EXPLAINED?

Several explanations have been proposed for placebo effects, as listed in Table 81-4.

1. Decreased anxiety
2. Learning
3. Expectations
4. Endorphins

TABLE 81-4. Explanations for placebo effects

Decreased Anxiety

Stress and anxiety adversely affect several physiologic processes and increase symptom reporting. There is some evidence that placebos may be most effective for highly anxious subjects, and placebo effects are often attributed to reduction in anxiety and suffering (61). Although placebos have been shown to decrease anticipatory anxiety (62), it is not clear whether anxiety reduction is a cause of the placebo effect or a component of it (63).

Learning

A treatment may have a positive effect because of its association with effective treatments the patient has had before (i.e., a learned or conditioned response). Neutral stimuli such as syringes, health care professionals, medical equipment, and hospitals can function as conditioned or discriminative stimuli for the alleviation of symptoms if they have been associated with powerful unconditioned stimuli (e.g., analgesic medication) that relieve symptoms (64). In support of this learning model are the findings that when placebos are given after active analgesic medications, the analgesic effect of the placebo is proportional to that of the active medication (28). Animal studies have demonstrated that after one or more injections of a drug, the physiologic effects of the drug can be elicited by an injection of saline (65,66). Experiments have demonstrated that placebo responses can be conditioned (67), and one study found the direct experience of conditioning to be more powerful than expectancy formed through verbal persuasion (68).

Crossover study designs present a good opportunity to study conditioned responses to placebos because one group of patients receives the placebo without prior drug exposure and another group takes placebo after drug exposure. A study of patients with mild to moderate essential hypertension tested the conditioning model prediction that the placebo response would be greater after drug exposure than before (69). After a 1-week baseline of no treatment, patients were randomly assigned to one of three groups. The first group of patients received placebo for 1 week, followed by 50 mg of atenolol daily for 1 week, followed by no treatment for 1 week. The second group of patients received atenolol for 1 week, followed by placebo for 1 week, followed by no treatment for 1 week. The third group received atenolol for 1 week, followed by nothing for 2 weeks. This last group was included to show any residual drug effects that might persist after the atenolol was stopped.

Averaging the mean arterial pressures of each patient during the last 4 days of each week and subtracting those values from the average mean arterial pressures over the last 4 days of the no-treatment baseline period gave a measure of the antihypertensive response of each patient for each week. There were no differences between the blood pressure changes of patients taking placebo *before* atenolol and those of patients taking nothing. In contrast, *after* atenolol treatment, patients taking placebo maintained an antihypertensive response, whereas those taking nothing after atenolol showed a return toward baseline. This demonstrates that the placebo response was more than a residual drug effect. This study is also one of a number that have demonstrated that placebo responses are not limited to subjective variables such as pain, but also include physiologic parameters.

Expectations

It has been argued that the effect of a conditioning procedure on placebo responses is mediated by expectancy (70). Expectations of pain relief with a treatment may result from prior classic conditioning or from other types of learning and have been hypothesized to mediate placebo analgesia (71). An implication of this is that drug expectancies may potentiate drug effects (70,72). A patient's expectation that a treatment will relieve his or her pain may reduce his or her anxiety and concerns and cause him or her to notice small improvements, to disregard negative events, and to interpret ambiguous stimuli favorably (73). Changes in patients' appraisals and expectancies may also result in behavior changes that lead to improved outcomes. For example, a patient with back pain may resume functional activities that he or she had avoided due to fear of pain or harm.

Endorphin Effects

Levine et al. (74) reported that high doses of naloxone, an opiate antagonist, abolished the placebo reduction of pain after wisdom tooth extraction, suggesting that

placebo responses might be mediated by endogenous opiate release in the central nervous system. However, subsequent studies have yielded contradictory results (75,76). At present, the role of endogenous opiate processes in placebo responses remains unclear.

Summary

Currently, there exists considerable controversy about placebo effects. At one extreme, it has been argued that “the extent and frequency of placebo effects as published in most of the literature are gross exaggerations” (77). Kienle and Kiene (77) assert that apparent placebo effects can be explained by a variety of factors, including the natural history of the disease, regression to the mean, concomitant treatments, methodologic flaws, and subject and observer biases. Clearly, studies designed to test these explanations are needed to understand the nature and characteristics of nonspecific effects in different pain therapies for different conditions.

RESEARCH IMPLICATIONS

Drugs, medical treatments, surgery, biofeedback, psychotherapy, and even diagnostic tests can have nonspecific effects that influence patient outcomes (41,64). Only randomized controlled trials can establish that a treatment results in greater improvement than would occur due to the natural history of the condition and nonspecific effects. Random assignment of subjects to treatment and control conditions is necessary to reduce systematic bias in group membership, which may lead to differential improvement due to differences in subject characteristics rather than in the treatment. However, even in randomized controlled trials, clinicians and subjects know there is a control and an experimental treatment, and outcomes may be influenced by their expectancies of outcomes with each treatment and beliefs about which treatment the subject received. If either or both can guess (e.g., by side effects) which treatment the subject has received or if one treatment is more credible, this may bias the study results. To the extent that the subject or clinician believes a treatment may be ineffective, the power of nonspecific effects will be reduced or underestimated.

The ideal randomized controlled trial is double-blind. However, even under “double-blind” conditions, subjects, clinicians, and evaluators often can distinguish at better-than-chance rates between active medication and placebo, and clinicians often can distinguish between different active medications (78,79 and 80). In addition, research has demonstrated that so-called blind evaluators of subject outcomes are biased in their ratings by their beliefs about what group the subject was in (81) and that subjects' guesses about what drug they are on are associated with their drug reactions and outcomes (82).

Therefore, the control treatment should be as similar as possible to, and as credible as, the active treatment. Visit frequency, contact, support, and side effects should be equivalent in the control and active therapy conditions. Although it can be difficult to create credible placebo controls, creative sham treatments have been devised (e.g., sham transcutaneous electrical nerve stimulation units, misplaced needling as a control for acupuncture, subtherapeutic weight as a control for traction, massage as a control for spinal manipulation). Trials in which control treatments mimic the active therapy typically have found less advantage of the active treatment over the control than have trials with obviously different types of therapy or with inert placebo controls (83,84).

Both a completely untreated group and a placebo-treated group are necessary to distinguish between nonspecific effects and the effects of the passage of time in a trial, although these may not be feasible in many situations. In studies of individuals with chronic pain, long baselines with multiple measures of pain before treatment can reveal changes in the absence of treatment and thereby help to estimate the magnitude of regression to the mean as a source of within-patient change (85,86).

Ethical and practical factors make it difficult to conduct surgery trials with sham controls. Randomized trials that compare alternative surgical procedures or surgery versus credible alternative nonsurgical therapies may be feasible and may yield useful information in many situations. For example, two prospective, randomized studies compared spine surgery with and without instrumentation in terms of clinical and technical outcomes and complications (87,88).

However, a prospective, randomized, placebo-controlled trial of knee surgery (89) demonstrates the feasibility and value of a placebo surgery trial. In this small pilot study, 10 patients with chronic osteoarthritic knee pain who gave full informed consent were randomized to three operations—arthroscopic lavage, a standard arthroscopic debridement, and a placebo arthroscopy. Each patient was taken to the operating room, and the randomization envelope was opened to reveal which procedure the patient was to receive. Patients undergoing placebo arthroscopy were prepared, draped, examined, and injected with local anesthetic in the same manner as the other two groups. Three stab wounds were made in the skin with a scalpel, but no instruments were placed into the knee. The knee was manipulated, instruments were requested and passed, saline was splashed, and a standard arthroscopic debridement was simulated as closely as possible in case the patient was not totally unaware during the procedure. One-half to 1 hour was spent performing the placebo surgery—the same amount of time as the other two operations.

At each postoperative visit, the patients and examining physician were questioned as to which procedure they believed the patient had received. The patients and physician were never able to guess the procedure correctly more often than would be explained by chance. Follow-up assessments were conducted by an orthopedic surgeon blinded to the procedure the patient received. At 6 weeks and 6 months after surgery, 80% of patients who received the placebo surgery reported believing the operation was worthwhile. At 6 months after surgery, all three treatment groups reported improved pain, with the average pain relief 3.8 on a 0 to 10 scale. Four of the five placebo surgery patients indicated they were satisfied with the surgery and said they would recommend it to family and friends, and the fifth patient was neutral.

In addition to providing information about the efficacy and effectiveness of a specific therapy, randomized controlled trials can also increase knowledge about nonspecific effects by including no-treatment and placebo/sham treatment conditions. The understanding of placebo effects will be advanced by studies designed to examine the factors other than specific treatment actions that influence patient outcomes. These include natural history, regression to the mean, patient expectations and beliefs, provider expectations and beliefs, characteristics of the treatment situation that influence patients and providers to behave in certain ways (e.g., to report improvement), conditioning and other types of learning, and psychophysiologic states of the patient such as anxiety and relaxation.

Finally, despite the important information that double-blind trials can provide, it should be noted that the effects of drugs in double-blind trials may not necessarily be the same as in actual clinical settings. In double-blind studies, subjects are aware that they may receive a placebo. In contrast, patients treated by drugs or other therapies in a clinical setting are not told the therapy may be a placebo and thus have a different cognitive set than subjects in a research study. The psychological (nonspecific) and pharmacologic or other specific, active effects of a drug or other therapy may be additive or they may be interactive (72). An active treatment effect in a clinical setting may be potentiated by the patient's expectations of improvement. A double-blind placebo-controlled study may find less effect for an active treatment than would be seen in an unblinded clinical setting.

CLINICAL IMPLICATIONS

Nonspecific effects accompany any treatment and, in fact, can be found with any provider-patient interaction. These effects can be quite strong and can lead patients and providers to mistakenly assume improvement is due to the specific effects of the treatment. Nonspecific effects may be strongest when the patient is anxious, the clinician is perceived as having great expertise, the patient and clinician believe the treatment is powerful, and the treatment is impressive and expensive. The demonstration of the role of learning in placebo responses suggests that past treatment responses may influence a patient's responses to subsequent treatments in a positive or negative manner, depending on the prior history.

The literature on placebo effects suggests several ways clinicians may be able to harness the power of nonspecific effects to improve the outcomes and satisfaction of their patients, as listed in Table 81-5. These include showing genuine warmth, interest, and concern and conveying “realistic optimism” about the patient's prognosis and treatments prescribed. In addition, visible signs of the clinician's expertise (e.g., diplomas, board certifications) and an air of confidence can help increase a patient's confidence in the clinician. Finally, eliciting and addressing the patient's concerns and goals for the visit, performing a physical examination, and providing a diagnosis and prognosis may have positive effects by increasing the patient's confidence that his or her symptoms have been diagnosed accurately and decreasing the patient's worries and fears.

1. Convey genuine warmth, interest, and concern.
2. Convey "realistic optimism" about treatments you prescribe.
3. Display diplomas, board certifications, and so forth where patients will see them.
4. Convey an air of confidence (but not arrogance).
5. Elicit and address patient worries, concerns, and goals.
6. Let the patient know you have reviewed previous medical records/tests and conduct a thorough history and physical examination, so the patient believes you have sufficient knowledge to make an accurate diagnosis.
7. Provide a diagnosis and realistic prognosis to the extent possible.

TABLE 81-5. Suggestions for harnessing the power of nonspecific effects

Given the current limits in most clinical settings on the amount of time available for patient visits, it can be quite challenging to accomplish all of the suggestions in the previous paragraph in addition to the other necessary components of the visit. However, visits can be structured so as to allow practitioners to harness the power of nonspecific effects while obtaining the information necessary to make clinical decisions. Asking the patient about his or her primary goal for the visit and primary worries and concerns at the beginning of the visit, and addressing these in the visit, can be very helpful and may actually save time (e.g., because the patient doesn't then bring up a major concern at the very end of the visit or because the patient feels confident in his or her ability to safely self-manage the problem and thus is less likely to make unnecessary return visits). Health care providers may also find that telling the patient what they are doing and why while conducting a physical examination results in increased patient understanding of their condition as well as reassurance that their symptoms are being evaluated thoroughly.

It can be useful to inquire as to what the patient has found helpful in managing his or her present symptoms recently or in the past and to encourage the patient to continue to use these strategies to manage pain. The practitioner may also suggest additional pain management strategies other patients have found useful and convey to the patient that such self-management strategies can be very effective. Handouts about specific syndromes (e.g., low back pain, headache), including information about their prevalence, about what percentage of patients improve over various periods of time (e.g., within 1 week, 1 month, 3 months, 1 year), and about effective self-management strategies, can be given to patients to take home and read. Such handouts may also include information to help guide patients in making decisions about whether and when they should return to their health care provider (e.g., “red flags” indicating a potentially serious problem that should be evaluated). The visit may be ended with one or more specific treatment recommendations (if appropriate), information concerning the likely time course of the patient's symptoms, and a plan for when the patient should return or call.

It is not valid to use a placebo to assess whether a patient's pain or disease is “real,” and it is a mistake to dismiss the complaints of patients who show a placebo response. To purposefully deceive a patient by prescribing a placebo may be argued to be unethical and may entail several risks, including patients' reacting negatively if they discover the truth; side effects; patients' becoming more worried, concerned, and pessimistic if they fail to improve (73); and increased risk of not improving with subsequent treatments.

CONCLUSION

Patients' pain problems and psychological and physical dysfunction are influenced importantly not only by physiologic processes but also by environmental and cultural factors, learning, and patient beliefs and expectations related to their pain. Changes in pain over time reflect complex interactions between physiologic processes and cognitive-behavioral and environmental factors. Nonspecific effects, natural history, and regression to the mean can influence patient outcomes in all pain treatment situations and must be distinguished from specific effects when examining the efficacy of medical and surgical treatments. It cannot be assumed that a response rate greater than one-third implies that a treatment is better than placebo. The extent to which patient outcomes after a medical or surgical treatment reflect nonspecific effects, regression to the mean, natural history, or specific treatment effects is unclear in the absence of randomized controlled trials with outcomes assessed by persons who are unaware of what treatment the patient received. Finally, aspects of the clinician-patient interaction can have powerful positive or negative effects on patient outcomes.

CHAPTER 82

*Clinical Trials**

Richard A. Deyo

Controversies abound in the clinical management of pain, and there are enormous geographic variations in care. Lumbar spine surgery rates vary fivefold among developed countries, with rates in the United States being highest and rates in the United Kingdom being among the lowest (1). Within the United States, rates of surgery for spinal stenosis vary more than fourfold among states, from less than 30 per 100,000 older adults in Rhode Island to 132 per 100,000 in Utah (2). In smaller geographic areas, variations become more striking. Within Washington State, county back surgery rates vary more than sevenfold, even after excluding the smallest counties (3).

Another problem in pain management is a series of fads in treatment that have been eventually discredited but that enjoyed widespread use, with substantial costs and side effects, before they were found ineffective. Examples include sacroiliac joint fusion for the treatment of low back pain, coccygectomy for coccydynia, bed rest and traction for back pain, and many others (4). Internal mammary artery ligation was once practiced for treating angina pectoris, and gastric freezing for duodenal ulcers (5). Such ineffective treatments drain resources from more useful interventions, have side effects, and eventually damage professional credibility.

Finally, we are faced with the affront of rising disability rates for chronic painful syndromes, despite steady improvements in the ergonomics of work tasks and technological advances in medicine. Rates of work disability due to back pain rose steadily during the 1980s (6) and claims data demonstrate that carpal tunnel syndrome and low back pain predict longer duration and cost of claims than other medical conditions (7). Thus, despite impressive gains in our understanding of the molecular and cellular origins of pain, there is an important gap in translating this knowledge into effective clinical management. One reason may be the limited quality of clinical trials of innovative treatments, with widespread use of inadequate research designs that lead to conflicting and confusing results. Biostatistical and epidemiologic methods make it possible to substantially improve this situation, but many of these principles are not widely appreciated.

CASE SERIES PARADIGM

Historically, much of pain treatment research consisted simply of case series in which treatment was applied to a group of patients, and the proportion who improved was reported. This remains a popular research design, but is vulnerable to many pitfalls.

First, many case series are retrospectively reported. After 30 or 100 patients have been treated, the clinician looks back at his or her experience and tries to summarize the characteristics, treatments, and outcomes of the patients studied. Unfortunately, in this retrospective approach, there is often incomplete baseline information on patient characteristics. For example, factors such as age, sex, previous surgery, disability compensation, neurological deficits, and pain duration are thought to have a major influence on the outcomes of back surgery. However, in a systematic review of outcome studies on surgery for spinal stenosis, 74 relevant articles were found, but less than 10% mentioned all these patient characteristics (8).

A second problem with the retrospective case series is that there is no blinding of patient, therapist, or outcome assessor to the nature of the treatment provided. This allows important unconscious biases to creep into the assessments. Most of us would not trust outcomes rated by a surgeon evaluating his or her own patients, and yet this is the norm in much of the literature.

By definition, case series do not include control groups for comparison. The assumption seems to be that patients with painful conditions, and especially chronic pain, will not improve unless effective treatment is given. However, there are many reasons why patients improve in the face of ineffective therapy, some of which are listed in Table 82-1. First, the natural history of many painful conditions is to improve spontaneously. This may be true even for patients with long-standing pain, who sometimes improve for unclear reasons. For acute conditions such as acute low back pain, rapid improvement is the norm. Second are placebo effects, which are not well understood but are consistently underestimated. Several factors may mediate placebo effects, including patient expectations, learning and conditioning from previous treatments, reduction of anxiety, and endorphin effects (5).

Natural history of a condition to improve
Placebo effects
Regression to the mean
Nonspecific effects: concern, conviction, enthusiasm, attention

TABLE 82-1. Why patients may improve with ineffective therapy

Another poorly appreciated factor is “regression to the mean.” This term was coined by statisticians who observed that in a group of patients who are assembled because of the extreme nature of some clinical condition, there is a tendency for the condition to return to some average level that is less severe over time. This is a result of random fluctuations more than a steady trajectory of improvement. For example, Figure 82-1 shows what we often assume to be the course of chronic pain problems, with a steady level of severity that falls after successful intervention. However, the second panel is more likely to represent the true natural history, with good days and bad days, and fluctuations being the norm (8). Patients seek us out when their symptoms are most extreme, and we might easily be misled by assessing outcomes at some subsequent time when random fluctuations have returned their symptoms toward a more average level. As Sartwell et al. pointed out, “the term chronic has a tendency to conjure up ideas of stability and unchangeability . . . it is changeability and variation, not stability, that is in fact the dominant characteristic of most long-lived conditions” (9).

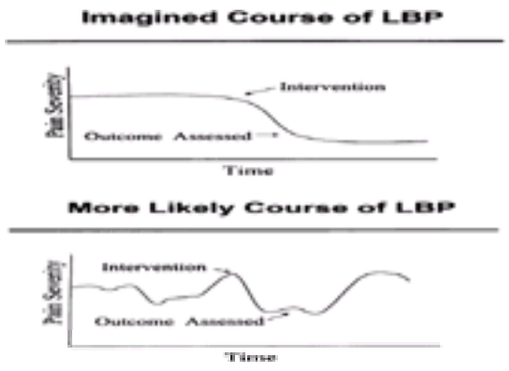

Figure 82-1. Hypothetical course of chronic low back pain (LBP). (From Deyo RA. Practice variations, treatment fads, rising disability. Do we need a new clinical research paradigm? *Spine* 1993;18:2153–2162, with permission.)

Finally, a host of nonspecific effects play an important role in patient improvement. The concern, conviction, enthusiasm, and attention of a therapist, a researcher, and a clinical staff may all have desirable effects. Table 82-2 shows a potential consequence of these factors, using data from a clinical trial of patients with chronic low back pain (8). The 31 patients in Table 82-2 had had back pain an average of 4 years. They were given a clinical intervention that resulted in 20% to 44% improvements in pain frequency, severity, and function, all of which were highly statistically significant. However, this seemingly effective treatment for chronic pain was a sham transcutaneous electrical nerve stimulation (TENS) unit, along with hot packs twice a week. This was the control arm of a randomized trial, and illustrates the substantial improvements that may occur among those with long-standing pain who receive ineffective treatments.

Outcome measure	Score improvement: Baseline to 1-mo follow-up	*p* Value
Overall function (SIP)	32%	.002
Physical function	44%	.001
Pain severity (VAS)	33%	.006
Pain frequency (5-point scale)	20%	.000

SIP, Sickness Impact Profile; VAS, visual analog scale.

TABLE 82-2. Therapeutic trial for patients with chronic low back pain: mean duration of 4 years, n = 31

CONTROL GROUPS: AN IMPROVEMENT OVER THE CASE SERIES

Given the variety of factors that may produce improvement with ineffective therapy, it is incumbent on investigators to have a comparison group of subjects, who might experience all the same reasons for improvement as a treatment group but who do not receive the active therapy. An investigator would want to reproduce many of the causes for improvement that are listed in Table 82-1 among such a control group. With this goal in mind, the appropriate comparison group is unlikely to be one that receives no care at all. Patients in such a group would not experience placebo effects or the nonspecific effects of clinical concern and enthusiasm. Thus, a preferable control group would be one that receives other credible, appropriate care that does not include the specific treatment under study. This might consist of "usual care" supplemented by a placebo of some sort. The placebo must be as credible and seemingly likely to help as the active therapy. This is the reason for providing inactive pills in the control groups of drug trials, but even for nondrug treatments, credible therapy should be provided. Examples include the use of sham TENS units in trials of TENS, the use of subtherapeutic weight in trials of traction, "misplaced needling" as a control for acupuncture, or even educational brochures that create the sense of some additional intervention and concern but that may have no effect on patient outcomes (10).

An implication of these considerations is that a "waiting list" control group is not adequate because these patients experience none of the placebo or nonspecific effects of the intervention group. Similarly, it would be unwise to choose as a control group patients who did not have adequate insurance coverage for the treatment being provided because insurance coverage is related to important sociodemographic characteristics. Patients with the best insurance are typically those with the highest salaries and the greatest incentive to improve, whereas those with less insurance coverage are likely to be those with lower incomes, less satisfying jobs, and less motivation to improve. Another convenient but misguided control group would be patients who were intended to receive a particular treatment but for some reason were not compliant. A striking example of the flaw in this line of reasoning is apparent from large-scale drug trials in which patients in the placebo arm were examined for their compliance with tablets. In a study of cholesterol-lowering therapy, control patients were divided among those who took more than 80% of their placebo tablets and those who took less than 80% (11). Even after adjusting for 40 coronary risk factors, there were enormous differences in mortality between the compliant and noncompliant groups. Patients who were compliant with their placebos had a 5-year mortality of only 16%, whereas those who were not compliant had a 5-year mortality rate of 26% (p = .000000007) (11). It seems unlikely that such a striking difference in a hard outcome such as mortality was entirely due to placebo effects, and it was probably related to important differences between the groups that were not apparent in either their compliance behavior or their coronary risk factors. These may have included other health habits, behaviors, attitudes toward risk, and occupations. Thus, noncompliant patients are often strikingly different from compliant patients, and we cannot assume that any differences in outcome are related only to treatment effects.

What about finding a control group in which patients are well matched to the treatment patients on a number of characteristics? As the cholesterol-lowering placebo study suggests, with its adjustment for 40 different risk factors, this procedure may not capture the important differences between two groups of patients. In fact, Table 82-3 shows how one might assemble two groups of objects that are well matched on five different characteristics and yet literally be comparing apples and oranges (8).Table 82-4 shows actual data for a comparison of outcomes of two groups of Medicare patients who underwent low back surgery. They were well matched on diagnosis (all had spinal stenosis), gender, age, insurance (all Medicare), and surgical procedure (all had a laminectomy without fusion). Despite being well matched on these five characteristics, the likelihood of reoperations differed almost fourfold between the two groups. Differences of this magnitude might easily be attributed to some dramatic advantage of the treatment used in group A. However, these groups were intentionally assembled in such a way that group A was composed of African-American patients who had not had prior surgery, and group B was composed of white patients with prior surgery (8). These two characteristics, which might easily have been overlooked and unmeasured, accounted entirely for the difference in reoperation rates.

	Apples	Oranges

TABLE 82-4. Two cohorts of Medicare patients with laminectomy for stenosis(1985)

If waiting lists, patients with insufficient insurance coverage, noncompliant patients, or carefully matched patients make poor control groups, is there a better solution? Fortunately, the concept of random allocation provides an ideal method of establishing a comparison group that is likely to be similar in nearly all respects to an intervention group.

RANDOMIZED ALLOCATION TREATMENT AND CONTROL GROUPS

The term *randomized trial* has become familiar among clinicians and yet is often misunderstood. Some assume that a randomized trial is one in which patients are randomly selected from a population of interest. However, just the opposite may be true. Patients may be highly selected from a group of potential candidates based on specific characteristics that make the study treatment safe and likely to succeed. Randomization does not refer to the selection of patients, but rather the patients' allocation to the treatment or the control group.

Why is randomization such a desirable way of creating a control group? It is attractive because many of the biases described previously with other types of control groups are largely eliminated. With random allocation, we may not even know the important prognostic factors, but they will be equally distributed (given a fair randomization and enough patients) between the treatment and control groups.

Some investigators have quantified the magnitude of bias that occurs when randomization is not used in trial design by looking at the maldistribution of known baseline prognostic factors and the magnitude of apparent treatment effects. One such study, shown in Table 82-5, compared blinded randomization (in which investigators could not know into which group the next patient would fall) with unblinded randomization (in which the investigators could know into which group the next patient would fall) and with nonrandom allocation of controls (12). The investigators examined a series of treatments for acute myocardial infarction, and as the table shows, demonstrated that maldistribution of prognostic factors was least with blinded randomization and greatest with nonrandom allocation of treatment and controls. Similarly, the likelihood of finding a substantial improvement in case fatality rate rose dramatically, from just 9% of trials with blinded randomization up to almost 60% of trials with nonrandom allocation. This observation suggests that using nonrandomly allocated controls is nearly a sure way of getting a positive result.

Allocation method	Prognostic maldistribution (%)	Difference found in case-fatality (%)
Blinded randomization	14	9
Unblinded randomization	27	24
Nonrandomized	58	58

Data from Chalmers T, Celano P, Sacks HS, Smith J. Bias in treatment assignment in controlled clinical trials. *N Engl J Med* 1983;309:1358–1361; reprinted from Deyo RA. Practice variations, treatment fads, rising disability: Do we need a new clinical research paradigm? Spine 1991;16:2153–2162, with permission.

TABLE 82-5. Bias in studies of myocardial infarction

The importance of randomized designs for pain treatments was further illustrated in a systematic review of TENS therapy for postoperative pain. The investigators found 17 randomized trials of efficacy and 15 of these showed no benefit. In contrast, among 19 nonrandomized studies, 17 had a substantial positive treatment effect. The authors concluded that nonrandomized trials overestimate pain-relieving effects and may lead to the wrong conclusions (13).

Thus, the best way to reduce bias in comparisons between a treatment and some alternative is to randomize patients and to ensure that the investigators are blind to which group the next patient will enter. Why is the blinding of allocation so important? Although this question has not been well studied, we can imagine a variety of reasons. If the investigator has a bias as to which treatment group is more effective—even a subconscious bias—he or she may approach the next subject differently if the intended study group is already known. This may affect the way in which a clinical trial is presented to a patient, the enthusiasm with which consent is sought, or the rigor with which eligibility criteria are applied. In one dramatic local example, patients were assigned to treatment arms according to their hospital numbers. The residents involved in the study actually manipulated the assignment of hospital numbers as patients were registered in the emergency room.

There is sometimes confusion about what constitutes randomization. Randomization requires using a list of random numbers that may be published or determined by a computer program, so each successive subject has an equal likelihood of being assigned to each treatment arm. Alternating assignment is not the same as randomization because it is absolutely systematic rather than random and creates the potential biases noted previously from unblinded randomization. Similarly, assigning patients without conscious bias, or haphazardly, is not the same as random allocation. Using hospital numbers, date of birth, or day of the week is not the same as randomization. The rigorous randomized study will report how the random sequence was determined and how investigators were blinded to the assignment of sequential patients.

For certain interventions, it may be undesirable or unfeasible to randomly allocate individual patients to a treatment or a control group. For example, if one were testing a guideline that involved changes in clinic organization and changes in management by nurses or other ancillary staff, it might be extremely difficult to ensure that all involved gave one particular approach to some patients and not to others. Furthermore, individual physicians would have difficulty treating certain patients according to a guideline and others not according to the guideline. In such a circumstance, one might wish to allocate clusters of patients, such as entire clinics, to intervention or control arms. Similarly, one might randomly allocate hospitals or physicians, with all of their patients, to intervention or control conditions. In these designs, in which entire clusters of patients are randomly allocated to one approach or the other, specific statistical methods are needed that account for the similarities among patients of a single physician or facility. Analytic techniques for such studies have been well described (14) and appropriate computer software is increasingly accessible.

The relatively rapid advances in other fields of medicine, such as oncology and cardiology, occur because a succession of large randomized trials, typically implemented in multiple centers, result in cumulative knowledge. Such trials are still the exception rather than the rule in pain treatment, perhaps in part because of lower research funding for nonfatal conditions. Nonetheless, other fields suggest a model for research that might be emulated by the pain community.

What outcomes should be measured in a clinical trial? In traditional clinical trials, investigators often seek the most objective possible outcomes for evaluation, such

as joint range of motion, spinal fluid endorphins, or dynamometer measures of muscle strength. Although the search for objective outcome measures is laudable, pain is inherently a subjective phenomenon and one that may correlate only modestly with these physiologic measures. For example, Table 82-6 illustrates several examples of reported dissociations between physiologic measures and pain or functioning (15).

• Biofeedback reduces paraspinal electromyography activity but not pain.
• Tricyclic antidepressants relieve pain and depression but do not alter cerebrospinal fluid beta-endorphin levels or paraspinous electromyography activity.
• Statements of pain severity correlate poorly with medication use, health care use, and activity level.
• Reduced spinal mobility may be associated with improvement in pain and disability or lower risk of pain.
• Muscle function does not predict 10-year incidence of back symptoms.
• Correlations between lumbar spine mobility and modified Oswestry questionnaire are only .04–.17 (absolute value).
• In a clinical trial of rigid corset, improvements in symptoms with activity were observed but not in spine mobility or straight-leg raising.

TABLE 82-6. Examples of dissociations between various outcome measures

Ultimately, some researchers have argued that the essence of “hard” data is their reproducibility under the same circumstances (16). Thus, reproducibility may actually be more important than who makes the measurement, whether it is preservable or whether it is numerical. Happily, many subjective phenomena can be measured in reproducible fashion. A good example is the use of visual analog pain scales and other ordinal rating scales for quantifying pain. However, most investigators would want to go beyond the self- report of pain to actually examine patients' behavior and function in their daily lives. Again, daily functioning may correlate poorly with basic physiologic measures and should therefore be measured directly rather than inferred (15). Performance measures such as a series of timed tasks or an “obstacle course” may have the attraction of seeming objectivity, and yet performance on such physical tasks is highly influenced by motivation, mood, setting, financial incentives, and other nonphysical attributes of the patient and his or her environment. Self-report measures of health status or functional status are quite reproducible and are increasingly incorporated into clinical trials of pain therapy. Examples include the Sickness Impact Profile (17,18) and the shorter SF-36 (19), as well as condition-specific scales such as the Roland Disability Scale for patients with back pain (20), the Arthritis Impact Measurement Scale (21), the Seattle Angina Questionnaire (22), and many others.

Work status is often used as an outcome measure for chronic pain treatment because of its clear relevance to both patients and to society. However, it has a number of drawbacks as an outcome measure, most important of which is that it is influenced by many nonmedical factors. For example, studies have demonstrated that the likelihood of return to work in the face of a painful medical condition depends importantly on job satisfaction, relationships with fellow employees and supervisors, regional unemployment rates, the presence of another breadwinner in the family, closeness to retirement age, and physical job demands. Similarly, the duration of pain-related disability is strongly associated with the patient's educational status, income (23), and the generosity of disability benefits. For many members of our society, including students, housewives, and retired persons, return to employment is simply not available as an indicator of outcome. Thus, although this measure of outcome is important in many settings, it should be interpreted in light of these many potentially confounding factors.

OTHER ISSUES IN THE DESIGN OF CLINICAL TRIALS

Table 82-7 lists several criteria that have been proposed for critical readers to evaluate studies of treatment efficacy (24,25). Although these were designed as guides for critical readers, they also create a departure point for clinical investigators. A similar but lengthier and more detailed set of criteria for evaluating clinical trials has been proposed by the back subgroup of the Cochrane Collaboration, an international effort to systematically review clinical trials of treatments for all medical conditions (26). The list of criteria in Table 82-7 begins with random allocation, which was discussed in detail previously.

Are the results of the study valid?
Primary guides
Was the assignment of patients to treatments randomized?
Were all patients who entered the trial properly accounted for and attributed at its conclusion?
Was follow-up complete?
Were patients analyzed in the groups to which they were randomized?
Secondary guides
Were patients, health workers, and study personnel “blind” to treatment?
Were the groups similar at the start of the trial?
Aside from the experimental intervention, were the groups treated equally?
What were the results?
How large was the treatment effect?
How precise was the estimate of the treatment effect?
Will the results help me in caring for my patients?
Can the results be applied to my patient care?
Were all clinically important outcomes considered?
Are the likely treatment benefits worth the potential harms and costs?
Reprinted from Guyatt GH, Sackett DL, Cook DJ. Users' guides to the medical literature. II. How to use an article about therapy or prevention. A. Are the results of the study valid? JAMA 1993;270:2598–2601, with permission.

TABLE 82-7. Readers' guides for an article about therapy

Complete Follow-Up

The second item in the list in Table 82-7 concerns completeness of follow-up for patients who entered the trial. Investigators should follow up on every patient who enters the study because those who drop out may be systematically different from patients who remain in the study. For example, disgruntled patients who have failed to improve may drop out of a trial, leaving an obvious bias in favor of the new treatment. On the other hand, patients with dramatic improvements may drop out because they are so much better they see no need for continued medical contact. Dropouts from clinical studies often differ systematically from those who remain with regard to their baseline characteristics.

In highly mobile societies, such as the United States, obtaining complete follow-up can be difficult. Strategies for maximizing follow-up include gathering multiple telephone numbers at the time of enrollment for the patient, relatives, and friends; excluding patients who are planning to move in the near future; excluding patients who have no telephone; multiple mailings of questionnaires; financial incentives to return data; using the briefest possible follow-up questionnaires; and even use of the Worldwide Web to track patients through public records.

A useful rule of thumb is that at least 85% of patients who enter a trial should be included at the end of the study. One way to ensure that the results are robust in the face of dropouts is to do a “worst-case analysis,” in which one assumes that all dropouts from the treatment group failed to improve, whereas all dropouts from the comparison group improved substantially. If this worst- case analysis does not change the conclusion, one can be confident in the findings (24).

As suggested in Table 82-7, it is also important that patients be analyzed in the groups to which they were randomized, regardless of whether they received the intended treatment (e.g., because of poor compliance). We have seen the hazards of assuming that patients who are noncompliant are otherwise the same as compliant patients. Indeed, patients who do not receive the intended therapy may be systematically different from those who do, and the only way to avoid a biased comparison is to keep patients for analytic purposes in the group to which they were assigned.

Blinding

It is common to talk about “double-blind” trials, but the term is sometimes used ambiguously. Typically, it is meant to imply that the patient is unaware whether he or she is receiving active treatment or a placebo, and the therapist is also unaware. In some cases, it may be impossible to “blind” patients or therapists, as in trials of surgical treatments or some rehabilitation interventions. However, there is a third party that may be blinded, an independent assessor of outcomes. Maintaining such

a blinded assessor should be feasible, even when it is impossible to blind patients and therapists.

As noted in the discussion of control groups, creativity can sometimes produce credible placebo or alternative treatments that at least help to maintain blinding. In many situations, it may be feasible and desirable to test the success of blinding at the end of a study. This has been done in clinical trials such as one examining beta blockers after heart attacks (in which reduced pulse and blood pressure tended to reveal the active treatment group) (27) and in studies of TENS for low back pain (in which sham treatment fails to produce the same sensation as active therapy) (28). In both of these examples, patients and physicians were able to guess better than random chance whether individual patients were in the treatment or control group, and yet the magnitude of blinding failure was sufficiently modest that the results could be presented with some confidence. The importance of blinding is that it helps to create similar expectations on the part of patients and similar enthusiasm by the therapists. Furthermore, it ensures that the same level of attention and concern is provided to both a treatment and a control group.

In trials of drug therapy, crossover designs have commonly been used because they help to reduce the effects of interpatient variability in baseline and outcome measures. For many pain treatments, however, such designs may be undesirable because they would preclude blinding. For example, a crossover study from sham TENS to true TENS, or from subtherapeutic weight to therapeutic weight with traction, or from mild exercise to strenuous exercise would almost certainly preclude patient blinding. Because of loss of blinding, a host of analytic problems (29), and the potential for improvement due to natural history, crossover trials may be undesirable for many types of pain therapy.

Baseline Similarity of Study Groups

Randomization usually provides the best way to produce groups with equivalent prognoses. However, randomization may not always work, and investigators should present a comparison of baseline characteristics of patients in the treatment and control groups. In a randomized trial, any observed differences are chance occurrences but may still be sufficiently large to compromise the validity of the study. When this occurs, investigators can adjust for baseline differences using statistical techniques, although this cannot adjust for differences in unmeasured prognostic characteristics.

Were Groups Treated Equally Except for the Experimental Treatment?

Sometimes patients in a treatment group are given multiple interventions, and yet the authors or readers are tempted to ascribe the results to a single feature of the treatment. For example, a patient who receives a sclerosant injection into the spinal ligaments along with corticosteroids and spinal manipulation might be said to have improved because of the sclerosant therapy, and yet much of the observed improvement might be due to the cotreatments (30). Thus, it is important that any cotreatments be given to the control group as well (31).

Furthermore, multiple treatments for chronic painful conditions are common. Many patients obtain over-the-counter pain medications; visit multiple physicians; or seek alternative forms of therapy such as chiropractic care, acupuncture, or massage. In outpatient trials, it may be difficult to prevent patients from obtaining such cotreatments, and it may simply be necessary to inquire about these “cointerventions” and ensure that they are roughly equivalent between two groups. Alternatively, investigators may make strenuous efforts to ensure that patients do not receive certain types of cointerventions. Even the nature of follow-up should be consistent between study groups. If one group has closer follow-up, for example, more adverse events might be reported, or treatment might be given more intensively. Furthermore, increased contact with a caring clinician can have important nonspecific effects, as noted previously.

Reporting the Results

In some studies, actual outcome measurements are not reported, and only the *p* values for the significance of results are provided. However, this gives a reader no idea what the magnitude of treatment effects may have been. In a very large trial, a trivial difference between groups may achieve statistical significance even though the difference is too small to be clinically relevant. On the other hand, in a very small trial, a large treatment effect might fail to achieve statistical significance because of the small numbers. Thus, the magnitude of treatment effect is somewhat independent of statistical significance, and must be reported. An ideal way to present the results is to give the actual estimate of success rates or mean scores along with 95% confidence limits, which allow the reader to see the range of results that would be consistent with the study findings. The 95% confidence limits are closely related to *p* values, but give readers a better understanding of the potential range of effects compatible with the data. Ultimately, a *p* value tells us how precise an estimate of treatment effect is, but not its magnitude.

Generalizability of Results

Although a clinical trial may be internally valid, it may not be applicable to other patients. Thus, it is important that patients and treatments be adequately described for a reader to know whether they would be likely to apply to his or her own situation.

Sometimes, subgroup analyses are used to examine clinically relevant groups of patients, and results are found to differ among subgroups. There is a great risk that subgroup analyses may be overinterpreted and may simply represent chance effects. Confidence in such subgroup analyses is enhanced if the treatment effects are large, were unlikely to have occurred by chance, occurred in an analysis that was specified before the study began, were found in one of very few subgroup analyses, and were replicated in other studies (25).

Another issue in judging generalizability concerns the outcomes that were measured. As we saw previously, improvements in physiologic end points do not necessarily translate into improvements in pain, functioning, or employment status, and if these latter phenomena are important, they should be measured directly.

Benefits Versus Harms and Costs

Sometimes, even effective treatments may not be widely implemented because of a high risk of complications or exorbitant costs. Although many clinical trials will not have the resources to perform formal cost-effectiveness analyses, it is important to account for the risks of the treatments being compared as well as their benefits.

NEW DIRECTIONS IN CLINICAL TRIALS

An important principle in most clinical trials is to assemble groups of patients who are relatively homogeneous in their expected prognoses and responses to treatment. For many painful conditions, this is difficult because of diagnostic ambiguity and the lack of precise classification systems. For example, clinicians and investigators often have different criteria for defining spinal segmental instability, carpal tunnel syndrome, whiplash, thoracic outlet syndrome, and many others. Thus, rather than simply attaching a diagnostic label to a group of patients, it may often be preferable to provide detailed clinical descriptions that would allow a reader to decide if the subjects meet his or her own criteria for the condition under study and whether they resemble his or her own patients. Similarly, in situations for which good prognostic data are available, one may wish to stratify patients entering a clinical trial so that the prognosis within strata is more homogeneous. For example, one might choose in a trial of back surgery to group patients with and without previous back surgery and examine the outcomes separately. One might choose to examine patients with and without disability compensation separately. This strategy is called *prognostic stratification* and may disclose patterns of treatment efficacy that would otherwise not be apparent. It amounts to specifying subgroup analyses in advance but may also influence recruitment strategies to ensure adequate numbers in key subgroups.

Some investigators may wish to consider the use of factorial research designs. With a factorial design, patients are simultaneously randomized to receive or not receive two different treatments. Thus, for example, one might simultaneously be allocated to receive study drug A versus a placebo and to receive exercise program A or exercise program B. Such factorial designs have important efficiencies if the dropout rate is low. If there is no statistical interaction between the two treatments (in this example drug therapy and exercise therapy) then one has an unbiased assessment of the effect of each treatment. Such designs might be useful in studying combinations of therapy such as an analgesic plus a muscle relaxant, drug therapy plus physical therapy, and other clinically relevant combinations. Indeed, this may be the best way to evaluate the multimodal therapy that is widely advocated for the treatment of chronic pain. If there is no synergy between treatments, the investigator essentially has two trials for the price of one. If there is synergy, there is no other way to identify this effect. Factorial designs introduce analytical complexities that are avoided in simple parallel designs, but in some circumstances, the benefits may outweigh the disadvantages (32,33).

Greater standardization of outcome measurement would represent an important advance in studying pain treatment. At present, individual investigators often choose unique and sometimes idiosyncratic measures of outcome that are difficult to compare with other studies. The lack of standardization of outcome measurements makes it difficult to compare individual studies, to synthesize results in the form of metaanalysis, and to interpret the results. The last occurs because readers may have little sense of the clinical relevance of a given percentage change or point change on a particular pain or functional scale. Efforts to provide some core

standardized measures across multiple trials would alleviate this problem, and such core instruments have been proposed for trials of back pain therapy (34). In addition, organizations such as the American Academy of Orthopaedic Surgeons have proposed batteries of outcome measures for a variety of musculoskeletal conditions, and such efforts may help to bring about greater uniformity of measurement. The advantage of a brief set of core instruments would be that there is greater comparability among trials but still flexibility for individual investigators to add specific measures that might be most relevant or important for their studies.

Many interventions for chronic pain require large numbers of patients to observe effects that may be relatively small yet clinically relevant. Enrollment of an adequate number of patients is nearly a ubiquitous problem for prospective studies, and this could be alleviated by the use of multicenter trials. Multicenter trials require both greater funding and greater organizational efforts than single-site studies but may be the only way to feasibly obtain answers to important questions. Not only do multicenter trials offer the advantage of more rapidly accruing adequate numbers of patients, but they also enhance the likelihood that results will be generalizeable at the end of a trial because the treatment has already been tested in different settings.

For clinicians, the results of rigorous randomized trials may become more accessible through the efforts of the Cochrane collaboration. This is an international effort to systematically review and where possible combine the results of multiple randomized clinical trials and make the results available on the Worldwide Web. Although this effort is relatively young, the database is rapidly building, and many of the literature syntheses are also being published in conventional journals.

CONCLUSION

Despite the rapid growth of research literature on the treatment of pain, there remain wide variations in care, a proliferation of unorthodox treatments, and a succession of fads that are often demonstrated to be ineffective when well-designed studies are performed. Disability due to painful conditions is increasing, and there is only a limited professional consensus on optimal approaches to many painful conditions. The disappointing pace of progress in this area may be partly the result of few comprehensive theories that would guide treatment innovations. However, an equally important factor may be the methodologic inadequacy of clinical trials that are necessary to evaluate innovations before introduction to clinical care. Flaws in research design jeopardize not only the internal validity of research results, but also their generalizability to other populations. Greater attention to scientific principles in the design of clinical research should accelerate progress in this area, lead to more consistent clinical practices, and improve patient care.

CHAPTER 83

Systemic Nonopioid Analgesics

H. Richard Miyoshi

The nonopioid analgesics discussed in this section include both that large group of chemically unrelated compounds generally known as *nonsteroidal antiinflammatory drugs* (NSAIDs) and some newer nonopioid analgesics with novel mechanisms of action that may fill the void left by opioids and NSAIDs. In addition, this chapter looks at some new areas of exploration that may lead to other kinds of nonopioid analgesics. Use of NSAIDs for specific pain syndromes is also discussed in Parts III and IV of this text.

GENERAL PRINCIPLES OF NONSTEROIDAL ANTIINFLAMMATORY DRUG PHARMACOLOGY: PROSTAGLANDINS AND CYCLOOXYGENASE

NSAIDs have myriad central and peripheral effects, many of which appear to be mediated by inhibition of prostaglandin (PG) synthesis. Investigations in the central nervous system (CNS) into the activity of inflammatory cells, release of enzymes and oxygen- derived free radicals, and other mechanisms are beginning to reveal NSAID effects that are independent of PG synthesis, but these are not yet well characterized (1,2 and 3).

It was about a quarter of a century ago that John Vane proposed that inhibition of PG biosynthesis was the mechanism of action of aspirinlike drugs (4). It was later found that the mechanism involved specifically the enzyme PG endoperoxide synthetase, now more commonly known as *cyclooxygenase* (COX) (5). This insight led to the development of the first generation of nonaspirin antiinflammatory drugs. In the early 1990s, COX was discovered to have two isoforms with different functions and distributions in the body, leading to a new way of looking at NSAID activity and new avenues for drug development.

PGs are a class of physiologically active, lipid-soluble compounds synthesized from arachidonic acid, a 20-carbon unsaturated fatty acid. These short-lived molecules are not stored and are synthesized in response to specific stimuli. They are essential to the regulation and normal physiology of, among other things, the gastric mucosa, renal blood flow, and smooth muscle in bronchioles. PGs are also a part of the inflammatory response. PGE_2 has been identified as a critical factor in the swelling and pain associated with inflammatory states. It also may regulate the effect of histamine and other mediators on nerve endings. Additionally, another closely related compound, thromboxane A_2, is an important factor in platelet aggregation, whereas prostacyclin (PGI_2) is important in disaggregation. This is just one of many examples of physiologic systems that are regulated by the opposition of two different prostanoids, of which one (in this case, thromboxane) could be considered pathologic and the other (in this case, PGI_2) could be considered homeostatic (6).

Synthesis of PG and thromboxane begins when phospholipase A_2 releases arachidonic acid from cell membranes (Fig. 83-1). Arachidonic acid can go through a number of metabolic pathways, yielding a number of biologically active compounds known as *eicosanoids*, which are derived from C20 fatty acids (eicosanoic acids). Included in this group are products of the lipoxygenase pathway such as the lipoxins, hydroperoxytetraenoic acids, hydroxytetraenoic acids, and leukotrienes, which are important in asthma. The COX pathway produces the prostanoids derived from prostanoic acid, which include the PGs, thromboxanes, and PGI_2. COX itself catalyzes two reactions. First, it acts as a cyclooxygenase, combining arachidonic acid with two oxygen atoms to produce PGG_2. Next, it acts as a peroxidase, reducing PGG_2 to PGH_2. A variety of synthases then convert PGH_2 to other PGs with a variety of specific functions (7).

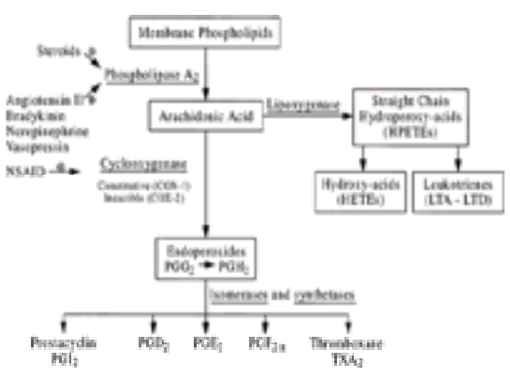

Figure 83-1. Biosynthesis of eicosanoids from arachidonic acid. (NSAID, nonsteroidal antiinflammatory drug; PG, prostaglandin.)

NSAIDs achieve many of their effects by inhibiting COX. As is discussed in more detail below, this includes many of their therapeutic effects, as they decrease PG synthesis at sites of inflammation, but it also includes many of their adverse side effects, as they also decrease PG synthesis needed for proper functioning of the kidney, gut mucosa, and smooth muscle. One of the more important developments in NSAID pharmacology is the discovery in the last decade that these two sets of effects are largely mediated by two different isoforms of COX. In general, COX-1 is the constitutive enzyme that produces PG needed for homeostasis, for example, in the kidney, gut mucosa, platelets, and endothelium, whereas COX-2 is inducible and produces PG as part of the inflammatory process. This division of function is not perfect; COX-2 plays a homeostatic role in some systems, such as the renal medulla and uterus (8), whereas COX-1 may produce some PGs that contribute to inflammation (9). However, the overall separation may make it possible to develop drugs that would produce most of the antiinflammatory effects of NSAIDs by selectively inhibiting COX-2, with many fewer of the side effects that current NSAIDs cause by also inhibiting COX-1 (10).

The two isoforms can be differentiated in a number of ways, but a simple biochemical way is to compare their sensitivity to the reference compound, aspirin. Aspirin inhibits the cyclooxygenase activity but not the peroxidase activity of COX-1. It affects COX-2 quite differently, converting it from a cyclooxygenase to a 15R-lipoxygenase. The two isoforms are also quite different in their distribution and mode of activation. COX-1, the “housekeeping” or constitutive form of the enzyme, is widely expressed in healthy tissue and appears to be localized in the endoplasmic reticulum. It produces PG needed for normal cell activity in response to stimulation by circulating hormones. Its concentration is relatively stable, but can increase two- to fourfold in response to hormones or growth factors (11). COX-2, the inducible isoform, is expressed in endothelial cells, macrophages, synovial fibroblasts, mast cells, chondrocytes, and osteoblasts after tissue trauma (12). It also has some constitutive expression in neurons and gastric mucosa (13). It is present at very low levels in other healthy tissue but increases more than 20-fold during inflammation (9,14). COX-2's highest concentrations are in the nuclear envelope, but it can also be found in endoplasmic reticulum and in the nucleus during cellular growth, replication, and differentiation. Cytokines, endotoxins, growth factors, and reactive oxygen molecules all may induce COX-2 gene expression (15). Conversely, the glucocorticoids and the cytokines that inhibit inflammation suppress expression of the COX-2 gene (10).

Another important area of investigation is the relationship between COX and nitric oxide (NO) (Fig. 83-2). Both COX and nitric oxide synthase (NOS) have constitutive and inducible isoforms. The constitutive isoforms regulate a number of homeostatic processes. The inducible isoforms, COX-2 and inducible NOS, are both either proinflammatory or yield proinflammatory compounds. The induction of both is inhibited by antiinflammatory steroids, raising the question of whether their encoding genes are in the same family. It appears that NO activates COX-2, increasing production of PGE_2 (16). In fact, NO appears to be an important modulator of COX activity, playing a significant role in regulating the extent of the inflammatory process. Numerous compounds that affect COX-2 or inducible NOS or both are being studied as potential antiinflammatory agents, with promising results (17,18).

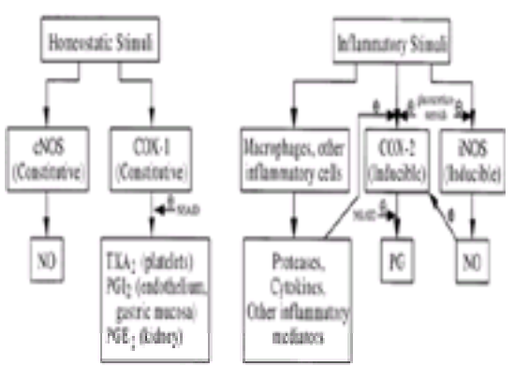

Figure 83-2. A proposed model of the interactions between nitric oxide (NO) and cyclooxygenase (COX) pathways. (NOS, nitric oxide synthase; NSAID, nonsteroidal antiinflammatory drug; PG, prostaglandin; TXA_2, thromboxane A_2.)

PHARMACOLOGY OF SPECIFIC NONSTEROIDAL ANTIINFLAMMATORY DRUG EFFECTS

Analgesia and Antiinflammation

The best understood aspect of the analgesic effect of NSAIDs is their impact on inflammation. Inflammation is the normal response of tissue to injury. It includes enzyme activation, mediator release, extravasation of fluid, cell migration, and tissue breakdown and repair. Many other products of COX are involved, but PGE_2 is the main eicosanoid found in inflammatory conditions and is an essential factor in producing both inflammation and pain. It stimulates nociceptors, either directly or, more likely, by upregulating their sensitivity to other algogenic agents such as bradykinin, which is released when cell membranes are ruptured (19). NSAIDs thus relieve inflammatory hyperalgesia in part by inhibiting COX-2 in inflamed tissues, thereby blocking formation of PGE_2. PGI_2 also causes hyperalgesia in animal models and is detected in inflammatory tissue at concentrations comparable to PGE_2. However, the hyperalgesia caused by PGI_2 is immediate and short-lived, in contrast to the slow onset and long duration of that caused by PGE_2 (20).

The full analgesic effects of NSAIDs probably go well beyond their effects on inflammation to involve a wide array of peripheral and central actions. Some other areas of peripheral action under investigation are lipoxygenase inhibition and a number of non-PG inhibitory actions. With respect to central actions of NSAIDs, the precise role of PG in normal and pathologic central functions is not yet clear (19). However, there is extensive evidence of the importance of COX and PG in central pain mechanisms.

PG, PGD_2, and PGE_2 receptors and PGD and PGE synthases have been found in numerous regions of the brain. The lack of specific antagonists for E, D, F, and I series PG to date has limited the elucidation of their exact function in the CNS. However, it has been shown that PG may increase the excitability of neurons receiving ongoing afferent input. They may achieve this by facilitating the release of excitatory neurotransmitters, by decreasing presynaptic bulbospinal inhibition, or by reducing neuronal membrane stability (21).

COX-1 and COX-2 also appear to play important roles in the CNS. COX-1 is distributed in neurons throughout the brain but is most abundant in the forebrain. Low levels of COX-2 immunoreactivity and COX-2 messenger RNA have also been detected in the forebrain. Forebrain PG may be involved in complex integrative functions, such as the control of the autonomic nervous system and sensory processing (22). Evidence is accumulating that COX-2 is closely involved in the brain's self-modulating response to afferent inputs and that NSAIDs may therefore influence that response. Patterns of COX-2 immunoreactivity seem to show that it is induced in certain groups of neurons in response to natural excitatory synaptic activity. COX2 has also been identified as a neuronal immediate early gene—that is, a gene whose expression can be rapidly induced with synaptic activity in the brain (23). COX2 appears to be involved as an immediate early gene in the development of certain long-lasting changes in neuronal responsiveness that result from brief noxious afferent input (24). Basal levels of COX2 expression have been found to be dependent on activation of the *N*-methyl-d- aspartate–type glutamate receptors that have been found to mediate neuronal plasticity in response to neuronal activation. Arachidonic acid, the substrate of COX, is also generated in brain in response to activation of glutamate receptors in the long-term potentiation model of neuronal plasticity (24).

Antipyresis

The full mechanism of the antipyretic action of NSAIDs is still in question. There are PGs in the hypothalamus. Endogenous, fever-producing PGE_2 is thought to originate from COX-2 induced by lipopolysaccharide or interleukin-1 in endothelial cells lining the cerebral blood vessels (25).

Sodium Retention and Hyponatremia

NSAIDs may cause mild sodium retention in 10% to 25% of patients. Several mechanisms for this effect have been suggested, including direct tubular and indirect vascular effects. NSAID-induced sodium retention tends to be much more severe in patients with edema due to such conditions as congestive heart failure, cirrhosis of the liver, and nephrotic syndrome. Using NSAIDs in these conditions or in cases of renal insufficiency can also lead to resistance to the natriuretic effects of diuretics, including loop diuretics (26).

PGE_2 and other PGs oppose urinary concentration mechanisms in the kidney. Consequently, NSAID reduction of PG synthesis may result in excessive urinary concentration and thus water retention and hyponatremia. This is usually not clinically significant, but it may become a problem in patients at risk for hyponatremia because of edema-causing disorders or other reasons (26).

Renal Failure

Under normal conditions, the rate of PG synthesis in the kidney is very low, so that inhibition of renal vasoactive PG by NSAIDs does not significantly affect renal hemodynamics or function (27). However, in states of renal hypoperfusion, vasodilator PGs serve an important role in the maintenance of glomerular filtration rate by means of their effects on renal arterioles. The use of NSAIDs in patients with renal hypoperfusion may lead to vasoconstriction of both afferent and efferent arterioles as well as mesangial contraction, significantly reducing glomerular filtration rate. Renal hypoperfusion may be due to overall volume depletion [induced by diuretics, gastrointestinal (GI) fluid losses, or hemorrhage, for example], to sepsis, or to intravascular volume depletion (e.g., that caused by the edema of congestive heart failure, cirrhosis of the liver, or nephrotic syndrome). Vasoconstrictive acute renal failure is the most commonly seen form of nephrotoxicity associated with NSAIDs and is frequently reversible when the drug is stopped and volume is replenished (26).

Much less frequently seen with NSAID use are renal parenchymal diseases including acute interstitial nephritis, often associated with nephrotic syndrome, and chronic progressive renal disease with or without renal papillary necrosis. These conditions are relatively infrequent but are more often seen in the elderly.

NSAIDs should be used with caution in patients at risk for hypoperfusion or who have decreased renal reserves (Fig. 83-3).

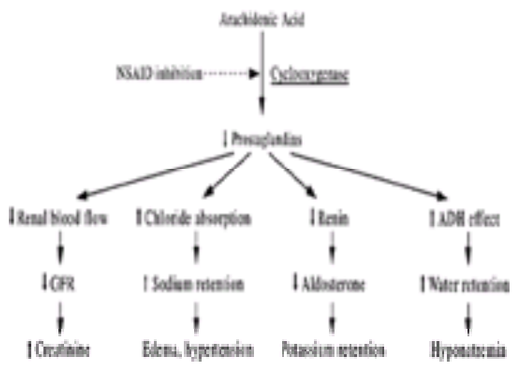

Figure 83-3. Cascade of renal effects of nonsteroidal antiinflammatory drugs (NSAIDs). (ADH, antidiuretic hormone; GFR, glomerular filtration rate.)

Vascular Tone

Prostanoids are known to regulate vascular tone. They modulate the vasoconstrictor and antinatriuretic effects of pressor hormones, especially the renin-angiotensin system. PGE_2 and PGI_2 have antihypertensive activity. PGH_2 and thromboxane A_2 have hypertensive activity (28). In the periphery, PGE_2 is a potent vasodilator. In arterioles there seems to be a tonal equilibrium between prostanoids, which dilate cerebral arterioles, and leukotrienes, which cause constriction (24). The effects of NSAIDs on vascular tone are therefore not simple, since the blocking of the arachidonic pathway decreases synthesis of all these modulators. However, except as outlined above in the setting of the hypoperfused kidney, the effects of NSAIDs on this balance are rarely clinically significant.

Intolerance/Sensitivity

The term *aspirin allergy* has fallen by the wayside. *Aspirin sensitivity* and *aspirin intolerance* are the terms current in the literature.

There are two different types of aspirin sensitivities that are most important. One is the urticaria-angioedema type, which is most commonly seen in patients with chronic urticaria and which has an overall incidence of 3.8%. The other is the bronchospastic type, with bronchospasm often occurring in a triad with severe rhinitis and nasal polyps (polyps being present approximately 50% of the time). Approximately 19% of asthma patients have this type of aspirin sensitivity. In asthma patients with nasal polyps and pansinusitis, the incidence goes up to 40% (29). Consequently, the traditional triad is now sometimes expanded to a tetrad of asthma, rhinitis, nasal polyps, and sinusitis (30).

The mechanism for both types of aspirin sensitivities is related not to an immunologic response mediated by IgE, but probably to the inhibition of COX and the consequent shunting of arachidonic acid metabolism to other pathways. The most important of these appears to be the 5-lipoxygenase pathway, with increased production of leukotrienes (LTB_4, LTC_4, LTD_4, LTE_4) resulting in bronchospasm, increased mucosal permeability and secretions, and neutrophil influx into the tissue (30).

There is cross-sensitivity with all the potent NSAIDs. Severe manifestations, up to and including anaphylaxis, have occurred with the use of some of these agents, so a careful history of sensitivity to aspirin and the aspirin sensitivity tetrad must be ascertained before NSAIDs are prescribed.

Compounds with weak COX activity, on the other hand, are usually tolerated by aspirin-intolerant patients. Acetaminophen, which generally produces only weak inhibition of COX, has been implicated in hypersensitivity reactions in only a small percentage of patients and may be seen as a reasonable alternative to NSAID in aspirin-sensitive patients (31). However, with a sufficiently large dose, a threshold may be reached and the risk of hypersensitivity reactions may increase (32).

Gastric Irritation

Gastric toxicity remains the most common morbidity of the NSAIDs and the major limitation to the use of these drugs in pain and inflammation. Most of the GI effects of NSAIDs are relatively manageable, but complications such as bleeding and perforation may occur and be life-threatening.

Gastric cytoprotection involves multiple mechanisms including adequate mucosal blood flow, epithelial cell renewal, surface active phospholipids, mucus production, bicarbonate secretion, and mediators including PGs, sulfhydryls, interleukin-1, and neuropeptides. Damage caused by NSAIDs probably involves many, if not all, of these mechanisms (33,34).

It has been demonstrated that the local effects of NSAIDs are important factors in gastric irritation and may be additive to the systemic effect of the inhibition of PG synthesis. First, NSAIDs are lipid-soluble, weak organic acids. They are unionized at the low pH of the gastric lumen. In the unionized state they easily penetrate the hydrophilic lipid-protective layer and enter the superficial lining cells of the mucosa. At the higher pH of the intracellular environment the compounds ionize, becoming trapped in the cell (ion trapping). The higher concentration of compound in the cell changes the permeability of the cell membrane, allowing increased influx of hydrogen ions into the cell and resulting tissue damage.

A second form of topical damage is mediated primarily by damage to mitochondria, with uncoupling of oxidative phosphorylation and decreased adenosine

triphosphate formation that results in loss of tight junction integrity, allowing backflow of pepsin and acid through the decreasing protective layer of mucus (34).

These local effects are compounded by NSAID inhibition of COX-1 constitutive synthesis of PGE_2 and PGI_2. In the stomach, these hormones normally act to protect the mucosa by reducing gastric acid secretion, exerting direct vasodilator action on the mucosa, and stimulating the secretion of mucus as a protective physical barrier and the secretion of duodenal bicarbonate to help neutralize excess acid. PGI_2 is also important in inhibiting adhesion between neutrophils and vascular endothelium, which may also be important in the genesis of mucosal injury. NSAIDs suppress the production of both PGE_2 and PGI_2 (33). Aspirin may also suppress the production of NO, which is also an inhibitor of adherence (35). The selective COX-2 inhibitors that are now available may produce less of these systemic aspects of NSAID GI toxicity. There are also drugs either on the market or in trials that are lipoxygenase inhibitors, PG/NSAID combinations (misoprostol/diclofenac), or NO-releasing/NSAID combinations (nitrofenac), all intended to provide adequate antiinflammatory activity with less GI toxicity than traditional NSAIDs (36,37). Aside from new drugs and drug combinations, the use of protectants (sucralfate), PGE analogs (misoprostol), H2 blockers (e.g., ranitidine), and proton pump inhibitors (omeprazole and others) is still helpful in preventing and treating NSAID-induced ulcers (38).

The question of whether gastric irritation caused by NSAIDs creates an avenue for infection by *Helicobacter pylori*, or conversely whether NSAIDs may decrease injury to gastric mucosa by *H. pylori* because of their antiinflammatory effects, has been extensively debated. Currently, the evidence does not seem to support an important relationship between NSAID use and *H. pylori* infection (39).

Anticoagulation

NSAIDs can interfere with platelet function by several mechanisms involving COX. Platelets are the prototype of cells that unequivocally contain COX-1 (9). COX is also found in endothelium. The PG and thromboxane produced in platelets serve both platelet-activating and platelet-inhibiting functions. PGI_2 is of particular interest because it prevents platelet aggregation but not adherence to the endothelium and is therefore important to minor endothelial injury healing (40). PGI_2 and NO produced in endothelium in response to the presence of activated platelets are platelet inhibitors and vasodilators. NSAIDs interfere with the synthesis of all these activating and inhibitory COX-1 products. However, in most cases, the overall clinical effect of NSAIDs is to inhibit coagulation by inhibiting production of thromboxane A_2.

Aspirin is the only NSAID that is used therapeutically for its antiplatelet effects. For most of the NSAIDs, the antiplatelet effect is transitory because it is concentration-dependent; when the serum drug level and thus the level of COX-1 inhibition drop below a threshold point, the antiplatelet effect is nil. With aspirin, however, the antiplatelet effect lasts for the life of the platelet after aspirin exposure, because aspirin irreversibly acetylates platelet and megakaryocyte COX and platelets are unable to synthesize new enzyme.

The net antiplatelet effect of NSAIDs may be useful in some patients who are vulnerable to thrombotic events, but it also creates a risk of excessive bleeding. Regular use of aspirin increases fecal blood loss and the risk of overt GI hemorrhage, especially in the elderly. With respect to perioperative bleeding, studies of NSAID effects have had conflicting results. In many cases, the potential effect on bleeding may be insignificant or outweighed by the risks involved in discontinuing the NSAID before surgery and allowing time for platelets to recover (at least a week for aspirin; hours to days for other NSAIDs). The risks of excessive bleeding are increased in patients with coagulopathies; patients who use alcohol, other anticoagulants, or zidovudine; or patients undergoing surgeries in which even small amounts of excessive bleeding may be harmful, but those risks should be considered carefully in all patients for whom regular NSAIDs are being prescribed (41).

Hepatic Dysfunction

Symptomatic hepatic effects attributable to therapeutic use of most NSAIDs are extremely rare and usually mild (42). There is no clearly established explanation for why some compounds are more hepatotoxic than others. It is possible that some compounds undergo oxidation, probably to the phenylic ring structure, yielding highly reactive metabolites. Compounds that cause mild hepatic damage, such as diclofenac and bromfenac, may produce some reactive epoxides during biotransformation (43). Some caution must be used in prescribing them to those with a history of hepatic dysfunction. NSAID overdose can lead to frank liver failure, especially with phenacetin and acetaminophen.

Uricosuria

Most NSAIDs increase the urinary excretion of urate and many, such as the salicylates, have been used to treat acute and chronic gout. This effect is dose-dependent, with low doses actually inhibiting urate excretion and high doses being necessary for gout treatment.

Central Nervous System Effects

Many NSAIDs cause CNS side effects, including headache, dizziness, and confusion. These can be severe enough to cause patients, especially the elderly, to discontinue treatment. The issue of memory loss with NSAIDs is still being debated. In one study, high-dose NSAID therapy was associated with a decline in longitudinal memory (44). Another study showed an inverse relationship between NSAID use and cognitive decline (45). NSAID use in Alzheimer-type and other dementias is an area that is just beginning to be studied. Some epidemiologic studies have shown a lower-than-expected prevalence or delayed onset of Alzheimer's disease in patients taking NSAIDs. The mechanism may involve COX-2–mediated suppression of microglial activity (46).

There have been reports of depression and paranoia with NSAID use. The mechanism and frequency of these adverse reactions have not been elucidated, but these reports indicate a need for caution in patients with psychiatric or substance abuse disorders.

Effects on Parturition

The inhibition of myometrial contractions during pregnancy depends on an equilibrium among a number of different inhibitors, which may include progesterone, PGI_2, relaxin, parathyroid-related peptide, and NO. Uterine responsiveness during pregnancy is controlled by estrogen and other uterotrophins during early stages and by uterotonins like oxytocin and PGs in later stages. The balance of these compounds may also be important at term, so that if one or more is withdrawn prematurely there may be a predisposition to premature delivery (47). The importance of PG in parturition is suggested by the increase in COX-2–mediated PG production in amniotic fluid at the approach of term, before the appearance of myometrial contractions. COX inhibitors are used to suppress myometrial contractility, thus delaying labor (48).

The closure of the ductus arteriosus is mediated by inhibition of PG synthesis. The constriction and ultimate closure of the ductus arteriosus can be accomplished by the use of potent NSAIDs, indomethacin being the most commonly used (49). With the advent of the COX-2 inhibitors, it may be possible to delay premature labor and close the ductus arteriosus with fewer side effects.

Effects on Dysmenorrhea and Menorrhagia

Primary dysmenorrhea is largely caused by endometrial PG. The endometrium and menstrual fluid of women with primary dysmenorrhea contain significantly higher levels of PG than those of women free of this condition. Three mechanisms have been identified by which PGs cause this type of pain. First, abnormal production of endometrial PG causes abnormal uterine contractility, which may be painful in itself. Second, this abnormal uterine activity can cause decreased uterine blood flow with resulting painful ischemia. Third, the cyclic endoperoxides that are intermediates in PG synthesis, along with relative increases in PGE_2, increase the responsiveness of pain fibers to such stimuli as movement or pressure, bradykinin, or histamine (50).

Most NSAIDs are significantly better than placebo at treating the pain of primary dysmenorrhea. This is at least in part the result of suppression of endometrial PG synthesis, as shown by the close correlation between reductions in pain and reductions in the concentration of PG in menstrual fluid. However, in this as in other types of pain, some of the analgesic effect may be the result of central mechanisms (50).

Menorrhagia is also in some cases the result of abnormal PG production. Specifically, some women with menorrhagia have been found to have elevated levels of PGI_2 metabolites compared to unaffected women. Since PGI_2 is a vasodilator that relaxes uterine smooth muscle and inhibits platelet aggregation, it is easy to see how abnormally elevated PGI_2 levels could contribute to menorrhagia. Studies have shown that women with menorrhagia may lose as much as 30% to 50% less blood

when they are treated with NSAIDs, such as ibuprofen, naproxen, or mefenamic acid, compared to treatment with placebo (50).

Prevention of Cancer

A number of studies have indicated a connection between NSAID use and decreased risk of colorectal cancers (51,52). The use of NSAIDs as a preventative measure for colorectal cancer is being studied and seems promising, but the appropriate dose and duration are still in question (53). COX has also been shown to be induced by polycyclic aromatic hydrocarbons, which thereby accelerate their own COX-mediated oxidation to more potently oncogenic compounds (54). COX-2 inhibitors may ultimately have a role in cancer prevention and treatment. Evidence is also accumulating that PGs produced by COX-2 are important to the growth and survival of many malignancies. PGs are known to affect mitogenesis, cellular adhesion, and apoptosis. There is evidence that some PGs enhance immunosuppressive effects of tumor cells. Some cancers, including cancers of the head and neck, breast, lung, and colon, form more PGs than normal tissues (55). A connection has been made between the activity of COX-2 and the development of colorectal cancer (53). The overexpression of COX-2 is associated with a resistance to apoptosis, and in one study this resistance was reversed by sulindac (56). If the risk of cancer may be increased by chronic inflammation via overexpression of COX-2, then the risk may be diminished by the use of prophylactic COX-2 inhibitors. With the advent of the selective COX-2 inhibitors, the use of NSAIDs in the treatment of cancers may turn out to be safe and effective.

PHARMACOKINETICS AND PHARMACODYNAMICS

Absorption

All NSAIDs and acetaminophen are readily absorbed from the upper intestinal tract and are generally given as oral preparations. Some absorption can also occur from the stomach, particularly if the pH is low. These drugs are also absorbed through any mucous membrane, so acetaminophen, aspirin, and many other NSAIDs can be given in suppository form, although this is done primarily with acetaminophen and aspirin for their antipyretic effect. The plasma concentration after oral administration reflects adequate oral dosage within 30 minutes and reaches a peak in approximately 2 hours. It gradually declines thereafter, depending on the half-life of the agent.

Physiochemical Properties

The NSAIDs are generally extensively plasma protein–bound (90% to 99%). The binding to other proteins and tissues varies between compounds. The exception is acetaminophen, which is only approximately 20% bound. NSAIDs are highly metabolized in the liver, with the exception of azapropazone and nabumetone, which are only 40% metabolized. Metabolism of NSAIDs in some cases serves to activate and in others to inactivate the compound and usually consists of hepatic conjugation to sulfuric or glucuronic compounds that return to the plasma. Small amounts of drug can be conjugated in other body tissues as well, but these amounts are insignificant. Most of the NSAIDs are acidic compounds. A few, such as azapropazone, are amphiprotic, having two ionizable sites.

Another property of interest is the chirality of some compounds, mostly the propionic acid derivatives or “profens,” ketorolac and etodolac. These compounds have a chiral center. Although they are used as racemates, the absorption, distribution, metabolic conjugation, and ultimate elimination of these molecules are stereospecific. In each case, the S-enantiomer is a much more potent COX inhibitor than the R-enantiomer. Conversion of the inactive R-enantiomer to the active S-enantiomer occurs unidirectionally *in vivo*, with the extent of the conversion varying between drugs and individuals. This may be part of the reason why the plasma concentrations of the profens (except naproxen, which is formulated as a pure active S-enantiomer) do not correlate well with effect, since both enantiomers are lumped together in ordinary measurements of serum concentration (57).

Distribution

Most NSAIDs and acetaminophen are rapidly (although unevenly) distributed throughout all body tissues by passive processes. The more lipid-soluble drugs have more CNS effects, both positive and negative. Because they are highly plasma protein–bound, the plasma concentrations are much higher than in other tissues. With ionization constants (pK_a) of most of the drugs being in the range of 3 to 5, pH is important to distribution (19,58).

One area of distribution that is of particular interest is the synovial fluid. The effective therapy of inflammatory conditions depends on getting the active form of drug (active metabolite, free fraction, or active enantiomer) to the tissue being targeted. In the case of arthritis, the target is the joint and the data show that NSAIDs seem to act primarily by inhibiting COX-2 in the synovial fluid. The synovial expression of COX-2 is different among inflammatory diseases with differing degrees of synovial inflammation (59). Uptake of NSAIDs into the synovial fluid occurs by a process of limited diffusion, which is affected by a number of physical and chemical properties (60). The half-life of NSAIDs in the synovial fluid parallels that in plasma.

Time Course of Effects

The relative time course of NSAID effects does not always follow the same curve as relative half-life. One possible explanation for this phenomenon is that different agents have different modes of COX inhibition.

A number of NSAIDs are reversible competitive inhibitors of both isoforms of COX (e.g., ibuprofen). A few are irreversible competitive inhibitors that covalently modify the enzyme (e.g., aspirin). For a third category, the course of action is more complex. These NSAIDs (e.g., flurbiprofen and indomethacin) are time-dependent inhibitors of COX-1 and COX-2 that show an apparent slow increase in the potency of inhibition over time. It appears that they initially form a reversible enzyme-inhibitor complex that subsequently becomes a less reversible complex, probably due to a change in conformation. There have been reports that some of the COX-2–selective compounds may be selective because of differences in the time-dependence of the inhibitor-enzyme complexes they form with COX-1 and COX-2. They may be weak competitive inhibitors of COX-1 and slow time-dependent inhibitors of COX-2. What this means clinically needs more study (61).

Excretion

All nonopioid analgesics are excreted primarily in the urine, both in free and in conjugated form. The relative concentrations of the free and conjugated forms vary with the pH of the urine, with higher concentrations of the more acidic form being found in alkalinized urine. Small amounts of these drugs are also found in the bile and thus pass into the intestine to be excreted in the feces.

CLASSIFICATION OF NONSTEROIDAL ANTIINFLAMMATORY DRUGS

A number of different classification schemes for NSAIDs have been suggested based on various clinical and pharmacologic features. One is to classify them according to their ability to inhibit COX-1 or COX-2, either in absolute terms or as a ratio between the two. Various attempts to create such a classification have yielded very different absolute measurements of inhibitory power, but similar results when rank-ordering the drugs according to their COX-2/COX-1 ratios. However, there are still too many variables for this classification scheme to be consistent enough to be useful (62).

Another potential way of classifying NSAIDs is by their mode of inhibition, as discussed previously under Time Course of Effects. Classification by serum half-life is of limited value because of the lack of correspondence between serum half-life and effect half-life. Classification according to acidity of the compound, which influences absorption, distribution, and side effects, is also not very helpful because so few of the NSAIDs are nonacidic at this time.

Chemical classification (Table 83-1), old-fashioned as it may be, remains the most useful way of sorting these drugs into groups with similar clinical properties and is used to organize the following discussion of individual drugs.

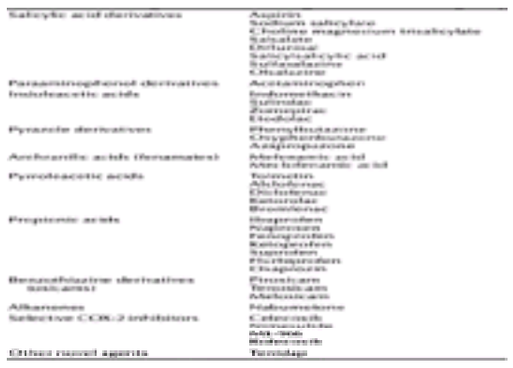

TABLE 83-1. Classification of nonsteroidal antiinflammatory drugs

PHARMACOLOGY OF INDIVIDUAL DRUGS

Salicylates

Aspirin

Aspirin is reviewed in detail here as the prototypic salicylate, but individual characteristics of other drugs of this class are also discussed. Table 83-2 and Table 83-3 outline their classification, pharmacokinetics, pharmacology, and adverse effects.

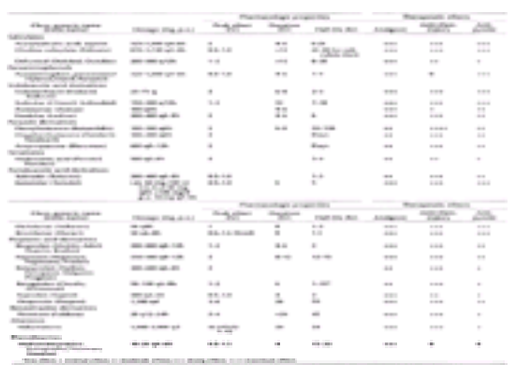

TABLE 83-2. Nonopioid (nonnarcotic) analgesics: classification, pharmacokinetics, and pharmacology of nonopioid analgesics

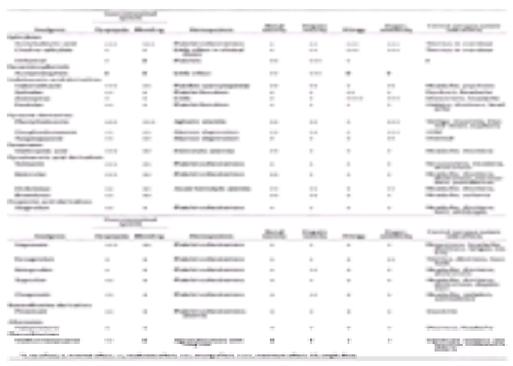

TABLE 83-3. Nonopioid (nonnarcotic) analgesics: adverse (toxic) and other physiologic effects of nonopioid analgesics

Pharmacology. Aspirin is probably the most widely used analgesic. It has strong antipyretic and antiinflammatory properties in addition to its analgesic effects. Aspirin covalently acetylates the active site of COX, irreversibly inhibiting the enzyme. Its clinical effects are all probably based on central and peripheral inhibition of PG production. The analgesic effect is primarily a peripheral effect, although a central action has been hypothesized, possibly in the hypothalamus.

Analgesia is most effective for mild to moderate pain arising from integumental structures rather than from the viscera. Aspirin is effective in relieving moderate to severe bone pain. It is also commonly used for its platelet-inhibiting effects to reduce the risk of myocardial infarction and stroke.

Aspirin is absorbed rapidly from the stomach and upper small intestine when taken orally, with peak plasma levels being reached in approximately 2 hours. It is approximately 70% converted to salicylate in approximately 30 minutes. The rate of absorption depends on multiple factors, including disintegration time and dissolution rate of tablets and pH of the surface of the mucosa. The dissolution time is the rate-limiting step in the process and is the target for different preparations. Rectal absorption is slower and is variable depending on retention time.

This compound is distributed throughout most body tissues by a passive pH-dependent process. It is bound to plasma proteins, especially albumin. This may be a cause for concern in hypoalbuminemic states such as those seen in rheumatoid arthritis. Its interactions with other highly bound medications are variable.

Metabolism occurs primarily in the liver, and excretion is through the urine and feces in conjugated forms. The plasma half-life for aspirin is approximately 15 minutes. For salicylate, one of its metabolites, the plasma half-life is 2 to 3 hours for low doses and up to 30 hours for high doses (63). Changes in urinary pH result in profound changes in excretion. The higher the pH, the greater the excretion rate (64).

Side Effects. The primary side effects of salicylate ingestion are epigastric distress, nausea, and vomiting. All salicylates can produce GI hemorrhage, exacerbation of peptic ulcer disease, and erosive gastritis. Chronic aspirin ingestion can produce iron deficiency anemia through blood loss from the GI tract. GI problems are usually dose-related but can be seen as a hypersensitivity response at low doses. Self-limiting and reversible changes of liver function can occur with high doses of aspirin (38). Bleeding time is prolonged with even small doses, and a single dose of aspirin can double the bleeding time for up to 1 week. Aspirin should therefore be avoided in patients with liver damage, hypoprothrombinemia, vitamin K deficiency, or hemophilia.

Salicylate intoxication is marked by CNS disturbances and significant alterations in acid–base balance and can be fatal.

Another complication of aspirin therapy is the hypersensitivity response, which was discussed in more detail previously. Briefly, it is more common in adults than in children, and a previous history of hypersensitivity to other chemicals or the tetrad of asthma, rhinitis, nasal polyps, and sinusitis are warning signs. An acute anaphylactoid response, which can be fatal, can also be seen with small doses of aspirin.

The use of salicylates in viral syndromes has been epidemiologically associated with Reye's syndrome, a two-phase illness that occurs predominantly in children and

adolescents. The first phase is a viral illness, most frequently influenza or chickenpox, which includes fever, vomiting, general malaise, or upper respiratory symptoms. At 3 to 5 days from onset of the viral illness, there is onset of vomiting and a change in neurologic state, probably caused by cerebral edema and hepatic dysfunction with a resulting increase in ammonia levels. Encephalopathy may persist for 1 to 4 days with a slow return to premorbid neurologic function over a number of weeks. It is not clear whether salicylates cause Reye's syndrome and, if so, by what mechanism, but it has been proposed that these drugs may act together with certain viruses to damage mitochondria in susceptible individuals. It has been suggested that after a viral illness, individuals who have a preexisting genetic or metabolic defect in metabolism may experience a higher than usual concentration of calcium in the mitochondria, which with the addition of salicylates could set the proposed reaction into motion. This reaction has been called *mitochondrial permeability transition* and is thought to involve mitochondrial swelling, depolarization, and the uncoupling of oxidative phosphorylation (65).

Aspirin is probably the most nephrotoxic of the NSAIDs. The nephrotoxicity of phenacetin/aspirin combinations, which was at one time attributed to phenacetin, may well have been due to aspirin. The combination of other analgesics with aspirin may synergistically exacerbate aspirin's nephrotoxicity (12). Such combinations should be used with caution, if at all.

Choline Magnesium Trisalicylate

Choline magnesium trisalicylate is a mixture of choline salicylate and magnesium salicylate. Its analgesic, antipyretic, and antiinflammatory properties are similar to those of aspirin. It does have some different properties, however, that can make it preferable to the more commonly used aspirin. It is water-soluble and thus is available in both tablet and liquid forms, making it more convenient for pediatric use. It has a much longer half-life than aspirin and can be prescribed on a once- to twice-daily basis, resulting in better compliance with the therapeutic course.

At therapeutic doses, choline magnesium trisalicylate does not demonstrate significant inhibition of platelet aggregation and can be used in circumstances in which the bleeding potential of aspirin is a problem (e.g., in patients with a bleeding diathesis or who are in the perioperative period). Because it is water-soluble, it causes significantly less irritation of the gastric mucosa, so it is often tolerated by those in whom gastric irritation precludes aspirin use.

Diflunisal

Diflunisal is a difluorophenyl derivative of salicylic acid marketed primarily as an analgesic. It is not a clinically useful antipyretic, probably because it does not cross into the CNS (66). It has an 8- to 12-hour half-life, but it also shows a gradual increase in drug levels over time with continued use. This means that dosing is necessary only twice a day but that a loading dose is necessary to reach effective plasma concentrations.

Diflunisal is less irritating to the GI tract than aspirin and also has much less effect on platelet aggregation, its effects being readily reversible on discontinuation of the medication. A potentially life-threatening hypersensitivity reaction has been reported, with fever, chills, and rash followed by progression to multiple organ involvement. This reaction has not been seen with other salicylates (67).

Paraaminophenol Derivatives

Acetanilid, a parent compound of paraaminophenol derivatives, was introduced as an antipyretic in 1886. Derivatives were synthesized because of its toxicity, and phenacetin was ultimately introduced as an analgesic-antipyretic. Acetaminophen (paracetamol) was identified as phenacetin's active metabolite in humans, and it is now the most common derivative of paraaminophenol in use. Phenacetin was removed from the market because of the high correlation found between its use and nephrotoxic effects.

Acetaminophen (Paracetamol)

Pharmacology. Acetaminophen (like phenacetin) has analgesic and antipyretic effects similar to those of aspirin. Acetaminophen appears to act as a PG synthesis inhibitor, but it seems that its effect is more pronounced centrally than peripherally (68). Perhaps this is why it is more specifically antipyretic than antiinflammatory, but it also suggests that the analgesic activity of all NSAIDs may be related to central activity as well as to peripheral antiinflammatory effects.

Absorption from the stomach is minor. Most of the drug is absorbed by passive diffusion in the small intestine, making the rate of absorption dependent on the rate of gastric emptying. Acetaminophen's plasma half-life is approximately 2 hours.

This mild systemic analgesic is often combined with weak opioids in compounds for the relief of mild to moderate pain. It is recommended as an antipyretic and can be used for those sensitive to aspirin and for children and adolescents, in whom Reye syndrome is associated with aspirin treatment for fever.

Side Effects. Toxic effects are rarely seen in individuals who adhere to recommended therapeutic doses, which are limited to a maximum of 4 g per day. When phenacetin was available, toxic effects from therapeutic doses appeared in individuals who could not metabolize the compound to acetaminophen.

The major toxicity of acetaminophen is on overdose, especially acute overdose (>;10 to 15 g). Nephrotoxicity, thrombocytopenia, and hepatic toxicity are the primary toxic side effects of acute or chronic overdose of phenacetin or acetaminophen. Methemoglobinemia and hemolytic anemia, although common with high doses of phenacetin, are rarely seen with acetaminophen.

The mechanism for damage by acetaminophen is through a highly reactive metabolite that normally is inactivated by glutathione. Overdoses of acetaminophen deplete glutathione stores, allowing the metabolite to accumulate and bind covalently to cell constituents. In severe cases, the result may be acute hepatic necrosis, which can progress to fulminant liver failure (69).

The combination of aspirin and phenacetin was once thought to be the cause of analgesic nephropathy, and there has been concern that acetaminophen could have similar toxicity (69). However, studies have shown that acetaminophen is unlikely to contribute to analgesic nephropathy. Aspirin and the salicylates, on the other hand, are more clearly nephrotoxic (70). Combinations of aspirin with acetaminophen or other analgesics may act synergistically to increase this potential toxicity (71). Since such combinations have not shown any advantage over either drug alone, they should be avoided.

Indoleacetic Acid Derivatives

Indoleacetic acid derivatives were synthesized after a search for drugs with antiinflammatory properties. The initial product was indomethacin, introduced to clinical care in 1963 specifically for the treatment of rheumatoid arthritis. Other compounds with less toxicity than indomethacin have been found, and it is likely that this group of compounds will yield more useful medications in the future (72).

Indomethacin

Pharmacology. Indomethacin has prominent analgesic, antiinflammatory, and antipyretic properties, similar to those of aspirin. Because it is one of the most potent inhibitors of COX, it is used primarily for its antiinflammatory properties in the treatment of rheumatologic disease. Additionally, after aspirin it is one of the analgesic drugs of choice for the initial treatment of pain associated with metastatic disease of bone (73). It is also a uricosuric and is used to treat acute gout. Once control of target symptoms has been attained with indomethacin, a less toxic NSAID should usually be substituted.

Side Effects. A high incidence of untoward side effects has been noted with the use of indomethacin (67), and approximately 20% of patients are intolerant of this medication. GI complaints, including nausea, anorexia, and abdominal pain, are common. Ulceration can occur anywhere in the upper GI tract, with perforation and hemorrhage. Acute pancreatitis has been reported, and rarely, fatal hepatitis and jaundice have been seen (74). Indomethacin can cause sodium and water retention; it also antagonizes the effects of diuretics and the antihypertensive effects of propranolol (70). It can produce severe headache and has also been implicated in the production of depression, psychosis, hallucinations, and suicide. Bone marrow depression and, rarely, aplastic anemia can occur with long-term administration. A hypersensitivity reaction similar to that noted with aspirin can occur, and some cross- sensitivity can be present. Because of the severity of some of these side effects it is recommended that indomethacin be used as tolerated over a limited period (e.g., 2 weeks) and that other less toxic compounds be substituted when the pain,

inflammatory process, or both, are under control.

Sulindac

Sulindac is closely related to indomethacin and was produced as an alternative with less toxic side effects (52). It is used primarily for the treatment of rheumatologic problems.

Sulindac is a prodrug (i.e., an inactive chemical that is metabolized to an active compound). Its sulfide metabolite is a potent inhibitor of COX. This probably accounts for sulindac's low rate of GI side effects, because the active drug does not appear in the GI tract.

Toxic effects are nevertheless primarily GI but are not severe and are restricted mostly to abdominal pain, nausea, and constipation. Drowsiness, dizziness, and headache can also occur. Skin rash and pruritus have also been reported. Some cross-sensitivity to aspirin can occur, with possible similar manifestations.

The best evidence linking an NSAID with liver disease is with sulindac. There are a number of reports in which hepatitis was seen on rechallenge, suggesting some sort of causal relationship (75).

Zomepirac

Zomepirac was produced from the indoleacetic acid molecule and is primarily an analgesic agent (72). It has antiinflammatory and antipyretic properties, but these, especially the former, are not pronounced; the antiinflammatory effects are far weaker than in other compounds of this class.

Zomepirac displays a low tendency to produce GI and hemopoietic side effects. It has been discontinued in North America, however, because of a relatively high incidence of fatal allergic responses associated with its use.

Etodolac

Etodolac is a chiral NSAID marketed as the racemate. It and its acylglucuronide metabolite are well distributed into synovial fluid (76). Etodolac appears to inhibit COX-1 and COX-2 equally well. It also inhibits the formation of bradykinin, which may add to its activity as an analgesic. It is used in rheumatoid arthritis, osteoarthritis, tendonitis, and bursitis as an analgesic and antiinflammatory. It has been used long term (>1 year) with few problems. It is a uricosuric and also has been used in acute gout (52).

Etodolac is well tolerated and causes less GI irritation and ulceration than a number of other compounds. This may be because of a minimal effect on PGE_2 and PGI_2 in gastric mucosa (62).

Pyrazole Derivatives

Pyrazole derivatives were originally introduced as antipyretics in the late nineteenth century. They were then found to have analgesic and antiinflammatory properties and came to be used for these as well. The two most common forms, antipyrine and aminopyrine, were used extensively and appeared in many over-the-counter medications until it was discovered that aminopyrine caused severe bone marrow toxicity. In 1938, aminopyrine was prohibited for use in the United States. Pyrazole derivatives interfere with PG synthesis by inhibiting COX, and this appears to be the basis for their antipyretic, analgesic, and antiinflammatory effects. They also induce hepatic microsomal enzyme systems and thus increase biotransformation of many other drugs.

Phenylbutazone

The introduction of phenylbutazone was somewhat accidental. It is a congener of antipyrine and aminopyrine and was used originally as a solubilizing agent for aminopyrine. When these compounds were withdrawn from clinical use, a search for pharmacologic relatives yielded phenylbutazone as a possible therapeutic agent.

Phenylbutazone has analgesic, antiinflammatory, and antipyretic properties. In addition to inhibiting the synthesis of PG, it inhibits the synthesis of mucopolysaccharide sulfates in cartilage and uncouples oxidative phosphorylation. All of these actions probably contribute to its antiinflammatory, antipyretic, and analgesic effects. It is more effective than aspirin as an antiinflammatory agent but less effective as an analgesic. It is used only for short-term acute gouty arthritis, active rheumatoid arthritis, active ankylosing spondylitis, and acute attacks of osteoarthritis of hips and knees where there is no other option. It should not be used when other less toxic agents are available (67).

Phenylbutazone has a short half-life and requires multiple daily dosing.

Although its primary untoward effects are GI, CNS effects are seen in a small number of individuals. The most important adverse effects are primary or activated ulcer disease, serum-sickness-type hypersensitivity, hepatitis, nephritis, and various forms of bone marrow depression, which can lead to aplastic anemia and agranulocytosis. These toxic reactions are more often seen in elderly individuals, and thus phenylbutazone should not be used in this population. Approximately 60% of the patients who develop hepatic injury from phenylbutazone do so within 6 weeks. Phenylbutazone should therefore be used only in the unusual case in which no other alternative is available, and only for the shortest possible time to minimize the risk of hepatic injury.

Oxyphenbutazone

Oxyphenbutazone is a metabolite of phenylbutazone and is primarily an antiinflammatory, but it can be used for its analgesic and antipyretic effects. It is more highly protein-bound than its parent compound and has a plasma half-life of up to several days. This gives it some possible advantages in that effective serum concentrations can easily be maintained.

Oxyphenbutazone tends to produce less gastric irritation than phenylbutazone and is more readily tolerated by some individuals.

Azapropazone

Azapropazone is another derivative of phenylbutazone and has similar activity. Its pharmacokinetics are similar to those of phenylbutazone but unlike the parent compound it is not extensively metabolized. It is excreted unchanged in the urine at a rate of 60% to 70%. It is used primarily for the treatment of rheumatic conditions, not as an analgesic. It has a potent uricosuric effect, so it is useful for treating acute gout.

Azapropazone has significantly fewer side effects than phenylbutazone and has low toxicity. The overall incidence of untoward reactions is probably lower than 10%. No cases of agranulocytosis have been reported to be associated with its use.

Anthranilic Acids (Fenamates)

The fenamates were discovered in the continual search for “a better aspirin.” The amine analog of salicylic acid and anthranilic acid was investigated, and a number of compounds derived from it were studied as analgesics, antiinflammatory agents, and antipyretics. Because of the toxicity of most of these compounds, few are now available for clinical use.

Mefenamic Acid

Mefenamic acid is a COX inhibitor. It may also act as a PGE_2-receptor antagonist, as it competes for PG-receptor binding sites *in vitro* (68). It has been proposed for use primarily for its analgesic properties in rheumatic diseases, but it can also reduce pain in soft tissue injuries, other painful musculoskeletal conditions, and

dysmenorrhea (77). However, due to toxicity it is rarely if ever indicated for these conditions.

In addition to a significant number of GI adverse effects, isolated cases of hemolytic anemia that might be of autoimmune origin have been reported with the use of mefenamic acid. In view of its toxicity and the fact that this drug offers no advantage over other available agents, it should not be used.

Pyrroleacetic Acid Derivatives

In the search for a molecule that would maintain antiinflammatory and analgesic efficacy with fewer side effects than current agents, elaboration on pyrroleacetic acid resulted in the discovery of tolmetin sodium in the mid-1970s and other compounds subsequently (78). However, as with most other families of compounds produced to date, clinical effectiveness in this class came only with the usual side effects and toxicity.

Tolmetin

Tolmetin has antiinflammatory effects somewhere between those of aspirin and phenylbutazone (78). It is structurally related to zomepirac. It also appears to interfere with the PG cascade to produce its antiinflammatory effects. It has good antipyretic and analgesic actions, although it is not primarily prescribed as an analgesic. Its main use as an antiinflammatory agent has been for rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis.

Overall, in clinically effective doses, the incidence of side effects is slightly lower than with aspirin and significantly lower than with phenylbutazone. Peripheral edema, sodium retention and hypertension have occurred. Each 200-mg tablet of tolmetin contains 0.8 mEq of sodium, a fact that should be considered in patients who require strict sodium restriction.

Alclofenac

Alclofenac is a new compound that is similar to tolmetin but is slightly less effective in terms of its antiinflammatory effects. It is not presently available in North America.

Diclofenac

Pharmacology. Diclofenac is a potent nonselective inhibitor of COX, but it does have a favorable ratio of COX-2 to COX-1 inhibition and so may provide antiinflammatory effects with less toxicity (79). It also may reduce the migration of leukocytes into sites of inflammation by causing them to shed l-selectin, an adhesion receptor involved in the initial binding of leukocytes to activated endothelium. Aspirin, indomethacin, and ketoprofen also appear to share this property (80). This may be another reason for the wide range of variability in NSAID effectiveness.

The bioavailability of diclofenac is 60% lower than many other NSAIDs due to significant presystemic elimination (81).

Diclofenac is commonly used for osteoarthritis, rheumatoid arthritis, and gout. It is also used in an ophthalmologic preparation for cataract surgery to maintain pupillary dilatation (82).

Side Effects. GI side effects are the most common ones reported. Elevation of hepatic aminotransferases occurs in approximately 15% of users and is usually reversible. There have been a number of case reports of hepatitis from diclofenac. In two cases, rechallenge led to hepatotoxicity. It is still not clear that diclofenac is more hepatotoxic than other NSAIDs, but the recommendation is that aminotransferases be evaluated during the first 8 weeks and that the drug be discontinued if abnormal levels persist or if there are any signs of overt liver injury. Impaired clearance of a metabolite may be the problem (75).

Ketorolac

See Table 83-4 for dosage guidelines for ketorolac.

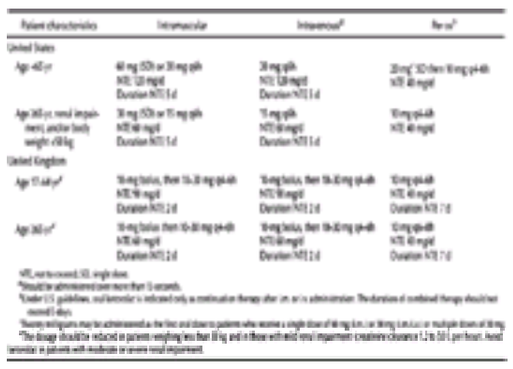

TABLE 83-4. Ketorolac dosage guidelines for the United States and United Kingdom

Pharmacology. Ketorolac is a potent analgesic, but its antiinflammatory activity is only moderate. However, because potential toxicity limits ketorolac to short-term use, actions other than analgesia are less important. Ketorolac may cause analgesia through some central opioid-related effect, the release of endogenous opioids, a modulatory effect on opioid receptors, or altered opioid kinetics. Another theory is that it influences NO, which in turn is thought to have an effect on COX (83).

Ketorolac's primary use is as an analgesic for mild to moderately severe acute pain states. The analgesia from ketorolac is delayed but lasts longer than that of the standard opioids. Combining it with opioids can allow opioid doses to be reduced by 25% to 50%, thus reducing opioid side effects. Ketorolac has been used for renal colic, migraine, sickle cell crisis, postoperative pain, and gynecologic surgery.

Ketorolac is available as a tromethamine salt, which enhances its aqueous solubility and makes it one of the few NSAIDs available in parenteral as well as oral forms. It also has antiinflammatory activity topically and is available as an ophthalmic preparation.

Maximum plasma concentrations are reached 30 to 60 minutes after intramuscular, subcutaneous, rectal, or oral administration. The half-life is approximately 5 hours in normal subjects and increases in the aged and renally impaired up to 6 to 7 and 9 to 10 hours, respectively.

Side Effects. The long-term use of ketorolac is not recommended because of an increased risk of adverse effects. The largest number of reported adverse effects are GI and hematologic. GI ulceration occurs most often in stomach and duodenum but colonic ulcers have also been found, suggesting a systemic effect. A postmarketing study of GI and operative-site bleeding found a correlation between risk of bleeding, age, drug dosage, and duration of therapy. There have also been cases of reversible nephropathy after even short-term parenteral treatment.

Bromfenac

Bromfenac is a phenylacetic acid derivative related to diclofenac. It was approved by the U.S. Food and Drug Administration in 1997 and is indicated for short-term management of pain, usually less than 10 days. It is a potent analgesic with rapid onset (30 minutes) and duration of action of approximately 8 hours. The compound has been studied against ketorolac, naproxen, and acetaminophen/oxycodone combinations and has shown efficacy.

The side-effect profile is equivalent to other drugs in the class, with GI upset and headache being the most common. It also carries a warning about severe hepatic

reactions, usually in patients taking the drug for longer than 1 month (84). It was removed from the market in mid-1998 due to liver toxicity.

Propionic Acid Derivatives

The search for new aspirinlike compounds has been most successful among compounds of the propionic acid family, which offer advantages over many older antiinflammatory analgesic compounds. In fact, some of these agents, such as ibuprofen and suprofen, are now marketed primarily as analgesics. They were introduced in the early 1970s, and newer compounds of the group continue to appear. This causes some difficulty for the practitioner because heavy promotion by pharmaceutical firms makes it difficult to identify which drugs are more beneficial than other nonopioid analgesics.

Propionic acid derivatives all have effective antiinflammatory, analgesic, and antipyretic activity. They all act by inhibiting COX and interfering with PG synthesis, although with widely varying potency from one agent to another. As would be expected, they produce GI side effects, cause GI erosion, alter platelet function, and produce prolonged bleeding times.

The compounds in this class, along with ketorolac and etodolac, are chiral drugs. Although marketed as racemic mixtures, there are differences in the activity and pharmacokinetics of different isomers. The NSAIDs in which this has been primarily studied are the two arylpropionic acids and ketorolac (85). Stereoselectivity has been shown to occur in conjugation reactions and in elimination. A unidirectional stereospecific inversion of inactive R-enantiomer to the active S-enantiomer occurs *in vivo* and is variable. The amount of conversion depends on drug and interpatient differences (7,20,85).

Ibuprofen

Ibuprofen is the most widely used of this class of compounds. It is now available as an over-the-counter preparation in North America (e.g., Nuprin, Datril, Advil) and as a suspension (e.g., Pedia-Profen). Ibuprofen is rapidly absorbed from the upper GI tract and is also available in suppository form as it is well absorbed rectally, although at a slower rate. It is 99% plasma protein–bound and passes slowly through the synovium, the site of greatest importance in the treatment of rheumatologic diseases. It is used equally as an analgesic and antiinflammatory and, although not advertised as such, also has antipyretic properties (67).

Ibuprofen has been approved for cautious administration in people with peptic ulcer disease, but its use is not advised when active untreated ulcers are present. A low incidence of other side effects is associated with its use.

Naproxen

Naproxen is readily absorbed from the GI tract when taken either orally or rectally. Uptake is rapid, but absorption of orally administered drug can be slowed by concomitant ingestion of food, aluminum hydroxide, or magnesium oxide or increased by ingestion of sodium bicarbonate. Naproxen has a long half-life in plasma of 12 to 15 hours; this is a factor in its popularity because it can be given two times a day.

Naproxen is somewhat more toxic than ibuprofen, having more GI and CNS effects. The CNS uptake of the drug is good enough that it is one of the first-line NSAIDs in migraine. There are rare reports of clinical liver disease. In the cases in which jaundice occurred, resolution was rapid and complete (75).

Fenoprofen

Fenoprofen is more often used for rheumatologic problems than as an analgesic (86). It is extremely well tolerated as compared to other nonopioid analgesics.

Ketoprofen

Ketoprofen is used primarily as an antiinflammatory agent in the treatment of rheumatic disease. Like some other NSAIDs, it may affect adhesion molecules and bradykinin (64). The primary side effect is GI disturbance, which occurs in approximately 15% of patients, causing discontinuation in approximately 5%.

Suprofen

Suprofen is the first of the propionic acid derivatives to be presented primarily as an analgesic, although it shares antiinflammatory and antipyretic properties with other compounds of its class (87). Its use has been associated with flank pain thought to be caused by uricosuric activity, and the oral drug was consequently removed from the North American market. The ophthalmologic preparation used for inhibition of intraoperative miosis is available in the United States (29).

Flurbiprofen

Flurbiprofen is one of the most potent of this NSAID class. It has been marketed most heavily for such unusual indications as periodontal disease, in which it (and other NSAIDs) have been found to reduce bone loss (88). Like suprofen and diclofenac, it is also marketed as an ophthalmic solution for prophylactic inhibition or reduction of intraoperative miosis. PG and other substances (substance P) appear to mediate contraction of the pupillary sphincter in response to surgical manipulation. This type of miosis is independent of the cholinergic receptors, and flurbiprofen does not interfere with the miotic effect of acetylcholine when this is administered to induce desired miosis intraoperatively (89).

Oxaprozin

Oxaprozin has a half-life of approximately 55 hours, making it the only propionic acid derivative that can be given once daily. It is well absorbed orally, with peak concentrations in 3 to 6 hours, which may be a disadvantage in acute pain. It has saturable protein binding, which may give it an advantage over other long half-life NSAIDs (e.g., piroxicam) in that it may be less likely to accumulate. It is also a uricosuric (16).

It is used for treatment of many painful inflammatory conditions such as osteoarthritis, rheumatoid arthritis, gouty arthritis, and other acute and chronic conditions such as tendonitis and bursitis (67).

Oxaprozin is well tolerated. The most frequently reported side effects are GI and mild CNS effects.

Benzothiazine Derivatives (Oxicams)

The benzothiazine derivatives are the latest class of chemical compounds to be studied for their combined analgesic, antiinflammatory, and antipyretic effects. They were introduced to the North American market in 1982 (90).

Piroxicam

Piroxicam is one of the oldest and most studied of the oxicams. It is used as a standard in numerous studies. Its long half-life and its relative COX-1 specificity make it theoretically not an ideal drug for short-term patients with other risk factors for toxicity.

Piroxicam is completely absorbed when given orally, and concomitant ingestion of food and antacids does not affect absorption. It is used primarily for arthritis and acute musculoskeletal injuries because of its combined analgesic and antiinflammatory effects. It has the advantage of a long half-life (50 hours), permitting once- or twice-daily dosing for improved compliance.

Up to 40% of patients experience GI side effects. These are severe enough to cause discontinuation of the drug in only approximately 10% of patients.

Tenoxicam

Tenoxicam is a derivative of the oxicam class. It has been studied in acute and chronic rheumatic diseases for analgesia and antiinflammatory activity. It affects leukocyte function and may affect oxygen radicals.

It is completely absorbed in 1.0 to 2.6 hours, which can be delayed to 4 to 6 hours by food, and has an elimination half-life of 60 to 75 hours. The long half-life is an advantage in chronic conditions, allowing once-daily dosing. It is one of the least lipophilic of the NSAIDs, which may decrease its risk of side effects in certain tissues such as CNS, fat, and skin. It has good penetration into synovial fluid, which may be the site for its activity in chronic inflammatory diseases.

Tenoxicam is comparable to piroxicam with respect to effectiveness and side effect profile. It is not marketed in the United States at this time.

Meloxicam

Meloxicam is a selective COX-2 inhibitor, with some COX-1 activity. At this time it is in late phase III trials and is not available in the United States. After oral dosing, the half-life of meloxicam is approximately 20 hours and its time to maximum concentration is 5 to 6 hours. There is also a parenteral form. Meloxicam is metabolized in the liver and the metabolites are excreted in urine and bile.

This drug has been studied in rheumatic diseases and found to be as effective as the NSAIDs to which it was compared (piroxicam, diclofenac, and naproxen) (91). These same studies showed that meloxicam, compared to a group of standard NSAIDs, caused fewer GI and renal side effects (92).

Alkanones: Nabumetone

Nabumetone is a member of another new class of NSAIDs, the alkones. It is a nonacidic prodrug that weakly inhibits COX. The metabolite 6-methoxy-2-naphthylacetic acid (6-MNA) is a potent inhibitor of COX. It is not known which COX 6-MNA inhibits in humans, but there is some evidence in animals that it might be COX-2–specific.

Because nabumetone is then metabolized into inactive metabolites that are excreted in the urine, there is no biliary excretion and no enterohepatic recycling. This fact, along with nabumetone's status as a nonacid prodrug, gives it a lower propensity for causing GI side effects. This has been borne out in a number of studies comparing it to naproxen and ibuprofen (93).

Nabumetone's reported side effects are still most commonly GI, but they are minor, usually involving abdominal pain, dyspepsia, diarrhea, and flatulence. Although there are GI side effects reported at comparable levels to diclofenac, ibuprofen, naproxen, and sulindac, there is little evidence to show that there is much GI toxicity (94).

Selective Cyclooxygenase-2 Inhibitors

Celecoxib

A number of new compounds are undergoing trials. Celecoxib is a nonacidic tricyclic selective COX-2 inhibitor that shows promise in rheumatoid conditions and pain. It has recently been released in the United States, as has Rofecoxib, a drug with similar characteristics.

Nimesulide

Nimesulide is a sulfonamide compound once thought to have a novel mechanism that is now believed to be weak inhibition of COX- 2. It may have other novel mechanisms including oxygen radical scavenging and inhibition of oxidative metabolism by neutrophils, plus effects on tumor necrosis factor-a and platelet activating factor. Nimesulide has a pK_a value of 6.5, which is an important factor for its favorable GI tolerability. It has been used for a number of years in Italy and is as effective as a number of reference agents (e.g., peroxicam, diclofenac, and etodolac) for a number of acute and chronic inflammatory conditions. It also has fewer reports than other NSAIDs of problems with cross-reactivity with aspirin or in patients with asthma (95). It is not marketed in the United States at this time.

Another compound is Rofecoxib, a long-half-life selective COX-2 inhibitor that is undergoing trials in osteoarthritis with good results and few side effects. It also crosses the blood–brain barrier, so it is of interest in Alzheimer's disease. It is also being studied for possible effects on colon cancer (96). It was released in the U.S. in 1999 and is indicated for osteoarthritis, acute pain, and dysmenorrhea. COX-2 inhibitors seem to reduce GI and platelet side effects, but renal toxicity remains a problem.

Other mechanisms are being tested, such as combined COX-2 and 5-lipoxygenase inhibitors (97).

Other Novel Agents: Tenidap

Tenidap is a new drug with a novel dual mechanism of action: It modulates the production and activity of some proinflammatory cytokines and inhibits COX. Its place in rheumatic diseases may include treatment *and* disease modification (2). It has a side effect profile consistent with other COX inhibitors, mainly GI and some renal effects. It can cause a reversible proteinuria that is probably due to the compound's inhibition of tubular function rather than to tubular or glomerular damage (98).

The use of tenidap and other disease-modifying antirheumatic drugs is likely to increase in the future, producing new information that may enable us to treat pain and inflammation more successfully and with much less toxic drugs.

The dramatic increase in information about mechanisms of nociception (Chapter 3) **[[AU: 6]]** is likely to lead to new drugs with higher specificity of action and, it is hoped, fewer side effects.

ACKNOWLEDGMENTS

The author wishes to acknowledge Dr. Stephen H. Butler and Dr. Constantino Benedetti, authors of the chapter covering this topic in the previous edition, some of whose text has been retained in this edition. The author also wishes to acknowledge Dr. Susan Woyna for her assistance in the editing of this chapter.

CHAPTER 84

Systemic Opioid Analgesics

H. Richard Miyoshi and Susan G. Leckband

This chapter discusses the pharmacology and some aspects of the clinical application of systemic opioid analgesics, which include opioid agonists, agonist-antagonists, and combination drugs used in pain control. For many decades, these drugs, given alone or as part of a multimodal program, have been the most frequently used method of pain control. The reason for their popularity and widespread use is that in most countries of the world they are readily available and inexpensive, and, when properly administered, provide effective pain relief (1,2,3,4,5,6,7 and 8). Recently, great advances have been made in our knowledge of pain and its mechanisms and of the pharmacokinetics, pharmacodynamics, and general pharmacology of systemic opioids. This has been accompanied by a marked improvement in older delivery systems and the use of novel new ones.

These advantages and recent advances in formulations and delivery systems usually permit the selection of an optimal drug, dose, and route for providing pain relief. However, this is often not done. Bonica indicated in the previous edition that most patients with acute pain, cancer pain, and chronic nonmalignant pain were not provided with adequate relief. Although this probably happens less often today, it continues to occur because students of medicine, nursing, dentistry, and other health professions responsible for providing care to patients in pain are still not appropriately trained in the clinical pharmacology and appropriate use of these drugs. Consequently, many practitioners underestimate the dosage range and overestimate the duration of action of systemic analgesics and have irrational fears of producing addiction, physical dependence, and respiratory depression.

This chapter provides some of the information that clinicians need to optimally use opioids. We present an overview of the pharmacology and clinical application of systemic opioids in three major sections: (a) basic considerations, which includes a review of the general principles of pharmacokinetics and pharmacodynamics and their application to the opioids, (b) pharmacology of specific opioids, and (c) finding a new consensus. Relevant information is also presented in Chapter 3, Chapter 4 and Chapter 5, Chapter 9, Chapter 10, Chapter 36, and Chapter 103.

BASIC CONSIDERATIONS

General Pharmacologic Principles

Pharmacology refers to all available information about a drug, including its history, source, production, and physical and chemical properties as a chemical or compound, as well as its interaction with the recipient organism (usually humans) with regard to absorption, distribution, biotransformation, excretion, biochemical and biological effects, mechanism of action, and therapeutic effects and uses. *Pharmacokinetics* is the study of drug disposition in the body over time, including absorption, distribution, biotransformation, and elimination. *Pharmacodynamics* is the study of the relationship between the concentration of drug at the site of action and the biologic or physiologic response.

Pharmacokinetics

Absorption. Absorption refers to the rate and extent that a drug leaves the site of administration. A drug must cross at least one membrane to get to the site of action. A number of physical factors govern this process, including the drug's molecular size and shape, solubility, and ionization constant and the relative lipid solubility of its ionized and unionized forms, on the one hand, and the physicochemical properties of the membranes it must cross, on the other. The best drugs from an absorption standpoint are small, lipid-soluble, neutral molecules, which can cross membranes with some ease.

The pK_a of a drug is the pH at which 50% of the drug is in the ionized form. Its value is derived from the Henderson-Hasselbach equation. The pK_a indicates how much unionized drug versus ionized drug will be present in a specific medium, such as the acidic medium of the stomach.

Among oral agents, aqueous solutions are the best absorbed, followed by oily solutions, suspensions, and oral solids. A factor affecting absorption of oral solids is the rate of dissolution. For example, a tablet with a slow dissolution rate will be absorbed more slowly than a capsule of the same compound, as gelatin capsules dissolve relatively quickly.

For injectables, the rate of absorption is related to concentration. A high concentration of drug in a small volume of solute leads to faster absorption, and a low concentration of drug in a large volume leads to slower absorption. The same can be said for the oral route—again, the higher the concentration of the compound at the site of absorption, the faster the compound is absorbed. Rates of absorption can therefore be controlled to some extent by changing concentration.

Modification of the surface area and perfusion of the absorption site can influence drug levels at the site of action. Measures as simple as the application of massage or heat to the area of absorption can increase perfusion. Conversely, vasoconstriction due to drugs, shock, or some other disease-related factor can decrease perfusion and may profoundly affect absorption. The surface area for absorption is also important. The pulmonary alveolar epithelium, the intestinal mucosa, and the skin are large areas that have been used.

Routes of Administration. The importance of knowing the choices in route of administration cannot be overestimated. Knowing the advantages and disadvantages of each route along with the availability of routes for each drug gives the clinician a wide range of options (Table 84-1).

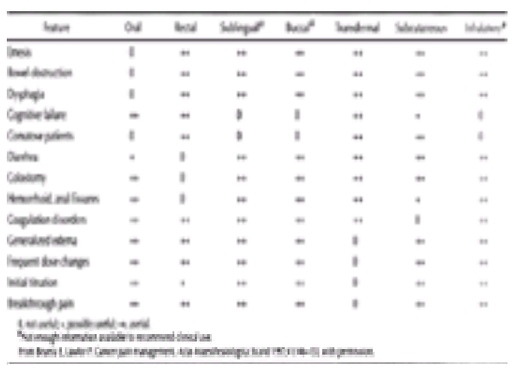

TABLE 84-1. Potential applications for various routes of opioid administration

Oral administration is the most common route. It is convenient, is usually cost-effective, and, for the most part, is the safest route. The disadvantages are slower and more variable onset of effect compared with parenteral routes. However, slow transit and variable absorption in the gut have also been used to therapeutic advantage. The oral route is the only route in which drug formulation can reliably control the distribution, metabolism, and excretion of a drug. For example, compounds that irritate the stomach, such as aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs), are available in enteric formulations designed not to dissolve until reaching the small intestine. A number of more complicated strategies have also been used to control or at least modify the rate of dissolution. In one common approach, the drug (initially morphine but more lately oxycodone and hydromorphone) is absorbed onto a hydrophilic polymer, which is then embedded in some form of matrix (wax or higher-molecular-weight aliphatic alcohols). Polymer and matrix are then ground up and compressed into solid dosage forms (tablets). After the tablet is administered the gastric fluid dissolves the tablet surface and hydrates the hydrophilic polymer, which turns into a gel. The rate of release is the rate of diffusion of the dissolved drug through the gel layer at the surface of the tablet. This is a function of the type of hydrophilic polymer, the type of hydrophilic matrix, or the ratio of the two.

A second approach to modifying absorption is to create a pellet that has an inert core onto which the drug is applied, which is then covered by a polymer coat of a specific thickness and porosity. Once the pellet gets to the gastrointestinal tract, the fluid diffuses through the outer coat to dissolve the drug. The combination of the type of inert core and the composition and thickness of the polymer coat regulates the rate of dissolution. A third approach uses a suspension in which the drug (most commonly morphine) is attached to small bead of ion exchange resin. This dosage form is ideal for those who cannot swallow pills or may need a “sprinkle” preparation (9).

Subcutaneous administration, initially used for multiple bolus injections, now is used for infusions and patient-controlled analgesia (PCA). Compared with the oral route, it obviates the need for normal gastrointestinal function and is somewhat faster for some analgesics. This route has variable uptake times. The more water-soluble the drug, the more prompt the absorption. In depot or repository forms (insoluble suspensions), the absorption is slower and more controlled. In edematous tissue, absorption may be erratic due to poor perfusion. Some of the limitations of the subcutaneous route are the need for small volumes and possible pain or necrosis at the site of injection.

Intramuscular (IM) administration is less variable for most compounds but again absorption is not rapid. It has the same advantages as the subcutaneous route, but larger volumes, oily vehicles, and some slightly more irritating drugs can be used.

Intravenous (IV) administration gives the most immediate effect with bolus administration and also makes it easy to maintain a steady state using continuous infusion. Unfortunately, the immediacy of effect can also be a disadvantage, and means that most drugs should be injected slowly. IV drugs must be water soluble. Large-molecular-weight proteins and peptides that would be poorly absorbed through a membrane can be delivered to sites of drug action readily via IV administration. The ability to dilute irritating drugs and give large volumes over time are additional advantages over other routes.

Rectal administration is often used for patients who have gastrointestinal upset, vomiting, or other reasons to avoid oral intake. The bioavailability of rectally administered drugs has shown a great deal of interindividual variation. For instance, for morphine the bioavailability was found to be approximately 53 ± 18%. Notably, availability of oral morphine is only approximately 37%, suggesting that at least for this drug, rectal administration allows partial avoidance of first-pass metabolism. Medications absorbed well by the upper part of the gastrointestinal tract are also absorbed well rectally. Passive diffusion appears to be the main absorption mechanism (10).

Sublingual administration is another option for patients with gastrointestinal upset who need to avoid or may not be able to obtain injections. There are also advantages and disadvantages to this route. Drugs given by the sublingual route enter the systemic circulation through the mucosa of the mouth and bypass hepatic first-pass metabolism. The proportion of drug absorbed is dependent on the drug's pK_a, the partition coefficient of the nonionized form, lipid solubility, molecular weight, rate of diffusion from the mouth, and, not least of all, the pH of the mouth (10). The best sublingual drug is therefore one that is not ionized at the pH of the mouth and has moderate lipid solubility. Morphine given sublingually has been used for many years but the data for its use by this route are equivocal (11). A newer, related delivery system is oral transmucosal fentanyl citrate, in which fentanyl in a candy mixture is shaped into a lozenge on a stick. The uptake from this oral transmucosal system is a combination of absorption directly through the oral mucosa and gastrointestinal absorption of drug swallowed in saliva (12,13).

Intranasal administration is another novel route. The surface area of the nasal cavity is relatively large (180 cm^2) and highly perfused. The best agents for intranasal administration usually have low molecular weights and are lipid soluble. Bypassing of first pass metabolism and a relative potency similar to the IV route are two of the advantages of the intranasal route. The best use of intranasal opioids may be in the treatment of breakthrough pain. A number of compounds have been tried, including butorphanol, oxycodone, meperidine, a number of the fentanyls, and diamorphine (14,15 and 16).

In *direct instillations*, a catheter is placed in the epidural or subarachnoid space to permit delivery of a restricted amount of drug directly to the nociceptive system, primarily at the spinal cord level (17,18). Central catheter placement near the periaqueductal gray is also used for opioid administration (19).

The *transdermal route* is currently being used in two forms: passive (conventional) systems and active (iontophoretic) systems. The variables that are most important in dermal delivery systems have to do with the permeability of the stratum corneum and include skin temperature, placement site, integrity of the skin, age, and ethnicity (20).

The passive system transfers the drug (e.g., fentanyl) from a reservoir with sufficiently high concentration gradient to the skin. The transferred drug establishes a secondary reservoir within the skin layers, which then releases the drug at a uniform rate for up to 72 hours. There are two phases to the absorption of the drug: a rapid skin absorption phase and then a plateau phase, when there is a sustained release for the duration of the placement. A problem with the passive system is that the plateau is fairly constant, but there is substantial interpatient variability in peak concentration. After the patch is on 48 to 72 hours, the patch is removed and the absorption continues from the secondary skin depot. The apparent terminal half-life is 16 to 25 hours, which means that after the patch is removed there will be drug on board for a considerable amount of time.

The active (iontophoretic) transdermal fentanyl system was developed to overcome the stratum corneum's inherent resistance to absorption of drugs. The system consists of a skin delivery electrode, a skin current returning electrode, and an electric power source. With the application of an electric field, charged components of drug are propelled through the skin. It appears that iontophoresis could be used to deliver clinically significant doses of other similar drugs. The advantage over the passive system is that the terminal half-life appears to be shorter. More research into this route is in progress (21).

Bioavailability. Absolute bioavailability refers to the fraction of a given dose of drug that reaches the general circulation as compared with the same dose given IV. *Relative bioavailability* compares the absolute bioavailability of two different dosage forms. *Physiologic bioavailability* is a measure of the effect of the administered drug.

Bioavailability is also affected by such factors as the form of administration (e.g., tablet or liquid) and the site (e.g., oral or IM). The rate of absorption from the site of administration (e.g., full stomach or empty stomach) is important. Plasma protein binding can also influence bioavailability and varies with differences in plasma protein levels because of diet, disease states, and hepatic function (22,23). There are also variables at the manufacturing level. Biologic nonequivalence has been seen with ostensibly equivalent drug preparations from different companies (24).

Distribution. Volume of distribution refers to the extent to which a drug is distributed within the body at a given time. It is defined as the amount of drug in the body divided by the plasma concentration. There are three main compartments for distribution: the vascular compartment (the bloodstream), which accounts for approximately 5% of body weight; the extracellular compartment, which is approximately 15% of body weight; and the intracellular compartment, which is approximately 30% of body weight. Large molecules and highly bound compounds usually stay in the vascular compartment. Hydrophilic compounds are distributed in both vascular and extracellular compartments. Highly lipid-soluble compounds are distributed in all three compartments. The volume of distribution might be greater than the volume of body fluids for some drugs at steady state, but for others (e.g., those that are highly plasma protein bound), it can be close to the plasma volume.

After drugs are absorbed or injected into the circulation, they are distributed throughout various areas of the body, including the compartment of their site of action. Activity is based on the concentration of the drug at the site of action and is influenced by distribution to the various body compartments. Distribution occurs in two separate phases: an early phase through the bloodstream to highly perfused organs such as the heart, liver, kidney, and brain, which is related directly to cardiac output and regional flow; and a second phase of slow diffusion into less well-perfused areas, such as the viscera, skin, muscle, fat, and bone. For some drugs, pharmacokinetic data allow this slow phase to be split further, and various artificial volumes of distribution have been defined (25). Obviously, differences in

distribution speed to various compartments greatly affect onset of drug activity, depending on the compartment where the site of action lies. A highly diffusible drug that acts on a highly perfused organ will have the most rapid effect.

In plasma, only the unbound and nonionized portion of the drug, the diffusible fraction, is free to leave the vasculature. The diffusible fraction determines the initial concentration gradient and therefore the rate of diffusion. The other factor in determining the rate of movement of the drug from plasma to tissues is lipid solubility.

The two major plasma proteins that bind drugs are albumin for acidic drugs and a_1-glycoprotein for basic drugs. Highly bound drugs have a low diffusible fraction, low volume of distribution, and little access to cellular sites of action. The metabolism and excretion of drugs, either directly or in metabolized forms, are also limited by high plasma protein binding.

Lipid solubility has various effects on distribution. Lipid-insoluble drugs do not cross tissue barriers readily and have a small volume of distribution but, more important, have limited access to sites of action. Highly lipid-soluble drugs diffuse rapidly to potential sites of action and then rapidly distribute out to other tissue, such as muscle. They can also accumulate in body fat, which can ultimately make a short-acting, lipid-soluble drug into a long-acting one by filling the fat store, leaving biotransformation and excretion as the only ways to terminate drug action.

In the normal system the pH of drugs is not usually a major factor in distribution, because the pH difference between intracellular and extracellular compartments is small (7.0 versus 7.4).

Mathematical models of drug distribution based on data from pharmacokinetic studies have made it easier to predict appropriate prescribing practices (26). These models have also explained some puzzling redistribution patterns within the body, suggested unrecognized sites of action, and explained some peculiarities observed with prolonged administration. As they are refined, these models will add more to our understanding of pharmacokinetics and facilitate improved patient care (27,28 and 29).

Biotransformation. Biotransformation refers to the structural change of a drug through enzymatic transformation in various organs of the body. For most drugs, the lipid solubility needed for passage through membranes is also a hindrance to elimination. The body must take these lipid-soluble compounds and biotransform them into polar hydrophilic compounds for them to be eliminated. This also terminates their activity. The enzymes that do this are present in the body to metabolize endogenous compounds. The fact that they metabolize drugs and other xenobiotics is coincidental. Biotransformation occurs primarily in the liver; to a lesser extent in the kidney; and to a slight degree in other organs such as skin, gastrointestinal tract, gastrointestinal flora, lung, brain, and placenta.

Biotransformation involves a number of different processes. *Functionalization reactions*, also known as *phase I reactions*, either add or expose a functional group on a molecule that can then either be excreted or react with endogenous compounds to form a water-soluble conjugate. Functionalization reactions may involve oxidation, reduction, hydrolysis, and hydration as well as isomerization. These reactions usually terminate a drug's pharmacologic activity, except in the case of pro-drugs, which need the reaction to form the active compound.

Conjugative reactions, also known as *phase II reactions*, create a covalent linkage between a functional group on the compound and another group such as glucuronic acid, sulfate, glutathione, amino acids, and acetate, among others, using a diverse group of enzymes. *Glucuronide synthesis* is the main conjugation reaction in the detoxification process. The glucuronide compounds are generally inactive and are easily excreted. Other conjugation reactions produce acetylated compounds, glycines, and sulfates, but to a lesser extent. Again, these compounds are inactive and are readily excreted, primarily in the urine but also in the feces through the biliary system. A few conjugated compounds, however, are active—for example, the M6-glucuronide of morphine, which is more potent than the parent compound.

Hydrolysis is the process that deactivates esters and amides (e.g., local anesthetics). *Reduction* detoxification has two pathways, one for azo compounds (RN = NR') and another for nitro compounds (RNO_2).

Oxidative reactions are more varied and include dealkylation, aliphatic and aromatic hydroxylation, *N*-oxidation, *N*-hydroxylation, sulfoxide formation, deamination, and desulfuration.

The mixed-function oxidation system, also known as the *cytochrome P-450 enzyme family*, is probably the major catalyst of drug biotransformation. These heme-containing, monooxygenase enzymes are found in smooth endoplasmic reticulum of such diverse tissues as liver, kidney, lung, and intestine. They catalyze a variety of reactions, both oxidative and reductive in nature involving myriad substrates. The P-450 mixed-function oxidases differ slightly from each other with respect to molecular weight, carbon-monoxide– binding spectra, electrophoretic and immunologic properties, and catalytic activities toward different drugs. The name comes from the spectral absorbance maximum produced at or near 450 nm when carbon monoxide binds to the enzyme in its reduced state.

The enzymes of this “gene superfamily” have been categorized into 12 families, four of which are involved in the metabolism of drugs. The nomenclature is as follows. The generic label CYP (for “cytochrome P”) is followed by the number of the subfamily, a letter for the specific enzyme, and a final numeral denoting the numeric order in which the enzyme was discovered. The most important isoenzymes with respect to drug-drug interactions are CYP1A2, CYP2D6, and CYP3A3/4. These enzymes all have powerful oxidizing capacity, low and overlapping substrate specificities, and low substrate affinities. They have various rates of activity depending on genetic factors (genetic polymorphisms) and on the influence of other compounds or chemicals in the system that can induce or inhibit enzyme synthesis and activity. These influences and the resulting effects of one drug on the metabolism of another are the subjects of intense current interest and a rapidly growing literature (30,31 and 32) (Table 84-2A and Table 84-2B).

TABLE 84-2B. Partial list of CYP3A3/4 inhibitors, inducers, and substrates

Elimination. Drugs are eliminated either primarily as polar compounds or primarily unchanged. Many drugs are excreted unchanged (e.g., some inhalation anesthetics). Elimination of polar compounds is primarily through renal excretion by glomerular filtration and active tubular secretion. Many drug metabolites formed in the liver are added to bile and excreted by the gastrointestinal tract, although usually these metabolites are found in the bloodstream and urine as well. Minor sites of elimination include sweat, tears, saliva, and breast milk. Excretion in breast milk can be problematic due to the risk of causing unwanted pharmacologic activity in the infant.

Clearance. Clearance is simply defined as the rate of elimination by all routes divided by the concentration of the drug, usually in blood or plasma. It is an important factor in selecting the doses and times of administration necessary to reach a steady state. Changes in renal or hepatic function, or both, can significantly change clearance. Variations in clearance may require modifying the dose, dosing interval, or both. Clearance is not much affected by changes in drug concentration at the range of clinical concentrations. This means that in clinical settings a constant fraction of drug is eliminated per unit of time, making it relatively easy to calculate dosage changes necessitated by clearance variations.

Half-Life. The half-life of a drug is the time it takes for plasma concentration to decrease by 50%. It serves as a measure of how rapidly drug concentration changes. It is a derived parameter that is inversely related to clearance and is directly related to the volume of distribution at steady state. For most drugs, terminal half-life serves as a useful measure of how rapidly drug concentration changes and how rapidly effects will dissipate. Terminal half-life is not as helpful in IV drugs that have intricate multicompartment pharmacokinetics, such as the fentanyl family of opioids. In these drugs, the rate at which concentration decreases and effects dissipate is determined not only by terminal half-life but also by the whole course of the infusion, because distribution into various compartments changes as the infusion continues. The concept of “context-sensitive half-time,” the time required for a 50% decrease in drug concentration after a particular infusion course, has been developed to take account of these complexities. Context-sensitive half-time is determined using computer modeling based on known pharmacokinetic parameters (33,34).

Steady State. A steady-state level of a drug occurs when the drug has accumulated in the body compartment under consideration, so that relatively little change in concentration is seen over time. This concentration plateau depends on the rates of administration and clearance from the phase in which it is active. Thus, when the rate of administration to a compartment equals the rate of clearance from a compartment a steady state is reached. The rate of decrease from a steady state depends on the half-life of the drug.

For example, the accumulation of nitrous oxide has a fast phase (3.5-minute half-life) and a slow phase (30-minute half-life). The rapid rise in its arterial concentration occurs during the fast phase because redistribution is minimal, but true steady state is prolonged because the terminal phase of accumulation depends on many factors. For clinical purposes a steady state is said to be reached after five to six half-lives (i.e., 96.9% and 98.4% of maximum concentration, respectively). For nitrous oxide this would be approximately 3 × 5, or 15 minutes.

Diazepam, on the other hand, has a redistribution half-life of 1 hour and a terminal half-life of 30 hours. Accumulation is slower and a steady state would not be reached for 506 hours with continuous infusion (analogous to breathing nitrous oxide). It is therefore given in bolus, and a steady state is not necessary or desirable for its clinical effectiveness.

Pharmacodynamics

Mechanisms of Drug Action

Receptor Binding. Most drugs act by binding to cell proteins, including receptors, enzymes, and proteins involved in transport processes. Receptors are proteins that bind drugs and initiate a response. There are many different types of drug receptors and many different mechanisms of receptor action. Receptors may activate G-proteins, open ion channels, or alter gene expression by binding DNA. Opioids act primarily on receptors, as described in more detail below. Drugs that act on receptors may function as agonists, triggering a response from the receptor, or as antagonists, blocking the activity of an agonist; antagonists may be competitive or noncompetitive.

Enzyme Inhibition. Enzymes are another common site of drug action; these drugs bind to enzymes and inhibit their activity. NSAIDs, for example, act by inhibiting cyclooxygenase, again as described in more detail in Chapter 83. Enzyme inhibitors may be either reversible (e.g., ibuprofen) or irreversible (e.g., aspirin).

Obviously, the structure and physiochemistry of a specific drug are the important determinants of its binding activity. Changes in molecular structure can increase potency but also tend to increase toxicity. Sophisticated techniques are increasingly allowing specific structural alterations to reach desired functional effects.

Other Mechanisms. There are mechanisms for drug activity other than protein binding. Some drugs interact with ions to produce an effect (e.g., antacids). Others are substituted by the body for cellular substrates, thus changing cell function. Others act by somewhat ill-defined physiochemical mechanisms that are not specifically related to structure.

Analgesia and Equianalgesia. The analgesic effect of a drug is the pain relief it induces. Equianalgesia is a way of comparing the analgesic effects of drugs with different structures. It indicates that the same degree of pain relief is obtained from two specified medications at the specified doses. For example, morphine, 10 mg IM, is equianalgesic to meperidine, 75 mg IM. This clinical usage of the terms “analgesia” and “equianalgesia” is appropriate only for opioids and is not based on the determination of an altered response to a noxious stimulus, as in the International Association for the Study of Pain (IASP) definition.

Potency. Potency refers to the intensity of effect for a given dose of drug. It is an estimate of the absolute concentration of a drug needed to produce a response. For therapeutic applications potency is stated in dosage units.

Therapeutic Index. The therapeutic index is an indication of the safety of a given drug, and is the median effective dose (TD_{50}:ED_{50}).

Relative Toxicity Ratio. The relative toxicity ratio is a comparison of the toxic effects of two drugs with the same desired clinical effect. For example, if pentobarbital and phenobarbital are given for seizure control, the toxicity ratio with respect to respiratory depression is 10:3 because phenobarbital has approximately a threefold advantage over pentobarbital as an antiseizure drug but an equal sedating effect.

Drug-Drug Interaction. Every time more than one drug is used there is a chance for a drug-drug interaction. With the addition of each additional drug the chance of an interaction increases. Any aspect of a drug's pharmacokinetics may be affected by drug interactions, including its absorption, biotransformation, and elimination. The pharmacodynamics of a drug can also be altered independent of changes in pharmacokinetics. The most important drug-drug interactions to be aware of are those affecting potentially toxic drugs with narrow therapeutic indices (32).

Drugs can interact with each other to produce potentiation or additive effects. *Potentiation* is said to occur when the net effect of two drugs used together is greater than the sum of their individual effects, as when an opioid analgesic is given with a nonopioid analgesic. *Additive effects* are said to occur when the net effect of two drugs used together is equal to the sum of their original effects. *Antipotentiation* occurs when the net effect of two drugs used together is less than the sum of their individual effects, as when an NSAID is given with another NSAID.

Clinical Pharmacology and Pharmacokinetics

Relation between Dose and Effect. As the tissue involved is exposed to increasing concentrations of drug, there is an increase in the number of receptors occupied, up to a point of saturation. After this concentration of maximal response there is usually no increase in effect and an increase in side effects. The drug concentration needed for a specific response has a wide range. This is why the concentration-response curve is usually converted to a log concentration-response curve, giving us the familiar sigmoid dose-response curve. Do not expect a simple relationship to exist between dose and effect, especially in a large population in whom individual differences in response further complicate the issue. The effective dose, side effects, and toxicity of drugs vary widely among patients with similar clinical problems. In one study of postoperative pain, a four- to fivefold difference in requirements for opioids was seen after major laparotomies (35).

Dosing of Drugs. The way in which a drug is administered—by a single dose, by an intermittent dose, or by continuous dosing—is determined by the clinical pharmacology of the drug and by the clinical situation for which it is used. A *loading dose* is an initial large bolus given to produce a rapid increase in the therapeutic blood level of a drug. A *maintenance dose* is the amount of drug necessary to maintain a steady state when given intermittently or by continuous infusion.

To take just a few examples, a single dose of an analgesic with a long half-life is appropriate for a relatively short pain experience. The use of methadone by IV bolus intraoperatively has been proposed to provide postoperative pain relief (36). For some procedures, such as herniorrhaphy, the long half-life of methadone (24 to 36 hours) can provide most of the postoperative analgesia with a single large dose so that NSAIDs might be all that are necessary for pain relief beyond its effective duration. Intermittent dosing with opioids of intermediate half-lives (e.g., morphine or meperidine) is commonly used for the relief of longer-lasting postoperative pain, as with a thoracotomy.

Continuous dosing by IV drip allows blood concentration closer to a steady state to be controlled and is especially appropriate for drugs with a short half-life. There has been some interest in this method for relieving postoperative pain using fentanyl or sufentanil (37). Postoperative pain management is discussed in Chapter 41.

Therapeutic Monitoring. For effective analgesia, the dose of a given drug must be matched to the requirements of a given patient and the timing must be such that blood levels remain at or above the minimum effective analgesic concentration (MEAC) for that patient. The balance must be maintained while the patient is monitored for overdose and significant side effects. Unfortunately, these real complexities are usually ignored and analgesics often are given by rote without consideration for the volume of distribution; for individual variations in absorption, metabolism, and clearance; or for the patient's clinical state.

Remarkable and rapid advances have been made in several fields pertinent to the treatment of pain. More information is available about the physiology of pain and its psychological effects on the individual, the interaction of pain and the personality, and emotional and psychological reactions and their modification by social and environmental factors. Knowledge of the pharmacology, pharmacokinetics, and toxicology of the rapidly expanding number of analgesics is becoming increasingly sophisticated and complex. Despite all this, treatment of pain is often inadequate, and medications used for pain relief can be a source of abuse. This can lead to the development of tolerance and physical dependence fostered unwittingly by both the patient and treating physician or can lead the patient to develop side effects, some of which are potentially lethal. Therefore, in approaching the control of pain, a few simple guidelines must be followed.

- *Evaluation of pain*. The source and cause of pain and its severity should be analyzed not only from a nociceptive viewpoint but also from a psychological-behavioral perspective.
- *Use of optimal drug and optimal dose*. The most appropriate medication for the problem should be selected for each individual patient in an optimal dosage.

  There is an optimal drug for each patient but no particular drug that is optimal for all patients. Morphine is used as a reference point. Other mu opioids may have faster onset, longer duration of action, or better tolerance for a particular patient, but none has more analgesic effect.

  Optimal dosage is the minimum amount of a drug repeated at appropriate intervals to give the desired therapeutic effect with a minimum of side effects. Appropriate monitoring of the patient by personal observation, and in some cases by blood studies, is necessary to follow compliance with dosage regimens, to assess the therapeutic effects, and to identify untoward side effects or toxicity of the medications prescribed. The effect of the first few doses is critically important to observe so that an accurate estimate of maintenance dose and dosing time can be made. Meticulous pharmacokinetic calculations and frequent measurement of blood levels would be ideal but are not practical in most institutions at present. Instead, clinical response is the primary consideration.

  In the hospital, monitoring is the primary responsibility of the nurses and physicians. In some cases, especially with the terminally ill who are treated at home, the family might have to be responsible for monitoring the patient. This requires the family to be conversant with the medication and its pharmacology as well as to be in close communication with treating physicians and nurses to optimize care. If the appropriate drug is given in the wrong dose and at the wrong interval, the health care system has failed. Unfortunately, this can be the case when analgesia is desired, and lack of careful therapeutic monitoring is usually the cause.

  The interaction of the drug and patient is highly dynamic. For example, pathologic alterations of hepatic or renal function, or both, can drastically decrease the metabolism and excretion of morphine to the extent that a previously appropriate analgesic dose can lead to drug accumulations and cause serious toxicity.
- *Type of pain.* As discussed repeatedly in this book, it is important to distinguish between nociceptive pain and neuropathic pain. It is also necessary to determine whether pain is acute, is associated with cancer, or is a chronic nonmalignant pain when choosing a therapeutic approach involving systemic analgesics. Generally the approaches to the treatment of acute pain problems and pain associated with cancer are somewhat similar, whereas the therapeutic approach to chronic nonmalignant pain is quite different. Opioid analgesics in adequate doses, given at appropriate intervals, as a continuous infusion, or as an infusion with a PCA unit, constitute the primary approach to most acute pain problems and to most pain associated with cancer. Opioids are generally not recommended as initial therapy for chronic continuous pain, but if properly prescribed, they can be useful in chronic recurrent or cyclical pain states of nonneoplastic origin. The whole issue of opioid treatment of chronic nonmalignant pain is one of the most debated areas of pain management. Other chapters discuss particular pain states and their individualized treatment in detail.

Clinical Pharmacokinetics and Pharmacodynamics of Opioids

After IV injection or absorption into the vascular system, an opioid must leave the plasma, diffuse into the tissues [primarily the central nervous system (CNS)], and reach the receptors to trigger its pharmacologic action. For rapid access to the CNS, an opioid must have both high diffusible fraction in plasma (unless the drug is directly instilled) and a high lipid solubility. Lipid solubility is an especially important property of intraspinal opioids, influencing their onset and duration of action, diffusion, and side effects (see Chapter 103).

The product of the diffusible fraction and the lipid solubility of an opioid is known as the *diffusion potential* into the CNS. The ratio of the diffusion potential of an opioid compared with that of morphine is called the *lipid diffusion index*. Thus, the lipid diffusion index of morphine equals 1, of meperidine equals 14, and of fentanyl equals 160.

After an IV bolus of fentanyl, this opioid enters the brain rapidly because of its high diffusion potential. As the plasma concentration falls as a result of removal of the drug by tissues and biotransformation, the gradient reverses and fentanyl leaves the brain equally rapidly. Meperidine follows the same process of forward and then reverse transfer to and from the brain, but more slowly because of its lower diffusion potential. Morphine has the lowest diffusion potential of all the common opioids, resulting in a slow dynamic interaction between plasma and CNS drug concentrations. First, there is a considerable delay between IV morphine injection and development of maximal brain concentration (and onset of maximal effect). Second, morphine leaves plasma so slowly that biotransformation or elimination lowers plasma concentration and further decreases the “driving concentration” during the onset period, causing a further reduction in its rate of diffusion into the CNS. Because of its low lipid solubility, however, less drug is nonspecifically bound by brain lipids and less is needed in the CNS to exert the same effects. Finally, once morphine has penetrated the CNS tissue, the diffusion back to the plasma is also slow. In 1979 Nishitateno et al. (38) elegantly demonstrated that the plasma concentration of morphine does not parallel the brain concentration of the drug. Instead, the brain concentration remains at higher levels compared with the decreasing plasma concentration over time (38).

Once a specific plasma concentration of opioid has been reached, the final effect is not equal for every individual. This varied response is best illustrated by considering the wide range that exists among patients with regard to the MEAC for each specific opioid. The MEAC is the minimal plasma level of an opioid that can control severe pain in a particular patient. For example, a patient with a plasma concentration of meperidine (pethidine) of 410 ng per mL might still experience severe pain, obtaining relief from pain when the concentration reaches 460 ng per mL. This is the MEAC for meperidine for that patient (39). Although the MEAC is fairly consistent for each individual patient [Mather et al. (40) found at most a twofold intrasubject variation], a great intersubject variation has been noted. Austin and colleagues (39) found that, in six patients, the intersubject MEAC varied from 270 to 700 ng per mL for meperidine, whereas Tamsen et al. (41) found a similar variation, ranging from 94 to 754 ng per mL. In practical terms, this represents an eightfold intersubject difference in meperidine requirements, confirming empiric clinical observations of a seven- to eightfold difference in opioid requirements. Morphine has a mean MEAC of 16 ng per mL, with a range of 6 to 33 ng per mL (42). Optimal control of pain is achieved by maintaining the plasma concentration of the opioid at a constant value just above the patient's own MEAC for that drug. All this underscores the necessity of individualizing opioid dosage according patient response.

Recent Advances in Opioid Pharmacology

Prompted by the introduction of the Melzack and Wall (43) gate theory of pain more than two decades ago, by the International Association for the Study of Pain, and

by many others, including the second edition of this text, exciting new results in pain research have made the pharmacology of pain treatment progressively more sophisticated. Knowledge of the neurophysiology and biochemistry of pain transmission and modulation systems (44,45 and 46), of drug receptors and their influences within these systems, and of changes in these systems produced by acute and chronic pain is continually increasing (13). More information is available about drugs long used for analgesia and about promising new drugs designed to be more specific for pain modulation. Drug delivery itself is becoming more specific with regard to the agents being administered and to the problems for which they are being given. A few of the areas where advancements are occurring are surveyed here.

Clinical Trials. As proposed by Beecher (47) and Houde (48), among others, controlled clinical trials with and without placebo are now comparing newer drugs of the opioid and nonopioid classes not only to placebos but also to standards of their class, such as morphine for the opioids and aspirin for the nonopioids. This has led to a reevaluation of the effectiveness of some older drugs as well as to the availability of new drugs. Close scrutiny of analgesic effects, side effects, and toxic effects in such trials in both humans and animals (49) has resulted in safer and more effective clinical care. The Oxford Pain Relief Unit has established a database that reviews all of the randomized trials from 1950 to 1990 (50). The data from this pool have been augmented by the efforts of the newly formed Cochrane Collaboration, the role of which is "to collaborate with others to build, maintain, and disseminate a database of systematic, up to date reviews of randomized controlled trials of healthcare" (51). With these impressive efforts to organize the masses of available data, we may be able to guide patients toward more effective treatments and away from unproven, ineffective and possibly harmful treatments.

Pain Measurement. Combined with the methodology of controlled clinical trials, newer techniques of pain measurement, both objective and subjective, have allowed more accurate evaluation of the effectiveness of analgesic medications in animals, in normal human subjects (52), and in those suffering from acute or chronic pain (49). There has been increasing interest in the psychology of pain as well, with recognition that pharmacology is only one component of effective pain treatment. Pain measurement is still in its infancy despite advances in the field, and a "pain thermometer" has yet to be found that could allow accurate objective measurement of pain and suffering.

Analytic Techniques. Analytic chemistry is another area where advances continue. Minute quantities of chemicals (including analgesics) in blood and in many other body fluids and tissues can be analyzed (49,52). Drug monitoring of analgesics is mostly used to evaluate suspected toxicity, but the same analytical tests could be used for therapeutic monitoring. There are multiple tests of different orders of complexity, from simple color spot tests, colorimetric tests, enzymatic methods, and immunoassays to thin layer and gas chromatography, high-performance liquid chromatography, and automated high-performance liquid chromatography (53). The *in vivo* release of neurotransmitters and its modification by different drugs in animal models can now be monitored (54). New imaging techniques (e.g., positron emission tomography, magnetic resonance imaging) allow the metabolism of the human brain to be observed and recorded and expand the prospects for more specific pain research in the future.

Pharmacokinetic Studies. The increasing accuracy of analytic chemical methods now allows the pharmacokinetics of opioids and nonopioids in tissue compartments of the body to be followed—for example, in plasma and in target structures such as the nervous and integumentary systems. This allows prediction of dose and correct dosing interval for these drugs so that adequate blood and tissue levels can be maintained for better pain control. These techniques are becoming more available and promise to be a future supplement to clinical monitoring. Analytic studies have also shown wide variations among patients with regard to plasma drug concentration (37,39,40,55,56,57,58,59 and 60). These results are still not widely enough known, however, so that many physicians still use fixed routine doses and intervals of dosing in patients with both acute and chronic pain, frequently resulting in inadequate analgesia.

Opioid Effects and Mechanisms

This section reviews that aspect of opioid pharmacology relating to opioid actions and their mechanisms, including analgesia and other common effects both desired and undesired. Opioids have pharmacologic effects on almost every organ and function in the human body (61). Some of these effects are beneficial, and some are not. The most important targets are the CNS and the gastrointestinal system, but the cardiovascular, pulmonary, genitourinary, and immune systems are all directly affected.

Site and Mechanism of Analgesia. Unlike the NSAIDs, which have a ceiling effect for analgesia, opioids act in a dose-dependent manner and usually can control all intensities of pain with increasing doses up to the induction of surgical anesthesia. The major drawbacks are the side effects, which increase proportionately with dose. Therapeutic analgesic doses of opioids control dull, prolonged, aching pain better than sharp colicky pain. At high doses (e.g., 2 to 3 mg morphine per kg body weight), however, they induce profound analgesia, with obliteration of autonomic responses, to the most intense nociceptive stimuli.

Systemic opioids induce analgesia at several levels of the CNS (62). In the spinal cord, they impair or inhibit the transmission of nociceptive input from the periphery to the CNS in a dose-related manner. In the basal ganglia, opioids activate a descending inhibitory system that modulates peripheral nociceptive input at the spinal cord level. In the limbic system, opioids alter the emotional response to pain, making it much more bearable (63).

Although great advances have been made in understanding the opioid system, our knowledge is far from complete, and a detailed and clear understanding of the intrinsic mechanism of action of opioids is still lacking. Several factors hinder the elucidation of this mechanism:

- The multiplicity of opioid substances, each of which interacts with more than one site on the macromolecules that form the opiate receptors (64,65).
- The ability of one substance to act as an agonist in one animal tissue and as an antagonist in another, adding further confusion (66). Certain compounds (tramadol) may act on a multitude of receptors both opioid and nonopioid in nature.
- The difficulty of finding agonists and antagonists that are receptor-specific. Naloxone, for instance, is a mu antagonist at low concentrations (up to 15 nM), but at higher concentrations antagonizes sigma and kappa (64).
- The discovery that animal tissues can transform the nonpeptide, nonmorphinan reticuline to morphine and codeine and that these substances are present in animals, although at levels so low that physiologic significance is unclear. There is some speculation that these peripheral opioid binding sites may have some role in the immune system (28,29,67,68 and 69).

Despite these difficulties, we now have a great deal of information regarding this complex system. Opioid agonists, either exogenous or endogenous, produce analgesia and other central effects by dynamically binding to specific receptors in the encephalon and spinal cord. Opioid binding can either stimulate or depress different neuronal populations. For instance, in most animal species, opioids stimulate the Edinger-Westphal nucleus of the oculomotor nerve to produce miosis and stimulate the chemoreceptor trigger zone in the area postrema to decrease the threshold of nausea and vomiting, whereas they depress the respiratory centers.

Evidence indicates that the descending antinociceptive system, activated mainly by opioids in the periaqueductal gray of the brainstem, requires a much lower concentration of these drugs to produce analgesia than the analgesia elicited strictly by the activation of the receptors of the substantia gelatinosa of the spinal cord (17). Therefore, opioids at low cerebrospinal fluid concentrations, such as those obtainable after oral, IM, or IV administration, act mostly through the descending antinociceptive system. After intraspinal administration, in which high cerebrospinal fluid concentrations are produced, the activation of opioid receptors in the substantia gelatinosa constitutes the major mechanism of analgesia (17).

Several opiate receptors are now known, each with more or less different functions and drug affinities (Table 84-3 and Table 84-4) (46,61,64,65,70). Five receptors have been identified: mu, kappa, delta, sigma, and epsilon (64,65,70). They are G-protein–linked receptors, which have been reviewed and are further explained in Chapter 3 and many other texts (71). Briefly, mu receptors (m_1, m_2) mediate supraspinal analgesia (spinal, in animals), euphoria, respiratory depression, and physical dependence. Kappa receptors (k_1 to k_4) mediate spinal analgesia, miosis, dysphoria, and sedation. Delta receptors (d_1, d_2) may mediate spinal analgesia, show little or no cross-tolerance with mu agonists, and when partially activated by a subanalgesic dose of delta agonists, greatly potentiate morphine analgesia.

TABLE 84-3. Opioid activity and selectivity by receptor type

TABLE 84-4. Opioid receptors and clinical effects

Sigma receptors mediate dysphoria, hallucinations, and stimulation of respiratory and vasomotor centers. Findings suggest that sigma receptor agonists, which include ketamine and phencyclidine (PCP, “angel dust”), are potent agonists of excitatory transmitters at the spinal cord level and are not reversed by naloxone. These characteristics suggest that the sigma receptor might not belong to the opiate receptor family but to the phencyclidine receptor family (70,72). The identity and existence of the epsilon receptor are also in question. Research is ongoing but is hampered by the lack of a currently available selective epsilon receptor ligand (73). Another receptor is called the *ORL-1* (opioid-receptor–like). It does not bind to conventional ligands but may have something to do with analgesia or hyperalgesia. Its opioid peptide, nociceptin/orphanin FQ, may have inhibitory activity at the cellular level (74,75). More research is needed to clarify its part in analgesia. There is also evidence for an M-6-glucuronide receptor (76,77 and 78).

Other Central Nervous System Effects

Limbic System. The detailed neural mechanisms by which opioids produce euphoria and tranquility or dysphoria are not completely clear (79). The study of reward systems and their role in addiction to opioids and other drugs has revealed layer after layer of complexity. Briefly, our current knowledge indicates that the mesolimbic system is the center of the reward system, with dopamine being the primary neurotransmitter involved. There seems to be a dual modulation of the mesolimbic dopamine system by mu and kappa receptors, which may be the key to the neurochemical mechanism of morphine and other mu agonist reward effects. Opioid-induced euphoria has been attributed to mu and possibly delta receptor activation. The production of dysphoria has been attributed to sigma and kappa receptors or a balance between mu and kappa receptors, but this is still uncertain (80,81). The model depends on the counterbalancing between “yin and yang,” the mu (and perhaps delta) versus the kappa agonists. These same mechanisms may be responsible for the reward and addictive properties of cocaine, amphetamine, and alcohol, as well as of opioid analgesics (82,83).

Hypothalamus and Pituitary. The hypothalamus is involved in the maintenance of body temperature and contains autonomic centers that control sympathetic and parasympathetic systems. A single dose of morphine slightly lowers body temperature in humans, whereas the chronic use of high-dose opioids seems to increase body temperature. In general, opioids decrease the response of the hypothalamus to afferent stimulation and reduce the stress response. This is apparently an indirect effect because the response of the hypothalamus to electrical stimulation is not altered by the administration of opioids.

The administration of opioids in the usual therapeutic dose causes a slight decrease in pituitary hormone levels. The acute administration of large doses of opioids is followed by a decrease in the concentration of luteinizing hormone, follicle-stimulating hormone, adrenocorticotropic hormone, and b-endorphins. This is due to decreased release of gonadotropin-releasing hormone and corticotropin-releasing factor from the hypothalamus (72). Tolerance soon develops, however, and patients receiving opioids chronically are found to have normal concentrations of circulating cortisol, luteinizing hormone, and testosterone (72).

The systemic administration of the opioid antagonist naloxone affects the release of several hypophyseal hormones. It increases the concentrations of luteinizing hormone and follicle-stimulating hormone, whereas it decreases those of prolactin and growth hormone. It may be that endogenous opioid peptides have a role in regulating secretion of some pituitary hormones (84).

Interpretation of the effect of opioids on antidiuretic hormone is controversial. Some studies have shown that the plasma concentration of this hormone increases with opioid administration and decreases with naloxone (85). Other authors, however, believe that opioid-associated diuresis is caused by hemodynamic or renal effects and not by alterations of antidiuretic hormone concentration in the plasma (72).

Brainstem and Medullary Centers

RESPIRATORY DEPRESSION. Opioids, in particular the mu receptor agonists but also kappa and sigma receptor agonists, have a direct effect on the respiratory centers of the pontine and bulbar brainstem. This is noticeable even at therapeutic doses of morphine and increases progressively with higher doses.

The effect of opioids on respiration is multifaceted. They depress both respiratory rate and tidal volume and, as a consequence, decrease minute ventilation. The major effect is a decrease in responsiveness of the medullary respiratory centers to carbon dioxide tension. Pain counteracts some of this depression. If the opioid is titrated to achieve adequate pain relief, clinically significant respiratory depression usually does not occur because pain is a powerful respiratory stimulant and counteracts the opioid-induced depression. On the other hand, this complication may occur if the drug is given in excessive doses or if adequate doses are administered too frequently. For example, severe depression can develop in debilitated patients who are given methadone too often, with consequent rapid buildup of plasma levels and perhaps accumulation of metabolites that are not analgesic but that still depress medullary centers. Sudden deterioration of hepatic or renal function that decreases the elimination of an opioid may also cause it to accumulate. PCA is one way to minimize such problems, as the patient will be able to titrate pain relief and side effects.

Another setting in which the risk of respiratory depression or even arrest increases is when a patient on opioid therapy undergoes a neurosurgical operation or nerve block that abruptly eliminates the pain and its respiratory stimulating effects. It is especially important to watch such patients closely during and after these procedures (86). Again, use of PCA will reduce this risk.

Other patients at risk may be those with sleep apnea syndrome or who depend on intercostal accessory muscle activity as with chronic obstructive pulmonary disease, morbid obesity, or postabdominal surgery, because for these patients rib cage breathing, which may be impaired by opiates, may be more important than diaphragmatic breathing (87).

Mild respiratory depression can be reversed by reducing the drug dosage, whereas moderate or severe depression should be treated with naloxone doses of 0.1 to 0.4 mg IV. Because naloxone is a fast but short-acting agent, repeated administration or an IV drip is usually necessary in patients taking long-acting opioids to prevent severe respiratory depression or arrest from recurring. For patients who have been on chronic opioid therapy, it is important to administer the naloxone slowly, because not doing so could precipitate severe withdrawal symptoms. Physicians should also be aware that naloxone has, on rare occasions, produced severe pulmonary edema (88).

COUGH SUPPRESSION. Opioids also cause depression of the cough reflex, probably via direct suppression of the cough center in the medulla. There appears to be no direct correlation between the cough-suppressant activity of an opioid and its respiratory depressant effect. In fact, opioids have been developed that effectively suppress cough without significantly impairing ventilation (87). Probably the most widely used opioid for this purpose is codeine. For some patients, the suppression of this reflex may be deleterious, due to a decrease in the clearance of sputum and secretions. All opioids should be avoided during asthma attacks because of possible histamine release, respiratory depression, and drying of secretions, a combination of effects that can be catastrophic.

NAUSEA AND VOMITING. Nausea and vomiting are common and highly disliked side effects of opioid therapy. Patients will often refuse these analgesics if emesis is not treated.

The physiology of nausea and vomiting is quite complex. The chemoreceptor trigger zone for emesis is located in the area postrema of the medulla. The vomiting center is also in the medulla, inside the blood–brain barrier. The vomiting center receives input from the gut, the cerebral cortex, and the vestibular system, as well as from the chemoreceptor trigger zone. All these inputs affect nausea and vomiting. Opioids cause direct stimulation of the chemoreceptor zone that causes emesis. This effect is potentiated by vestibular stimulation (hence, ambulatory patients suffer more emesis than supine patients); it is antagonized by certain substances with potent dopamine blocking effects (e.g., chlorpromazine, droperidol).

These complexities, plus a considerable degree of interdrug variability in individual patients, make the treatment of this common side effect something of an art. However, nausea and vomiting can usually be prevented or effectively treated. Nausea can be prevented by the concomitant use of hydroxyzine, by giving a reduced dose of opioids (89), or by the concomitant use of prochlorperazine or haloperidol. Transdermal scopolamine (Transderm Scop), commonly used to prevent emesis associated with motion sickness, is also an effective treatment.

If the patient is vomiting, the antiemetic drug should be given IM, rectally, or transdermally. In such cases it may also be desirable to switch to rectal administration of opioids. Morphine and dihydromorphinone are available in suppository form. In patients for whom opioids are prescribed for home care, it is often advisable to issue a week's supply of an antiemetic drug to be used prophylactically to avoid nausea and vomiting.

SEDATION. Excessive sedation, drowsiness, confusion, dizziness, and unsteadiness can develop during the first few days of opioid therapy but usually clear in 3 to 5 days. Persistent sedation and drowsiness can be ameliorated, either by reducing the dose of opioid but increasing the frequency of administration to ensure sustained analgesia, or by the concomitant use of amphetamines for relatively short- term therapy and for patients with terminal cancer or perhaps with nonmalignant chronic pain states (90).

There has been concern over the possible impairment of cognitive and psychomotor performance by psychotropic drugs. The effect of short- and long-term opioids has been reviewed (91). The results were reassuring. If the patients on opioids show any impairment, it is a function of slowed response, not impairment of accuracy. People on stable doses of opioids for extended periods of time, whether for treatment of cancer pain or heroin-abuse treatment, show little or no impairment, suggesting some kind of tolerance or habituation occurs (92,93).

RIGIDITY. High doses of opioids injected IV at a rapid rate can induce muscular rigidity associated with a decrease in chest compliance that could progress to the inability to ventilate. This occurs not only in humans but also in rats and other experimental animals. The precise mechanism of this effect is not known, but it is probably caused by the interaction of opioids with receptors located in the substantia nigra and striatum (94). Although there is no convincing evidence that one drug is worse than another, highly lipid-soluble drugs (e.g., alfentanil, remifentanil), which develop a fast equilibrium between blood and brain after rapid bolus administration, are the ones most likely to produce this phenomenon (77). Opioids also have some association with other types of tonic-clonic movements or myoclonus.

CONVULSIONS. Some opioids can cause convulsions of several different types. Morphine, methadone, and d-propoxyphene, when given in high doses, cause convulsions that are reversible with naloxone. For this reason, and except for normeperidine (norpethidine) because there is little if any evidence that opioids cause electroencephalographic changes in generalized cortical activity in humans (95), these “seizures” are not likely to be epileptic and may be more closely related to opioid-induced rigidity. Meperidine, its metabolite normeperidine, and thebaine produce multifocal myoclonic convulsions that are not reversed by naloxone but sometimes (although not always) respond to anticonvulsive agents (96). In humans, fortunately, opioids induce convulsions and seizures at doses that are much higher than those required for analgesia.

PRURITUS. Opioid-related pruritus mostly occurs with intraspinal opioids and is usually limited to the face and torso (97). Its mechanism is not known but it appears to be centrally mediated. It can be controlled by small, carefully titrated doses of naloxone or nalbuphine (98,99,100 and 101). Because nalbuphine is a mu antagonist-kappa agonist, pruritus may be mu-mediated. Many endogenous compounds may be involved. Histamine, prostaglandins, tachykinins (substance P), opioid peptides, serotonin, interleukins, or a combination of these compounds have all been strongly implicated (102).

Peripheral Effects. Different opioids act on various organ systems in similar ways but with different intensities (Table 84-5). Clinical trials have shown that potent opioids, administered in equianalgesic doses to the general population, produce a similar statistical incidence and degree of effects. Depending on the particular circumstance, these may be either welcomed or undesired. However, certain patients experience one or more of these effects to a greater degree than the general population and may show different susceptibility to different opioids. Thus, all patients receiving opioid therapy should be closely monitored for adverse side effects and complications, and if side effects are particularly intense, other opioids should be tried at equianalgesic doses.

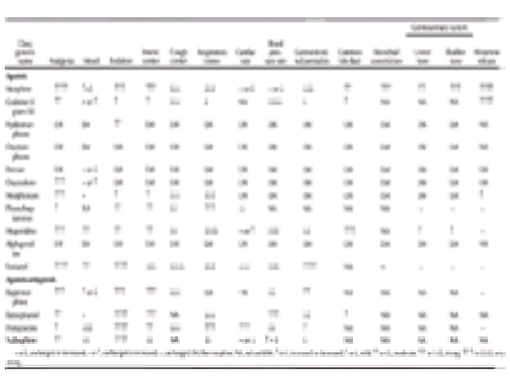

TABLE 84-5. Systemic pharmacologic and toxicologic effects of common opioids

Cardiovascular System. Therapeutic doses of opioids do not have a significant effect on the myocardium of healthy individuals. In patients with coronary heart disease, however, therapeutic doses of morphine cause a decrease in oxygen consumption, cardiac work, left ventricular pressure, and diastolic pressure (72). Large doses of opioids are therefore used to induce anesthesia in cardiac cripples.

Hypotension due to histamine release can be problematic after large doses of morphine (103). Histamine-blocking agents only partially reverse this hypotension, but it is completely reversed by naloxone. Fentanyl analogs sufentanil, alfentanil, and remifentanil do not release histamine. Histamine release can also cause dilatation of cutaneous blood vessels, with resultant flushing and sweating, mostly of the face and trunk.

Morphine and morphinelike opioids, such as fentanyl and its analogs, have a vasodilating effect on peripheral arterioles and veins. Morphine should be used with caution in hypovolemic patients because it can aggravate hypotension or even induce hypovolemic shock. The hypotension caused by opioids can be treated with IV fluids and, if need be, a-adrenergic agonists. Equally important, morphine should be used with great care in patients with cor pulmonale because sudden death has been reported (72).

The minor cardiovascular effects observed with opioids may be due to stimulation and depression of different parts of the CNS involved with cardiovascular regulation. During shock caused by sepsis, hypovolemia, or spinal cord injury, the administration of opioids worsens the clinical picture, whereas large doses of naloxone may lead to improvement (72). Fentanyl and its analogs reduce heart rate and can cause bradycardia if used in conjunction with vagal-stimulating procedures such as laryngoscopy. This lowering of heart rate can be advantageous in procedures in which lower heart rate improves the balance between oxygen supply and demand. Meperidine, on the other hand, increases heart rate with its anticholinergic activity. Cardiovascular stimulation can also be seen with the agonist-antagonists (pentazocine, nalorphine) and on occasion with fentanyl analogs.

Pulmonary System. It has been reported that high doses of meperidine or morphine can cause constriction of the bronchi. This is rarely seen with usual analgesic doses. During an asthma attack, opioids should not be used because their depressive action on the respiratory center, release of histamine, drying of secretions, and decrease of the cough reflex might worsen the clinical picture by decreasing respiratory drive and increasing airway resistance. Pulmonary edema is a potential complication that usually occurs only with opioid intoxication. In one series of cases, patients developed pulmonary edema while being treated for cancer pain. These cases usually involved high doses with rapid dose escalation (93).

Gastrointestinal System

MOTILITY. Opioids have a generalized depressant effect on gastrointestinal motility (72,104). They reduce longitudinal peristalsis and increase sphincter tone. Constipation is the predictable result. Along with nausea, this is one of the opioids' most common and troublesome side effects. The prophylaxis of constipation needs to be considered as soon as an opioid is initiated. Chronic constipation can be more difficult to treat than the pain itself.

STOMACH. Opioids slightly decrease secretion of hydrochloric acid, increase antral tone, and decrease gastric motility, resulting in increased time for gastric emptying (up to 12 hours) and consequent poor absorption of other oral medication. Slowed gastric emptying also creates increased risk of esophageal reflux.

SMALL INTESTINE. Digestion of food in the small intestine is decreased, along with biliary and pancreatic secretion. Smooth muscle tone increases and propulsive peristaltic contractions decrease markedly. Even though the amplitude of rhythmic, segmental contractions is enhanced, they are nonpropulsive. The duodenum is more affected by opioids than the ileum. More water is absorbed and the viscosity of the chyme is increased because of the prolonged time that chyme is in the small intestine.

LARGE INTESTINE. Propulsive contractions of the colon are greatly diminished or completely abolished by opioids. The mechanism of action seems to be both at the level of the gastrointestinal tract and at the level of the CNS. Tone can increase to the point of spasm, further delaying the transit of the gastrointestinal contents. The feces lose a considerable amount of water and become dry and compacted, which causes constipation that may progress to frank bowel obstruction. Tolerance to the constipating effect of opioids does not develop to a great extent, and most patients on chronic opioid therapy suffer from constipation. It cannot be too strongly recommended that initiation of opioids be accompanied by a bowel care regimen that may include extra fluids, stool softeners, or cathartics.

BILIARY TRACT. Therapeutic doses of opioids cause increased biliary tract pressure. This is thought to be due to either constriction or spasm of the sphincter of Oddi and can last 2 to 12 hours after administration of a therapeutic dose. This increase in pressure can cause epigastric distress, which can be relieved by small amounts of naloxone (105); smooth muscle relaxants such as nitroglycerin, 0.6 mg sublingually; or amyl nitrate.

The effects of opioids on the sphincter of Oddi are complex and early study results were inconsistent. With the use of endoscopic retrograde cholangiopancreatography the studies are more reproducible (105). Equianalgesic doses of fentanyl, meperidine, morphine, and pentazocine increase the pressure in the common bile duct 99%, 61%, 53%, and 15%, respectively, above baseline (106). Other opioids, mixed agonist-antagonists, partial agonists, and other agents (tramadol) have been tested. The best alternatives to meperidine, the traditional favorite, seem to be buprenorphine (partial agonist), nalbuphine (agonist-antagonist), and, with some reservations, tramadol.

Genitourinary Tract

URETER AND BLADDER. Opioids tend to increase the tone and amplitude of contraction of the ureter, but this response varies in humans (107). They can also produce urinary urgency by increasing the tone of the detrusor muscle of the urinary bladder. Increased tone of the sphincter vesicae may make urination difficult to the point of requiring catheterization, after even therapeutic doses of morphine. This has been observed particularly in a large percentage of male patients receiving intraspinal opioids (97). Naloxone antagonizes this action. Tolerance also develops to opioid effects on the bladder.

UTERUS. Therapeutic doses of opioids decrease uterine contractions and can prolong labor (108). Large doses of opioids should not be used during labor, not only because of this effect on the mother, but also because they can cross the placenta and reach the CNS of the fetus. Their effects can persist in the neonate, who is particularly sensitive to the respiratory depressant effect of opioids. Uterine hyperactivity, however, is decreased by morphine, which tends to return contractility to normal. In this particular situation the duration of labor and delivery can be shortened by morphine.

Immune System. There is some evidence that the opioid receptors expressed by immune cells are similar to or even the same as the neuronal subtypes, mostly mu, delta, and kappa. There may also be novel opioid receptors (mu_3) and/or binding sites on immune cells that are selective for morphine (109). Delta agonists appear to function in an autocrine/paracrine manner. Kappa receptors are present on a number of peripheral and central cells involved in host defense, and kappa agonists modulate both cellular and humoral immune responses. Some research has shown that opioids can act as cytokines to regulate a number of functions of both granulocytes and mononuclear cells. The opioid peptides, a-endorphin and enkephalins, appear to be able to function as endocrine hormones when secreted into the systemic circulation and may mediate the influence of the CNS on the peripheral cells that provide host defense and immunity.

Morphine alters a number of mature immunocompetent cells that are involved in cell-mediated and humoral immune responses. It also influences the differentiation of pluripotent stem cells into myeloid and lymphoid cell lines. It reduces or halts thymocyte proliferation in response to interleukin-2 or mitogens across the entire T-cell line.

There may be important differences between autoregulation of the immune system by endogenous opioids as part of a complex system involving numerous signal molecules and cell types, and immune modulation by exogenous opioids. The immunomodulating effects of opioid drugs may have clinical importance. There is evidence that opiate addicts have increased rates of lymphadenopathy, infectious complications, and cancer consistent with a degree of opiate-induced immunosuppression. There is also evidence that in some circumstances morphine may enhance human immunodeficiency virus expression. Further study is needed to allow the risks of opioid drug–induced immunosuppression to be minimized and any potential therapeutic applications to be identified and put to use (109,110 and 111).

Tolerance and Dependence

Tolerance. Tolerance is a normal pharmacologic response to chronic opioid therapy. It is defined as reduction of response to a drug after repeated administration or the need for a higher dose to maintain the same effect. Tolerance develops at different rates for various effects. For example, tolerance to the analgesic and euphoric effects of morphine develops much more rapidly than tolerance to its constipating effects. Tolerance to analgesia also seems to develop more slowly with PCA than with continuous infusion, for reasons that are still not clear.

One of the reasons for the development of tolerance may be pharmacokinetic, involving changes in distribution of the drug or changes in its rate of metabolism due to enzyme induction. There may also be a pharmacodynamic change, such as a change in receptor density or a change in the relative numbers of multiple receptors. Tolerance may also involve opioid receptor desensitization (71). Some interesting new data have come out of research on morphine suggesting that *N*-methyl-d-aspartate (NMDA) receptors and nitric oxide receptors are required for the induction and maintenance of tolerance (112,113 and 114). Other studies suggest

the delta and kappa receptors have a specific role in the development of tolerance.

The earliest sign of tolerance is the patient's complaint that the duration or degree of analgesia, or both, has decreased, although no increase is seen in the nociceptive input. This is usually treated by increasing the frequency or dose of the drug, or both. Alternatively, because cross-tolerance among opioids is not complete, switching to an alternative opioid often results in adequate pain relief. The mechanism for this is not at all clear but may have to do with the differential receptor occupancies of each drug. The alternative opioid is given in equianalgesic doses; the patient is carefully monitored; and the dose, time interval, or both are either increased or reduced according to individual needs.

Physical Dependence. Physical dependence is another physiologic response to the pharmacologic effects of chronic opioid use. It is defined as the potential for an abstinence syndrome after abrupt discontinuation, precipitous dose reduction, or administration of a specific antagonist (115). The abstinence syndrome consists of yawning, lacrimation, frequent sneezing, agitation, tremor, insomnia, fever, tachycardia, and other signs of hyperexcitability of the sympathetic nervous system. The rule of thumb is that for each drug the abstinence syndrome is the opposite of the effect (usually peripheral) of the original drug. The time of onset and the characteristics of the abstinence syndrome vary, usually depending on the half-life of the drug. It can be prevented by slowly tapering the dose of the opioid at a rate of 15% to 20% daily, and it can be effectively treated by reinstituting the drug in doses of approximately 25% to 40% of the previous daily dose (86).

Addiction and Pseudoaddiction. Physical dependence on opioids is pharmacologic and, like the development of tolerance, does not in itself constitute addiction (116). Addiction is a behavioral pattern of drug use characterized by an overwhelming involvement with compulsive drug use, use of the drug for effects other than pain relief despite adverse consequences, and/or preoccupation with acquisition of the drug. Unlike mere physical dependence, addiction is associated with a high tendency to relapse after withdrawal (117).

Fear of addiction has been an important factor in the underdosing of opioids in patients with severe pain, but opioid addiction rarely occurs in patients receiving opioids for medical purposes. In a study of nearly 40,000 hospitalized medical patients who were monitored for psychological dependence, Porter and Jick (118) found that among the nearly 12,000 patients who received one or more doses of opioids, only four cases of psychological dependence were documented in patients who had no previous history of addiction. In another study of cancer patients receiving chronic opioid therapy, Kanner and Foley (119) found that drug abuse and psychological dependence did not occur in this population. Moreover, in patients with severe pain caused by recurrent or metastatic advanced cancer who are likely to require opioid therapy until death, addiction and physical dependence should not be considered as reasons to not give opioids in adequate doses. Patients with cancer pain who are to be managed with opioids should be given ample doses for effective pain relief for as long as necessary.

Pseudoaddiction to opioids is an iatrogenic syndrome of behavioral changes, similar to those seen with idiopathic opioid addiction, that can develop as a direct result of inadequate pain management (120). Uncontrolled pain of malignant or nonmalignant origin can cause perfectly responsible patients to engage in inventive behavior that may appear demanding or even sociopathic, simply because their pain relief regimen does not provide adequate analgesia. Many of these patients are mislabeled as “drug-seeking” or “antisocial types” until they are questioned appropriately by a clinician who knows what questions to ask. The best way to avoid such unnecessary rifts in the therapeutic alliance is to be sure that the pain management regimen is adequate, closely monitored, and frequently adjusted to compensate for changes in the patient's needs. The patient's reports of pain should be acknowledged and validated. The backbone of the medication regimen should be adequate, scheduled (*not* pain-contingent) doses, with additional drug available for breakthrough pain, and adjustments to the scheduled doses if breakthrough pain is frequently occurring.

Despite current efforts to improve clinicians' understanding of effective pain management, in many if not most communities there is still a great deal of opiophobia. Opiophobia is the syndrome of failure to administer adequate opioid analgesics because of the fear of producing addiction or toxicity. The etiology of opiophobia is multifactorial: Peer pressure (provider and patient), regulatory agency pressure (real or perceived), and lack of education on opioids and the fundamentals of pain management all contribute to its persistence. Lower socioeconomic groups, younger patients, and other minority populations are particularly likely to be its targets; these patients frequently receive lower doses of opioids but higher levels of scrutiny (121). All of these factors contribute to the underuse of these relatively simple and very effective medications, due to no fault of the patients.

PHARMACOLOGY OF SPECIFIC OPIOIDS

Classification of Opioids

There are several ways to classify the opioids. One system subdivides them into weak opioids with low addiction potential and stronger opioids with higher addiction potential. Another system considers opioids for their agonist, partial agonist, and agonist- antagonist activities. Opioids can also be divided into naturally occurring, semisynthetic, and synthetic groups. The weak/strong dichotomy is easy but not that helpful, so the latter two classification systems are discussed here (Table 84-6).

TABLE 84-6. Two classification systems for opioids

The naturally occurring opioids are the alkaloids of opium and comprise two chemical classes. Those of one class contain the three-ringed phenanthrene nucleus and include morphine, codeine, and thebaine. The other class consists of the benzylisoquinoline alkaloids, which lack any analgesic activity; examples of this group are papaverine and noscapine. The semisynthetic opioids are obtained by simple modification of a naturally occurring alkaloid. For instance, heroin is derived from morphine and etorphine is derived from thebaine. Synthetic opioids contain the phenanthrene nucleus of morphine but are completely synthesized. The synthetic opioids are further subdivided into several groups based on their chemical structure (e.g., morphinans, phenylheptylamines, phenylpiperidines).

The most useful opioids are described in some detail in this section. Table 84-7 contains summary data for comparison. Again, because of great intersubject variability, the dosages indicated after each drug are only given for orientation and represent the average dose required to control moderate to severe pain in adult patients. In the clinical setting the dose for each individual must be titrated with regard to amount and frequency for adequate pain control.

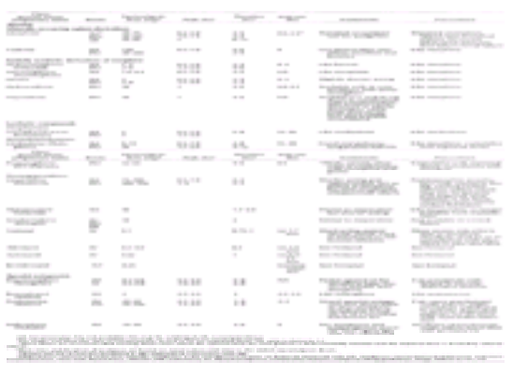

TABLE 84-7. Pharmacokinetic and pharmacodynamic data of common opioid analgesics used for pain

Pharmacology of Individual Opioids

Agonist Opioids

An agonist drug creates its pharmacologic effects by binding to and activating stereospecific receptors. Agonist opioids include morphine, codeine, meperidine, dihydromorphinone, and methadone, among others. Naturally occurring agonists are described first, followed by semisynthetic and synthetic agents.

Naturally Occurring Opium Alkaloids

Morphine. Morphine is the reference standard for all the potent opioid analgesics. The effects and side effects of mu opioids are as for morphine. Despite our long familiarity with morphine, many details of its pharmacology and pharmacokinetics remain unresolved. There are still some unanswered questions about its physiochemical nature—for example, its relative lipophilicity and whether that explains its relatively rapid onset of effects (122).

Morphine is metabolized in the liver and possibly also in the brain and kidneys. There are two major metabolites, morphine-3-glucuronide and morphine-6-glucuronide, which are mainly eliminated in urine and bile. It appears that although glucuronides are normally thought to be inactive, morphine-6-glucuronide is actually more potent than the parent compound. Morphine-3-glucuronide may have a part in the side effects of morphine. In patients with impaired renal function the accumulation of these metabolites becomes important, causing first increased effect and then, as more drug accumulates, toxic effects (123).

Among clinically used opioids, morphine gives the clinician the most options for effective routes of administration. It can be instilled directly via intrathecal and epidural routes. It has also been used for cancer pain using the intracerebroventricular route. When rapid onset is important, IM and subcutaneous administration, with their peak plasma levels at 20 minutes, provide alternatives to IV administration (124). There are also a number of protocols for using morphine either IV or subcutaneously for both continuous infusion and PCA (see Chapter 36, Chapter 41, Chapter 42 and Chapter 43, Chapter 103). Morphine is absorbed from all mucous membranes, allowing sublingual, buccal, and rectal administration, but not from intact skin. Oral absorption takes place in the small intestine and is virtually complete. There are myriad oral preparations, from oral solution and immediate-release tablets to the multiple sustained- release preparations that allow dosing once to three times daily rather than every 3 to 5 hours.

The controlled-release preparations of morphine offer great advantages for long-term therapy in patients with terminal cancer pain and noncancer pain because they provide constant plasma levels for long periods of time. There are controlled-release tablets, capsules, suspensions, and suppositories. The preparations are not necessarily bioequivalent, but with some minor dose adjustment, equal analgesia can be obtained across a number of controlled-release options (9). The outcome will be smoother, more consistent pain relief for long-term therapy, regardless of the diagnosis.

Side effects associated with the use of morphine are those common to all the opioids. Tolerance and physical dependence develop when morphine is given for a period of several weeks to months.

Codeine. Except for aspirin, codeine is probably the most widely used analgesic—and the most commonly used prescription opioid—in the world. Codeine's major disadvantage is its lack of effectiveness in treating severe pain, and stronger opioids must be used in such cases. Codeine has a low affinity for opioid receptors and so produces a lower incidence and degree of physical dependence than most other opioids. The analgesic effect of codeine is due to its conversion to morphine. Approximately 10% of administered codeine is demethylated to form morphine. Codeine has strong antitussive effects that are mediated by codeine's active metabolites depressing the cough reflex in the medulla. There may also be distinct receptors that bind codeine itself.

Codeine has a high oral-to-parenteral potency ratio, both as an analgesic and as a respiratory depressant: 60 mg of codeine given IM or subcutaneously is equivalent to 180 mg orally. This is thought to be due to less first pass metabolism in the liver with parenteral administration. Only levorphanol, oxycodone, and methadone have a similarly high oral-to-parenteral potency ratio. Codeine's half-life ranges from 2 to 4 hours, with analgesia lasting 3 to 6 hours.

Genetic differences in P-450 enzymes are known; some patients may not be able to convert codeine to morphine, and this drug could therefore have no analgesic properties for such individuals. Codeine is a CYP2D6 enzyme substrate and a minor CYP3A3/4 enzyme substrate. Codeine's analgesic effects, as well as side effects, may be decreased with concomitant use of enzyme inhibitors such as quinidine, cimetidine, phenothiazines, haloperidol, ritonavir, and some of the selective serotonin reuptake inhibitors (SSRIs). Its analgesic effects are increased with cigarette smoking, probably due to enzyme induction.

Even with little renal elimination (5% to 17%) and apparently unaltered disposition of orally administered codeine in renal failure, two cases of codeine-induced narcosis in patients with renal failure have been reported, as well as one case of respiratory arrest precipitated by codeine in a child with chronic renal failure (125,126 and 127). Decrease the dose by 25% in patients with creatinine clearance of 10 to 50 mL per min and 50% in patients with clearance of less than 10 mL per minute. Codeine is available in the United States in oral, subcutaneous, IM, and IV formulations.

Partially Synthetic Morphine Derivatives

Dihydromorphinone (Hydromorphone). Hydromorphone (Dilaudid) is a semisynthetic derivative of morphine that is approximately six to eight times as potent. The most agreed-upon conversion is that 1.5 mg of hydromorphone is equianalgesic to 10 mg of morphine. It is easily absorbed by the gastrointestinal tract and is thus effective after oral and rectal administration. It can also be used parenterally and intraspinally. Due to its high solubility, it is particularly useful subcutaneously (128,129). Hydromorphone is hydrophilic; when given epidurally, its long half-life resembles that of epidural morphine, and its short latency of analgesia is similar to meperidine's (130). A controlled-release hydromorphone, available in some countries, has been shown to be as effective administered every 12 hours as immediate-release hydromorphone administered every 4 hours (131).

Dihydrohydroxymorphinone (Oxymorphone). Oxymorphone is a congener of morphine with a substitution of a ketone group at the C-6 position, conferring a more rapid onset of effect, greater potency, and slightly longer duration of action than morphine (132). Oxymorphone has a short half-life, but due to slow dissociation from its receptor sites it has a prolonged duration of action that correlates poorly with its plasma concentration. It is approximately seven to 10 times as potent as morphine, with a high affinity for mu receptors. Oxymorphone is less likely to produce histamine release than morphine (128,133). It is available in the United States in injectable and rectal formulations (Numorphan).

Diacetylmorphine. Diacetylmorphine, or heroin, is rapidly hydrolyzed to 6-monoacetylmorphine (6-MAM) and further hydrolyzed to morphine (134,135). Both heroin and 6-MAM are more lipid soluble than morphine and enter the CNS more readily. However, it is hypothesized that 6-MAM and morphine are the moieties responsible for heroin's pharmacologic actions. Due to its high lipid solubility, IM heroin has a faster onset of action but a shorter duration of action than morphine and is twice as potent as morphine.

Heroin is not available for clinical use in the United States. There are campaigns to make it available, but with the marketing of high potency hydromorphone, the need for it becomes less urgent. It is used in other parts of the world, however, especially for the treatment of terminal cancer pain, although several studies have failed to show an advantage for this drug over other opioids used at equipotent dosages (136,137,138,139 and 140). Parenteral heroin is not superior to morphine in terms of analgesia, effects on mood, or side effects (134,138). Heroin is seldom given orally; after oral administration, only morphine, not heroin or 6-MAM, can be measured in blood (128,134).

Dihydrohydroxycodeinone (Oxycodone). Oxycodone is a derivative of thebaine but can also be made by modifying morphine. It is a potent mu agonist with analgesic potency almost equivalent to that of morphine when given parenterally and is nearly 10 times as potent as codeine when given orally (141). Oxycodone is reported to have fewer side effects than morphine; morphine caused more nausea in a double-blind, crossover study (142). It is metabolized by *N*- and *O*-demethylation and

conjugation, catalyzed by CYP2D6 (143). At least part of its analgesic action appears to be mediated by active metabolites (141). Oxycodone is available as a single-entity formulation or with aspirin or acetaminophen as a fixed-dose combination. The dose limitation of the combination is based on toxicity of the nonopioid analgesics when used in high dose. Oxycodone has a half-life of 2 to 3 hours, with a duration of action between 4 to 5 hours. A controlled-release product is also available (Oxycontin) (144).

Dihydrocodeine. Dihydrocodeine has analgesic and antitussive efficacy. It has also been used in maintenance programs for those addicted to opioids (145). It is available in tablet form in both regular-release and controlled-release formulations and is also available for parenteral administration.

There are reports of significant interindividual differences in dosage requirements with this drug (145). This may in part be due to its metabolism. Dihydrocodeine is *O*-demethylated to dihydromorphine, catalyzed by CYP2D6, and *N*-demethylated to nordihydrocodeine, predominantly catalyzed by CYP3A (145,146). In other opioids that are dealkylated (i.e., codeine, hydrocodone, and oxycodone), the metabolite has a higher affinity for the mu receptor and is usually more active than the parent compound (145). Approximately 7% of the population of whites are poor metabolizers via the CYP2D6 pathway. This means some patients will achieve only suboptimal pain relief with these drugs even when taking a standard therapeutic dose.

Dihydrocodeine also shows altered kinetics in renal failure patients. One study reported a delayed peak, greater area under the curve, and still-detectable urine levels after one dose in the majority of such patients receiving dihydrocodeine (147). Dihydrocodeine-induced narcosis in an anuric patient undergoing hemodialysis has also been reported (148).

Synthetic Compounds. Synthetic opioids include morphinans, phenylheptylamines, and phenylpiperidines.

Levorphanol. Only the *l*-isomer of levorphanol has analgesic effect. The *d*-isomer, dextromethorphan, is devoid of analgesic actions but has antitussive activity. Levorphanol's analgesic effects are similar to those of morphine, but there are reports of less nausea and vomiting with levorphanol. Levorphanol is typically given subcutaneously, but may also be given by slow IV infusion, IM, or orally. Levorphanol is less effective when given orally, but its oral-to-parenteral potency ratio is relatively high and comparable to codeine and oxycodone.

Levorphanol is slowly metabolized, with a half-life of 12 to 16 hours, but its duration of analgesia is shorter, ranging from 4 to 6 hours, slightly longer than that seen with morphine. Due to its slow metabolism and the discrepancy between plasma half-life and duration of analgesia, repeat dosing can lead to drug accumulation. Levorphanol acts primarily through the mu receptors but does have some effect at kappa $_3$ and delta, as evidenced by the lack of complete cross-tolerance between morphine and levorphanol. Due to its effect on multiple opiate receptors, levorphanol is often used as a second-line agent after morphine or in patients tolerant to morphine (128).

Methadone. Methadone is a synthetic opioid that is slightly more potent but less dependence-producing than morphine. Methadone produces less euphoria and less sedation than many other opioids. The central mechanism of action is similar to that of morphine. It is well absorbed when taken orally, so it is of little advantage to administer it parenterally. The subcutaneous route of administration is not recommended due to local skin toxicity (149).

Methadone has a long and unpredictable half-life, ranging from 13 to more than 100 hours, and consequently a longer duration of action than any of the aforementioned opioids, making it ideal for long-term administration. It is commonly used in addiction rehabilitation programs and is useful in managing pain problems that require prolonged opioid treatment. Its longer duration of action is mainly due to extensive plasma-protein binding (150). There may also be other mechanisms, such as renal ion trapping, that add to the half-life of this weakly basic molecule. To reach steady state, however, it must be administered for several days, so during the first 2 to 3 days of use, doses should be given every 4 to 6 hours and thereafter every 6, 12, and even 24 hours. The convenience of extended dosing intervals must be balanced against greater likelihood of peak-related side effects with larger doses.

Oral doses of 5 to 10 mg every 6 to 8 hours are often prescribed. Doses of up to 20 to 30 mg every 4 hours have been given without ill effects, however, in terminal cancer patients and other individuals with high degrees of tolerance. Due to the large interindividual variations in pharmacokinetics, the range of dosage and frequency varies according to the severity of the pain and the patient's tolerance (151,152).

Methadone has proven efficacy in the management of terminal cancer patients with pain, and it has been given for up to 2 years in such cases without any significant incidence of abuse. Less clear are indications for its long-term use in chronic nonmalignant pain problems; in general, long-term opioid administration should be avoided in such cases. However, patients with chronic pain with cyclic variations of intensity and severe time-limited bouts of pain, such as low back pain, can certainly be treated with methadone (or with any other long-acting opioid) on a recurrent basis.

Levo-Alpha-Acetylmethadol. Levo-Alpha-acetylmethadol (LAAM) is a congener of methadone used in the United States only in government-designated maintenance programs for the treatment of opiate dependence. It is effective for heroin addiction presumably because of its protracted duration of action; a single dose of LAAM can be given every 72 hours (153). LAAM is slowly converted to active metabolites and therefore has a slow onset of action. Dosages range from 10 to 140 mg three times a week.

Propoxyphene. Propoxyphene is available as either propoxyphene hydrochloride or propoxyphene napsylate. Sixty-five mg of propoxyphene hydrochloride is equivalent to 100 mg of propoxyphene napsylate. Propoxyphene is structurally related to methadone. It binds primarily to mu receptors but is less selective than morphine, as evidenced by incomplete cross-tolerance between propoxyphene and morphine (72). Only the *d*-isomer has analgesic activity. Several clinical trials have shown that 90 to 120 mg of propoxyphene is equipotent to 60 mg of codeine, and doses of 60 mg are no more effective than 600 mg of aspirin. Doses of 32 mg or lower are no more efficacious than placebo (154). Propoxyphene is often compounded with other medications, such as aspirin or acetaminophen. From clinical experience propoxyphene appears to have an abuse potential but it is not certain whether this is physiologic or psychological. Unless the drug has been used at high dosages, such as 800 to 1,200 mg per day, it is not clear that withdrawal reactions ensue after abrupt cessation of the drug. Thus, propoxyphene appears to be less effective as an analgesic than codeine and to have enjoyed some popularity because of supposedly lower dependence potential, a property not observed in practice. Its higher cost should also discourage clinicians from prescribing it as a codeine substitute.

Propoxyphene has an onset of action of one-half to 1 hour, with peak effects seen at 1 to 2 hours and a duration lasting 4 to 6 hours. Its half-life is 6 to 12 hours, longer than that of codeine; however, propoxyphene is metabolized to norpropoxyphene, an active metabolite with a half-life of 30 to 34 hours that can accumulate. Very high doses of propoxyphene can cause respiratory depression, CNS depression, and convulsions. Delusions, hallucinations, confusion, cardiotoxicity, and pulmonary edema have also been noted (155). Naloxone antagonizes propoxyphene-induced respiratory depression, convulsions, and some cardiotoxic effects.

Meperidine. Meperidine (pethidine) is a synthetic phenylpiperidine opioid analgesic often used interchangeably with morphine. At equianalgesic doses, meperidine produces less smooth muscle contraction and causes less constipation and urinary retention than morphine, probably due to its greater ability to enter the CNS (72). Meperidine is absorbed by the gastrointestinal tract, but the oral dose is approximately 50% less effective than when given IM (72). Meperidine's absorption after IM administration may vary as much as 50% or more even when administered at the same site (39,156). Given IM, meperidine does not significantly affect heart rate, but IV use frequently causes a marked increase in heart rate (72). Given during labor, meperidine may increase the frequency, duration, and amplitude of uterine contractions but does not interfere with normal postpartum contraction or involution of the uterus and does not increase the incidence of postpartum hemorrhage (157). Meperidine produces less respiratory depression in the newborn than does an equianalgesic dose of morphine or methadone.

Meperidine is *N*-demethylated to meperidinic acid and normeperidine. The latter is an active metabolite with one-half the potency as an analgesic but twice the potency as a proconvulsant compared with the parent compound (158). Chronic dosing can lead to accumulation of the metabolite, which can result in CNS irritability (mood changes, anxiety, tremor, multifocal myoclonus, and occasionally seizures) (159). The ratio of normeperidine to meperidine in the plasma is higher in patients with renal failure (160). Naloxone does not reverse meperidine-induced seizures and is to be used with caution in patients receiving meperidine long term due to possible precipitation of seizures by blocking the depressant action of meperidine but allowing the convulsant activity of normeperidine to emerge (161). Meperidine is relatively contraindicated for the management of chronic cancer pain because of these potential complications (128).

Meperidine is involved in some clinically significant drug interactions. Concomitant use of meperidine with a monoamine oxidase inhibitor may cause severe respiratory depression, delirium, hyperpyrexia, convulsions, and death. This interaction has not been observed with other opioids (162,163 and 164). Tricyclic antidepressants and chlorpromazine may increase the respiratory depressant effects of meperidine. Phenobarbital and phenytoin increase the systemic clearance and decrease the oral bioavailability of meperidine, causing an increase in the concentration of normeperidine in the plasma.

Alphaprodine. Alphaprodine is another derivative of phenylpiperidine and is similar to meperidine but approximately twice as potent as an analgesic, with an even shorter duration of action. Alphaprodine analgesia lasts 1 to 2 hours, whereas meperidine's lasts 2 to 4 hours (158). The shorter duration of action is due to the smaller volume of distribution and higher plasma clearance for alphaprodine (158). In comparison with other opioid analgesics, both fentanyl and alphaprodine are shorter acting than meperidine and fentanyl is shorter acting than alphaprodine (144). Due to the short duration of action, it has been used frequently for analgesia during the early phases of labor when epidural block is not available to the patient. It is no longer available in the United States.

Ketobemidone. Ketobemidone is structurally related to meperidine. It is not available for use in the United States and is currently considered a schedule I narcotic. In other parts of the world, it is available in two formulations: ketobemidone and ketobemidone in combination with the spasmolytic A29 (*N,N*-dimethyl-3,3-diphenyl-1-methylallylamine chloride) (165,166). Data have demonstrated that ketobemidone, like methadone and dextropropoxyphene, is a weak noncompetitive NMDA-receptor antagonist, in addition to being an opioid receptor agonist (167,168). NMDA receptors are thought to be involved in the development and maintenance of neuropathic pain. Ebert et al. suggest that there is “a presumed opioid-insensitive component,” involved in neuropathic pain, and this component can apparently be blocked by NMDA-receptor antagonists (168). In an animal model equivalent to neuropathic pain in humans, the NMDA-receptor antagonist component of ketobemidone contributed to its pharmacologic effect (168,169). It is unknown at this time if these findings apply to humans.

Ketobemidone can be administered parenterally, orally, or rectally. The pharmacokinetic parameters and equianalgesic dose are roughly equivalent to morphine's. Ketobemidone undergoes extensive first-pass metabolism to norketobemidone, which has five times more potency at NMDA receptors than the parent compound (170). Norketobemidone is readily conjugated and eliminated even at high doses. This may give ketobemidone an advantage over meperidine, although perhaps not other opioids, in renal failure (171).

Fentanyl. Fentanyl, the first of the 4-anilinopiperidine class, is a chemical congener of the reversed ester of meperidine. Unlike morphine, it has high lipid solubility, which facilitates its transfer across the blood–brain barrier (172). Fentanyl is metabolized primarily in the liver to phenylacetic acid, norfentanyl, and small amounts of pharmacologically active *p*-hydroxyl (phenethyl) fentanyl (172). Like all other highly lipid-soluble drugs (with the exception of remifentanil) its elimination half-life is influenced by the duration of prior administration, which determines the extent of fat sequestration. In steady state, the elimination half-life is usually 7 to 12 hours (172).

Fentanyl is 75 to 100 times as potent as morphine (173). Its low molecular weight and high lipophilicity make it a good candidate for transdermal administration (174). The transdermal systems are designed to release fentanyl at a nearly constant rate along a concentration gradient from patch to skin. Typically, fentanyl is detected in the blood 2 hours after the initial transdermal patch application, but considerable delays from 17 to 48 hours have occurred that have been attributed to depot accumulation of the drug within the skin before diffusion into systemic circulation (172). Skin temperature may also play a role in fentanyl absorption. An elevation in body temperature up to 40°C may increase the absorption rate by one-third (172).

Transdermal fentanyl gives the same degree of pain control as morphine but is associated with significantly less constipation, nausea, and daytime drowsiness (173,174). The incidence of constipation has been shown to be reduced 50% to 66% after patients switch from oral morphine to transdermal fentanyl (172,173,175). This may be due to the difference between the concentrations required to achieve analgesia and those required to elicit a reduction in intestinal activity (172). Other side effects seen with fentanyl are typical of those seen with other opioids. An unusual side effect reported in approximately 3% of patients is mild to moderate itching and transient erythema; however, this is thought to be due to the plastic patch or adhesive rather than the drug itself (172,176,177). Rarely, an opioid withdrawal syndrome is seen when switching patients from sustained release morphine to transdermal fentanyl, which is attributable to physical rather than psychological dependency (172). Symptoms may be managed with short-acting oral morphine rescue doses. Transdermal fentanyl is contraindicated in patients with acute postoperative pain.

Fentanyl is also formulated as a lozenge for oral transmucosal administration. Transmucosal fentanyl was compared with oral hydromorphone in pediatric patients for burn care and was found to have similar efficacy (178). Transmucosal fentanyl offers an alternative route of opioid administration when IV administration is unavailable or undesirable (178).

Alfentanil. Alfentanil is a congener of fentanyl. It is approximately 10 times less potent than fentanyl but has a more rapid analgesic effect, shorter time to peak effect, shorter distribution, and shorter elimination half-life than fentanyl or sufentanil. The volume of distribution and total body clearance with alfentanil are smaller than with fentanyl and sufentanil, giving it a shorter half-life after bolus. The extremely high proportion of nonionized molecules of alfentanil result in a very short onset and peak effect because most of the drug can pass the blood–brain barrier. Alfentanil is slightly more lipophilic than fentanyl and is indicated for incremental injections, continuous infusions, and anesthetic induction. Because its formulation is preservative-free, it may be used intrathecally and epidurally. Alfentanil may be given intraspinally, due to its high lipophilicity. As with fentanyl, the dosage of alfentanil should be titrated to effect and based on ideal body weight rather than actual weight.

Alfentanil is predominantly metabolized by CYP3A3/4. Erythromycin can inhibit the oxidizing activity of this enzyme system and decrease the clearance of alfentanil by 50%. Cimetidine may also prolong opioid action by decreasing hepatic metabolism. Halothane can induce the activity of microsomal enzymes and has been reported to decrease the analgesic activity of alfentanil. Propofol inhibits the oxidative enzymatic degradation of both alfentanil and sufentanil (179).

Sufentanil. Sufentanil, a thienyl derivative of fentanyl, is five to 10 times more potent than fentanyl, with an affinity for opioid receptors 30 times greater than fentanyl's (180). Sufentanil has a volume of distribution, distribution half-life, and elimination half-life between those of fentanyl and alfentanil (181). Sufentanil and fentanyl are 50% protein bound, compared with 33% of alfentanil. It is likely that sufentanil's shorter elimination half-life is due to higher hepatic metabolization and reduced volume of distribution compared with fentanyl. Sufentanil has a somewhat faster onset of action and a shorter duration of respiratory depression than fentanyl (180). It has higher lipid solubility than fentanyl, alfentanil, and possibly remifentanil (181). After long-term administration, as with other highly lipid-soluble drugs, the elimination half-life is prolonged and is a function of the duration of administration.

Sufentanil should be dosed based on ideal, rather than actual, body weight.

Remifentanil. Remifentanil, GI-87084B, is an esterase-metabolized opioid of the 4-anilidopiperidine class (182,183). Remifentanil is unique in its rapid hydrolysis by nonspecific esterases in blood and tissues (182,183 and 184). It is not hydrolyzed by pseudocholinesterase, acetylcholinesterase, or carbonic anhydrase (182). Clearance should be unaffected by cholinesterase inhibition. The hydrolytic activity in blood is associated with red blood cells rather than plasma constituents, although plasma protein binding protects the drug from rapid hydrolysis (182).

Pharmacokinetic comparisons between remifentanil and alfentanil show that, although the volume of distribution at steady state is similar, remifentanil's clearance is significantly greater, at approximately 3 L per minute (182,183). There is a low interindividual variability in clearance when the ideal body weight is used in dosing calculations (182,185). This suggests that the relationship between infusion rates and blood concentrations will be more predictable than for other opioids (185). Remifentanil's pharmacokinetics are unaltered in renal failure and severe liver disease but are influenced by age (182). Bolus doses should be halved and infusion rates decreased to one-third in the elderly (182,185).

Despite remifentanil's rapid clearance, infusion rates should be titrated according to clinical response. Remifentanil has a distribution half-life of approximately 2 to 4 minutes and an elimination half-life of 10 to 20 minutes (186). The rapid onset of effects and rapid approach to steady state often allow bolus doses to be omitted; however, there is a rapid offset of effects as well (186). The interruption of an infusion will result in the offset of effects within 5 to 10 minutes. The rapid offset of effects permits the use of an opioid-based anesthetic technique and allows for early extubation but requires that there be adequate early postoperative analgesia orders in place (182,186).

Remifentanil is currently available for IV use. It is not for intrathecal or epidural administration due to the presence of glycine in the formulation. Glycine is an acidic buffer used to facilitate the preparation of remifentanil by providing a visible product after lyophilization, but when given intrathecally or epidurally, it causes motor impairment, perhaps through inhibition of spinal motor neurons.

Remifentanil is no more efficacious than other opioids in the piperidine family. Its potential advantages and disadvantages are due directly to its unique pharmacokinetic profile (182).

Agonist Combination Products

A number of products are available combining an antipyretic-analgesic, such as aspirin or acetaminophen, and an opiate agonist, such as codeine, hydrocodone, dihydrocodeine, opium, oxycodone, meperidine, or propoxyphene. Often other substances are added to aid in pain relief, such as caffeine, promethazine, belladonna, or butalbital. The combination of an antipyretic-analgesic and an opiate agonist often provides more analgesia than a single agent, allowing a lower dose of both agents to give adequate pain relief with minimum side effects (187). Opiates such as codeine and hydrocodone are weak mu agonists and therefore not indicated for chronic, severe pain.

These combination agents are sometimes considered pharmacologically “dirty,” but they provide a reasonable way to treat mild to moderate pain inexpensively and easily. They serve a need and conform to the spirit of the World Health Organization ladder (188).

Hydrocodone. Hydrocodone is available only as a combination product with acetaminophen or aspirin. It is important to note that the acetaminophen amount varies, ranging from 167 mg for the elixir to 750 mg for Vicodin ES, so care must be used when dosing in order not to exceed the maximum recommended amount of eight tablets per day for hydrocodone, 2.5, 5, or 7.5 mg, with acetaminophen, 500 mg, per tablet, or five tablets per day for hydrocodone, 7.5 mg, with acetaminophen, 750 mg, per tablet.

In comparison with codeine, 30 mg, combined with acetaminophen, 300 mg, hydrocodone, 5 mg, with acetaminophen, 500 mg, gave significantly more pain relief and a slightly longer duration of action, but this may be due to the acetaminophen content (187). One double-blind study showed a comparable degree of analgesia between codeine, 60 mg, and hydrocodone, 10 mg, and a superior degree of analgesia compared with placebo (189). Single doses of 500 mg to 650 mg of acetaminophen show more efficacy in relieving pain than 300 mg (190).

Hydrocodone is metabolized by CYP2D6 to an active metabolite, hydromorphone (dihydromorphinone) (191). Hydrocodone displays relatively weak mu receptor binding. Hydromorphone shows stronger mu receptor binding and may mediate hydrocodone's pharmacologic effects (192).

Agonist-Antagonist Derivatives

There is some confusion about the agonist-antagonist label. These compounds are kappa and mu receptor partial agonists. Their pharmacology once again relies on the opposing effects of mu and kappa (81). Agonist-antagonist opioids are less efficacious than the pure mu agonists but can produce analgesia with less respiratory depression and have a lower abuse potential. A ceiling effect on respiratory depression as well as on analgesia has been noted with this class of opioids. In an attempt to identify drugs with high analgesic activity and low incidence of side effects, several drugs with agonist-antagonist activity or with partial agonist activity have been introduced to clinical practice.

Buprenorphine. Buprenorphine is a highly lipophilic, semisynthetic derivative of thebaine and is a member of the C-bridged oripavine series (193). It is a potent partial agonist at the mu receptor and appears to be a kappa antagonist (72,194,195). Buprenorphine is approximately 30 times more potent than morphine when given IM. It is easily absorbed from the oral mucosa, and a sublingual preparation is used in most parts of the world (196). Buprenorphine produces its analgesic effect 45 to 60 minutes after parenteral administration. Its duration of action varies from 3 to 14 hours after a single dose. Data from more than 9,000 patients indicate that the mean duration of action is a little over 8 hours (193). The side effects are similar to those of morphine, but euphoria seems to be less frequent, whereas sedation is more evident (193). Buprenorphine is 96% protein bound (72).

Buprenorphine exhibits a bell-shaped dose-response curve for analgesia, gastrointestinal motility, and respiratory depression in some animal studies (193,197,198). The bell-shaped dose-response curve is unique in that, with increasing doses, antinociceptive effects are reduced to almost zero.

Chronic pain patients have been given sublingual buprenorphine for several months without the need to increase the dosage, indicating that the development of tolerance to its analgesic effect might be slower than with other opioids (199). Some patients chose to discontinue the drug because of side effects, especially sedation and nausea, rather than failure to obtain analgesia. Abrupt withdrawal of buprenorphine in dependent patients causes a mild to moderate abstinence syndrome that is much less severe than after morphine withdrawal (200). The abstinence syndrome is delayed in onset for 2 days to 2 weeks after drug discontinuation, peaks at approximately 2 weeks, and lasts for more than 1 week (72). Patients using other opioids should not be abruptly switched to buprenorphine because this could precipitate an abstinence syndrome.

The side effects of buprenorphine are mostly sedation, nausea and vomiting, constipation, diaphoresis, and some respiratory depression. Naloxone is ineffective in reversing serious respiratory depression induced by buprenorphine, suggesting that it dissociates slowly from opioid receptors (72,193,194 and 195).

From a study of deaths from buprenorphine in France, it was concluded that IV injection of crushed tablets, concomitant intake of psychotropics (especially benzodiazepines), and high formulation dosages are risk factors for fatality (194,201). Respiratory and cardiovascular collapse has been reported in a patient who received therapeutic dosages of buprenorphine and diazepam (202). There is a case report of severe postoperative respiratory depression following IM ketorolac after epidural buprenorphine (203).

Buprenorphine is *N*-dealkylated by CYB3A3/4. Protease inhibitors, ritonavir, indinavir, and saquinavir inhibit the metabolism of buprenorphine and methadone, which can lead to accumulation (204).

Butorphanol. Butorphanol is a morphinan congener, 14-hydroxymorphinan, with a profile of action similar to pentazocine's (72,205) but with greater analgesic efficacy and fewer side effects. Like pentazocine, butorphanol exhibits a “ceiling” for inducing respiratory depression; dosages of butorphanol of greater than 2 mg do not result in a corresponding increase in respiratory depression (72,206). Increasing dosages of butorphanol do increase the duration of respiratory depression (206). Butorphanol is also similar to pentazocine in its ability to produce a significant increase in pulmonary arterial pressure, increase in cardiac workload, and decrease in systemic arterial pressure (72,206,207).

The principal actions of butorphanol result from its agonist activity at kappa receptors and antagonist activity at mu $_1$ receptors (206). Butorphanol has also been reported to be a partial agonist at sigma receptors (208). Parenterally, butorphanol, 2 to 3 mg, is approximately equal to morphine, 10 mg, in producing respiratory depression and analgesia, with onset, peak, and duration of action similar to morphine (72). Its parenteral use is associated with significant sedation even though patients remain responsive (72). It produces approximately 50% less nausea and vomiting than morphine, and side effects such as constipation and urinary retention are less frequent after chronic administration than with morphine if used at therapeutic doses.

Butorphanol undergoes significant hepatic first-pass metabolism when orally administered, with a bioavailability ranging from 5% to 17% (206). Due to this extensive metabolism, butorphanol has been formulated for IV, IM, and transnasal administration (206). These three routes of administration result in similar plasma concentration-time curves, with no first-pass metabolism associated with IV, IM, or transnasal administration (206). Noninvasive transnasal administration of butorphanol results in rapid absorption with an onset of analgesia within 15 minutes, peak plasma concentrations within 30 to 60 minutes, and elimination half- life ranging from 4.7 to 5.8 hours; elimination half-life is increased in the elderly and in patients with impaired renal function (206).

Adverse effects associated with transnasal use are related to the duration of use and include nasal/sinus congestion, nasal irritation, rhinitis, pharyngitis, upper respiratory infection, tinnitus, and epistaxis (206). Psychotomimetic effects, such as hallucinations and dysphoria, are usually seen in less than 1% of patients with injectable and transnasal butorphanol (206). A case report of psychosis with visual hallucinations has been reported with butorphanol, 1 mg IV (209).

Nalbuphine. Nalbuphine is an analgesic derivative of the agonist oxymorphone and the antagonist naloxone and is a kappa agonist and mu antagonist (16,210,211). Mu-mediated effects such as respiratory depression, constipation, nausea and vomiting, and abuse potential are less frequent or less severe than with other opioids. However, the kappa-mediated analgesia produced by nalbuphine is less than that produced by pure mu agonists, so nalbuphine is not recommended for severe pain. Kappa receptor activity also produces its own set of side effects, including sedation, dysphoria, and diuresis (184). Euphoria is observed after administration of 8 mg of nalbuphine IM. Dysphoria and psychotomimetic reactions are not problematic until 70 mg have been given. A primary side effect is sedation, which is similar to that induced by butorphanol.

The analgesic effect after IM administration appears after 45 to 60 minutes and has a duration of action slightly longer than that of morphine. The plasma half-life of nalbuphine is approximately 5 hours. It is metabolized mainly in the liver. Tolerance and physical dependence have been described. Because nalbuphine is a mu antagonist it can precipitate an abstinence syndrome in patients taking large doses of morphine over time; therefore, these patients should not be switched to nalbuphine abruptly. Nalbuphine has been studied for use in the treatment of morphine side effects, especially itching (100,101).

Pentazocine. Pentazocine is a benzomorphinan derivative that is a weak competitive antagonist at the mu receptor and agonist at the kappa $_1$ and possibly kappa$_3$ receptors (72,206,212). A single IM or subcutaneous dose of 30 to 60 mg produces analgesia similar to 10 mg of parenteral morphine but with an overall shorter duration of action; however, its analgesic activity is weak and unpredictable (72,195). Pentazocine, 35 mg, given orally gave analgesia equivalent or less than equivalent to 600 mg aspirin (195,213,214 and 215). Its half-life is 2 to 3 hours and its IM-to-oral relative potency ratio is 1 to 3 (128). The respiratory-depressant effect of pentazocine plateaus at doses greater than 30 mg (128).

Pentazocine is associated with a high incidence of adverse psychotomimetic effects, such as hallucinations, dysphoria, euphoria, and depersonalization, which are dose-related and more prevalent in long-term use (72,128,195). Pentazocine is not recommended in the management of patients with chronic cancer pain and is relatively contraindicated in patients with cardiac dysfunction due to its propensity to increase left ventricular end diastolic pressure, systemic vascular resistance, left ventricular work, and systemic and pulmonary artery pressure, causing increased cardiac workload (128,195,216). Pentazocine causes less elevation of intrabiliary pressure than does morphine but significantly more than does buprenorphine (72,195). Pentazocine passes the placental barrier but reportedly less than does meperidine (72). Like meperidine, it may increase uterine activity and shorten the first stage of labor (195). Vomiting with nausea is less commonly seen with pentazocine than with morphine (72,195).

When given to postaddicts, pentazocine, 40 mg IV or subcutaneously, produces morphinelike effects, but doses of 60 mg produce nalorphinelike effects of nervousness and loss of energy (72). Pentazocine may precipitate withdrawal symptoms in patients dependent on morphine due to its antagonist action at the mu receptor (72).

To discourage the use of tablets as a source of injectable pentazocine, they are formulated with naloxone, which is rapidly destroyed in the liver after oral consumption but will produce aversive effects when used parenterally in subjects dependent on opioids (72). Prior to the addition of naloxone, oral preparations of pentazocine (Talwin, “Ts”) and tripelennamine (PBZ, “Blues”;), an H $_1$- blocking antihistamine, were commonly used IV as a substitute for heroin, but frequent use resulted in pulmonary artery occlusion from the cellulose and talc tablet binders.

Dezocine. Dezocine is a bridged aminotetralin with mixed opioid agonist/antagonist properties (217). Dezocine displays a 10-fold greater affinity for mu than delta receptors, which may modify the mu response, and a 40-fold greater affinity for mu than kappa receptors (217). On a milligram-per-milligram basis, dezocine is at least as potent an analgesic as morphine and exhibits a similar duration of action (217). The anesthetic-sparing effects of dezocine in animals are much greater than those of older agonist/ antagonist opioids such as butorphanol and nalbuphine and approach those of morphine and fentanyl (217). As with other agonists/ antagonists, there is a ceiling effect for analgesia, but there are some reports that dezocine exhibits a higher ceiling than other drugs in that class. Successive IV doses of dezocine, 0.15 mg per kg, produced a ceiling of analgesia at 0.30 mg per kg, with further doses failing to increase the level of analgesia (217). There is also a ceiling effect for dezocine-induced respiratory depression. In single analgesic doses, dezocine is a slightly more potent respiratory depressant than morphine (217).

Dezocine is equipotent with morphine in producing opiatelike effects, including euphoria, unlike other agonist/antagonists such as nalbuphine, pentazocine, and cyclazocine, which produce signs and symptoms readily distinguishable from those of morphine. However, multiple dosing of dezocine does not result in either tolerance or limiting adverse effects.

Dezocine exhibits a large volume of distribution and a very high total body clearance. It is *O*-glucuronidated to dezocine glucuronide and dezocine sulfate (217).

Meptazinol. Meptazinol is a centrally acting analgesic belonging to the hexahydroazepine series (195). Structurally it is similar to the opiates, with actions resembling those of the mixed opioid agonist/antagonists, but it has many properties that are not typical of opiates, in particular low incidence of respiratory depression, constipation, and miosis (195,218). Meptazinol does exhibit a high propensity for causing nausea and vomiting (184). Meptazinol combines selective mu$_1$ receptor antagonism with cholinomimetic activity (184,218,219). Studies in various pain states show characteristics of analgesia of meptazinol comparable to those seen with equianalgesic doses of pentazocine, meperidine, or a combination of dextropropoxyphene and acetaminophen (paracetamol) (220). Meptazinol has a faster onset of action and a shorter duration of action than morphine, buprenorphine, and pentazocine (220).

Animal studies have revealed an antiarrhythmic effect of meptazinol (220,221,222 and 223). It has been suggested that meptazinol might have beneficial effects in hemorrhagic and endotoxic shock (219,224,225). In some patients, it has produced significant changes in blood pressure, cardiac output, mean arterial pressure, heart rate, and rate/pressure product during anesthesia (220). Improved ventricular performance has also been reported in some patients (220). Meptazinol may improve the myocardial oxygen demand/supply ratio by combining a negative chronotropic effect with an ability to decrease afterload (220,226).

Peak plasma concentrations occur within 0.5 to 2 hours (220). The bioavailability of meptazinol is low due to extensive first- pass hepatic metabolism to inactive metabolites (220). The elimination half-life of meptazinol in adults averages 2 hours but is extended in the elderly (219). The plasma half-life in the neonate is similar, at approximately 3 hours (219). In comparison, the half-life of meperidine in the neonate is approximately eight times that in the adult (219,227).

Propiram. Like ketobemidone, propiram is a schedule I substance in the United States. Propiram displays partial agonist activity; it can both suppress and precipitate abstinence symptoms. It has specific affinity for mu receptors, and is one-seventh to one-tenth as potent as morphine as an agonist and approximately one–two hundredth as potent as nalorphine as an antagonist (228). Propiram is inactive at sigma receptors (228). Propiram shows less psychotomimetic effect and exhibits lower physical dependence and abuse potential than pure mu agonists. It displays a faster onset but similar duration of action compared with meperidine, pentazocine, and possibly codeine. Propiram has an onset of action of one-half hour, a duration of action of approximately 4 hours, and an elimination half-life of 5 to 7 hours (228). When administered parenterally, it produces a degree of respiratory depression similar to morphine, 10 mg (228).

Nonopioid Centrally Acting Analgesics

Tramadol. Tramadol hydrochloride is a centrally acting synthetic analgesic with a modest affinity for mu receptors and a weak affinity for kappa and delta receptors (229). Tramadol is approximately 10-fold less potent in binding the mu receptor than is codeine (229,230). Tramadol's effectiveness as an analgesic appears to have multiple mechanisms of action beyond the binding of opioid receptors; it also inhibits serotonin and norepinephrine reuptake and enhances neuronal serotonin release, which may potentiate descending inhibitory pain pathways (184,185,229,230). Tramadol is a racemate, possessing both positive and negative enantiomers (185,229,230). The positive enantiomer has a higher affinity for mu receptors and is a more potent inhibitor of serotonin reuptake (185,229,230). The negative enantiomer is a more potent inhibitor of norepinephrine reuptake (185,229,230).

With reduced interactions with mu receptors, tramadol is less likely to produce significant tolerance, physical dependence, and abuse (230,231) than opioids. Postoperative tramadol caused significantly less respiratory depression and sedation than morphine, but the incidence of nausea, vomiting, and dizziness was not significantly different (220). Adverse events correlate with dose and have been reported in 15.3% of patients.

An increased incidence of seizures has been reported in patients receiving tramadol (185). It has been suggested that the occurrence of convulsions may be increased with doses of tramadol above the recommended dosing range of 400 mg per day, but seizures have also been reported at doses within the recommended range (232). Tramadol should be used with caution in patients taking other medications that decrease the seizure threshold (e.g., tricyclic compounds, neuroleptics) or in conditions with a recognized risk for seizures (e.g., epilepsy, head injury) (232). Tramadol should not be used in combination with the monoamine oxidase inhibitors, tranylcypromine, or phenelzine (232). Tramadol is contraindicated during anesthesia due to an increased rate of intraoperative recall (184).

Tramadol is demethylated and conjugated to an active metabolite, (+)- *O*-desmethyltramadol (+)(M1) by CYP2D6 (229,232). (+)(M1) is up to sixfold more potent than its parent compound and binds to opioid receptors up to 200-fold more; however, it is weaker at inhibiting monoamine oxidase (229). The contribution of (+)(M1) to analgesia and potential opioidlike abuse is unknown (229). Quinidine will inhibit the metabolism of tramadol to (+)(M1), thereby increasing tramadol serum levels and reducing (+)(M1) serum levels (232). However, it produced little change in tramadol analgesia in one study, despite (+)(M1) serum reductions by one-third to

one-fourth the levels of placebo-control subjects (229).

Concomitant use of tramadol with enzyme inducers such as carbamazepine has been reported to reduce tramadol's half-life by 33% to 50%. The total daily dose of tramadol may need to be increased to achieve the same level of analgesia when using this drug with carbamazepine. Conversely, tramadol's half-life has been reported to increase 20% to 25% when used concurrently with cimetidine, an enzyme inhibitor; therefore, dose reduction may be required. Dose reductions are required in patients older than 75 years of age and in patients with renal or hepatic impairment.

Opioid Antagonists

In 1915 Pohl produced the first opioid antagonist by making a minor change in the structure of the codeine molecule (97). Minor changes in other opioid agonists have produced substances that bind to one or more opioid receptors and have no pharmacologic effect. These can displace or, more probably, replace an opioid agonist from the receptor, reducing or abolishing the pharmacologic effect of the opioid agonist in a dose-dependent fashion. Naloxone and naltrexone show a relative lack of intrinsic agonistic properties and are safe and efficacious in reversing opioid-induced respiratory and CNS depression. Their predecessors, levallorphan and nalorphine, are not pure antagonists and can induce respiratory depression (188).

Naloxone. Naloxone is a synthetic *N*-allyl derivative of oxymorphone. It acts by antagonizing the actions of opioids and has few effects unless opiate agonists are administered (72). It is a relatively pure competitive antagonist with clinically insignificant intrinsic agonist activity. Subcutaneous doses of up to 24 mg of naloxone produce only slight drowsiness (72,188). It is often used to reverse the respiratory depression induced by an overdose of opioids; however, it has also been used for the diagnosis of physical dependence, and it has been studied for use in the treatment of shock, stroke, and spinal cord and brain trauma (72,233,234,235,236,237,238 and 239).

Naloxone is administered parenterally, as oral doses are almost completely metabolized by the liver before reaching the systemic circulation. Naloxone is metabolized primarily by conjugation with glucuronic acid (72). It is administered IV at a dose of 1 to 5 mg per kg. The effect is rapid and the respiratory depression is promptly corrected. IV naloxone, carefully titrated, is often used after administration of intraspinal opioids to abolish unwanted side effects such as pruritus, urinary retention, nausea, and vomiting without significantly affecting the analgesia (see Chapter 103). Naloxone is a short-acting medication (30 to 45 minutes) and supplemental doses may be needed in patients with respiratory depression induced by long-acting opioids. IM injections of twice the initial IV dose can provide therapeutic plasma levels of longer duration (239). Alternatively, a continuous infusion of 5 mg per kg per hour of naloxone can be used for long-term treatment of respiratory depression, such as that induced by a high dose of intraspinal opioid.

Rapid injection of IV naloxone can cause nausea and vomiting, which can be mostly prevented by giving the therapeutic dose over 2 or 3 minutes. Cardiovascular stimulation has occurred after administration of opioid antagonists. Tachycardia, hypertension, pulmonary edema, and cardiac dysrhythmia up to ventricular fibrillation have occurred after the administration of naloxone. These effects are attributed to a sudden increase in sympathetic nervous system activity.

Naltrexone. Naltrexone is a cyclopropyl derivative of oxymorphone, structurally similar to naloxone and nalorphine (240). It is much more efficacious orally than naloxone. Its duration of action is approximately 24 hours, with a peak plasma concentration reached within 1 to 2 hours. Naltrexone is twice as potent as naloxone in morphine-dependent subjects (240). Naltrexone is metabolized to 6-naltrexol, which is a weaker antagonist than its parent compound but has a longer half-life. Naltrexone has a half-life of up to 10 hours, with almost no accumulation in long-term use. Similar to naloxone, naltrexone produces negligible opioid agonist effects. High doses were reported to cause mild dysphoria in one study but have caused no subjective effects in several other studies (240).

Cholecystokinin. The duodenal mucosa secretes an octapeptide, cholecystokinin, which increases the contractility of the gallbladder and relaxes the sphincter of Oddi. Evidence suggests that cholecystokinin release is controlled selectively by delta receptors and occurs in response to the activation of spinal cord receptors by morphine (114). When administered directly into the CNS, it antagonizes the analgesic effect of opioids. It has been suggested that cholecystokinin might be an endogenous opioid antagonist. This hypothesis is further substantiated by the fact that proglumide, a cholecystokinin antagonist, potentiates opioid analgesia in animals (241).

FINDING A NEW CONSENSUS

The detailed pharmacology of the opioids is complex. In addition to all the individual and environmental factors that can affect each aspect of pharmacokinetics, opioid pharmacodynamics include activity at many interacting levels. Multiple parts of the CNS, multiple receptor types, and multiple intracellular processes, from G-protein–mediated signal transduction to nitric oxide, are all involved and all influence each other in ways we have hardly begun to understand.

From a clinical point of view, matters are somewhat simpler: To treat pain rationally you just need to know a few things about the pain and the patient. Is the pain neuropathic or nociceptive? Is it acute, chronic, or chronically intermittent? What caused it? What are the patient's age, sex, renal and hepatic function, and history of opioid use? With the answers to these and a few other similar questions, the clinician can make a rational choice of drug and treatment strategy, drawing on the growing body of clinical research and experience described in the remainder of this text.

These choices will ideally be based on an assessment of risks and benefits. For example, morphine is the standard by which all other systemic opioids are measured. No one has succeeded in identifying any compound that is a more effective analgesic. Another agent is chosen when that agent has some advantage over morphine—less risk of nausea, perhaps, or faster onset of action—that is not outweighed by other drawbacks. In pharmacology, risks and side effects are never eliminated. They are just traded off. Vigilance in monitoring; repeated reassessment of the patient and the pain; and a willingness to change agents, doses, or routes when indicated are the affordable price of good clinical care.

The biggest obstacles to rational opioid use are not complicated pharmacology or lack of good drugs, but bias and lack of education. The most common reasons for inadequate treatment of pain are probably fear of respiratory depression, fear of causing tolerance and addiction, and fear of increased regulatory scrutiny. As discussed previously, respiratory depression is rarely a clinical problem (and in the comfort care of the terminally ill it probably should not even be considered a major risk). New research into kappa agonists may make it even less anxiety provoking in the future. Tolerance is a practically inevitable physiologic response that is usually easily managed—in the treatment setting by increasing doses or changing agents and in the discontinuation setting by the use of reasonable tapering protocols. In the future, NMDA antagonists may decrease the incidence of tolerance and potentiate analgesia (242), and nitric oxide synthase inhibitors plus or minus NMDA antagonists may be able to attenuate or block the opioid withdrawal syndrome (243). Addiction is another danger more feared than real; it rarely develops in the medical treatment of pain. The treatment of pain in addicts is a difficult problem that often elicits punitive responses from otherwise compassionate clinicians. It is not for the faint of heart, but with a well-thought-out interdisciplinary plan based on specific contracts with the patient, the experienced pain clinician can treat an addict's pain safely and adequately without exacerbating the addictive illness. Doing so is not “giving in.”

In short, “opiophobia” is still among us. Fortunately, regulatory agencies are slowly moving toward more humane pain treatment. The Agency for Health Care Policy and Research in the United States and the World Health Organization are continuing to fine tune their guidelines in the direction of humane and adequate treatment of pain. Input from the American Pain Society is also helping to bring consistency in adequate pain treatment closer to reality (244). On a more local and economic level, the trend toward using patient satisfaction surveys as a guidepost in clinical planning is forcing private hospitals and publicly funded academic institutions to find more effective pain treatments. This progress toward a more rational, humane consensus on pain management philosophy in the clinical community, along with advances in pharmacology and new routes of administration for pain medications, makes the future of pain treatment promising.

ACKNOWLEDGMENTS

The authors wish to acknowledge Dr. Stephen H. Butler and Dr. Constantino Benedetti, authors of the chapter covering this topic in the previous edition, some of whose text has been retained in this edition. The authors also wish to acknowledge Dr. Susan Woyna for her assistance in the editing of this chapter.
