Some psychologists emphasize the difference between state and trait psychological measures. The term *state* refers to a situation -specific condition linked to, and defined by, specific circumstances. Postoperative pain, therefore, is clearly state variable. A *trait*, in contrast, is a relatively enduring tendency to feel or behave in a certain way across most circumstances much of the time. Chronic low back pain, that endures for years or decades and limits normal behavior in all areas of life, is a trait variable. The interpretation of measures differs for state versus trait variables although the actual measurement tools may be the same.

In assessing a patient or evaluating an intervention, one should conceptualize the state versus trait distinction clearly to predict treatment-related changes in either state or trait indicators. State changes in measures drawn from chronic pain patients, although easy to obtain (e.g., ratings of pain intensity), are usually of limited value because it is the trait variable that is in question. Trait measures, in contrast, allow the clinician to determine whether the chronic pain has really changed; they are often indicators of pattern or trend. Goals of measurement with acute and chronic pain can be viewed as analogous to short-term and long-term variability in the values of market stocks. Day-to-day levels are highly variable and of limited use in predicting the success of a long-range investment. Trends of values over months (traits), on the other hand, provide useful predictors for long-term investment. If, in contrast, one plans to withdraw funds from the market by next week, the long-range trend is less relevant than the short-term movement. The treatment of pain in a chronic pain patient is clearly like a long-range rather than a short- range investment. Therefore, assessment of chronic pain must involve trends and long-range change. In addition, it usually extends beyond the measurement of pain intensity alone to the measurement of the effect of pain on patterns of physical and psychosocial functioning.

APPROACHES TO MEASURING PAIN

Below, we present the major approaches to the quantification of pain and attempt to describe their advantages and limitations.

Pain as Self-Report on a Single Dimension

Category Scales

Category scales consisting of verbal or visual descriptors offer patients a simple method for reporting the private intensity of pain. These scales require only the choice of the best word or picture from the patient. For example, Melzack and Torgerson (5) introduced the following scale for pain intensity: mild, discomforting, distressing, horrible, and excruciating. Alternatively, one can use an eight-point facial expression picture scale for pain assessment (6) (Fig. 15-1). In developing countries, picture scales with differently sized familiar objects, such as cooking fires or coins, have worked well for scaling pain intensity. These approaches may be most effective for older people unaccustomed to scaling their experiences, those with limited language or verbal fluency, the young, or poorly educated populations, because scaling of this sort is not limited to words. The disadvantages of this scaling approach include the need to remember or have a printed form for the words or pictures and the limited possible range of responses to the number of words or pictures in the list. Statistical manipulation of category data is usually limited to nonparametric methods, which reduces the robustness of such scales. Moreover, on some scales, patients tend to use the middle rather than the ends of category scales, thus distorting the judgment process and further reducing the possible range of responses.

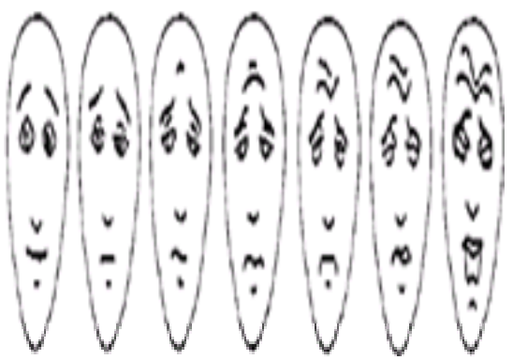

Figure 15-1. Faces Pain Scale for Adults and Children. (From Bieri D, Reeve RA, Champion GD, et al. The Faces Pain Scale for the self-assessment of the severity of pain experienced by children: development, initial validation, and preliminary investigation for ratio scale properties. *Pain* 1990;41:139–150, with permission.)

Numeric Rating Scale

In clinical settings, it is often important to be efficient and minimize staff and patient burden when collecting data. The simplest and most frequently used approach to assessing pain states is a numeric rating scale (NRS). Patients indicate how intense their pain is on a scale from 0 to 10, on which 0 typically represents “no pain at all” and 10 “the worst pain imaginable.” Such tools typically scale pain severity or intensity, but some clinical investigators use them to study the aversiveness or bothersomeness of pain (its affective dimension). Most patients readily understand this type of scale, and a nurse or physician can administer it either orally or in written form. McGrath and colleagues (7) developed a scale for children that uses color to code sensory intensity and faces with varying expressions to code affect. The child gives a nonverbal response on each dimension, but the instrument provides the caregiver with a corresponding NRS. This approach demonstrates the possibility of extracting a numeric score from a measurement device having a nonnumeric interface.

Visual Analog Scale

An equally simple and efficient to administer alternative is the visual analog scale (VAS), which usually consists of a 10-cm line anchored at one end by a label such as “no pain” and at the other end by a label such as “the worst pain imaginable” or “pain as bad as can be.” The patient simply marks the line to indicate pain intensity, and the provider then measures the length of the line to the mark on a 101-point scale (8). A slide rule–like device with the line on the patient's side and numeric score on the obverse facilitates clinical assessment. The main disadvantage of the VAS is the time required to measure the scale. For busy clinicians or researchers with large volumes of data, this can be an impediment to assessment. Although these tools are relatively straightforward, researchers have reported that 7% to 11% of patients are unable to complete the VAS or find it confusing (9,10), and one reported that 26 of 98 patients in a particular sample could not complete a VAS (11). Examples and practice using common pain problems, such as headaches of varying intensity, can help patients who seem not to understand use of the scale.

Nonwritten versions of the NRS or VAS work with very sick patients if the provider instructs them to give a number from 0 to 10 or asks them to hold up from 0 to 10 fingers, or if someone runs a pencil slowly along a VAS while the patient nods his or her head at the point that corresponds to current pain.

Fig. 15-2 provides examples of several simple pain scaling instruments. Clear patient instruction in their use is essential for meaningful data collection. For the NRS and VAS, patients must understand the labels at the two end points and that they are free to indicate a response at any point in the scale.

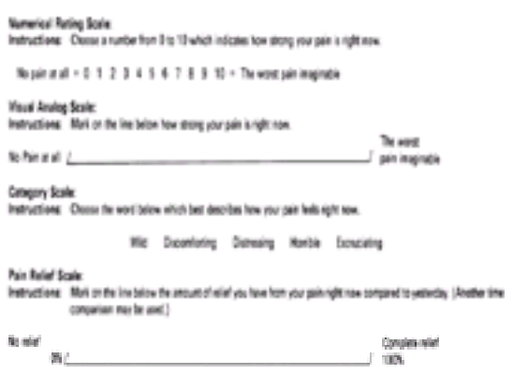

Figure 15-2. Single-dimension, self-report measures. These include the following scales: Numerical Rating Scale, Visual Analog Scale, Category Scale, and Pain Relief Scale.

Carlsson (12) critically evaluated the VAS as an indicator of pain state or pain relief in chronic pain patients, comparing different forms of the scale. Reliability, as judged from consistency of response to the two forms, was low, and Carlsson concluded that the validity of VAS procedures for chronic pain populations might be unsatisfactory (see also reference 13). Other research, however, has supported the reliability and validity of the VAS as a sensitive measure of pain and change in pain (14).

Mantha and colleagues (15) advocated using statistical confidence intervals (CIs) with VAS data. A CI provides a range of values based on the observed data that contains, with a specified probability, a true but unknown variable typifying a population of scores, usually the mean. In other words, instead of reporting a simple mean VAS score, an investigator might report the mean together with the 95% CI for that mean. This has practical value in studies of analgesic effect. If we define as *effective* a treatment that reduces pain to a level within 0 to 30 on a 100-point VAS and then carry out a study, we need to determine whether the treatment really worked. If the entire 95% CI for the posttreatment scores falls within the 0- to 30-point range, then we may assume with confidence that the treatment was effective. If only the mean falls within that range, our confidence in the outcome is less. This approach lends itself well to graphic depiction.

A plethora of other, more subtle issues about scale construction and presentation have emerged in the literature but do not merit detailed description here. The important point is that even a simple and rapidly administered tool can fail if the provider does not exercise sufficient care to ensure accurate, valid, and reliable reporting. The primary limitation of single dimension subjective scaling of pain resides in the strong risk of oversimplifying assessment of the pain problem by not adequately addressing the complex nature of the experience. A simple, subjective indicator of pain intensity provides, for example, no information about the effect of the pain on sleep or function.

Pain as Self-Report on Multiple Dimensions

For all but the most brief, predictable, procedural pain, competent measurement requires, at minimum, that clinical investigators ask patients to report intensity, qualities of the pain (e.g., burning, aching, throbbing), location(s), and interference with function (16,17). Location is usually indicated by having patients point to where on their bodies they feel painful sensations or by having them mark a body drawing (Fig. 15-3). Although location is difficult to use as research data, other than descriptively, it assures clinicians that they understand where the patient feels pain and assists in defining etiology. Interference with function is important when pain occurs while patients are expected to perform other activities. Without interference ratings, a clinician would consider a patient with pain intensity of 3 on a scale from 0 to 10 to have good pain treatment. However, if the clinician discovers that the pain is only at a 3 because the patient does not move off the couch, pain management is clearly less than adequate. Verbal descriptors of the sensory qualities of pain are increasingly important as we define treatments specific to different characteristics. The major distinction currently is between somatic or visceral pain versus neuropathic pain. Verbal descriptors and precise location description are the best measurement tools for differentiating these etiologies. Words selected from the McGill Pain Questionnaire (MPQ; see following discussion) can be used to distinguish burning, shooting, electric, or pins and needles pain from throbbing, aching, heavy pain, and these two groupings have been used effectively to define appropriate treatment (18).

Figure 15-3. The McGill Pain Questionnaire. (From Melzack R. The McGill Pain Questionnaire: major properties and scoring methods. *Pain* 1975;1:277–299, with permission.)

Some investigators compensate for the unidimensionality of NRSs and VASs by using several of them, each designed to assess a different dimension of pain such as intensity or unpleasantness. With this approach, it is difficult to ensure that the response to the first scale administered does not influence the response to following scales. Carlsson (12) emphasized that patients must respond to each scale without the opportunity to compare the present response with other, previous VAS estimates.

Alternative approaches offer multidimensional scaling, but they do so at the cost of increased responder burden. Many investigators prefer to develop instruments that simultaneously measure pain on multiple dimensions, sometimes combining VASs, NRSs and category scales. Below, we review several instruments that illustrate the variety in multidimensional pain measurement approaches.

McGill Pain Questionnaire

The MPQ (19) is one of the more extensively tested multidimensional scales available. It scales pain in three dimensions: sensory, affective, and evaluative (see Fig. 15-3). The test instrument consists of 20 sets of words that describe pain. Patients select the sets that are relevant to their pain and circle the words that best describe the pain within any selected set. Each set has from two to six words that vary in intensity for the quality described by the set. The first ten sets represent sensory qualities, the next five are affective, set 16 is evaluative (intensity), and the last four sets are miscellaneous words. It is possible to score each dimension and to obtain a total score. An adjunct questionnaire, termed the *Dartmouth Pain Questionnaire,* can supplement the MPQ through the assessment of three additional factors over and above pain quality. These include a general affective dimension, the time course and intensity of pain, and behaviors affected by pain (20). One advantage of the Dartmouth Pain Questionnaire is its consideration of remaining positive aspects of functioning rather than just impairment. As Sacks (21) has emphasized in his discussion of impaired neurologic patients, evaluation of patient weakness and limits to the exclusion of strengths and assets is an incomplete evaluation and possibly a disservice to the patient.

Statistically, numerous studies have supported the factor structure of the MPQ, its reliability, and its concurrent validity (22,23). The MPQ takes between 5 and 15 minutes to complete, however, and thus it places a larger burden on the patient than a VAS or NRS; some patients cannot handle the vocabulary of the instrument; and the scoring procedures available have limitations (22). Walsh (11) commented that when patients complete the MPQ in the presence of their spouses, the spouse may interfere by offering alternatives or urging changes. Turk and colleagues (24) critically evaluated the MPQ and various approaches to its scoring. They concluded that the total score is valid as a general measure of pain severity, but one should not interpret individual scale scores. They could not demonstrate adequate discriminative validity to support scaling at the level of sensory, affective, and evaluative dimension subscales. This paper calls to question the multidimensional scaling capability of the MPQ.

As a clinical tool, the MPQ helps define the quality of a patient's pain, both in its sensory dimensions and its affective effect. It is helpful to review the words with patients to ensure that they understand the meaning of each word, and it is possible to administer the scale orally, reading each word set and having patients indicate which word in the set, if any, describes their pain. With this method, even quite sick patients have been able to complete the measure. Research indicates, however, that oral and written responses to the MPQ are not necessarily equivalent. Therefore, one should maintain a standard format to compare scores obtained in two ways (25).

One can use the MPQ in combination with other tools. Haas and Nyiendo (26) evaluated the diagnostic value of the MPQ for low back pain, combining it with the Oswestry Disability Questionnaire. They found the combination of these inventories valuable for ruling out nonspecific low back pain and ruling in radiculopathy, with and without neurologic deficits. This suggests that the MPQ in combination with measures of function may prove clinically useful.

Memorial Pain Assessment Card

Perhaps the fastest means of assessing multiple dimensions of the pain experience in sick patients, or those undergoing evaluation for pain control is the repeated use of a VAS. The Memorial Pain Assessment Card scales pain, pain relief, and mood on VASs and adds a set of adjectives reflecting pain intensity (27). The card is illustrated in Figure 15-4. The advantages of this measurement tool are that it takes only seconds to use, it is correlated with other, longer measures of pain and mood, and the provider can fold the card so that the patient sees only one scale at a time.

Figure 15-4. The Memorial Pain Assessment Card. (From Fishman B, Pasternak S, Wallenstein SL, et al. The Memorial Pain Assessment Card: a valid instrument for evaluation of cancer pain. *Cancer* 1987;60:1151–1158, with permission.)

Pain Perception Profile

A radically different approach to multidimensional scaling comes from a psychophysical technique, known as *cross-modality matching*, that quantifies a sensory experience by matching it to the experience of a precisely controlled stimulus in a different sensory modality. For example, one might match the intensity of a toothache produced by electrical tooth shock to the perceived loudness of a controlled tone. The technology by which spontaneous pains of natural origin are matched to controlled stimuli is too complex to warrant description here. The typical procedure involves matching words describing pain to measurement in another dimension (e.g., line length or hand grip strength), matching both to experimental pain, and then deriving scaling standards for the relationship of words describing pain to actual pain. One can apply such methods to clinical pain assessment. Some investigators use them to assess multiple dimensions of pain, such as intensity and unpleasantness, as demonstrated by Gracely and colleagues (28).

The Pain Perception Profile (29) uses cross-modality matching. It (a) measures sensation threshold; (b) uses magnitude estimation procedures to judge induced pain; (c) measures pain on intensity, reaction, and sensation dimensions via psychophysical scaling of verbal pain descriptors; and (d) allows the user to administer the three dimensions of psychophysically scaled verbal descriptors in a diary format for repeated assessment over time. Compared with the MPQ, cross-modality matching is shorter and less demanding once the psychophysical scaling is complete. Doctor and colleagues (30) used this approach to develop the Descriptor Differential Scale of Pain Intensity. It offers potentially more reliable and valid data than the simpler VAS scales. However, this approach and that of Gracely and colleagues (28) require validation work for different patient populations. This necessitates experimental pain testing and a substantial amount of development before clinicians can interpret data from a broad sample of patients confidently. These methods seem promising as measurement tools for the future.

Pain as a Multidimensional Experience that Includes Effect on Daily Living

Clinicians often measure pain to assess the effect of an intervention to relieve it. A single pain rating, or even ratings that include sensory and affective components, cannot provide a comprehensive indicator of patient well-being or functional capability. If, after treatment, a patient experiences increased levels of physical activity, less fatigue, better mental concentration, and more social interaction, but the same reported average pain intensity, then the clinic may take satisfaction in a job well done. On the other hand, if the patient reports good pain relief but demonstrates no improvement in physical activity and other functioning, then the pain report is either spurious or an incomplete indicator of treatment effect. Ultimately, a cost-effective intervention for pain must relieve the negative effect of pain on daily living. What patients can do after treatment is as important as what they say about their subjective sense of pain relief.

The impetus for development of new instruments that assess pain and impairment of function is economic as well as clinical. Pain clinics must demonstrate that their sometimes costly interventions have made a difference in pain patients' ability to work, worker productivity, and health care use. A growing literature now underscores the importance of assessing the functional capability of chronic pain patients, and it offers several instruments that can scale the impact of pain on daily living.

The measurement of function in chronic pain patients is problematic for two reasons. First, different pain syndromes appear to require different measures of pain effect. The effect of low back pain on a patient differs from that of temporomandibular joint pain or shoulder pain. Therefore, measurement instruments are becoming specific for syndromes. Second, the relationship of the disease causing the pain (e.g., arthritis) to the degree of impairment is rarely, if ever, strong. This makes it difficult to interpret the relationship of pain as a subjective state to functional impairment. Finally, sex differences exist in daily function that require different norms for men and women (31). Generic indices of functional status do not take these into account, and this can become problematic for some highly specific pain syndrome instruments. Similarly, the activities of daily living change over age. A single instrument might fare poorly for adolescents and geriatric patients if its designers had middle-aged people in mind. Thus, before using any measure, identification of the sample in which the instrument was standardized is important.

Brief Pain Inventory

Cleeland and Ryan (32) described the history of the Brief Pain Inventory (BPI) (Fig. 15-5), its reliability and validity across cultures and languages, and its particular usefulness for cancer pain research. The design of the BPI reflects an important principle. The goal of pain relief is to reduce two targets: the subjective intensity of pain and the disability that pain causes. The BPI quantifies both targets.

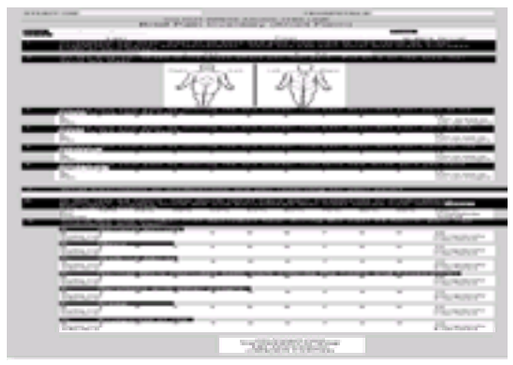

Figure 15-5. Brief Pain Inventory. (From Cleeland CS, Ryan KM. Pain assessment: global use of the Brief Pain Inventory. *Ann Acad Med Singapore* 1994:23:129–138, with permission.)

The BPI is a quick, multidimensional pain measurement tool with demonstrated reliability and validity in patients with cancer, AIDS, and arthritis (33,34 and 35). In 5 to 15 minutes, patients provide subjective ratings of pain intensity (pain worst, pain least, pain average, and pain right now), and, importantly, they also report the effect

of pain on multiple functions (general activity, mood, ability to walk, normal work, socializing with others, enjoyment of life, and sleep). All but 6% of 1,200 hospitalized cancer patients selected for study were well enough to complete the questionnaire, and only 7% refused to participate in the study. Thus, this measure is a good choice for multidimensional pain measure in patients with progressive diseases. Portenoy and colleagues (36) and Breitbart and colleagues (37) used a pain-related functional interference index (sum of the seven item BPI subscales) in a study of pain and functional impairment in patients with life-threatening disease. This instrument is available in several languages, including French, Spanish, and Chinese (38).

Investigators studying cancer pain are on the lookout for simple measures that correlate strongly with both intense pain and major impairment of function. Serlin and colleagues (39) explored the relationship between numeric ratings of pain severity and ratings of pain's interference with such functions as activity, mood, and sleep. They used interference measures to grade pain severity. They grouped severity scores into three categories: mild, moderate, and severe. Based on the degree of interference with cancer patients' function, severity ratings of 1 to 4 corresponded to mild pain, 5 to 6 to moderate pain, and 7 to 10 to severe pain. Thus, brief measures of pain severity can convey information about expected levels of functional impairment in cancer patients.

West Haven–Yale Multidimensional Pain Inventory

The West Haven–Yale Multidimensional Pain Inventory provides an alternative to the MPQ (40). This questionnaire, by design, is shorter and more classical in its psychometric approach to multidimensional scaling than the MPQ. The 56-item inventory comprises three parts: (a) five general dimensions of the experience of pain and suffering, interference with normal family and work functioning, and social support; (b) patients' perceptions of the responses of others to displays of pain and suffering; and (c) frequency of engagement in common daily activities. The instrument is linked to cognitive-behavioral theory and assesses constructs beyond subjective distress, including effect of the pain problem on general functioning. As such, it represents a broader approach to scaling than the MPQ. The Multidimensional Pain Inventory has found wide use with diverse pain syndromes, and various studies have replicated the scale structures.

The West Haven–Yale Multidimensional Pain Inventory assesses dimensions relevant in chronic pain problems. With acute or persisting pain problems of progressive nature, such as cancer or rheumatoid arthritis, extensive evaluation of social contingencies for pain behavior is not always necessary. Furthermore, with patients who are quite ill, one must balance needs for speed and minimal response burden against the value of multidimensional assessment.

Sickness Effect

The presence of persisting pain can limit and frequently disable a patient. For the patient with low back pain (the best-studied type of patient in the chronic pain population) this effect consists of increased hours spent reclining or in bed rest, restriction of normal social and recreational pursuits, emotional distress, and expressed inability to maintain gainful employment. The concept of sickness effect is for most practical purposes interchangeable with that of disability.

No comprehensive, validated objective indicators of sickness effect exist at present. Instead, investigators use behaviorally oriented subjective report procedures. Activity diaries, which provide a daily record of up time or down time, medication use, and type of activity, provide a common example of this approach (41). One can tabulate a variety of variables obtained from diary forms and plot them over time. It is possible, however, to go well beyond the daily diary in an attempt to scale systematically the physical, social, and psychological limitations imposed by (or adopted in response to) sickness.

One of the most carefully developed and fully validated of the behaviorally oriented instruments is the Sickness Impact Profile (SIP) (42,43). This instrument is a general indicator of health status and health-related dysfunction rather than a pain-specific test. An interviewer can administer it, or the patient can complete it. Patients respond only to the sickness-related behavior change items that describe them appropriately. The SIP provides general scores along three dimensions of disability (physical, psychosocial, and overall) and 12 specific category scores that include, for example, communication, social interaction, and home management. Its measures are derived from responses to 136 items.

Follick and colleagues (44) studied the SIP scores of 107 patients seen at a multidisciplinary pain clinic, 75% of who were receiving worker's compensation payments. The outcomes supported the validity of this instrument as an indicator of functional status in patients with low back pain. The psychosocial dimension of the SIP correlated significantly with Minnesota Multiphasic Personality Inventory scores; the physical dimension score related inversely to independent measures of standing and walking and correlated positively with down time as recorded on activity diaries. These authors concluded that the SIP is a useful means of assessing functional impairment in patients with back pain. The SIP is gradually gaining validation in other populations of patients with chronic pain. The Chronic Illness Problem Inventory (45) shows promise as a useful alternative measure of dysfunction in chronic low back pain patients because it is shorter and easier to score than alternatives.

Back Pain and Function

Functional limitation and disability are an important part of the low back pain syndrome (46). A set of largely objective physical function measures is available for use with patients with low back pain (47). This group of rehabilitation-focused indicators, which works in concert with a battery of psychological measures, includes eight categories of measurement: range of motion, cardiovascular fitness and muscular endurance, gait speed, timed simulation of daily activities, static lifting, lifting under load, isometric and isokinetic dynamic trunk strength, and a global effort rating. A definitive study repeated these measures through the course of treatment and provided feedback on functional capacity to patient and surgeon. Although 92% of patients were unemployed before treatment, only 18% failed to work when treated with this objectively derived rehabilitation model combined with psychological intervention. Again, although not direct measures of pain, these measures of functioning may offer as much or more value in successful treatment or treatment planning as self-report of pain intensity. It is worth noting that even with the high rehabilitation rate of the patients in the study cited, and with a significant decrease of self-reported pain, these patients maintained a mean VAS pain report of 77 out of a possible high score of 150. Clearly, in the treatment of chronic pain, one must define goals and priorities to determine which measures indicate successful treatment.

Many alternatives exist for assessing disability associated with back pain. The Quebec Back Pain Disability Scale (48,49) quantifies functional disability for patients with low back pain, operationalizing disability in terms of perceived difficulty in performing simple physical activities. It is a 20-item scale that assesses six empirically derived categories of activity associated with back pain. Beurskens and colleagues (50) assessed and compared four instruments designed to quantify functional status in low back pain patients: Oswestry, Million, Roland, and Waddell disability questionnaires. The validity and responsiveness of all four seemed favorable. These authors commented that “Functional status measures are not currently used in many settings in which they would be valuable.”

Manniche and colleagues (51) introduced the Low Back Pain Rating Scale, a tool that quantifies pain intensity, disability, and physical impairment. By design, the scale monitors the outcome of clinical trials of low back pain treatment. Westaway and colleagues (52) developed the Patient-Specific Functional Scale and demonstrated that it is an efficient and valid measure for assessing disability and change in disability in persons with low back pain and knee dysfunction.

Pain as Behavior

Many pain states entail certain consistent behavior patterns. For example, studies have shown that patients with back pain tend to grimace, guard their movements, rub themselves, and sigh (53; see Chapter 25). When clinical pain is operationally defined as behavior, one can use objective measures. Clinical researchers can identify selected behavior patterns related to pain, quantify them in terms of frequency or rate of occurrence, and assess them via direct or videotaped observation of patients in settings involving specific task performance. Because behavioral patterns are complex, many of the newer behavioral measures are multidimensional.

Measurement of Pain Behaviors

Medication use (daily amount, frequency of self-administration) is a common measure of pain behavior, although this approach does not provide an adequate measure of pain intensity. It represents an objective measure in a hospital setting, but it is subject to some bias if dependent on patient self-report (see Self-Reports of Behaviors, later in this chapter). A number of other examples exist in the literature of how one can quantify pain behaviors; in general, the method tallies behaviors over time and scores them in terms of frequency. Keefe and Block (54) developed an observational system for scoring pain behavior in patients with chronic back pain. They assessed guarded movement, bracing, rubbing, and sighing. These indexes proved reliable and valid (in relation to reported pain), and the behaviors were more frequent in pain patients than in normal persons or control patients with depression. Keefe and Hill (53) extended this approach by placing pressure transducers in patients' shoes to assess the parameters of walking. Patients and normal persons were required to walk a 5-m course while being videotaped. Patients walked more slowly than normal persons, took smaller steps, did not show normal symmetric gait patterns, and exhibited more pain behaviors. Patients receiving disability payments had significantly longer stride length and longer limb swing time than other patients. This approach thus appears promising for the assessment and objective quantification of back pain, although it is sometimes difficult to separate the effects of pain from those of other causes of functional limitations.

When designing pain behavior measures, the clinical investigator should observe patients in activities likely to evoke pain behavior but not to induce pain. For the patient with back pain, these activities would include walking and changing position, and for the patient with facial pain they might include talking and eating. The pain behaviors one might record for frequency or occurrence or nonoccurrence should be common indicators of pain in the location of interest. These might include grimacing, sighing, or holding the afflicted area. It is then essential to test the consistency of the observers, evaluate the reliability of the measure, and assess validity. Typically, the investigator must infer validity by comparing predicted changes before and after treatment, by examining the relationship of observed behavior scores to self-report of pain and other measures of functioning (see next section), and by looking for expected differences in rates of behavior between the target group and patients with pain at other locations or patients who do not have pain.

Weiner and colleagues (55) examined a group of elderly community-dwelling patients with back pain and lumbosacral osteoarthritis. They compared behavioral observation methods to self-report instruments and the degree to which pain and pain behavior related to disability. They used types of behavioral observations: One was identical to that of Keefe and Block (54), and the other simulated activities of daily living that involve an axial movement activities of daily living protocol. Self-report included a VAS scale and the MPQ. Correlational results revealed that self-reported pain was associated with pain behavior frequency. The association was stronger for the activities of daily living protocol than for the Keefe and Block protocol. The association between pain and disability was modestly strong with both self-report instruments and pain behavior observation under activities of daily living protocol conditions, but not with the Keefe and Block protocol. These authors concluded that observation of elders during performance of activities of daily living may be a more sensitive and valid way of assessing pain behavior than observing pain behavior during sitting, walking, standing, or reclining. Measures of behavior are particularly valuable for patients who are cognitively impaired or otherwise unable to produce self-report of pain. The major limiting factor is that correlations between self-reported pain and pain behavior are modest at best.

A significant limitation of the behavioral observation approach is that pain behaviors are highly specific for each pain syndrome. Patients with shoulder pain or headache, for example, might be indistinguishable from normal subjects on the Keefe and Hill (53) test. Keefe and colleagues (56) undertook behavioral evaluations of pain in patients with cancer of the head and neck to address this issue. They found that such patients displayed their pain primarily through facial expression rather than through guarded movements. Several investigators have developed syndrome-specific pain behavior and disability measures. For example, Heald and colleagues (57) developed the Shoulder Pain and Disability Index, and Vernon and Mior (58) developed the Neck Disability Index.

The search for more global indicators of pain behavior that might have broad application to different clinical populations continues but does not appear promising. Linton (59) investigated the hypothesis that reported pain intensity is inversely related to general activity level in patients with back pain (as measured by self-monitoring or observed behavior in a test situation). He found no relationship between activity level and intensity of chronic pain. Thus, behavioral indicators, used in conjunction with other measures, seem useful as highly specific and precise ways to quantify certain pain problems, but thus far they are not viable options as broad indicators of pain states. Much more definitive work is needed before we can use this approach to address a wide range of pain problems.

Self-Reports of Behaviors

One way to gather information about patients' behavior patterns and habits is to ask the patient, spouse, or some other day-to- day observer. This approach combines the simplicity and efficiency of self-report methods with the theoretical perspective of the behaviorist. It presupposes, however, that the patient (or the spouse) is a reliable and accurate historian. Ready and colleagues (60) found that patients with chronic pain, when asked to report medication use, gave information that was 50% to 60% below actual drug intake. Kremer and colleagues (13) compared patient records with staff observations of patient activity of social behavior and found significant discrepancies. Sanders (61) studied automated monitoring of up time in healthy control subjects, psychiatric inpatients, and patients with chronic back pain. He found moderate positive correlations between self-report and automated monitoring. All groups averaged less self-reported up time than the automated report indicated, the discrepancy being greatest for patients with chronic back pain.

These observations call into question the validity of some self-reports about behavior. When other observation measures are not available, however, and for clinical use, it is often desirable to have a patient complete a daily pain diary, rather than merely report retrospectively on a persisting or chronic pain problem. A *pain diary* is a log of pain-relevant activities broken down into small blocks of time, such as hourly or quarter-hourly segments. The diary form divides activity into such categories as sitting, walking, and reclining, and the patient reports the specific activity under the appropriate category and the time the activity occurred. Typically, diary forms require that the patient rate the pain level on a 0 to 10 numeric scale for each hour and record medication use (Fig. 15-6).

Figure 15-6. A pain diary page for 1 day.

The use of a pain diary with chronic pain patients offers several advantages: (a) Because patients complete the diary each day, it is less subject to distortion based on the patient's current pain experience at the time he or she visits the doctor's office (see Temporal Referent in Self-Report of Pain , later in this chapter); (b) it provides information on patterns of normal activity relative to patterns of pain behavior (or pain-linked inactivity) that is not available from other behavioral assessments; (c) it is inexpensive; and (d) it provides direct information about patient behavior in the home. From the pain diary it is possible to determine behavioral patterns, defined in terms of the time of day or activity, that result in high pain levels versus average pain levels. It can also yield information about time the patient spends in various activities or inactivity over a week. In general, it helps clarify the relationship between pain, activity, and medication use.

The limitations of the pain diary merit comment. For example, the reliability of the pain diary is unknown, because it depends on the accuracy of the patient and the patient's compliance. Some patients complete the form on a daily or hourly basis as directed, but others fill out the form incompletely or do it retrospectively just before their office appointments. With these limitations in mind, we believe that this measure is a useful supplement to subjective pain report when other behavior observation data are unavailable.

SOME SPECIAL CONSIDERATIONS IN PAIN MEASUREMENT

Temporal Referent in Self-Report of Pain

Patient memory for pain, while the patient is in a relatively pain-free state, is reasonably accurate up to a week after postsurgical pain (62,63). For pain problems that do not remit, research has demonstrated that current pain intensity produces systematic distortions of memory for prior pain, independent of treatment outcome (64). This influence of current pain on memory of past pain in persistent or chronic situations suggests that the most unbiased measure of pain would specify current level.

In acute pain circumstances, clinical investigators most commonly ask patients to rate their current pain. With persistent pain, patients more often rate their worst pain in the past 24 hours and their average or usual pain in the past 24 hours. Although more vulnerable to deficits in memory, clinicians sometimes ask about pain in the past week.

Assessment of Pain in Children

Measurement of pain in children requires awareness of developmental stages (see Chapter 44). Just as verbal fluency and the ability to follow instructions develop

with age, pain behavior also appears to vary with development. When assessing pain in infants, one must rely on gross motor indicators of generalized body reaction, reflex withdrawal, and crying. Toddler pain behavior can include pressing the lips together, rocking, rubbing, kicking, hitting, biting, attempting to run away, or opening the eyes wide (65). Although categorizing neonatal and toddler responses is progressing, none of these behaviors is unequivocally pain specific; reliable behavior observation measures available for assessing pain at these early ages are still at issue.

For pediatric patients from age 3 and older, a range of tools is available for self-report and behavior observation. In the area of self-report, a number of studies have indicated that children from approximately age 5 are able to reliably complete a VAS (66,67). With a young child, it is helpful to practice with a VAS on familiar pain problems, such as a skinned knee, to be certain the child understands the scaling before assessing the current pain problem. For children younger than age 5 or those who have difficulty with a VAS, a number of alternatives exist. These include a NRS in the form of a thermometer (68), a color-matching technique in which children choose a color that best represents their pain (69), the *Oucher*, a picture scale validated with children as young as 3 (70), or the Faces Pain Scale (71,72), validated in children from 4 to 8, with good validity and rank order as well as approximate ratio scaling properties. These scales are strictly single-dimension ratings of pain intensity. For multidimensional self-report, some investigators hold that the MPQ is valid for children down to age 12 (65).

Development of behavior observation measures specific to children has focused on pain associated with invasive diagnostic procedures in cancer patients. Researchers have recognized that these children often cannot discriminate between the affective (anxiety) dimension and pain intensity; and consequently these measures tend to be a composite index of distress. Katz and colleagues (73) found that young children display a greater variety of anxiety behaviors over a longer time than older children. As children age, they tend more toward withdrawal and muscle tension behaviors in response to painful procedures. Several researchers have developed behavior checklists with similar types of observed activities (73,74 and 75). Jay and colleagues (74) have revised and developed the work of Katz and colleagues (73) to produce the Observation Scale of Behavioral Distress. The categories in this measure are weighted according to intensity and include crying, screaming, physical restraint, verbal resistance, requests for emotional support, muscular rigidity, verbal expression of fear, flailing, nervous behavior, and information seeking.

As with adults, the multidimensional measurement of pain in children enhances ability to determine appropriate intervention and to assess treatment outcome. In addition to measuring pain intensity and pain behavior in children, it is valuable to assess parental anxiety, because a significant relationship exists between child behavioral distress and parental anxiety (74).

Assessing Pain in the Elderly

Adults of any age may be capable of completing any of the assessment measures described previously (see Chapter 45). However, when patients are older, examiners should anticipate a number of factors that are less often considered in younger adults (17). The areas to assess are the same. The selection of instruments may need some adaptation. Disputes in research results make it unclear whether the elderly are more likely to make errors in completing VAS format pain intensity ratings or other types of intensity scales (9,76,77). If questions exist as to whether a patient is able to understand the VAS or NRS, the Faces Pain Scale for the elderly (6) has been well validated and demonstrates excellent rank order and test-retest reliability, with even some support for ratio scaling. Recommendations from Herr and Mobily (17) are worth repeating. Avoid time pressure; if necessary, select fewer instruments rather than trying to rush an elderly patient who may be having difficulty with comprehension or vision. Evaluate impairments in hearing, vision, dexterity, comprehension, and articulation, along with ability to communicate verbally. One option is to have the patient read a part of the assessment tool to evaluate some of these capabilities. Even mild hearing problems can reduce concentration and understanding if background noise is interfering. Common visual impediments must be considered in selecting tools. These include reduced visual acuity, rate of visual accommodation, color discrimination, and adjusting to glare of lights on paper or eyes. Large, simple, upper and lower case letters help, as does greater space between lines. For their Faces Pain Scale, Herr and colleagues recommend 4-cm-high drawings, with heavy, dark lines (6). Keeping the content simple and providing practice examples can help the patient to comprehend and pay attention. Oral response to items, or scales that allow pointing, can ease some visual and dexterity difficulties. If self-report capability is limited, observer reports may be needed. No tools yet exist that offer clear, reliable, and sensitive behavioral methods for use with cognitively impaired elderly (78).

Cultural factors may inhibit pain report in the elderly. Reasons that patients may be less inclined to acknowledge pain include the following: (a) a belief that pain is expected and must be lived with as one ages; (b) fear that pain may lead to further loss of independence; (c) fear that pain may forebode serious illness or death; (d) unfamiliarity with what others may consider common terms in pain language; (e) justifiable concern that pain complaints will be dismissed as elderly hypochondriasis and lead to people avoiding them; and (f) stoicism (17,78). Other factors that influence perception of pain in the elderly lead to unpredictable modes of pain presentation. Although pain perception does not necessarily decrease with age (17,78,79), atypical presentations are not uncommon, particularly absent or mild pain report with serious illness such as myocardial infarction, peptic ulcer, appendicitis, and pneumonia. Conversely, pain complaints may be used to solicit interaction or may be heightened by boredom, loneliness, and depression. In their study of 758 nursing home elderly, Parmalee and colleagues (79) concluded that, although cognitively impaired, patients may underreport pain; their self-reports, when made, were as valid as those who were cognitively intact.

In summation, pain assessment in the elderly must be undertaken by planning to use the same tools as used with younger patients, but prepared for a wider range of evaluation before assessment and for adaptation of the assessment strategy if the factors described previously apply to the individual patient.

Physiologic Indicators of Clinical Pain

Pathophysiologic changes accompany acute and chronic pain (22,23). When pain is acute, it can be associated with motor reflexes that produce muscle spasm or splinting. When surgical or other trauma has occurred to the chest or abdomen, such reflexes impair ventilation. Autonomic reflexes also accompany acute pain and can inhibit gastrointestinal and genitourinary function, producing ileus and smooth muscle spasm (80). Less specific patterns of autonomically mediated arousal can contribute to distress and fear. Liberation of catecholamines increases blood pressure and cardiac output and increases rate of ventilation.

Secretion of b-endorphin (and b-lipotropin, a precursor) often occurs during acute pain, and in their presence pain intensity is diminished. Szyfelbein and colleagues (68) observed that the concentration of endorphins in plasma was negatively correlated with acute pain report. The greater the levels of b-endorphin, the lower the reported pain. Because endorphins are also linked to stress, however, their presence does not provide objective evidence of the presence of nociception. Therefore, plasma endorphin concentrations might be better indicators of endogenous pain modulation than of pain itself.

Pathophysiologic changes sometimes characterize the area of painful focus in patients with chronic pain. Skin temperature is perhaps the best studied. Some physicians use thermography, the measurement of skin temperature, in evaluation of certain types of chronic pain (81). Complex regional pain syndromes are characterized by temperature changes in the extremities (82). Myofascial pain syndromes, certain cancer pain syndromes, and certain other pain problems manifest low skin temperature in the area of the painful focus, which is indicative of altered sympathetic nervous system function. Pain accompanying some arthritic or rheumatologic conditions is associated with abnormal warmth because of acute inflammation.

Trophic changes occur with some types of chronic pain. When pain is related to trigger points in middle-aged and older patients, it is often accompanied by subtle indicators of autonomic dysfunction, such as enhanced pilomotor segmental reflex, vasomotor and sudomotor disturbances of the skin, and trophedematous changes in subcutaneous tissue (83).

Other physiologic correlates of pathologic pain states exist. Pupil dilation occurs with certain types of migraine headache. Cluster headaches classically involve skin flushing in facial areas. None of these signs, however, proves the presence of pain; nor does the absence of such signs mean that pain is not present. The presence of such correlates increases the probability that pain is present, but correlates do not validate or definitively indicate pain.

Measurement of Analgesia and Pain Relief

Analgesia strictly denotes complete absence of pain, but the term is ubiquitously misused to indicate any diminution of response to a painful stimulus or any relief of existing pain. To facilitate communication, we use the term *analgesia* rather than *hypalgesia* here to indicate reduced pain sensibility (diminished response to a painful stimulus rather than complete absence of ability to feel pain), but we distinguish it from the relief of clinical pain because the latter is a different concept. The term *pain relief* represents the therapeutic alleviation of clinical pain, as determined by subjective report.

The relationship of analgesia to pain is in some ways like the relationship of cold to heat. One can only define cold as the absence of heat, and it is necessary to measure cold in heat units. Similarly, analgesia by definition is the absence of pain in the presence of a normally painful stimulus. We must quantify analgesia in the pain units. The analogy breaks down somewhat, however, because pain is a complex perception that cannot be measured on a single scale, and pain is inherently

subjective. Just as many operational definitions for pain exist, so there can be many operational definitions of analgesia.

Many different analgesic phenomena exist. The mechanism of the analgesia caused by injection of a local anesthetic at a peripheral nerve is not the same as that induced by hypnosis, infusion of an opioid, or administration of a nonsteroidal antiinflammatory drug. In selecting a measure of pain for the evaluation of analgesia, it is important to recognize these differences and select an operational definition of pain that fits the phenomenon in question. Just as no generic index for pain suits all applications, so no all-purpose procedure exists for assessing analgesia. In general, however, the measurement of analgesia requires a pain challenge stimulus. Therefore, analgesia is defined in terms of the difference between a patient's normal or baseline response to the pain challenge and his or her response after an intervention.

Pain relief has occurred when a patient reports reduction in a subjectively defined clinical pain state after intervention. Clinical interventions of many sorts can relieve a pain state without reducing a person's ability to perceive a pain challenge stimulus, such as a pin prick. Nonanalgesic pain relief occurs when a treatment enhances endogenous inhibitory pain modulation mechanisms (e.g., the release of b-endorphin), blocks excitatory pain modulation mechanisms such as algogesic substances or sympathetic nervous system hyperactivity, or selectively blocks or eliminates the pathologic origin of the pain.

Scaling pain relief differs from measuring analgesic effect. It does not require a pain challenge stimulus, and it does not rely on pain scores. Patients typically estimate the amount of pain relief they have experienced in percentage units. They may report this scaling orally from 0% to 100%, or perhaps they use a VAS with anchors of “no change” to “100% pain relief” (see Fig. 15-2). This form of assessment presupposes that the underlying pain is relatively constant (if not chronic) and well known to the patient. Therefore, although this approach could prove problematic in assessing the benefits of a treatment for a postoperative pain that is novel to the patient and variable in intensity over hours or days after surgery, it might work well for cancer patients. Kaiko and colleagues (84) administered morphine to patients with cancer when their pain was either moderate or severe. Patients used a categorized scale to report pain relief: no relief (0), slight relief (1), moderate relief (2), lots of relief (3), and complete relief (4). Patients reported pain relief hourly for up to 6 hours. They constructed a total morphine pain relief score by summing the hourly pain relief scores. Total morphine pain relief varied with dose of drug, initial pain intensity, and site of pain. Complex differences in pain relief were also associated with age and race.

Caregiver Ratings of Pain and Pain Relief

It is sometimes necessary (never do if expedient, only if no other choice) to use judgments made by physicians, nurses, or family members about the patient's pain rather than the patient's own reports. Such data usually take the form of simple category scales such as no pain, slight pain, moderate pain, or severe pain. In some cases, scales incorporate judgments of what the patient can or cannot do on certain tasks, such as bending over to pick up a weight. Sometimes providers judge the success of a therapeutic intervention on an arbitrary scale, such as no pain relief, slight pain relief, moderate pain relief, or total pain relief.

Advantages exist to using such procedures in some populations. For example, patients who are too sick to make reports, are mentally incompetent, are heavily medicated, are on respirators, cannot speak English, or are too young to defy assessment by other than caregiver ratings. Moreover, it is efficient and inexpensive to collect data in this way.

The limitations of caregiver pain judgments are many in acute and chronic settings. First, caregiver judgments are not true measurements and cannot fully substitute for true measures. Pain is a subjective experience, and another individual can never truly observe a patient's pain. One can only infer pain in a patient. In acute care settings, confounding factors can distort such judgments (e.g., the rater's expectations, past experience, or belief about the patient's situation). Knowledge of the patient's organic condition can also bias the pain rating. Moreover, some raters stereotype patients. It is easy to say, for example, that Norwegians are always stoic after surgery, that Italians always vociferate even if the surgery is minor, that women cannot bear pain as well as men, all redheaded patients are hyperreactive, and that children are not as sensitive to pain as adults. These or other stereotypes might be accurate some of the time, but individual patients vary widely and no justification exists for gross generalizations, even when the literature has demonstrated trends in certain directions. If allowed to influence the data, stereotypes can greatly damage the quality of a study. Caregiver rating data are meaningful only when a well-trained rater generates them, using well-defined criteria for judgment. Often it is best to use multiple trained raters.

In the chronic pain setting, in which the efficacy of therapeutic interventions is at issue, different biases can affect rater judgments. Interactions between patient and therapist can lead to positive or negative bias in the therapist's judgments. Moreover, for many clinicians it is impossible to respond independently to each patient. The clinician's perceptions of success or failure concerning the day's preceding cases can greatly affect the ratings of pain relief made for any given patient. In such settings, it is often necessary to rely on a rater who has not been involved directly in the care of the patients undergoing assessment.

Caregiver perception of pain in an older pediatric patient population has proven problematic. Vetter and Heiner (85) compared patient VAS self-report of pain intensity with trained caregiver judgments (multiple raters, satisfactory interrater reliability). The patient-generated and caregiver-generated pain scores correlated poorly.

The limitations of the caregiver rating approach are evident in the literature. Many early studies of acupuncture analgesia, for example, obtained no actual measures of pain or pain relief. Instead, clinician investigators published their own ratings of therapeutic outcome. This was also true of early Chinese studies of acupuncture for pain control. It seemed expedient at the time to rush into print with minimal data, because acupuncture was a pressing mystery. History has dismissed most such studies as inconclusive, and these studies have had no effect on the way Western medicine views acupuncture.

We recommend using caregiver rating data to assess pain and treatment effect only when the patients in question are unable to answer for themselves or when the data are for medical records that will never be used for scientific purposes. If it proves necessary to use such ratings, it is worthwhile to develop and maintain rigorous criteria for the judgments made, to have multiple raters and periodically test their percentage agreement, and, if possible, to have collateral measures of pain or pain relief.

Limitations and Problems in Pain Measurement

In the process of measurement the clinician must (a) conceptualize the patient's pain problem clearly; (b) decide which attributes of the pain to quantify (i.e., the dimensions to scale); (c) decide on the goal of the measurement; and (d) initiate a process that attaches numbers to pain, either by clinician judgment, patient report, or both. Several limiting factors make the clinical measurement of pain a difficult challenge.

- Because no satisfactory objective indicators of pain exist, pain is a fundamentally subjective state. Even when the clinician elects to gather objective indicators of behavior in measuring pain, it is necessary to validate such measures with subjective reports of pain. This restriction to subjectivity reduces pain to a scientific metaphenomenon and forces the investigator or clinician to depend on the patient for accurate and reliable data. Moreover, clinical pain intensity does not vary directly with the extent or severity of clinical pathology or even with the number of nociceptors stimulated. For example, a poor relationship exists between reported pain and the size of a surgical wound (86) as well as between the severity, location, and extent of a burn injury and the pain of the patient (87).
- Pain is a multidimensional experience. The clinician can quantify it on a single dimension using, for example, a single VAS, but this approach risks potentially significant oversimplification (12). Pain has sensory, emotional, motivational, cognitive, and behavioral dimensions.
- The characteristics of pain worth quantifying depend on the patient population in question, the purpose of the assessment, and perhaps the theoretical orientation or scientific assumptions of the clinician investigator. No default standard exists for pain measurement. As emphasized elsewhere in this book, many ways exist to define pain as a clinical problem. Definition depends on the patient population at hand and the basic assumptions of the clinician or investigator. A neurologist approaching chronic pain as a sensory problem might well use operational definitions that are different from those of a behaviorist or a psychoanalytically oriented psychiatrist. No universal index of pain is equally useful for all health care professionals.
- The greatest difficulty in measuring pain is the intrinsic predicament of measuring subjective states of any sort. Measurement is only valid when the numbers obtained correspond in a one-to-one fashion to the underlying variable undergoing measurement. One can never test this validity in the assessment of pain states; consequently, numbers obtained from patients or test instruments as pain measures are not so much actual scores as estimates of pain. One can readily obtain numbers that appear to be measures of pain but in fact are not valid. Inexperienced clinicians may err by oversimplifying the problem (e.g., by measuring only pain intensity in a chronic pain patient), using a weak or unreliable scaling method, or by failing to clearly instruct patients about how to report their pain in numbers.

GUIDELINES FOR SELECTING TEST INSTRUMENTS FOR PAIN EVALUATION

What makes a satisfactory instrument for pain measurement? Most test instruments are based on patient self-report, although it is possible to restrict measurement to

the quantification of behavior alone. In general, clinical pain assessment requires that instruments for subjective report the following: (a) place a minimal burden on patients; (b) be understandable from the patient perspective; (c) produce a wide range of scores and show sensitivity to analgesic or psychological intervention; (d) demonstrate appropriate reliability and validity; and (e) have appropriate norms. For a given application, the choice of a testing device or procedure depends on the unique needs and theoretical bent of the clinician and the limitations of the patient population. No substitute exists for careful planning and forethought in the selection of assessment procedures; no single instrument or procedure is a standard for all applications.

Defining the goal of the assessment is the first step in determining an appropriate choice of measures. In an acute pain situation lasting minutes, and in which the goal is to determine an appropriate medication level, a brief numeric rating of pain intensity from 0 to 10 before and after medication administration might suffice for assessing the adequacy of intervention or the need for further assessment. In chronic pain situations, however, it is nearly always advisable to assess pain with a multidimensional model that includes self-report, behavioral observation, and functional evaluation.

Pain problems exist in which various aspects of multidimensional assessment are uniquely important. For example, the patient who talks cheerfully to family but tearfully complains of pain when alone might require assessment of observed pain behavior and functional status as well as self-report of pain. The same is true for the patient with acute pain who wakes up long enough to ask for medication but is asleep again before the medication arrives. Measurement goals might be defined beyond a generic determination of appropriate treatment. Diagnosis of disease state might be the primary target of assessment. Alternatively, it might be useful to assess the effect of pain on functioning, to define areas of remaining function or well-being, or to evaluate the dependence of pain behavior on environmental factors. Setting clear goals permits the clinician to choose measures within and beyond pain assessment *per se* that provide the most comprehensive yet selective information required for the problem.

The algorithm in Figure 15-7 provides an example of how one might select pain measurement tools for different clinical situations. For immediate purposes, we have defined *brief acute pain* as that which lasts minutes, hours, or days and for which appropriate brief medical intervention is usually the defined goal. *Acute persistent pain* is defined as that which lasts weeks or even months, with slowly healing organic pathology, but has a clear nociceptive origin. Proper diagnosis or adequate medication coverage might be the primary goal of assessment, but it might also be necessary to assess the effect of pain on functioning, to look at environmental contingencies that might support the development of a chronic problem, or to assess the potential effectiveness of an intervention over and above administration of medication. When pain is related to progressive diseases, acute episodes might emerge intermittently in response to nociceptive events (e.g., the painful diagnostic procedures repeatedly performed on cancer patients). In addition, the level of functional impairment varies from individual to individual as a function of factors other than pain intensity alone. Therefore, optimal selection of measurement tools depends on the goal of assessment and the individual being assessed. With chronic pain problems that are not progressive, it is nearly always advisable to assess pain behavior and general functioning in addition to self-reported pain level. In many cases, it is also important to evaluate the personality and environment of the patient in planning appropriate treatment.

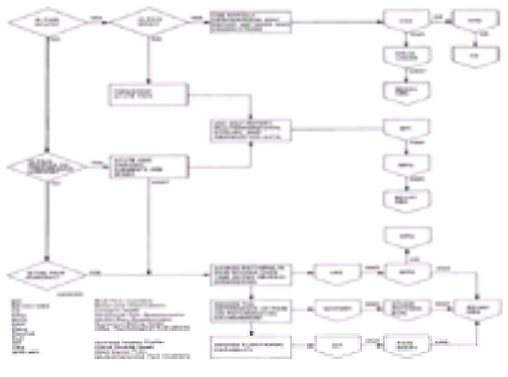

Figure 15-7. Algorithm for selection of pain measurement instruments.

Although thoroughness is of value in treatment planning and assessment of treatment effectiveness, redundancy in information provides only copious information for its own sake and risks alienating or decreasing the motivation of the patient. Unless one is testing the validity of a number of measures for use in a certain population, it is advisable to choose a single measure to assess each of the required dimensions. As an example, if a clinical investigator measures pain quality with the 20-word sets of the MPQ and pain intensity by a VAS, it would not then be necessary to complete the pain intensity ratings of the McGill questionnaire or to complete other measures of pain quality. Establishing a preset plan for pain assessment—a readily available set of forms, scoring procedures, and, most important, plans for use of the resulting information—can ease the work for staff and patient while ensuring that effort has value.

Developing a Clinical Database

A clinical database for pain can greatly facilitate patient management and evaluation of therapy. Until the 1990s, only university clinics or large medical centers could collect, store, and analyze patient data. With the advent of personal computers and easy to use software, the individual physician in practice or the private clinic can afford a small system and the required programs.

Value of a Database

The advantages of a database are obvious. The computer can retrieve and graph important data on patients from all previous visits. From such records, trends in activity level, reported pain, social behavior, or other relevant factors are readily available for examination. This makes it inexpensive to evaluate the effects of changes in medication, surgery, behavioral interventions, or other treatments. Below, we offer some basic guidelines for the physician who wishes to develop a database for pain patients and demonstrate the effectiveness of intervention for third-party payers.

Guidelines for Database Development

Design the Data Layout Carefully from the Beginning

Most commercial database programs assist in data layout, but they are for business rather than for medical applications. Therefore, the physician must plan carefully or enlist the aid of a programmer with expertise in database work. It is often best to find the programmer before buying the software. A database consists of a matrix of rows, which are cases, and columns, which are variables. If the database is poorly structured, one may have trouble with information retrieval or graphics.

Consider Automated Data Collection

In most settings, it is feasible to collect data from patients via a computer interview conducted at an office terminal or via palm-top devices that patients can take away. The latter option exploits rapidly expanding technical possibilities for automated two-way communication between providers and patients. Technological advances offer at least three important benefits to clinicians: (a) automated data collection is economically advantageous; (b) computer technology is more accurate and reliable than human data collection; and (c) technology can accompany the patient in virtually all settings 24 hours a day. Experience shows that most patients are comfortable with, and like, the computer interview. Many believe that automated processing increases their privacy.

The economic advantages of computer technology stem largely from the reduced manpower requirements. With paper-based technology, an office needs a nurse or psychometrist to administer the test forms and score the instruments when data collection is complete. Entry of scores into the database requires that someone hand-enter data into the computer. To ensure accuracy, standard psychometric practice dictates that someone enters the data a second time and examines all discrepancies in the two entered records. Computer technology ensures accurate scoring and data entry automatically, thus saving substantial day-to-day manpower costs.

The accuracy and reliability advantages of computer technology derive from the greater computational power and accuracy of computers. Putting standard testing inventories onto a computer is straightforward. Computer administration differs from paper administration in that the computer can insist that the patient respond to all

items, and it can perform ongoing checks to ensure that all scores are in the expected range. Sophisticated testing programs can detect contradictions and nonsensical responses. This ensures a cleaner and more complete data record than one would normally obtain with paper instruments.

Finally, computers offer a great advantage because they can track the activity, medication intake, and pain levels of patients in their home and work environments. It is possible to beep or otherwise request that patients activate an interactive data collection program on a pocket-sized electronic interview instrument, or even call a phone number and use the phone number pad as the response method. This allows for powerful examination of chronologic pain patterns, including breakthrough pain, and it also provides a basis for tracking or facilitating medication compliance. The simplest approach requires patients to bring the hand- held computer device to every office visit. The nurse can quickly download its contents into the database. More sophisticated, and increasingly common, approaches involve transmitting the data on a daily basis from the patient's hand-held device to the clinic via telephone or, in some cases, radio signals.

Automated data collection systems sometimes offer a fourth advantage for clinical practice. A sophisticated system can update a centralized patient record almost instantaneously. Building on this, physicians can design interactive records that display data in summary form. For example, for a cancer patient a data record could chart pain and opioid side effects across days or weeks, thus affording visual pattern recognition of trends. The physician on rounds could look at pain and side effects patterns across time at the nurses' station. Gleaning the same information from a printed chart would take hours, and this clearly is infeasible in today's economic climate. We expect revolutionary progress in automated data records within a few years of the publication of this volume.

Avoid Collecting Too Much Data

A common mistake of inexperienced clinical database developers is the tendency to collect copious information for its own sake. It is easy to assume that data collected now might prove useful later. However, extra data collection burdens the patients, degrading their motivation and compliance in a way that compromises the overall quality of the measurement process, and it diffuses the focus of the investigation. In some instances, the clinician may fail to collect critical information because a hurried patient or a busy nurse has given priority to obtaining the extra information instead of data for the core testing devices. Moreover, when data collection involves complex test devices, the scoring of test data can become costly and time consuming. Costs of patient evaluation and research escalate in proportion to the amount of data collected. It is therefore important to streamline data collection and minimize patient information demand.

Be Sure the Test Instruments Fit Your Patient Population

Some testing forms or instruments demand more of certain patients than they can provide. For example, the MPQ uses a vocabulary that is too complex for poorly educated patients. Other tests are not useful with patients from certain cultural subgroups because the tests presume that patients engage in activities that they never perform. Still others are too great a burden for very sick or heavily medicated patients, such as certain cancer or AIDS patients. Always check the appropriateness of an instrument's norms for the population at hand.

Take Care to Collect Responses to All Items on All Forms

As we noted previously, patients who use paper forms sometimes feel uncertain about how to answer particular items and therefore leave them blank. The result is a missing element in the database. Large amounts of missing data render the database useless. Clear instructions, a minimal responder burden, and a quick check by the nurse or data gatherer at the end of testing help minimize lost data.

SUMMARY

The measurement of pain remains a knotty problem, but it has received considerable attention and there has been substantial progress in the development of theory and technology. Most clinicians now recognize that the perception of pain is a complex phenomenon and that it is prudent to guard against oversimplification in assessing pain. Sensory, emotional, functional, motivational, and cognitive aspects of pain merit evaluation in many settings. New instruments for pain measurement have taken this complexity to account in various ways. For a comprehensive review, see the Turk and Melzack volume (1). Subjective report and behavioral observation methods have advanced in recent years and promise to continue evolving in valuable directions.

CHAPTER 16

Psychological and Psychosocial Evaluation

Judith A. Turner and Joan M. Romano

Chronic pain that is associated with significant physical and psychosocial dysfunction poses a difficult, often refractory, problem for the patient, his or her family, the clinician, and society. In such cases, a comprehensive psychological evaluation can provide information useful in identifying psychological and behavioral factors that may be contributing to the individual's pain and disability, as well as elucidate the impact that a chronic pain problem may have on physical, psychological, and social functioning. The psychological evaluation can also provide information essential to the planning and implementation of successful treatment.

Current conceptual models of chronic pain are based on the recognition that, in addition to whatever pathophysiologic factors may underlie a pain problem, psychological or behavioral factors often contribute to the persistence and severity of chronic pain and disability. As a pain problem persists over time, greater opportunity arises for psychological and behavioral processes to influence the course of pain and disability. The experience of pain, as well as of associated loss of vocational, home, family, recreational, and social activities and roles, can have profoundly negative effects on mood, self-image, and interpersonal relationships. These changes, in turn, can contribute to persistent suffering and disability, in a vicious circle. Causal relationships are difficult to delineate, but for patients with disabling chronic pain, a complex mix of physical, psychological, and behavioral factors almost always perpetuates dysfunction. Defining these factors is critical to designing effective treatment for such patients. Failure to address these issues can result in poor response to traditional somatically focused treatments. The psychological evaluation can also be useful in selecting particular therapeutic approaches for given patients. For example, evidence of severe depression, stress-related problems, family conflict, or alcohol abuse indicates the need for specific interventions beyond those for pain.

In this chapter, we discuss indications for and purposes of the psychological evaluation of the patient with chronic pain, preparation of the patient for the evaluation, the important components of the evaluation (including interview topics for both the patient and significant other), and several instruments that may be used to supplement the clinical interview.

BASIC CONSIDERATIONS

Indications for Psychological Evaluation

A psychological evaluation can be useful in all cases in which pain interferes significantly with a patient's ability to engage in normal activities, in which pain has adversely affected interpersonal relationships, and in which the patient shows signs of significant psychological distress (e.g., depression, anxiety). Psychological assessment is also indicated when the patient repeatedly and excessively uses the health care system, persists in seeking invasive investigations or treatments after being informed these are not appropriate, or uses opioid or sedative-hypnotic medications or alcohol in a pattern of concern to the patient's physician (e.g., escalating use).

Purposes of a Psychological Evaluation

The psychological evaluation is useful for delineating specific psychological and behavioral factors involved in pain, suffering, and disability. These can include such diverse processes as social and environmental reinforcement of pain behaviors, depression, and avoidance of activities believed to cause pain. The psychological evaluation can also reveal aspects of the patient's psychosocial history that are relevant to the current problem. Knowledge of history of psychological disorders (e.g., depression), substance abuse or dependence, vocational problems, family role models of pain or chronic illness, and recent life stress can often enhance understanding of the patient's current pain problems. A further purpose of the evaluation is to determine which psychological and behavioral treatment strategies are indicated for a particular patient and the conditions necessary for optimal chances of successful treatment.

The psychological evaluation cannot give definitive information about the cause of the pain. The presence of psychological factors likely to be influencing pain and disability does not exclude the possibility of organic pathology, just as the presence of positive physical findings does not necessarily imply the absence of important psychological influences. Conversely, the absence of positive physical findings does not indicate that the pain must be “psychogenic.” A number of problems are associated with the use of this term. Such labeling tends to obfuscate the specific psychological and behavioral factors contributing to the pain problem. It perpetuates the outdated conceptual dichotomy between “organic” and “psychogenic” or “functional” pain, an oversimplification that does not consider current concepts of pain that acknowledge the role of psychological factors in pain, regardless of cause (see Chapter 26). Furthermore, it underestimates the complexity of most chronic pain syndromes, in which some mixture of psychological and pathophysiologic influences is found.

Another problem associated with the use of the term “psychogenic” arises in physician-patient communication. Patients typically interpret the term to mean unreal or imagined and react with anger and defensiveness if their pain is so labeled. This interferes with the physician-patient relationship and creates a negative setting for seeing the psychologist. Many patients seen in pain clinic settings have been told or have the impression that their physicians think that the pain is “all in their head,” and often much effort needs to be expended to convince the patient that those on the staff accept the validity of the pain. In such circumstances it is difficult to develop a working alliance.

The psychological evaluation can identify risk factors for poor response to surgery, although it cannot lead to a precise prediction of whether a particular patient is going to respond well or poorly to surgery for the pain problem (see Chapter 76). Although a number of studies (1,2,3,4 and 5) demonstrated a moderate statistical association between various psychological factors or *Minnesota Multiphasic Personality Inventory* (MMPI) results and surgical response, the strength of such associations is not sufficient to warrant reliance on such techniques for making surgical decisions in individual cases. The decision for or against surgery must be made on the basis of the patient's history, physical examination, and diagnostic test findings, but the psychological evaluation can be useful in identifying patients with psychological characteristics that are associated with poor response to surgery. Such patients may benefit from psychological treatment as an adjunct to medical and

surgical management.

Preparation of the Patient for Psychological Evaluation

Patients with chronic pain may be concerned that referral for a psychological evaluation implies that their physician believes that their pain is “not real” or that they have a mental disorder, or both. Patients may not see the relevance of such an evaluation to their pain problem, which they view as having a biomedical etiology. When compensation or litigation issues are present, patients can be sensitive to the financial implications of the psychological evaluation report. Careful explanation of the reasons for recommending the assessment can reduce guardedness and defensiveness and enhance patient receptiveness to and cooperation with the evaluation.

Whether the psychological evaluation is a routine part of the practitioner's or facility's assessment procedure, or the patient is referred to the psychologist after a medical evaluation has been completed, adequate preparation of the patient is invaluable. It is helpful to state explicitly that the evaluation is to be conducted not because it is believed the pain is psychogenic or not real, but because the evaluation can provide information useful both in determining factors that might be increasing suffering and functional disability and in suggesting specific treatments for managing pain and enhancing the ability to engage in normal activities. This can be illustrated in a way personally meaningful to the patient by pointing out symptoms the patient has reported (e.g., sleep disturbance, fatigue, depression) and stating that such problems are frequently associated with chronic pain and can make the pain and suffering worse, thus creating a vicious circle. The patient can then be told that certain psychological techniques can improve these symptoms, as well as help him or her to manage the pain better.

COMPONENTS OF THE PSYCHOLOGICAL EVALUATION

General Format

This chapter describes a comprehensive psychological evaluation and areas important to address in such an evaluation. Even when conducted by an experienced psychologist, such an evaluation can require as many as 3 hours, including a review of relevant medical records, interviews with patient and significant other, feedback to the patient, and report preparation. We recognize that in many situations and settings it is necessary to conduct a less time-consuming and hence less comprehensive assessment. In such situations, the psychologist must consider the purpose(s) of the evaluation in deciding what topics to cover and in what detail. Major psychological disorders can be screened for by asking a few questions or by asking the patient to complete self-report questionnaires before the interview. If the psychologist will continue to see the patient in treatment after the initial evaluation, some topics and questions can be deferred to a subsequent session.

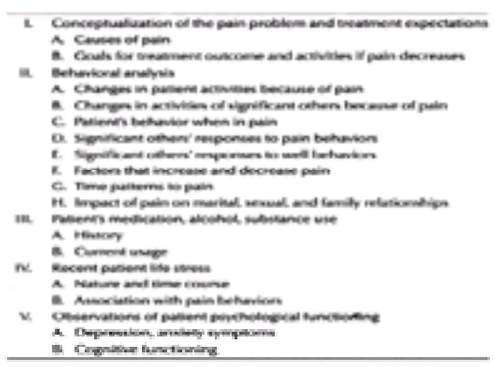
In addition to an interview with the patient, it is extremely useful, if at all possible, to separately interview the patient's spouse, family member, or close friend who has had regular contact with the patient over a long period (for the sake of brevity, we refer to such a person as a “significant other”). The reasons for this should be discussed in advance with the patient. Patients can be given the rationale that such interviews greatly increase the information needed to understand the patient's pain problem thoroughly and can provide another perspective on pain-related changes that have occurred over time. It might also be helpful to mention that family members are affected by the pain problem as well and often appreciate the opportunity to express their views and feelings.

It is most helpful to spend a small portion of the evaluation in an initial conjoint interview with the patient and significant other to observe how they interact and the remainder of the time in separate interviews. Patients and spouses alike typically speak more freely and openly in the absence of the other. The clinician conducting the evaluation, however, needs to be alert to issues of confidentiality. At times, problems can arise when the patient or significant other requests that important information be withheld from the other or from professionals involved in the patient's care. Such problems can often be resolved by discussing the reasons for wanting this information withheld and then frankly addressing the limitations this imposes on clinical recommendations and care. Alternatively, some clinicians may want to ask the patient and significant other before the interviews begin if it is acceptable to openly discuss with one partner all information conveyed by the other. Discrepancies in information given by the patient and significant other (e.g., concerning drug or alcohol use or sexual functioning) must be clarified in a sensitive manner. In cases in which assessment or treatment decisions are influenced by this information, it is usually best to achieve clarification at the time of the evaluation by openly discussing the discrepancies with the couple. The patient and significant other should be informed at the beginning of the interview of the limits of confidentiality, as required by law (e.g., the requirement that child abuse and elder abuse must be reported).

The sequence of topics covered in the interview is important. The interview can be structured, as shown in Table 16-1, so as to decrease patient guardedness and increase patient ease by initially focusing on the history of the pain problem and the patient's current subjective experience of the pain and then by exploring activity and functional changes, pain behaviors, and responses of others. Questions about substance use and symptoms of psychological disorders are best deferred until later in the interview, when rapport has been established and the patient presumably feels more comfortable.

TABLE 16-1. Patient interview topics

Table 16-2 provides an outline that might be used for a separate interview with the significant other. Important areas to assess include the significant other's conceptualization of the cause(s) of the patient's pain and goals for treatment. In addition, questions should be asked about pain-related activity changes for the patient and spouse, with attention to how these relate to any changes in the marital relationship and family functioning. Pain behaviors observed and the responses of family members to these are also of great importance, as are the significant other's observations of the patient's medication and alcohol intake and of stressors affecting the patient. Finally, the significant other can provide important observations concerning symptoms of psychological disorders. These points are discussed further below.



I.	Conceptualization of the pain problem and treatment expectations
	A. Causes of pain
	B. Goals for treatment outcome and activities if pain decreases
II.	Behavioral analysis
	A. Changes in patient activities because of pain
	B. Changes in activities of significant others because of pain
	C. Patient's behavior when in pain
	D. Significant others' responses to pain behaviors
	E. Significant others' responses to well behaviors
	F. Factors that increase and decrease pain
	G. Time patterns to pain
	H. Impact of pain on marital, sexual, and family relationships
III.	Patient's medication, alcohol, substance use
	A. History
	B. Current usage
IV.	Recent patient life stress
	A. Nature and time course
	B. Association with pain behaviors
V.	Observations of patient psychological functioning
	A. Depression, anxiety symptoms
	B. Cognitive functioning

TABLE 16-2. Interview outline for significant other

General areas to assess in the patient interview are outlined in Table 16-1 and below. The categorical distinctions we make are of necessity somewhat artificial and arbitrary because areas overlap. Each area pertains to the overall goal of determining the specific psychological and behavioral factors that may be associated with pain, physical and psychosocial disability, and appropriate treatment strategies.

History of Pain and Current Subjective Pain Experience

It is important to determine when and how the pain started and what the pain experience (i.e., qualitative, quantitative, and temporal) has been over time. The circumstances of onset may be associated with current psychological dysfunction, as in the case of posttraumatic stress disorder (discussed later in this chapter) or anger at perceived negligence in an accidental injury. Information about the pain experience, of course, must be interpreted in light of the type of pain syndrome (e.g., low back versus headache versus phantom limb) and any associated physical findings that could influence clinical presentation and course. Identification of times of the day or particular situations associated with increased or decreased pain can provide data as to potential environmental reinforcers for pain behaviors, stressors associated with increased muscle tension, and other possible contributors to ongoing pain and suffering.

Patient and Significant Other Pain Explanatory Model, Expectations, and Goals

In planning treatment and in optimal preparation of the patient for treatment, it is important to understand the patient's and significant other's conceptualizations of the cause(s) of the patient's pain (explanatory model) and his or her expectations and goals regarding treatment. Does the patient want or expect medical diagnosis and treatment to eliminate the cause of the pain, or is the patient receptive to learning ways to better manage the pain? It is frequently the case that the patient or significant other believes that the medical workup has been inadequate, that further medical diagnosis is necessary, and that the only appropriate treatment is surgery to eliminate the cause of the pain. Similarly, a patient's and significant other's goal of obtaining or continuing on disability compensation is inconsistent with treatment aimed at improved physical functioning and return to work. Unless such beliefs are addressed and some consensus is reached between patient and clinician as to problem conceptualization and treatment goals, behavioral and other psychological treatment efforts are unlikely to succeed.

Previous and Current Treatments

It is useful to inquire about previous and current pain treatments and the effects of these so that this information can be used in planning future interventions. Assessing the nature and extent of treatments is important. Patients might state that they have unsuccessfully tried a particular treatment modality (e.g., physical therapy, biofeedback, antidepressant medication), yet might not have had an adequate trial of treatment for reasons of misapplication, patient noncompliance, or failure to persevere with the intervention for a sufficient period of time to test it adequately. “Failure to respond” under such conditions does not necessarily preclude that particular treatment from being tried again, provided that patients are given an adequate rationale for doing so. Patients should be asked not only about traditional medical treatments but also about chiropractic treatment and other complementary treatments (e.g., herbal therapy, massage therapy, vitamin therapy, homeopathy, acupressure, acupuncture, naturopathy), because use of these may be associated with their explanatory models of their pain problem.

Medication and Alcohol and Substance Use

Obtaining a clear picture of the extent and pattern of a patient's use of analgesic and sedative-hypnotic medications, as well as of alcohol or illicit substances, is important for several reasons. First, medication and substance use may be affecting a patient's physical and psychological functioning. Second, information concerning the effects of past and current medication regimens on pain and functioning is useful to physicians in making decisions concerning whether such medications should be continued, modified, or discontinued. Third, some patients with chronic pain problems may exhibit patterns of problematic or escalating use of these medications in the absence of progressive disease (6,7). This is a frequent reason for patient referral to a multidisciplinary pain center for evaluation. Fourth, abuse of or dependence on alcohol or other substances can interfere with efforts to treat pain and disability and may require specialized treatment beyond that used for pain.

Although the use of long-term opioid therapy may be appropriate for some patients with chronic noncancer pain (8), the circumstances under which such therapy should be considered need to be defined on an empiric basis, and this remains an area of controversy within the field of pain management. An in-depth discussion of the pros and cons of this practice is outside the scope of this chapter (see Chapter 84). However, as part of the psychological evaluation of patients with difficult, disabling pain problems, it is important to elucidate patterns of medication and substance use as accurately as possible to identify their potential contributions to patient physical and psychological functioning, and the resulting implications for treatment.

Inappropriate medication use and substance abuse complicate assessment of the pain problem for a number of reasons. Excessive alcohol, sedative-hypnotic, and opioid use may contribute to dysphoria, irritability, mood swings, decreased energy, sleep disturbance, cognitive impairment, and appetite and weight changes, which may not be recognized as substance- or medication-related (9). In a minority of patients, pain behaviors may function to legitimize drug-seeking and use.

As part of the patient psychological evaluation, inquiry about previous and current medication use can easily follow from other questions concerning previous treatments for the pain problem and the patient's response to those. Having patients keep 1 to 2 weeks of diaries of medication use can also be helpful, although patients may underreport use (10). Questions about alcohol and other substance use are best asked later in the interview, when patient-interviewer rapport and patient comfort with the interview are likely to be higher. The CAGE questions (11) may be used to screen for possible alcohol problems (Have you ever felt the need to *C*ut down on drinking? Have you ever felt *A*nnoyed by criticism of drinking? Have you ever had *G*uilty feelings about drinking? Have you ever taken a morning *E*ye opener?). Sensitive questioning concerning current and past patterns of alcohol and substance use, driving under the influence of alcohol or substances, or any history of alcohol- or substance-related interference in work or family life can provide detail necessary to decide whether a referral to a chemical dependency treatment program may be warranted.

Because patients may be reticent to disclose alcohol and substance use or may underestimate consumption, it can be informative to ask significant others about these issues. We also find that questioning the significant other about the effects of medications on the patient's physical and cognitive functioning, mood, and behavior can provide important information not obtained from the patient.

It is usually necessary to refer patients for whom substance abuse or dependency is a major problem to a chemical dependency treatment program before treating the pain problem. Most pain programs are not equipped to treat such problems, which are likely to interfere with maintenance of improved function after treatment. Tapering of prescribed opioid and sedative-hypnotic medications can usually be accomplished as part of a pain treatment program.

Behavioral Analysis

One of the primary aims of the psychological evaluation is to determine whether behavioral factors may be playing a role in a patient's pain behaviors and disability (see Chapter 25). Reinforcement of pain behaviors by social or environmental contingencies may contribute to ongoing patient disability, in addition to the influence of other factors, such as guarding, deactivation, depression, and other psychological disorders. A behavioral analysis is an important part of the comprehensive psychological evaluation of the chronic pain patient and can yield information crucial to treatment planning. This analysis entails identifying, at least on a presumptive basis, social and environmental factors that may contribute to the maintenance of pain behaviors and disability, and assessing the feasibility of modifying these factors in treatment.

Contingencies maintaining pain behaviors may take the form of direct positive reinforcement—for example, pain behaviors may be followed by greatly increased support and expressions of caring from significant others. In other cases, reinforcers may involve the avoidance of aversive situations or activities, such as family conflict or a stressful or dangerous work environment. Often, reinforcers may be quite subtle and difficult to identify. Pain behaviors may function to elicit involvement from an otherwise uninterested spouse or may allow patients and significant others to avoid dealing with stressful problems such as sexual dysfunction or cognitive deterioration.

A thorough behavioral analysis, based on interviews with the patient and significant other, can provide a basis for generating hypotheses to be tested in further observations and interactions with the patient and for treatment planning. Fordyce (12) provides a detailed description of the theoretical background and method of conducting a behavioral analysis. The two major foci of the behavioral analysis, patient and significant other pain-related activity changes and social responses to pain behaviors, are discussed in the following sections.

Activity Changes

A careful analysis of how the patient's activity patterns have changed since pain onset can be a rich source of information bearing on possible reinforcers for pain behaviors as well as factors contributing to depression and stress in the patient's life. Activity changes can suggest that learning factors may play an important role in the maintenance of pain behaviors and disability, as well as highlight significant losses in the patient's life that may be related to emotional distress and that may be important to address in treatment.

Patients typically describe major changes in their activities and lifestyle as a result of their pain problem. Often they describe significant decreases in work, home, social, and recreational activities and a concomitant increase in sedentary activities such as watching television or resting during the day. Patients frequently describe such changes as distressing and as resulting in increased boredom and isolation. However, the assessment can also reveal positive consequences of the pain problem for the patient, such as increased closeness to or support from family, removal from a stressful or dangerous job situation, reduction in family conflict or demands, or increased amounts of time available to spend with a spouse or children. The presence of such consequences does not imply malingering but can suggest the influence of operant (learning) factors on pain behaviors and the need to address these factors in a pain management program (see Chapter 88). It should be noted that positive and negative consequences for pain behaviors (such as those listed above) may coexist, complicating the assessment process and contributing to difficulties in rehabilitation. Although patients understandably may focus on the losses they have experienced as a result of pain, it is important to examine the overall balance of positive and negative consequences for pain behaviors in assessing readiness to engage in rehabilitative treatment. As part of this analysis, it is also important to identify patient readiness to pursue behavioral goals and acquisition of pain coping strategies, alternative strategies the patient may have available to obtain social and financial support, and whether the patient has or can develop effective strategies for coping with stressors.

Another line of inquiry that often proves fruitful concerns what future activities the patient and significant other would like to and realistically could perform if the pain posed fewer limitations. The identification of activities that were highly reinforcing for the patient in the past and that might be targeted as part of a rehabilitation program can be useful in planning goals for treatment. A rehabilitation program is unlikely to be successful unless such behavioral goals can be identified.

The interviewer conducting a behavioral analysis can start by asking patients to list specific vocational, home management, social, and leisure activities that they used to do until the pain began but are doing less or are not doing now. It can be informative to ask the same questions of the significant other separately, with the aim of learning how frequently each activity was performed before the onset of pain, as well as which activities were pleasurable and which were not. Some patients may state that they used to do many pleasurable things (e.g., sports) that they no longer can do; careful questioning sometimes reveals that these activities were actually engaged in rarely immediately preceding the onset of pain. It is useful to observe the degree of congruence between the patient's current affective state (depression versus apparent comfort in current lifestyle) and activity change (major losses versus no major losses in pleasurable activities). If marked incongruence is present, further questioning may reveal additional relevant information that was missed previously.

Inconsistencies in activities that have been reduced or eliminated because of pain can help to identify positive and negative reinforcers of pain behaviors. An example is the situation in which one usual activity is performed, but another, with similar physical demands, is not. Often, the former activity is found pleasurable by the patient, whereas the latter is aversive. Not uncommonly, however, an activity is avoided, not because it is aversive, but because the patient fears that it will produce increased pain. This issue is discussed further in the section on guarding.

Social Relationships and Reinforcers

The behavioral analysis includes an examination of how the patient's significant others respond to his or her pain behaviors and how this might affect the patient's pain behaviors, coping, and functioning. To assess the probability of direct social reinforcement of pain behaviors, it is necessary to ask the patient and the significant other how others know when the patient has increased pain and how others respond at those times. Even if patients do not complain directly of pain, significant others frequently report that they infer pain from behaviors such as facial grimacing, lying down, limping, or taking medications. The responses of significant others to these behaviors need to be detailed, as well as whether these are viewed positively or negatively by the patient and significant other.

The significant other's responses to “well behaviors”—that is, behaviors inconsistent with the sick role—must also be determined. If patient activity, such as beginning a household task, is followed by the significant other's attempts to discourage that activity or take it over or if patient behaviors associated with being well are followed by withdrawal of affection and attention or renewed demands, or both, rehabilitation can be difficult unless these responses are modified. Also, it is important to identify aspects of the patient's pain and disability that are reinforcing to family members, with or without their awareness. Shifts in family members' roles and responsibilities can occur in response to patients' pain problems and can be highly reinforcing. Patients' attempts to resume their former roles and duties can meet with some resistance if family members' needs are not addressed.

Behavioral formulations of chronic pain problems (e.g., 12) have noted that responses by the significant others to patient pain behaviors and well behaviors may be one factor contributing to ongoing pain behaviors and dysfunction (see Chapter 88). Solicitous behaviors—that is, behaviors characteristic of taking care of someone who is ill or disabled (e.g., encouraging rest and reduced activity, taking over tasks, comments and actions conveying concern or sympathy for the patient's physical condition)— have been examined most frequently in this regard. Such behaviors would appear to have high potential for reinforcing pain behaviors, given that they are frequently provided on a pain-contingent basis and many patients describe such responses in positive terms, as evidence of significant others' care and support.

Empiric support for solicitousness as a potential reinforcer of pain behaviors has come from studies demonstrating that solicitous responses of significant others to patient pain behaviors are associated with higher pain ratings and lower patient activity level (13,14), more frequent pain behaviors (15,16), and higher levels of disability (16). If family members frequently respond to the patient's verbal and nonverbal pain behaviors, it is likely that social reinforcers are important in maintaining pain behaviors and should be addressed in treatment. However, social reinforcement of pain behavior may take forms other than solicitous responses, including ignoring or expressions of irritation or anger, and must be evaluated in the context of the relationship. For example, in a conflicted marriage, being left alone may be quite reinforcing. Social reinforcers of pain behaviors thus must be defined on the basis of their impact on behavior, not on their presumed positive or negative qualities.

It is helpful to ask about the quality of the marital relationship over time and about the effects of the pain problem on the relationship. Patients and significant others often report changes in the marital relationship due to the patient's pain problem and associated dysfunction. Often patients become more irritable and depressed, causing increased interpersonal conflict. Consistent with this, several studies have reported increased rates of marital dissatisfaction and psychological distress among the significant others of patients with chronic pain (17,18,19 and 20). In other cases, however, patients and significant others may report increased closeness as a result of coping with chronic pain.

It is also important to assess the effect of the pain problem on the couple's sexual relationship. Many couples report a decrease in sexual activity since pain onset, due to the patient's decreased sexual desire, due to increased pain caused by sexual activity, or both. Significant others may avoid sexual activity due to fear of causing increased pain. A decrease in sexual activity or quality of the sexual relationship can be very distressing to one or both partners and can negatively affect the marital relationship. However, changes in marital satisfaction or sexual activity can also be the result of long-standing conflicts within the relationship, perhaps exacerbated by or explained in terms of pain. Pain may also legitimate avoidance of intimacy in some individuals (e.g., if sexual activity had been aversive, as is sometimes the case because of its association with previous trauma, such as sexual abuse). Thus, the evaluation of relationship changes and effects of pain can be fully understood only in the context of the history of the relationship and of each partner.

It is also important to consider the relationship implications of changing the patient's functioning in treatment. In some cases, the marital system may depend on the patient being “ill” to maintain stability; in such situations, one partner may, at some level, fear that the other will leave if the patient becomes more functional and independent. Alternatively, the spouse may fear that the patient will no longer “need” the significant other if he or she gets better. Such relationship issues may form formidable barriers to patient improvement if not recognized and addressed (e.g., with marital therapy).

Guarding, Deactivation, and Activity Pacing

Many patients show guarding behaviors—that is, they avoid certain activities or body movements that have been associated with increased pain. Fordyce and his associates (21) described certain pain behaviors (e.g., limping) that can effectively reduce nociceptive input during the acute phase after an injury. Over time, such behaviors become habitual, and the patient no longer allows himself or herself the opportunity to engage in activities, such as normal limb use, due to fear of provoking increased pain. Such patterns of avoidance may lead to disuse syndromes, and initial attempts to reverse this pattern are likely to lead to increased pain,

confirming patients' beliefs that such activity is painful and likely damaging. If this appears to be the case for a particular patient, treatment should be aimed at helping the patient learn that not engaging in the guarding behaviors is safe and at gradually shaping normal use of the affected part of the body. As Fordyce and colleagues (21) emphasized, this must be achieved by setting up a program in which the patient gradually increases performance of the feared behavior, because information provision alone is unlikely to produce a change in beliefs or behaviors (see Chapter 88). It is important to inform patients that such a program typically results in increased discomfort initially, but this does not mean it is harmful, and that such treatment is necessary to regain normal use patterns involving the affected part of the body and to prevent further complications of disuse.

A problem closely related to avoidance learning is deactivation or deconditioning. This is a common accompaniment to chronic pain, especially common musculoskeletal pains such as low back and leg pain. Many patients find that pain is worsened by activity and reduced by rest. Because this pain reduction positively reinforces resting behavior, resting is likely to occur more frequently in the future (22). Excessive resting over time often results in decreased physical strength, flexibility, stamina, and conditioning. This sets up a vicious cycle in which any attempt at activity results in increased pain, which punishes such attempts and reinforces inactivity. This also reinforces the patient's fears that activity is harmful. As this cycle progresses and patients become progressively more deactivated, they lose opportunities to engage in positive activities that would have physical and psychological benefits for them, such as social or recreational activities, and have increased opportunities to think and worry about pain, both of which can contribute to depression and further withdrawal. Such patterns can result in profound physical and emotional deterioration, with some patients spending nearly 24 hours a day reclining and having difficulty engaging in even basic self-care activities because of this progressive pattern of deactivation and pain. Activity diaries, described below (see also Fig. 16-1), are a useful means of determining the frequency and duration of time spent in rest versus activity each day. Excessive time spent resting indicates the need for a treatment program that involves gradual systematic increases in activity.

Figure 16-1. Activity diary.

Another pattern seen with frequency in patients with chronic pain is dysfunctional activity pacing. Many patients respond to periods of decreased pain with overactivity (”I'll get all the house and yard work done now while I can”). This overactivity causes increased pain, and the patient responds by resting until he or she feels better. Patients who tend to have cycles of underactivity followed by overactivity often benefit greatly by learning how to plan activities in advance so that they are paced and there are periodic breaks.

Vocational Assessment

Obtaining a vocational history and clear picture of current vocational status and future prospects is often critical in understanding the pain problem and in treatment planning. If the patient is not currently working, is return to work a desired and realistic goal? If so, is the patient's former job available and feasible? Is vocational retraining necessary? If so, how could this be funded? This is a very complex area. Many patients injured at work receive wage replacement income, and these patients may, understandably, be afraid of losing this steady income, especially if the customary job is aversive or no longer available, if income from the job is unreliable (as in seasonal work), or if the patient fears reinjury or increased pain if he or she returns to work. Patients whose medical conditions prevent them from returning to work at their accustomed jobs can find this loss and the financial ramifications very distressing. Patients involved with workers' compensation systems may be angry if they perceive they are being treated unfairly or forced to return to work at a lower-paying job. Any such pertinent issues must be addressed directly before and as part of treatment; otherwise, chances of successful treatment are greatly diminished.

Compensation and Litigation Issues

The extent to which financial compensation for disability (e.g., wage replacement after a job injury) or unresolved litigation related to the pain influences the maintenance of pain behaviors and the response to treatment is of great clinical and economic importance. Some studies have suggested that patients with chronic low back pain who do not receive financial compensation and who do not have pending litigation have better treatment outcomes than do those who are on workers' compensation or have pending litigation (23,24 and 25). The ways in which various compensation and litigation systems influence the maintenance of pain problems and response to treatment are complex and might well interact with other patient characteristics.

In clinical settings, knowledge of compensation and litigation issues can help to clarify contingencies that the patient perceives to be associated with getting better versus those involved with remaining disabled. We have observed that many patients have unrealistic expectations concerning the duration of wage replacement payments and the amount of settlement awards likely to be received. It is frequently valuable to discuss these issues openly with the patient (and the patient's attorney) before treatment begins to ensure that all concerned have the same expectations regarding future financial compensation and its relationship to treatment outcome.

Social History

Obtaining a brief childhood and family history can yield valuable information concerning patients' prior learning experiences regarding pain and illness behaviors, significant role models for pain and disability, and the characteristic response of the family to health problems. A history of chronic pain and disability in the family can result in learning-restricted and maladaptive behavioral responses to illness and discomfort. This can be explored by questioning the patient and significant other about the range of responses to pain and illness shown by the patient and family members. For example, is there a history of long periods of time off work after injury; financial compensation for disability; or significant disability in normal vocational, avocational, and household roles? Significant others can be asked similar questions about their personal and family history to determine if they are responding to the patient's pain behaviors in maladaptive ways based on past learning experiences.

A family history of depression or other psychological disorders can alert the clinician to the potential contribution of such factors to the patient's current situation and developmental history through biological predisposition, learning patterns, or both. Similarly, familial alcohol or drug abuse and childhood abuse or neglect are often seen, suggesting the need to assess their impact on the patient.

We have observed, and studies have reported, high rates of childhood and adult sexual abuse in women with chronic pain problems, especially chronic pelvic pain (26,27 and 28) (see Chapter 70). If the clinician wishes to assess for a history of abuse, a thorough assessment involves specific questions about emotional, physical, and sexual abuse. The clinician's responses, of course, are important. As noted by Jacob and DeNardis (29), it is unhelpful to imply disbelief, ask questions that are perceived as intrusive, challenge the patient's responses, or minimize the importance of the abuse. It is helpful to respond in a sensitive manner, expressing concern and asking about the patient's comfort after disclosure. Jacob and DeNardis (29) suggest, and we agree, that it is not appropriate to obtain a detailed history of abuse experiences in a pain management setting, in which the focus should be on a general understanding of the abuse and how it might bear on the patient's pain problem. A referral to someone with special expertise in treating victims of abuse can be offered if the patient has symptoms or concerns related to the abuse.

Cultural Factors

In any assessment of chronic pain, the influence of cultural factors on the expression of somatic complaints and pain behaviors should be acknowledged. Cultural values and beliefs can affect patients' responses to chronic pain and illness, patient-provider relationships, and providers' responses to patients' problems (30,31).

Although few studies have examined the role of culture in pain behaviors and pain-related health care use, attention to such relationships might help the clinician to understand the meaning of a patient's pain and health care–seeking behaviors within the context of family and culture more clearly and suggest ways to prepare the patient and family for pain treatment approaches. An evaluation by a psychologist should always be conducted in accordance with the ethical principles of psychologists (32), which recognize that ethnic and cultural differences (among other factors) may significantly affect the process of psychological assessment and treatment. Additional training or consultation should be obtained, or an appropriate referral made, if needed, to ensure that competent services can be provided to patients of different ethnic backgrounds.

Stress

Many reports have considered the relationship between stress and disease, injury, and illness behavior (33). Within this broad area, attention has increasingly focused on basic research in underlying psychophysiologic processes and adaptational and coping mechanisms thought to mediate stress responses. An association has been reported between life stress and pain description in some patient samples (34,35), but these relationships appear to be complex, possibly influenced by a number of factors requiring further clarification.

We have often seen such an association in our clinical experience, although patients can initially deny or minimize the contributions of stress to their pain problems. The interview with the significant other frequently reveals information about stresses affecting the patient. In many cases, no major stressor can be identified as associated with pain onset, but current stressors in the patient's life can contribute to psychophysiologic dysfunction, such as increased levels of muscle tension, illness behavior and disability, and use of medications or alcohol as coping strategies (33).

Of course, pain, inability to engage in normal social, recreational, vocational, and homemaking activities, and worry about the prognosis or cause of the pain are themselves often sources of major stress. Worry about the cause of the pain and its implications can profoundly affect the patient's emotional functioning and interpersonal relationships. Identification of stressors and of their effects on pain, suffering, and family functioning indicates directions for treatment, which include stress management training, relaxation training, and psychotherapy, as well as techniques aimed at altering stressful situations (e.g., marital or family therapy).

Psychological Disorders

Psychological disorders, especially depression and anxiety disorders, are common in patients seeking health care but are frequently undiagnosed in medical patients (36,37). This is probably a result of a number of factors, including patient denial or minimization of psychological symptoms, patient attribution of psychological symptoms to pain or physical disease, and lack of physician time spent with patients in discussing psychosocial issues. Certainly, the emotional impact of chronic pain and disability can result in mood disturbance, and the psychological evaluation needs to address these issues in detail.

Depression is a particularly prevalent and treatable disorder in chronic pain populations (38,39) and should therefore be assessed routinely as part of the psychological evaluation. For purposes of descriptive evaluation and consistency of communication across disciplines and settings, the *Diagnostic and Statistical Manual* (4th ed) (40) criteria specified by the American Psychiatric Association are recommended (see Chapter 26). Assessment of depression should not be limited to asking about depressed mood, because patients may deny or minimize this. Other depressive symptoms, such as decreased interest or anhedonia, fatigue, insomnia, and suicidal ideation, may be present but not reported spontaneously by the patient. All patients should be asked questions to assess possible suicidality, and an assessment of the patient's risk for suicide should be included in the report of the psychological evaluation. Identification of clinically significant depression among chronic pain patients is facilitated by the use of brief self-report questionnaires, as described below, but such testing does not serve as a substitute for a thorough clinical interview and evaluation.

A brief screening for other psychological disorders should be included in a comprehensive psychological evaluation. Anxiety and somatization disorders, for example, are seen with some frequency in chronic pain patients. It is important to obtain a thorough history from the patient and significant other, and from records of the past medical history, to determine whether the patient has a history of multiple medical problems and treatments suggestive of somatization disorder.

Posttraumatic stress disorder (PTSD) may be present in individuals whose pain stems from a motor vehicle accident (MVA) or other traumatic event or situation experienced or witnessed by the patient and involving actual or threatened death or serious injury. This disorder is characterized by persistent reexperiencing of the traumatic event, avoidance of stimuli associated with the event, and symptoms of increased arousal (40). There appears to be a high prevalence rate of PTSD and also of depression in individuals with chronic pain associated with an MVA (41,42,43,44,45,46 and 47) and a high prevalence of chronic pain in combat veterans with PTSD (48). Thus, it may be useful to screen for PTSD symptoms as well as for depression in all individuals with pain due to an MVA or serious injury. The PTSD Checklist can be used as a brief screening instrument for PTSD (49). The presence of PTSD may increase suffering and disability associated with chronic pain and requires specialized treatment (42).

In older patients, previously undiagnosed dementia is common. Pain can be used as an excuse to avoid certain activities the patient finds difficult to perform because of intellectual deficits. Intact social skills can mask the severity of the cognitive impairment, and a structured mental status examination is a useful screening tool for dementia (50). The *Mini-Mental State* (51) (Table 16-3) is a brief measure that is a useful screening tool; however, it is highly sensitive to education, and a well-educated individual with a mild to moderate level of dementia can perform well on this measure. Furthermore, the *Mini-Mental State* cannot provide information about the source of cognitive impairment (e.g., depression, medication, Alzheimer's). Subtle impairment might not be detected by the mental status examination, however, and formal neuropsychological testing is a more sensitive indicator when clinical observation and family report suggest some deterioration of cognitive function.

TABLE 16-3. Some measures useful in the psychological evaluation of the patient with chronic pain

INSTRUMENTS FOR ASSESSMENT

A number of instruments are useful for supplementing information obtained through interviews (see Table 16-3). Those most frequently used and clinically relevant instruments are highlighted below. For a more detailed review of self-report assessment instruments developed for use with chronic pain patients, see Turk and Melzack (52).

Minnesota Multiphasic Personality Inventory

The MMPI (53) and the MMPI-2 (54) are commonly used in the assessment of personality characteristics of chronic pain patients. The original MMPI is a 566-item true-false questionnaire developed in the 1930s and 1940s that describes a patient on three validity scales and 10 scales designed to assess psychological disturbance. A revised version of the instrument, the MMPI-2, designed for use with adults aged 18 or older, was published in 1989 and includes 567 items and the same scales as those in the original (54). A number of items on the original MMPI were eliminated or modified, and the normative sample for the MMPI-2 is more representative of the U.S. population. The MMPI-2 has less objectionable and more contemporary item content than the original MMPI. In general, an individual's profile types are similar when tested with either version; however, MMPI-2 profiles are slightly less elevated than MMPI profiles. A thorough discussion of the MMPI is

beyond the scope of this chapter; interested readers can find more information in several sources (54,55,56,57,58 and 59).

Of particular interest is Keller and Butcher's (60) book on the use of the MMPI-2 in the assessment of patients with chronic pain. This book presents MMPI-2 data from 502 patients who participated in a chronic pain rehabilitation program in Minnesota from 1985 to 1987 and recommends using a standardized score (T-score) cutoff of 65 and above to indicate clinical significance instead of the traditional T-score of 70.

The MMPI can be used to corroborate clinical impressions and to generate hypotheses about a patient's personality and psychological factors involved in a patient's pain problem. A substantial body of research has demonstrated low to moderate associations between certain MMPI scales and profile configurations and particular behavioral characteristics of patients with chronic pain (61,62).

Perhaps the most extensively researched area is the ability of the MMPI to predict response to medical and surgical therapies for pain. Although some negative results were reported, a number of studies (1,2,3,4,63,64,65,66 and 67) found an association between elevations on the hypochondriasis and hysteria scales and poor response to medical and surgical treatments for back pain. Caution is warranted in applying these findings to individual patients, however, because the association is moderate and, although statistically significant, can only be suggestive rather than prescriptive in clinical application.

Interpretation of the MMPI requires training and specific experience with the patient population of interest. As noted previously, although certain scale elevations and profile patterns can be statistically associated with certain patient characteristics, such an association might not be present in a particular person. MMPI interpretations should be regarded as providing probable hypotheses regarding patient functioning rather than definitive conclusions.

A number of drawbacks are associated with the use of the MMPI. It is lengthy, and many patients view it as irrelevant to the evaluation of their pain problem. Despite its drawbacks, however, much information exists about the meaning of MMPI scores. In the hands of someone skilled in its interpretation with patients with chronic pain, especially in conjunction with clinical interview data, the MMPI is useful in assessment and treatment planning.

Depression Inventories

Because depression is such a common and treatable disorder in patients with chronic pain, self-report depression measures are a useful supplement to the clinical interview. The *Beck Depression Inventory* (68,69) and the *Center for Epidemiological Studies- Depression Scale* (70) are commonly used. A study found both measures to be valid in identifying major depression in patients with chronic pain (71).

Activity Diary

Fordyce et al. (21) described diaries in which patients record, on an hourly basis, all medications used (type and amount), activities, position (sitting, standing or walking, or reclining), and pain intensity for 1 or 2 weeks (see Fig. 16-1). Although several studies found that patients with chronic pain typically underreport medication use and activity levels (10,72,73), another study (74) reported high positive correlations between patient and spouse diaries of patient lying and standing-walking time and medication use (number of pills). This study also found that lying, sitting, and standing-walking times and medication use were relatively consistent over a 1-week period. Patients and spouses knew that they were recording the same variables at the same time, which might explain the higher agreement found in this study.

Despite the unresolved issue of the degree of accuracy of diary information, in our experience, diaries are generally sufficiently representative of a patient's activity level, medication use, and pain intensity patterns to provide valuable information of assistance to the clinician. For example, the diary can be used as an indication of whether medication use may be excessive or inappropriate. Regular use of opiate or sedative-hypnotic medication every few hours may be a sign of medication dependence.

The diary also indicates the degree to which the patient is deactivated. Patients seen in pain clinic settings not infrequently record up to 20 hours or more spent reclining each day. Such a pattern indicates the need for a reactivation program involving exercise that gradually increases in duration and intensity. This may be initiated in physical therapy, using a “quota” system (12), and continued in a regular unsupervised exercise program and in a volunteer or job station program of gradually increasing daily duration.

The activity diary can also reveal consistent patterns in pain intensity. Such patterns might be temporal—that is, pain is consistently worse at a certain time of day or on certain days of the week, and the reasons for these patterns can be explored with the patient in the interview. Fluctuations in pain levels reliably seen in tandem with certain events can help in identifying situations found by patients to be physically or psychologically stressful. Identifying these situations and assessing the associated stresses can shed light on factors potentially maintaining pain and disability, as well as indicate directions for intervention.

ADDITIONAL CONSIDERATIONS

As this chapter indicates, the psychological evaluation of chronic pain problems is a highly complex task, involving a broad range of clinical questions and issues. In light of the current health care environment, it is important to note that the complexity of such a psychological evaluation might not be recognized by managed care organizations. Efforts to communicate what can and cannot be done in the time authorized are needed to avoid misunderstandings and to educate managed care organizations about the amount of time required for, and the usefulness of, a comprehensive evaluation.

The overriding theme of the psychological evaluation is the delineation of psychological and behavioral factors involved in persistent pain, disability, and suffering, with a view toward prescription of appropriate interventions for altering these patterns. The outcome of this evaluation is a synthesis of the information gathered, resulting in a list of problems reflecting the contribution of specific psychological and behavioral processes to the maintenance of suffering and disability. The appropriateness of various treatment strategies should be suggested by the data gathered in the course of the evaluation. Decisions as to the intensity and duration of treatment are affected by the extent to which factors such as medication dependence, deactivation, and entrenched patterns of social reinforcement appear to maintain illness behaviors. The degree to which variables such as social reinforcement, patient beliefs about pain, patient cognitive and behavioral responses to pain, marital and family conflict, depression, and stress play a role in pain problems determines whether the intervention program should incorporate strategies such as behavioral therapy techniques, cognitive-behavioral therapy, marital or family therapy, and antidepressant medication.

CHAPTER 17

Evaluation of Function and Disability

James P. Robinson

The purpose of this chapter is to outline some of the problems that surround disability determination in patients who claim incapacity because of pain. Problems are described at the level of individual physicians who try to make disability determinations and at the level of public policy. Also, practical suggestions are provided for the clinician who is asked to make disability determinations about patients whom he or she is treating.

Two caveats are appropriate at the outset. First, the scientific underpinnings of disability evaluation in painful conditions are weak. As a result, any discussion of the subject must be tentative and speculative. The goal of this chapter is not to “solve” the problem of disability evaluation in painful conditions but rather to explore some of the factors that have made solutions so difficult to achieve. Second, this chapter focuses almost exclusively on problems associated with pain and disability in the United States. This reflects the practical fact that my knowledge of disability systems is limited to those that operate within the United States. Clearly, other countries are struggling with the problem of pain and disability (1,2,3 and 4), and the issues considered in this chapter may well be relevant to these countries. As the following discussion demonstrates, however, generalizations across countries and even across disability systems within a single country are hazardous.

OVERVIEW OF THE PROBLEM

Some people with chronic pain seek assistance from society because of incapacity associated with their pain. The requests for assistance take various forms. For example, some may claim that they are unable to walk long distances and request disabled parking stickers. They may say they are unable to manage routine chores at home and request subsidized chore worker services. Or, they may claim that they are incapacitated from work and request work disability benefits under various private, state, or federal disability programs. This chapter focuses on the problems associated with the evaluation of work disability secondary to pain. For simplicity, the term “disability” is used as a synonym for “work disability.”

The problem of disability secondary to pain is an elusive one that yields conflicts and contradictions at multiple levels of analysis. At a clinical level, conflicts and distrust frequently develop between disability applicants and the physicians and disability adjudicators who are involved in their claims. Independent medical examiners and attorneys often become participants in these conflicts. Patients often think that physicians and others discount their complaints. Physicians and adjudicators experience doubt or outright skepticism about complaints of pain in the absence of corroborating physical findings.

At an administrative level, disability programs are run by bureaucracies that have certain imperatives. For example, the Social Security Administration (SSA), which runs the two largest disability programs, strives for uniformity, objectivity, and cost containment in its disability evaluation procedures (5). However sensible these goals are from a bureaucratic standpoint, they often are at odds with the clinical realities of patients with chronic pain (6).

At a societal level, additional concerns and perspectives emerge. Disability programs reflect an ethical commitment to support citizens who are incapable of working. If a program is too restrictive, it may consign needy applicants to poverty; if it is too lax, it may encourage disability applications from people who are actually capable of working. Even if a program is meeting its ethical mandate quite well, it may strain the financial resources of the country to the breaking point. This is precisely the concern that is now being voiced about many of the programs run by the U.S. SSA.

At a scientific level, issues related to disability are usually unanswerable because the research underpinnings for “disability evaluation science” are so meager. Moreover, the search for scientifically valid conclusions about disability may be compromised by the adversarial settings in which disability evaluations are made and the enormous financial stakes involved.

Finally, at a philosophical level, the problem of disability evaluation in chronic pain rests on an epistemologic dilemma—the information available to an individual experiencing pain is fundamentally different from the information available to any external observer who attempts to assess the pain. Scarry succinctly captured this dilemma when she said, “To have pain is to have certainty; to hear that another person has pain is to have doubt” (7). In clinical situations, chronic pain patients frequently communicate the sense that they are severely incapacitated by pain and ask physicians to support their claims. Typically, physicians who evaluate these patients cannot identify tissue damage or organ pathology that make the limitations communicated by the patient seem inevitable or even plausible. The physician then has the dilemma of integrating the subjective reports of a patient with the objective evidence of tissue damage or organ pathology to come up with some final judgment about the extent to which the patient really is incapacitated. At one extreme, a physician might simply ignore a patient's self-assessments and make a disability determination based strictly on objective findings of tissue damage or organ pathology. At the opposite extreme, the physician might accept the patient's definition of the situation and give a disability rating that is congruent with the patient's self-assessment. Most physicians feel uncomfortable with either extreme, but it has proved extremely difficult to find some middle ground in which both objective evidence and self-assessments by patients can be incorporated into disability evaluations.

BASIC CONCEPTS: IMPAIRMENT AND DISABILITY

Any discussion of pain and disability runs the risk of foundering on the heterogeneity of disability systems. In the United States, these include the 50 state workers' compensation systems, the three federal workers' compensation systems, two disability programs run by the SSA, a Veterans Administration disability program, and several disability programs offered by private insurance companies. Because of the multitude of disability programs, virtually any statement about disability is likely to have exceptions, and it is difficult even to define concepts unambiguously. The following discussion attempts to mitigate this problem by focusing on the largest disability programs.

Impairment is defined in the American Medical Association's (AMA's) *Guides to the Evaluation of Permanent Impairment* (4th edition) as “an alteration of an individual's health status. [It] is assessed by medical means and is a medical issue. An impairment is a deviation from normal in a body part or organ system and its functioning” (8).

Disability is a more difficult term to define. The AMA *Guides* defines it as “an alteration of an individual's capacity to meet personal, social, or occupational demands, or statutory or regulatory requirements, because of an impairment. Disability refers to an activity or task the individual cannot accomplish” (8). This definition is general; it refers to activity limitations in any arena. In contrast, agencies that administer work disability programs have developed a variety of more restricted

definitions of disability. The definition of disability used by an agency identifies the criteria a patient must meet to be eligible for benefits. For example, the SSA defines disability as “the inability to engage in any substantial gainful activity . . . by reason of any medically determinable physical or mental impairment that can be expected to result in death or that has lasted or can be expected to last for a continuous period of not less than 12 months” (9). In contrast to the definition in the AMA *Guides*, the one used by the SSA refers only to a person's ability to work.

As a practical matter, there are different “kinds” of disabilities, based on the regulations and definitions of the different agencies that administer disability programs. For example, disability can be total (meaning that an individual is judged to be incapable of any employment) or partial (meaning that the individual is judged to be incapable of certain kinds of work). It can be permanent or temporary. Some programs (e.g., workers' compensation) emphasize causation—that is, they award disability only if a worker's incapacity has been caused by an injury or illness at work. In other programs, such as the SSA's disability programs, causation of a patient's incapacity is irrelevant. Some programs provide a single cash settlement to compensate an individual for his or her disability; others provide ongoing wage replacement payments. This chapter focuses on disability programs administered by the SSA and uses its definition of disability.

A close relation exists between impairment associated with pain and disability associated with pain. This is because all disability systems construe impairment as a necessary condition for disability. The logic underlying this requirement is simple. Disability programs are designed to assist individuals who are unable to compete in the workplace because of a medical condition. In essence, disability programs attempt to partition individuals who fail in the workplace into two large groups: ones who fail because of a medical condition and ones who fail for other reasons (e.g., advanced age or lack of demand for their skills). Therefore, disability programs require evidence that an applicant has a medical problem underlying his or her workplace failure. Impairment provides the needed evidence, as it can be viewed as a marker that an individual has a medical problem that diminishes his or her capability. Conversely, if an individual has no impairment, this means that he or she does not have limitations due to a medical condition.

In addition to the qualitative requirement that a disability applicant must be impaired, informal observation strongly suggests that disability programs act on the assumption that the probability of disability increases as the severity of impairment increases. This hypothesis is difficult to prove because the decision-making rules of most disability agencies are not open to public scrutiny. But some of the largest disability administrations, including the SSA and the California workers' compensation system, openly state that severity of impairment is one important consideration in disability awards (10,11).

The discussion so far indicates that impairment is necessary, but not sufficient for disability. This raises an obvious question: What factors other than impairment are considered in disability determinations? No single answer to this question exists because different disability programs have different criteria for identifying an individual as disabled. In a general way, however, disability programs attempt to integrate medical information regarding a disability applicant with nonmedical factors that bear on his or her ability to compete in the workplace. For example, as described under Pain and the Social Security Administration Disability Evaluation Process, the SSA considers not only an applicant's impairment, but also his or her age, education level, and past work experience.

Another key question is the following: Who gathers information about disability applicants, integrates medical data with nonmedical data, and ultimately decides which applicants receive disability awards? Again, the answer varies from one disability program to another, but in general, both physicians and nonmedical adjudicators play a role. Physicians are expected to determine the diagnoses of disability applicants and the severity of their impairments. Also, physicians are often asked to give opinions about the vocational implications of patients' medical problems (e.g., to state whether a patient is capable of light, medium, or heavy work). Physicians who provide this information occupy a variety of niches within disability systems. In some instances, the physician who is treating a patient provides medical information. In other instances, independent medical examiners are commissioned by insurance companies, disability agencies, or courts to examine disability applicants and provide necessary medical information. Independent medical examiners function as consultants to disability agencies rather than employees. Their impartiality can be questioned, as each side in a disputed case wants its own examiner(s). Finally, disability agencies sometimes hire physicians to provide the information needed.

Regardless of the specific niche they occupy, physicians typically report their findings and opinions to nonmedical disability adjudicators. It is the adjudicators who actually make disability decisions, after combining medical and nonmedical data on applicants.

This chapter uses the term *disability evaluation* to describe the evaluations that physicians perform on applicants for disability benefits. Physician disability evaluations generally include assessments of impairment, but they also address other issues. Thus, an impairment rating is construed here as a component of a physician disability evaluation. A physician disability evaluation, in turn, is only one component of the overall evaluation that a disability applicant undergoes. It is supplemented by information gathered and interpreted by nonmedical adjudicators. For simplicity, this chapter focuses on the challenges that physicians face during disability evaluations; it ignores the roles that nonmedical professionals play in the disability determination process.

PAIN AND THE AMERICAN MEDICAL ASSOCIATION IMPAIRMENT RATING SYSTEM

Because impairment represents the medical component of disability, it is critical to consider the manner in which impairment associated with pain is assessed. I do this in relation to the impairment rating system developed by the AMA because it is the one that is used most widely in the United States.

It is helpful to start an analysis of the AMA approach to impairment associated with pain by considering problems in which pain and other subjective complaints do not play a major role (e.g., an amputation in a patient who has no significant pain complaints). Complications introduced when the system is applied to painful conditions can then be addressed.

General Features of the American Medical Association Impairment System

The AMA impairment system represents an ambitious attempt to quantitate impairment affecting essentially all organ systems and body parts. The first step in an impairment rating is for a physician to give a quantitative measure of loss of function in an organ or body part. The measure is supposed to be based on objective, publicly available information. For example, an amputation at the metacarpophalangeal joint of the thumb corresponds to a 40% impairment of the hand (8).

The rating process then involves a series of abstractions so that a measure of “whole person impairment” can be achieved. For example, the patient with an amputation at the metacarpophalangeal joint of the thumb would be judged to have a 36% impairment of the upper extremity (8) and a whole-person impairment of 22% (8). Whole-person impairment is conceptualized as a unidimensional scale running from 0% (for an individual with no measurable deficit) to 100% whole-person impairment (for a person who is comatose or has some other type of problem that is totally incapacitating). The whole-person impairment concept thus has two essential features: It measures the severity of impairment (with a range from 0% to 100%), and it permits direct comparisons to be made among impairments involving different organs and different diseases.

The AMA system raises several obvious questions:

1. *Can the functioning of organs be measured objectively? How should this be done? How reliable are the measurements?* As an example of problems in this area, experts have debated the appropriateness of range of motion measurements in the assessment of impairment associated with disorders of the spine. As a result, two different systems are described in the fourth edition of the AMA *Guides*. The range of motion model includes spinal range of motion as one factor in determining impairment; the injury model completely eliminates range of motion in impairment ratings. The duality of the AMA's present approach to spine impairment rating reflects lack of consensus among experts about the reliability with which spinal motion can be measured and the relevance of the measurements (12,13 and 14).
2. *Is it possible to interpret measurements of organ function throughout the range from completely normal to completely absent or dysfunctional?* Often, the impact of organ impairment on whole-person functioning is relatively easy to measure at the extremes. For example, if there is no impairment of the organ, there is no associated deficit in an individual's activities. If an organ or body part has essentially no function, the individual either dies (if the affected organ is a vital one) or demonstrates fairly predictable activity deficits (e.g., as in T-8 complete paraplegia). But the impact of partial organ impairment is often difficult to assess and may be modified by a variety of psychosocial characteristics of the affected person. Some people are resourceful and determined in overcoming impairments. Their activity limitations are likely to be smaller than would be anticipated on the basis of their impairments. Other patients show different patterns of adaptation to impairment and have relatively large activity limitations. The personal factors that modify the impact of a partial loss of function in an organ are extremely difficult to quantify and factor into an impairment rating.
3. *Is valuable information lost in the process of abstraction that occurs when specific deficits are converted to whole-person impairment?* For example, a patient with an amputation of an upper extremity at the shoulder and one with significant renal insufficiency might both have whole-person impairments of 60%, but the specific activity deficits of the two patients would be entirely different.
4. *What does the concept of whole-person impairment mean? Is the concept supported by research that demonstrates its construct validity?* Because the AMA

> construes impairment as existing at the level of specific organs or body parts, the meaning of whole-person impairment is unclear. One could construe it as a global measure of a patient's activity deficits. This meaning is suggested at one point, when the AMA *Guides* states, “An impairment percentage derived by means of the *Guides* is intended, among other purposes, to represent an informed estimate of the degree to which an individual's capacity to carry out daily activities has been diminished” (8). However, this interpretation makes whole-person impairment similar to the AMA's concept of disability. Surprisingly, the AMA *Guides* contains only a brief discussion of whole-person impairment and says nothing about how it compares with disability.

Given the ambiguity of the whole-person impairment concept and the strong possibility that critical clinical information is lost when an examiner converts an assessment of organ impairment into a whole-person impairment rating, there is an obvious need for research to validate the whole-person impairment construct. Presumably, such research would focus on relations between quantitative measures of whole-person impairment and quantitative evidence of limitations in activities of daily living. However, virtually no such research exists (15). In essence, whole-person impairment is a concept that is at best questionable as far as face validity is concerned and lacks validation through research.

American Medical Association's Rating System for Painful Conditions

The discussion so far has explored generic problems with the AMA impairment system rather than problems specific to the assessment of impairment secondary to pain. When the AMA system is applied to painful conditions, new strains emerge in the relations among disease, organ impairment, whole-person impairment, and activity limitations. The essential new element introduced by pain is the tension between objective and subjective perspectives on impairment. As noted earlier, the AMA system rests on the assumption that organ impairment can be assessed objectively. This is precisely the assumption that is challenged by patients who report incapacity secondary to pain. The recurring problem is that the patients report incapacitation that exceeds any objectively measurable evidence of organ dysfunction.

The issues surrounding impairment assessment in painful conditions vary from one pain problem to another. A key point is that chronic pain is frequently one of many manifestations of a chronic medical condition. The pain associated with the medical condition often cannot easily be abstracted from the other manifestations of the condition. For purposes of analysis, most painful conditions can be placed in one of five categories on the basis of relations among the pain, other manifestations of the underlying disease, and impairment: incidental pain, expected pain, magnified pain, unverifiable pain, and psychogenic pain.

- Incidental pain—Pain occurs along with evidence of organ dysfunction severe enough to produce severe impairment by itself. Example: a patient with congestive heart failure and angina pectoris.
- Expected pain—Pain occurs in the context of objective evidence of organ dysfunction. The pain appears to be consistent with the objective findings and is a major reason for the patient's incapacitation. Example: A patient with imaging and electrophysiologic evidence of a persistent L-5 radiculopathy reports pain in an L-5 distribution of the affected leg and does not demonstrate any evidence of symptom magnification. Significant atrophy of the affected leg exists.
- Exaggerated pain—Pain occurs in the context of objective evidence of organ dysfunction and is a major reason for the patient's incapacitation. An examining physician, however, judges the pain to be exaggerated relative to the objective findings. Example: a patient with the same clinical syndrome as in incidental pain, but the patient reports severe pain in both legs, reports that he is spending 22 hours per day in bed because of his pain, and demonstrates several nonorganic signs (16) on examination.
- Unverifiable pain—Pain occurs in the context of a medical condition that normally does not produce objective signs of organ dysfunction. Examples include chronic headache and fibromyalgia.
- Psychogenic pain—Pain is judged to be a manifestation of a psychiatric disorder—that is, a somatoform disorder, such as pain disorder associated with psychological factors (17).

Relations among pain, disease, and impairment for each category are diagrammed in Figure 17-1.

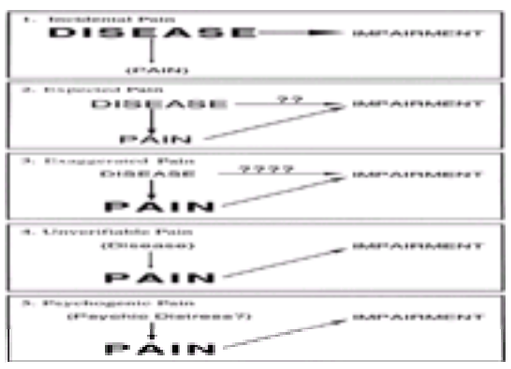

Figure 17-1. Categories of pain, based on relations among pain, impairment, and an underlying disease. 1. Incidental pain: The underlying disease directly causes impairment, regardless of whether there is associated pain. Pain may or may not be present but is not a central determinant of the impairment. 2. Expected pain: Disability agencies treat conditions in this category as if the disease leads directly to impairment; however, as the figure indicates, this causal chain is questionable. Although the disease may cause objectively measurable impairment, the major driver of the patient's activity restrictions is pain. The apparent severity of the patient's pain and pain-related restrictions appears to be appropriate to the disease. 3. Exaggerated pain: The connection between pain and impairment is even more questionable for conditions in this category. There may be objectively measurable impairment, but the objective findings are grossly inadequate as an explanation of the patient's apparent activity restrictions. Also, the link between disease and pain is questionable for conditions in this category—that is, the patient's apparent pain exceeds what would be expected for the disease. 4. Unverifiable pain: In this category, the disease postulated to underlie pain and impairment is inherently not objectively measurable. A disease may be inferred by an examining physician, but the inference is completely dependent on the patient's pain behavior—that is, the presence of the disease can be established only by asking the patient about his or her pain. Thus, although a disease is presumed to exist, it is “invisible.” 5. Psychogenic pain: In the extreme, there is no disease at all underlying the patient's pain complaints—that is, there is no anatomic or physiologic abnormality that can be construed as the source of the patient's complaints. As noted in the text , concepts surrounding psychogenic pain are poorly developed. Some experts suggest that psychic distress or unresolved emotional conflict “takes the place” of an abnormally functioning organ as the source of pain. Although the patient refers his or her pain to an organ or body part, the source of the pain is “in the mind” rather than in the organ or body part.

The above typology highlights the variety in relations among impairment, pain, and other manifestations of disease. In terms of this typology, the AMA *Guides* is devoted almost exclusively to patients with incidental pain or expected pain. A discussion of pain as a manifestation of a psychiatric disorder is included, but no details are given either about how to place a patient in the psychogenic pain category or how to rate impairment in such a patient. No useful information is provided on the rating of patients with exaggerated pain or unverifiable pain. Thus, the AMA impairment system is probably adequate for some categories of pain but not for others. More generally, it is quite possible that any system for evaluating impairment associated with pain will need different approaches for the different categories outlined. However, with the exception of the Report of the Commission on the Evaluation of Pain (18), discussions of pain and disability have rarely dealt with the implications of different categories of pain. The implicit assumption has generally been that the problem of impairment from pain could be discussed without any detailed consideration of the ways in which pain and other manifestations of disease interrelate.

Expected pain deserves special consideration. For practical purposes, the AMA impairment system seems to work fairly well for this category. However, a system that rates conditions with expected pain on the basis of objective findings can be confusing conceptually because its emphasis on objectivity obscures the factors that actually create impairment. As an example, consider a patient with a chronic right L-5 radiculopathy severe enough to produce essentially complete loss of function in the right L-5 spinal nerve. Because of the objective findings, such an individual might well be eligible for benefits under various disability programs. But in what sense would he or she be severely impaired? At the level of organ function, it would be said his or her spine is impaired. To understand this statement, the biological functions of the spine should be considered. Briefly, the lumbar spine plays four major roles: It contributes to structural support for the person (e.g., provides attachment points for muscles and space for vital organs such as the lungs and abdominal viscera), permits upright posture, permits motion, and protects spinal nerve roots. Only the last function is significantly compromised in an L-5 radiculopathy, and the functional loss can readily be compensated for with a short leg brace. In fact, an individual with an L-5 radiculopathy is not incapacitated by loss of function of the lumbar spine but rather by pain. At best, the patient's clinical findings (e.g., epidural scarring around the L-5 root, weakness, and atrophy of the right leg) validate that the individual has sustained a significant lumbar radiculopathy—they do not demonstrate substantial loss of function of the spine.

In a monograph on the SSA's disability programs, Osterweis et al. emphasize the distinction between loss of function of an organ and incapacitation from pain as follows:

> The notion that all impairments should be verifiable by objective evidence is administratively necessary for an entitlement program. Yet this notion is fundamentally at odds with a realistic understanding of how disease and injury operate to incapacitate people. Except for a very few conditions, such as the loss of a limb, blindness, deafness, paralysis, or coma, most diseases and injuries do not prevent people from working by mechanical failure. Rather, people are incapacitated by a variety of unbearable sensations when they try to work (6).

A CLOSER LOOK AT THE PROBLEM OF INFERENCE IN PAIN ASSESSMENT

Physicians must use complex inferential processes when they make judgments about whether patients with chronic pain are disabled. This is inevitable because no clear-cut rules exist for deriving disability judgments from clinical data on these patients. The inferential processes underlying disability judgments are typically implicit and may well differ from one evaluator to another. However, these processes have received little attention in research, so the following discussion is based mainly on informal observation. Although it is speculative, the discussion highlights possible reasons why these evaluations are so difficult and contentious.

Implicit Beliefs and Cognitive Dissonance

As noted under Overview of the Problem, only the patient directly experiences his or her pain. Any other person can only make inferences about the patient's pain based on his or her pain behavior. As Fordyce and others (19,20) have forcefully argued, pain behavior has multiple determinants so that its interpretation is frequently ambiguous. At one level, the distinction between the pain experience of a sufferer and the pain behavior that others can observe is simply a restatement of the conundrum of solipsism that has occupied philosophers for thousands of years. But there are specific aspects of pain experience and pain behavior that go beyond the generic issue of subjective versus objective information.

Every human being has multiple experiences with pain and develops conceptual models about pain on the basis of these. These models are difficult to articulate rigorously because they are typically implicit (21). Common beliefs about pain probably include the following:

1. Pain usually signifies a significant injury or illness.
2. Pain can be incapacitating (most people have episodes of pain that completely dominate consciousness and behavior).
3. Although the severity of pain is usually correlated with the severity of the underlying disorder, it is possible to have incapacitating pain in the absence of a catastrophic or even serious medical condition (e.g., migraine headaches and acute back sprains).
4. Physicians are limited in their ability to interpret pain. It is thus possible for a patient to have pain whose significance is missed by a physician.
5. Activity limitations because of pain are typically not absolute. Pain frequently makes activities difficult but rarely makes them completely impossible.
6. Patients can “fake” pain—that is, they can deliberately exaggerate its severity and impact.
7. More generally, pain behavior is often at least partly under voluntary control. Even if a person is not deliberately faking pain, his or her pain behavior may well be influenced by its consequences.

Taken together, these assumptions highlight the variety and ambiguity of relations among disease, pain experience, and pain behavior. A patient's complaints might signify anything from malingering to a serious medical condition that physicians have missed. Thus, the daunting task for a disability examiner is to determine the significance of pain behavior in an individual patient. Moreover, it is highly likely that examiners differ significantly in their conceptual models of pain. These differences may well underlie some of the conflicts that occur among different physicians, between physicians and adjudicators, and so forth as they attempt to reach a common understanding of a patient's pain.

The discrepancy between the incapacity reported by a patient and the objective markers of incapacity available to an observer is sometimes extreme, and it is in this setting that the dilemma of interpreting pain reports becomes most acute. For example, many patients with fibromyalgia report overwhelming incapacitation in the absence of any objective markers of disease except tender points (22,23 and 24). A physician evaluating such patients might understandably think that he or she is faced with extreme choices. One is to accept what seem like extraordinary statements by the patient about the severity of his or her incapacitation more or less at face value. The alternative is to reject the statements. This alternative is likely to set up cognitive dissonance (25,26) within the examiner. The dissonant cognitions are (a) “I respect Mr. X, and believe that he, like most patients I see, is honestly trying to tell me about his pain” and (b) “Mr. X has just told me things about the severity of his pain and the impact of pain on his life that I find preposterous.” The simple resolution to this pair of dissonant cognitions is to conclude that the patient is telling preposterous tales because he or she is a liar or has some significant psychiatric disorder. Thus, the examining physician often experiences difficulty in distinguishing between evaluation of the patient's medical condition and evaluation of the patient as a human being. That is, the physician often believes that he or she has only two choices: to ally with the patient and accept the patient's view of his or her condition or to reject the patient's condition and impugn the integrity or mental status of the patient.

It may well be that the pressure to line up with the patient or against the patient underlies some of the frustration and hostility that not infrequently surface during treatises on pain and disability (27,28 and 29). As an interesting example of the pejorative attitude that some physicians have toward pain patients, consider the terms that have evolved to describe individuals with persisting symptoms (usually pain) after a compensable event. Mendelson (30) gives a list of 37 such terms, including *accident neurosis*, *aftermath neurosis*, *American disease*, *attitudinal pathosis*, *Greek disease*, *greenback neurosis*, *justice neurosis*, *railway brain*, and *unconscious malingering*.

The pressure toward extreme positions vis-à-vis a pain patient may be accentuated by a simplistic tendency among some physicians to group patients broadly into two classes: (a) ones who honestly describe their problems to a physician and (b) malingerers. This dichotomy fails to do justice to the richness of interactions between patients and physicians. It is beyond the scope of this chapter to review this complex area (30,31), but a few observations are in order. First, the extensive literature on the operant conditioning of behavior suggests that the manner in which patients present themselves may well be shaped by previous interactions with various health providers (19). Because most chronic pain patients have large numbers of interactions with these providers, there is ample opportunity for their stories about themselves to be shaped in ways that maximize their apparent incapacitation. This process may go on without any conscious planning or intent to deceive. Second, patients engage in impression management when they interact with physicians, just as all people (and even infrahuman organisms) do whenever they engage in social interactions (30,3233 and 34). As Shorter points out, patients do not want to be ridiculed when they describe their problems to physicians (29). In their attempts to be taken seriously, some pain patients undoubtedly “overplay their hands,” making exaggerated statements that sound improbable to an examining physician. This may reflect poor social judgment but not necessarily malingering.

A realistic view of the subtleties of social interaction between patients and physicians makes it quite probable that patients are often incorrect in their statements about their pain but are not malingering or deliberately lying. Thus, a physician who is aware of these subtleties might feel comfortable in rejecting a patient's statements about incapacity but not impugning the moral or psychiatric status of the patient. But it is difficult to find this middle ground. The message from many pain patients is, “I live with my pain and know more about it than anyone else. I demand that you accept what I say about my pain at face value.”

Cannot versus Will Not

Regulations governing disability systems often demand that patients receive benefits only if their incapacitation is both objectively determinable and categorical. The demand for categorical incapacitation is manifested in the wording of questions to physicians. Physicians are asked whether patients can or cannot do certain kinds of work, how many pounds they can lift on a frequent basis, and so forth. This wording presupposes a sharp delineation between what a person with a medical problem can and cannot do. The dichotomous categories of can and cannot often do not match the realities of activity restrictions that patients face, even when pain is not a factor. For example, Brodal (15) wrote a thoughtful essay about his functioning after experiencing a stroke. He pointed out that many of his deficits could be overcome by strenuous effort—that is, there was no sharp line between what he could do and what he could not do.

In general, activity limitations can be stated fairly precisely when there is complete loss of function in an organ or body part. Thus, a patient who is completely blind cannot use visual cues; a patient with complete T-6 paraplegia cannot use his or her legs, and so forth. But when there is incomplete loss of function, the distinction between cannot and chooses not to becomes blurred. For example, a patient with lower extremity paresis secondary to an incomplete T-6 spinal cord injury might well be able to walk but would demonstrate gait abnormalities and show poor endurance when walking. It might be said that this patient can walk, but not as well or as long as someone with a normal spinal cord. It would be anticipated that there would be no single, precise time when such a patient would report fatigue that prevented

further walking. Thus, the boundary between being able and unable to walk would be fluid and would be influenced by the patient's motivation to succeed, use of coping strategies, and so forth. It would be difficult for an external observer to decide whether the patient's activity limitations reflected what he or she could not do or what he or she chose not to do.

Although the distinction between what a person cannot do and what he or she chooses not to do is difficult in many conditions, it is especially acute in the interpretation of incapacitation from pain. A person with chronic pain is much more similar to a patient with an incomplete spinal cord injury than to one with a complete spinal cord injury in that he or she usually can do a wide range of activities. But the quality of performance may be reduced, the duration of activity may be reduced, and the patient may report aftereffects of the activity in the form of a pain flare-up.

The activity restrictions in a patient with chronic pain can best be modeled as shown in Figure 17-2, in which pain is conceptualized as an aversive drive that tends to produce inhibition of activities that provoke it (36,37). The strength of this aversive drive can be inferred from the strength of the incentive that must be provided to induce a person to engage in the painful activity. The effects of different strengths of the aversive drive are divided into three zones. In the unrestricted zone, the aversive drive is either completely absent or so trivially small that any incentive can override it and induce the person to engage in the “painful” activity. At the opposite extreme, in the compulsory zone, the aversive drive is so strong that no incentive induces the person to engage in the behavior. For all practical purposes, the person cannot do the activity. In the middle is the discretionary zone. When the strength of the aversive drive is in this region, the person engages in the painful activity, but only in response to substantial incentives. One might say that the person can engage in the activity, but with difficulty.

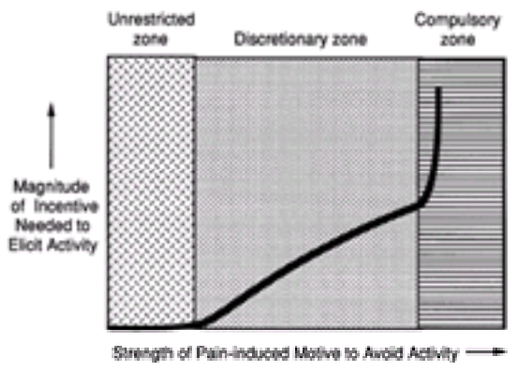

Figure 17-2. Motivational consequences of pain.

Although the model shown in Figure 17-2 is quite abstract, it appears that many physicians who examine patients with chronic pain follow something like it. In particular, examiners typically look for evidence of inconsistency in the activity levels of pain patients, especially when the inconsistency is predictable on the basis of changes in incentives. If, for example, a back pain patient shows severe activity restrictions during an independent medical examination but is shown playing volleyball on a surveillance videotape, a physician is likely to be skeptical about the activity limitations described and demonstrated during the examination.

The previous discussion focuses on personal factors, such as motivation, that blur the boundary between can and cannot in a patient with chronic pain. It is worth noting briefly that the boundary is also indistinct because of factors extrinsic to the patient. Many of the work restrictions imposed by medical conditions—including painful ones—can be circumvented by appropriate modifications of the workplace. As a simple example, a paraplegic cannot walk up stairs but can have access to all floors of a building equipped with an elevator. The potential for work site modifications (or accommodations, as they are described in the Americans with Disabilities Act) to offset activity restrictions complicates the assessment of what a patient can do in two ways. First, an evaluator has to define the patient's activity limitation carefully. In the preceding example, the paraplegic is incapable of walking up stairs but may be capable of reaching all the floors of the building where he or she works. Second, the evaluator must consider the availability and practicality of various job site accommodations that might mitigate the detrimental effects of a medical condition.

Changes over Time

Changes over time in the apparent incapacitation associated with painful conditions should be analyzed at two levels. At the level of individuals, some patients with pain problems seem to become more focused on their pain as time elapses and to lose their motivation to remain productive despite pain. Clinicians often observe these trends among individuals who have sustained disabling work injuries—that is, they see injured workers who become worse rather than better as time elapses after an injury and who seem to use medical information to buttress the conviction that they are disabled. A paucity of systematic data exists to validate or invalidate these clinical observations. Studies have shown that work disability after various industrial injuries follows something like an exponential decay curve, as shown in Figure 17-3 (38). Basically, the curve indicates that most people recover quickly after a workplace injury, but that the recovery curve flattens out over time so that, for example, individuals who are disabled more than 3 months tend to remain disabled for extended periods. It is possible that people in the “tail of the curve”—that is, those with very prolonged disability—have learned to emphasize their pain and incapacity as a result of interacting with the complex, often contradictory environment that injured workers face (39,40,41,42 and 43). The term *disability syndrome* is sometimes used to describe the behavioral and attitudinal changes that are thought to lead to prolonged disability in these injured workers. It is important to note, however, that although the concept of disability syndrome is clinically plausible, it is highly speculative. It is not really known why some injured workers end up in the tail of the recovery curve (44).

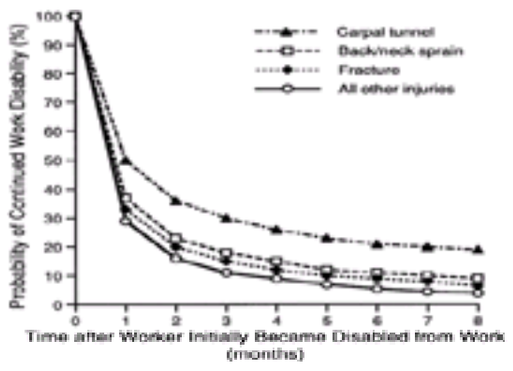

Figure 17-3. Recovery curves after industrial injuries. (Adapted from Cheadle A, Franklin G, Wolfhagen C, et al. Factors influencing the duration of work-related disability: a population-based study of Washington State workers' compensation. *Am J Public Health* 1994;84:190–196.)

At a societal level, there is evidence that the apparent incidence and prevalence of painful disorders change as a function of social conditions and public policies regarding disability (45,46,47 and 48). One possible explanation for these changes is that large groups of people gradually learn the “templates” for certain diseases and present to physicians with symptoms that adhere closely to these templates (30). That is, patients may interpret bodily sensations in terms of disease templates available in their culture; then hone, modify, and selectively process the sensations; and then organize their communications with physicians in ways that render the symptoms coherent and understandable in terms of an accepted disease. This hypothesis is a broad one that is difficult to prove or disprove conclusively, but there are historical instances that at least make it plausible. For example, repetitive strain injuries (RSIs) of the upper extremities became a major problem in the Australian workforce during the early 1980s and then rapidly diminished in apparent incidence and severity after legislative action and court decisions reduced the probability that workers could receive benefits for the condition through the industrial compensation system (49,50,51,52,53,54 and 56). Littlejohn (52) gave a detailed account of the social forces that influenced the rapid spread of RSI, describing the roles played by physicians, unions, the media, patient support groups, ergonomic specialists, the compensation system, and litigation. For example, he described the role of unions as follows:

> Unions played a prominent role in the epidemic. It was through the publicity generated by the unions that most workers developed knowledge of RSI. Workers were warned to look for the first early symptoms of the condition. Any ache or pain was suggested as a sign of early RSI. Publicity was generated to indicate that the condition occurred in a graded fashion; a staging system was suggested and adopted by the unions with vigor. Patients were warned that they would pass from stage 1 (mild transient aches) through to stage 3 (severe intractable aching) and on to long-term crippling without any chance of cure (52).

This and other statements by Littlejohn suggested that publicity surrounding RSI sensitized workers and persuaded them to interpret various sensations in terms of the RSI construct.

Another possible example is fibromyalgia. It appears to have increased substantially in prevalence since 1980, and at least one historian (30) has emphasized that this epidemiologic trend is attributable to the spread of information about the condition. If the “template” concept applies to fibromyalgia, the year 1990 must be considered pivotal because it was in that year that a group of prominent rheumatologists published diagnostic criteria for fibromyalgia (57). Perhaps in response to the growing awareness of fibromyalgia, disability awards for the condition in the Canada Pension Plan increased by a factor of six between 1987 and 1993 (4).

The possibility that individual patients or large segments of society learn pain behaviors that make them convincing has implications both for the clinical evaluation of disability in chronic pain and for social policies involving pain and disability. The individual examiner must consider the possibility that he or she is seeing manifestations of disease that have been modified by the past experiences and selective reinforcement to which a patient has been exposed. Policy makers must consider the possibility that pain may be “elastic”—that is, that the apparent amount of pain-related disability in the United States depends on how social policies regarding pain and disability are crafted.

Decision-Making Strategies

Physicians frequently attempt to assess the credibility of patients during disability examinations. They may rely on the Waddell signs (16) or a variety of other tests and signs to decide whether a patient is exaggerating or falsifying information. The decision a physician reaches about the credibility of a patient depends not only on the data he or she collects on the patient, but also on the decision-making strategy that he or she uses to interpret these data. As a hypothetical example, consider a population of chronic pain patients that is made up of two distinct subpopulations—honest reporters and malingerers. Imagine that an examiner uses a 50- item “malingering test” to gather information about whether each patient is an honest reporter or a malingerer. The examiner needs to develop some cutoff point for the malingering test, so that patients who score above the cutoff point are designated as malingerers, whereas ones who score below it are designated as honest reporters. As shown in Figure 17-4, the cutoff points developed by the examiner will probably be influenced by two factors—(a) the examiner's beliefs about the relative sizes of the honest reporter and malingerer subpopulations and (b) the costs he or she associates with different classification errors.

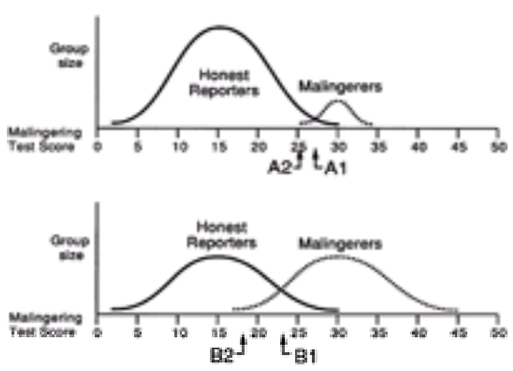

Figure 17-4. Cutoff points for honest reporters versus malingerers. In **A,** honest reporters outnumber malingerers. In **B**, malingerers are thought to be more common. See text.

Figure 17-4A shows a situation in which the examiner estimates the honest reporter subpopulation to be much larger than the malingerer subpopulation. The arrow labeled *A1* shows the cutoff point the examiner might use if he or she was equally concerned about misclassifying malingerers as honest reporters and honest reporters as malingerers. The arrow labeled *A2* shows the cutoff point when the examiner wants to be sure not to miss a patient who is malingering.

Figure 17-4B shows a situation in which the examiner believes that the malingerer subpopulation is as large as the honest reporter subpopulation. The arrow labeled *B1* designates the cutoff point the examiner might use if he or she was equally concerned about the two kinds of classification errors; the arrow labeled B2 designates the cutoff point that might be chosen if the examiner wants to be sure not to miss a patient who truly is a malingerer.

As Figure 17-4 demonstrates, the cutoff points A1, A2, B1, and B2 are all different. The figure thus highlights the fact that even when two examiners have the same information about a patient, they can differ markedly with respect to their conclusions about the credibility of the patient. The differences are often the result of implicit assumptions that different examiners make about the relative frequencies of different subpopulations of pain patients and the costs that they associate with different kinds of classification errors. These decision-making issues underlie some of the distrust that frequently exists between independent medical examiners and treating physicians.

PAIN AND THE SOCIAL SECURITY ADMINISTRATION DISABILITY EVALUATION PROCESS

To understand how a disability system handles applications by patients with pain problems, one must look at the details of its procedures for awarding disability to applicants in general. These procedures differ from one disability agency to another. The discussion focuses on the way in which the SSA evaluates disability applicants. The SSA administers two disability programs— Social Security Disability Insurance (SSD) and Supplemental Security Income (SSI) (58). They are by far the largest disability programs in the country. They are virtually identical in terms of their definitions of disability and the procedures they follow to determine disability; the two programs differ only with respect to nonmedical eligibility requirements.

The operating rules of the SSD/SSI evaluation process can be seen by examination of the five steps that are followed in evaluating an applicant. These are shown in Figure 17-5. In essence, evaluators address questions in the sequence indicated and determine the eligibility of each applicant on the basis of the answers. A few issues stand out:

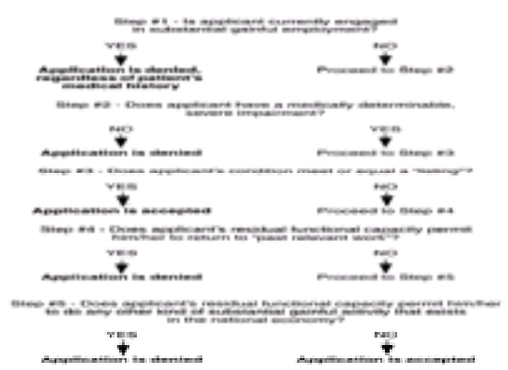

Figure 17-5. Steps in the evaluation of Social Security Disability Insurance and Supplemental Security Income applications.

1. An applicant is rejected at step 2 unless he or she has a medically determinable, severe impairment. Thus, impairment is a necessary condition for an SSD/SSI award. In a comprehensive review of the role of pain in SSD/SSI awards, Osterweis et al. (6) pointed out that many applicants with pain problems are rejected at step 2 of the evaluation process.
2. The SSA has developed a set of “listings” for various medical conditions. A listing typically incorporates a medical diagnosis plus some markers of severity. If an applicant has an impairment that meets the criteria for a listing, his or her application will be accepted without further ado.
3. The SSA permits a disability award to be granted if an applicant has several different impairments that cumulatively are believed to be as disabling as a listed condition.
4. In steps 4 and 5, evaluators specifically consider “vocational factors” as well as an applicant's impairments. These include the applicant's age, educational level, past work history, and transferable skills. For example, an older applicant with a poor educational background might be awarded disability even when his or her impairment is not severe enough by itself to warrant the award.

In essence, the SSD/SSI evaluation process provides alternative routes by which an applicant might be awarded disability. Medically determinable, severe impairment is a necessary condition for an award (see step 2). Among applicants with a medically determinable, severe impairment, the ones who receive awards may follow at least three different “paths” *en route* to the awards:

1. The applicant's main problem might be characterized as an impairment that meets criteria for a listing.
2. The applicant may have a combination of impairments that cumulatively are disabling enough to equal a listing.
3. The applicant may receive an award on the basis of a combination of an impairment and vocational factors.

The disability evaluation procedures of the SSA have been subjected to far more public scrutiny than those of any other disability agency. Of special relevance to the present chapter, the federal courts have played a significant role in defining the manner in which the SSA should interpret pain. The judicial history in this area is complex. Relevant decisions through the mid-1980s are summarized in Osterweis et al. (6). More recent cases are reviewed by Wolfe and Potter (59). They summarize various standards that have been considered by the courts as follows:

> [In] a landmark decision of the Ninth Circuit in 1991 . . . , the court considered three competing standards that might be used in evaluating disabling pain. The first . . . held that a finding of disability could be made without requiring that the claimant produce medical evidence of an impairment. The court rejected this standard. . . . The second standard . . . is known as the Cotton standard. It requires “the claimant to produce medical evidence of an underlying impairment which is reasonably likely to be the cause of the alleged pain. When this evidence is produced, the Cotton standard does not require medical findings that support the severity of the pain and, thus, the adjudicator may not discredit the claimant's allegations of the severity of pain solely on the ground that the allegations are unsupported by objective medical evidence.” The third standard . . . required not only objective medical evidence of impairment, but also corroborating medical evidence of the severity of the alleged pain. The Ninth Circuit . . . rejected [this] standard [and supported the Cotton standard] (6).

The Cotton standard supports the role of a physician in determining that a disability applicant with chronic pain has an impairment and in determining whether the impairment is likely to produce symptoms similar to the ones the applicant alleges. But it rejects the idea that a physician can objectively determine how severely an applicant is affected by the impairment.

If the severity of pain-associated impairment (or activity limitation) cannot be determined objectively by a physician, how can it be determined? SSA adjudicators are instructed to consider two issues: the activity limitations actually demonstrated by an applicant, and the credibility of the applicant. To get actual data on an applicant's activity limitations, adjudicators communicate with people close to him or her, such as family members and coworkers. As far as credibility assessment is concerned, a recent SSA ruling states

> When the existence of a medically determinable physical or mental impairment(s) that could reasonably be expected to produce the symptoms has been established, the intensity, persistence, and functionally limiting effects of the symptoms must be evaluated. This requires the adjudicator to make a finding about the credibility of the individual's statements about the symptoms(s) and its functional effects. Because symptoms, such as pain, sometimes suggest a greater severity of impairment than can be shown by objective medical evidence alone, the adjudicator must carefully consider the individual's statements about symptoms with the rest of the relevant evidence in the case record in reaching a conclusion about the credibility of the individual's statements. It is not sufficient for the adjudicator to make a single, conclusory statement that “the individual's . . . allegations are (or are not) credible.” The determination or decision must contain specific reasons for the finding on credibility, supported by the evidence in the case record, and must be sufficiently specific to make clear to the individual and to any subsequent reviewers the weight the adjudicator gave to the individual's statements and the reasons for that weight (60) .

The emphasis that the SSA places on assessing credibility is interesting. On the one hand, assessment of the credibility of a pain patient is crucial if one acknowledges (as the SSA does) that the effects of pain of functioning cannot be determined fully by objective measures of organ impairment. On the other hand, there is evidence that clinicians have difficulty assessing the credibility of statements made by patients with various subjective complaints (61,62).

In summary, the SSA has a multilayered algorithm for evaluating disability applicants. Problems associated with disability evaluation in painful conditions have been subjected to detailed scrutiny in the federal courts. The SSA's solutions to these problems are at odds with central assumptions in the AMA *Guides*. In particular, the SSA evaluation process embodies the assumption that physicians are frequently not able to assess objectively the severity of pain-related impairment.

EPIDEMIOLOGY OF PAIN-RELATED DISABILITY

Important questions about the epidemiology of pain-related disability include the following: How many individuals in various communities experience chronic pain? How many of them experience significant activity restrictions because of their pain? How many of them receive disability benefits because of their pain? However, these questions are difficult to answer because of a number of methodologic issues.

Several population-based surveys have shown that chronic pain is a common complaint among individuals in the United States (63,64); western European countries (65,66,67 and 68); and various countries in Africa, South America, and Asia (69). The exact prevalence of chronic pain is difficult to determine because the apparent prevalence depends on a number of methodologic issues such as the exact wording of questions posed to respondents (70). Crombie (71) cited six epidemiologic studies in which the reported prevalence of chronic pain varied from 7.0% to 63.5%; the mean of the rates published in the six studies was 31%. It is beyond the scope of this chapter to attempt to reconcile these discrepant data, but it appears that perhaps 20% to 30% of residents in the United States and western European countries experience chronic or frequently recurring pain.

A different picture emerges when disability associated with chronic pain is investigated. Epidemiologic studies have used varying definitions of “disability,” but it has typically been defined in terms of self-reported activity restrictions rather than in terms of whether a respondent is receiving disability benefits. Von Korff et al. (64) demonstrated the importance of distinguishing between chronic pain and disabling chronic pain. Although 63.5% of their subjects reported chronic pain, only 8.1% reported associated disability—that is, reported that during the previous 6 months they had experienced days when their pain had prevented them from carrying out usual activities. These data strongly support the idea that although chronic pain is common, it does not necessarily cause disability (in the sense of self-reported activity restrictions).

A similar conclusion was reached in a study of chronic pain among primary care patients in 15 countries (69). The authors found that 31% of their chronic pain subjects were judged by interviewers to be moderately or severely disabled in work, homemaking, or volunteer activities (versus 13% of subjects without chronic pain). Although disability was thus fairly common among chronic pain subjects, more than two-thirds of the subjects did not appear to be disabled by their chronic pain. Moreover, the authors point out that the statistical association between pain and disability was not consistent across participating countries. (In contrast, chronic pain was strongly and consistently related to anxiety, depression, or both.)

In summary, epidemiologic studies highlight the fact that in countries throughout the world there is a large reservoir of individuals with chronic pain. These individuals can be viewed as the group at risk for seeking disability benefits because of pain. At significantly greater risk are the people who report substantial activity restrictions because of pain. It is somewhat heartening that this subgroup represents only a minority of individuals with chronic pain, but the subgroup is large enough to

underline the importance of questions related to disability evaluation in painful conditions.

PAIN AND DISABILITY IN THE SOCIAL SECURITY SYSTEM

None of the preceding studies addresses pain-related disability in the sense of receiving benefits through a disability program. Disability in this sense can meaningfully be examined only in relation to specific disability systems because eligibility rules differ from one system to another. The present discussion focuses on chronic pain as the basis for SSD or SSI awards.

Two important questions regarding the epidemiology of pain-related disability in the SSD and SSI programs are the following:

1. Are substantial numbers of patients with chronic pain receiving disability benefits?
2. How adequately does the SSA distinguish disabled from nondisabled people among applicants with chronic pain—that is, what are the reliability and validity of its decisions?

Information related to both of these questions is sketchy. During the 1980s, the problem of pain as a reason for disability was believed to be important enough that two major studies of the role of pain in SSD/SSI awards were undertaken (6,18). Both expert panels concluded that data on the outcomes of SSD/SSI evaluations of patients with chronic pain were inadequate. However, with the exception of research undertaken by Rucker and colleagues (discussed later in this section), the situation is not much better today (76). Reasons for the lack of adequate data include the following:

1. As noted earlier, chronic pain is frequently one of many manifestations of a medical condition. The pain associated with a medical condition often cannot easily be abstracted from the other manifestations of the condition. Thus, if a person with a painful condition is awarded SSDI, the role of his or her pain in the award is often ambiguous. For example, a patient with chronic congestive heart failure and angina pectoris has pain (the angina) and would generally qualify for SSDI. His or her pain, however, might be only a minor factor in the decision by the SSA to grant benefits. The SSA makes no attempt to identify the role that pain plays in its decisions. In fact, as Osterweis et al. (6) noted, the SSA is likely to obscure the role of pain by its emphasis on objectively determinable impairment.
2. The problem of "disentangling" pain from other manifestations of disease is magnified by the fact that in the *International Classification of Diseases,* Ninth Revision (*ICD-9*), medical conditions are classified in multiple ways. For example, a person with a low back problem could be given a diagnosis (e.g., 724.2, low back pain), which highlights the fact that he or she has back pain, but he or she could also receive a diagnosis based on the suspected pathophysiology underlying his or her symptoms (e.g., 722.2, lumbar disc herniation). Virtually all disability agencies, including SSA, use diagnoses that emphasize biological derangement (e.g., lumbar disc herniation) rather than ones that emphasize symptoms.
3. In its publications, the SSA groups disability recipients into 15 broad diagnostic categories (72). This grouping completely obscures the role that pain may be playing in SSD/SSI awards. For example, patients with fibromyalgia, lumbar disc disease, and rheumatoid arthritis are all lumped into the category "musculoskeletal disorders."
4. The SSA is an administrative agency that operates in a political arena. As such, it often does not have the luxury of doing scientific research and making policy based on the results. The history of the continuing disability review program during the early 1980s is a compelling example (5). Continuing disability reviews are reevaluations of the functional and medical status of individuals who are already receiving SSD or SSI benefits. In theory, continuing disability reviews permit the SSA to improve the accuracy of its decision making because doing so gives the agency a second chance to consider the extent to which an individual is incapacitated. In 1980, a study of SSD beneficiaries indicated that more than 500,000 of them were not disabled severely enough to deserve benefits. The SSA responded to this information by intensifying its program of continuing disability reviews on beneficiaries and ended up dropping approximately 450,000 of them between 1981 and 1983 (73). This led to a flood of legal appeals and outcries by members of Congress. Finally, in 1984 a beleaguered SSA cut its continuing disability review program back drastically and has never reinstituted it on a scale that approaches its intensity during the early 1980s. In essence, for a program like SSD, scientific questions about the validity of decisions are entangled with societal concerns about justice and with the politics of interest groups.

Despite the limitations described, at least some data bear on the question of whether SSD/SSI benefits are frequently awarded to patients with chronic pain. Wolfe et al. (74,75) present data on the frequency with which patients with fibromyalgia are awarded SSD. In their first study, they demonstrated that the prevalence of fibromyalgia in the community is approximately 2%. The second study dealt with self-reported disability among fibromyalgia patients who were attending one of six university-based rheumatology clinics around the United States. Twenty-six and one-half percent of the 1,144 respondents reported that they had received disability payments of some kind during their lifetimes. SSD was by far the most common source of disability payments, with 16.2% of respondents reporting SSD benefits. Wolfe et al. noted that among subjects who began receiving disability benefits after 1988, 44.4% reported that the award was granted for a diagnosis of fibromyalgia. (Other respondents reported receiving disability for a variety of diagnoses, including back conditions, miscellaneous other musculoskeletal conditions, systemic lupus erythematosus, miscellaneous other medical conditions, and psychiatric conditions.)

Wolfe et al.'s data are subject to a variety of interpretations. As the authors note, their subjects were patients at university-based rheumatology clinics and therefore may not have been representative of fibromyalgia patients as a whole. Also, more than one-half of the patients who received disability payments reported that they were nominally given the payments for a condition other than fibromyalgia. But despite these caveats, the data clearly show that individuals are getting SSD benefits for conditions characterized mainly by chronic pain. In this regard, it is important to note that in terms of the categories given earlier, fibromyalgia should be classified as an unverifiable pain problem—there are no truly objective findings. Thus, Wolfe et al.'s data indicate that the SSA, despite statements about the need for "medically determinable severe impairment," actually grants SSD to many individuals strictly on the basis of reported pain. Moreover, the number of SSD awards for fibromyalgia appears to be high. If we multiply the number of adults in the United States (approximately 200,000,000) by the prevalence of fibromyalgia (2%) by the probability of being on SSD among fibromyalgia patients (16.2%) by the proportion of fibromyalgia patients who receive benefits on the basis of a diagnosis of fibromyalgia (44.4%), we would conclude that approximately 290,000 individuals are currently receiving SSD benefits because of fibromyalgia. This figure is undoubtedly too high, but Wolfe et al.'s data forcefully make the general point that substantial numbers of Americans are being awarded SSD for conditions characterized by chronic pain in the absence of other manifestations of disease.

I am not aware of data on SSD awards among any other patient groups with chronic pain. As noted, statistics published by SSA are virtually useless in determining how many awards are given primarily because of pain. There are suggestions, however, that pain is a common problem in SSD and SSI applicants. For example Rucker, who has done extensive research in conjunction with the SSA, cites unpublished data suggesting that pain is at least a factor in 40% to 60% of all SSD and SSI awards (76).

The fact that some disability applicants are awarded benefits largely on the basis of pain says nothing about the reliability or validity of the decisions that the SSA makes on these applicants. The SSA does have a quality control program and keeps track of the reproducibility of decisions made when individuals submit their initial applications for disability. These initial applications are evaluated by adjudicators and physicians who work for a Disability Determination Service (DDS) in the applicant's community. When applicants' files are randomly reevaluated by staff at one of the SSA regional offices, the concordance rate between their decisions and the decisions made by evaluating DDS teams is approximately 95% (77). These data suggest that the disability determination process is highly reliable. However, the interpretation of the data is unclear for two reasons. First, the SSA quality-control program deals with all applicants—it does not give information about the reliability of decisions regarding applicants with chronic pain. Second, and more important, 24% of the individuals whose applications are denied during the initial SSA evaluation are awarded benefits on appeal (64). Thus, although the decisions made by DDS teams agree well with decisions made by reviewers at the SSA regional offices, the SSA decision-making system as a whole is unreliable because judgments made at the DDS level are frequently overturned on appeal.

As far as predictive validity is concerned, research conducted by Rucker and colleagues (76,78) provides the most useful data. They were commissioned by the SSA to develop a system to assess disability applicants with chronic pain. They developed the Multiperspective Multidimensional Pain Assessment Protocol (MMPAP) to accomplish this goal. It consists of a questionnaire for patients to fill out, a standardized physical examination, and standardized physician ratings of patients' behavior. The MMPAP was administered to 691 individuals who were filing initial disability applications (either for SSD or SSI). All subjects were described as having chronic pain, defined as pain lasting at least 6 months. No detailed medical information was reported on the subjects. All subjects went through an initial MMPAP assessment. To test the reliability of assessments, the researchers recruited 20% of the subjects to return for a repeat assessment approximately 4 weeks later. Subjects were contacted 8 months later, and their employment status assessed by self-report. Key findings were the following:

1. The MMPAP demonstrated adequate test-retest and interrater reliability.
2. One hundred fifty-seven of the subjects (22.8%) were awarded disability; the other 532 (77.2%) were denied. [This award rate is lower than the initial award rate of 31% for all disability applicants (73).]
3. Applicants who were awarded disability were less likely to be working at follow-up than ones who were denied disability (chi square = 6.78, p <.01). It is worth noting, though, that even among the denied patients, only 14% were employed at follow-up.
4. Discriminant function analysis revealed that approximately 65 of the items from the MMPAP were predictive of whether a subject would be employed or

unemployed at follow-up. The authors noted that the predictors came from several domains, including rated pain intensity, mental health status, physical examination findings, activity limitations reported by the subject, and functional abilities rated by a physician examiner.

Rucker et al.'s research provides some support for the validity of the SSA's decisions regarding applicants with pain problems. Specifically, the investigators found that at 8-month follow-up, 14% of individuals rejected by SSA were working, as opposed to 6% of those who received disability awards. This difference was statistically significant at the .01 level, but it is hardly impressive. In fact, the most parsimonious explanation of Rucker et al.'s data is that disability applicants with chronic pain do poorly as far as return to work is concerned, regardless of whether their disability applications are accepted or denied. It is also noteworthy that the acceptance rate for Rucker et al.'s patients was low compared with the acceptance rate among all disability applicants.

In theory, continuing disability reviews could provide some information about the validity of the SSA's decisions. As a practical matter, however, the SSA has done few continuing disability reviews since the early 1980s (79). At this point, individuals who get SSD awards almost all stay in the system until either death or age 65 years (when they become eligible for old age insurance) (80). Because few continuing disability reviews are done, there are no useful data about the actual medical status of individuals who are receiving benefits or about the predictive validity of the decisions that the SSA makes when it initially awards benefits. In essence, political considerations make it difficult for the SSA to study individuals after they have received awards.

Longitudinal studies on disability applicants who were denied benefits might also provide important information about the validity of the SSA's decision-making procedures. Aside from Rucker et al.'s 8-month follow-up study, however, research in this area is virtually nonexistent.

CLINICAL MANAGEMENT OF DISABILITY ASSOCIATED WITH PAIN

The discussion so far has focused on conceptual and public policy quandaries involved in the evaluation of pain-related disability. At a more practical level, physicians are frequently confronted with the task of evaluating disability in chronic pain patients whom they are treating. This is often an uncomfortable task for several reasons:

1. They frequently feel pressured to do the evaluations. Insurance companies typically create pressure by threatening to withhold benefits from the patient or payment from the physician if disability forms are not filled out.
2. Often, they are not familiar with the disability systems with which they are interacting. For example, they may not grasp the implications of signing a job analysis or stating that a patient has reached maximal medical improvement (MMI). Thus, they worry that they may inadvertently prejudice disability applications of their patients.
3. They may not be familiar with the types of medical issues that should be addressed in contested situations that may end up in court. For example, they may not make a clear distinction between subjective and objective findings, or they may not be familiar with the mechanics of performing impairment ratings according to the AMA system.
4. They often implicitly recognize the difference between the clinical role they normally play when they treat patients and the adjudicative role that is required during a disability evaluation. Informal observation as well as examination of the limited literature on these roles (81,82,83,84) suggests the differences shown in Table 17-1. Physicians probably recognize that significant ethical issues arise when they switch back and forth between these two roles (84). As a result, many of them feel uncomfortable making adjudicative judgments on patients they are treating.

Clinical role	Adjudicative role
The physician's primary obligation is to his or her patient. It is appropriate for the physician to be a patient advocate and to do everything possible to help his or her patient return to health.	The examiner is not a patient advocate and is not obligated to meet the needs of the patient being evaluated (some critics would assert that independent medical examiners often function as advocates for insurance companies).
A patient's history provides 90% of the clinical information that a physician needs. The physical examination and laboratory tests are important but secondary sources of information.	The emphasis in an evaluation should be on objective findings (e.g., on physical examination or imaging findings) rather than on the patient's complaints.
When there is doubt about the accuracy of a patient's statements, the patient is given the benefit of this doubt.	Be skeptical of patients' reports.
A major task of a physician is to diagnose a patient's problems—that is, to identify the pathophysiology underlying the patient's symptoms.	The focus should be on legal causation of a patient's symptoms.
A physician's job is to provide medical or surgical assistance, not to become embroiled in a patient's legal problems.	The major job of the independent medical examiner is to relate a patient's clinical condition to applicable laws or administrative regulations that define the responsibilities of third-party payers.

TABLE 17-1. Role expectations for physiciansclinical versus adjudicative

5. Partly because of the role conflict noted, clinicians often end up feeling caught in the middle between their patients and disability systems. Disability agencies might seem bureaucratic and unenlightened; they might make demands for documentation that seem unreasonable to the clinicians. At the same time, patients might express a degree of incapacitation that seems extraordinary and then try to enlist the physicians as advocates during negotiations with disability agencies.

The purpose of this section is to outline skills and strategies that physicians may use as they attempt to negotiate the turbulent waters of disability evaluations of patients they are treating. Broadly speaking, when clinicians address disability issues in patients they are treating, they need special skills in two areas—evaluating patients and interfacing with disability systems.

Patient Evaluation

In the usual clinical situation, a physician evaluates a patient by eliciting a history, performing a physical examination, and perhaps performing ancillary investigations such as laboratory studies. The goals of the evaluation are to diagnose the patient's problem and to develop a treatment plan. These skills are all essential in a setting where the clinician is evaluating the disability status of his or her patient, but a number of additional issues must also be addressed:

1. *Are the patient's examination findings "subjective" or "objective"?* There are at least two reasons why this distinction is important. First, disability systems typically require physicians to identify the objective findings on which their conclusions are based. Second, the distinction highlights a problem that physicians must consider when they treat patients who are also interacting with a disability system. It is that the behavior of such patients might be subtly altered by their involvement with the system. In this context, it is important for the physician to distinguish between findings that are completely beyond the control of the patient and ones that are at least partially under the patient's control (and therefore subject to change in response to environmental influences).

   However, the distinction between subjective and objective findings is not entirely clear-cut. At the extreme, a subjective finding is a report by a patient of something a physician cannot directly observe (e.g., "My arm is beginning to tingle"), whereas an objective finding is one that is completely unrelated to any voluntary response of the patient. To state it differently, a completely objective finding is one that could be obtained in a comatose patient or one who was completely uncooperative or disingenuous. Examples include x-ray findings and laboratory findings. In actual clinical settings, there are many physical examination findings that are "semiobjective," in the sense that they are partially under the control of a patient. Examples include muscle spasms or tenderness, restricted range of motion, and some deep tendon reflex abnormalities. The attorneys and disability agency adjudicators who routinely ask for objective findings are generally unaware of the subtleties.
2. *Is there a clear-cut diagnosis?* Sometimes a patient's signs and symptoms represent a textbook case of some medical condition. In this instance, the physician can at least be reasonably comfortable that his or her diagnosis is correct. However, many patients—especially ones with chronic pain problems—present with a set of symptoms and signs that only loosely fit a well- defined medical condition. In this situation, the clinician is faced with ambiguity from the outset because he or she cannot be sure what (if any) medical problem the patient has.

   A related issue involves the consistency of the patient's symptoms and signs over time. A clinician can be most confident of his or her diagnosis when the patient demonstrates the same clinical picture over a series of assessments or shows the kind of progression of symptoms and signs that is typical of the condition that has been diagnosed.
3. *How much impairment is usually associated with the diagnosed condition? What kinds of activity restrictions are typical?* An experienced clinician has a general idea about the kinds of activity limitations that are expected in a patient with a certain medical condition. For example, patients with acute lumbar radiculopathies frequently do not tolerate sitting, bending, or lifting and can be severely incapacitated. Patients with carpal tunnel syndrome are often intolerant of repetitive hand activities and are often awakened at night by uncomfortable paresthesias.

The clinician should be alert to a patient who either claims much greater incapacitation than one would expect for a given medical condition or reports activity restrictions that are qualitatively different from the ones that are expected. These kinds of mismatches should prompt the clinician to consider carefully the reasons for the patient's atypical presentation.

4. *Is there any evidence of symptom magnification or nonorganic findings?* If these are present, they should alert the clinician that the patient's apparent limitations are probably not explainable entirely in terms of the biology of his or her medical condition. The physician should consider hypotheses to account for nonorganic symptoms or signs.
5. *How credible is the patient's presentation overall?* This is a global judgment that takes into account items 1 through 4.
6. *Has the patient reached MMI?* A patient is said to have reached MMI after an injury when three conditions have been met: (a) The patient has had the benefit of therapies considered appropriate for the injury, (b) enough time has elapsed that healing is likely to be complete, and (c) the patient has reached a plateau as far as functional improvement is concerned. The issue of MMI comes up routinely on disability forms. Most disability programs operate on the premise that long-term decisions about a disability applicant should be made when the applicant has reached MMI. Some, such as SSD/SSI, reject applicants if there is reason to believe that they will improve within a year. However, the concept of MMI is fraught with ambiguity. It is beyond the scope of this chapter to review all the complexities related to the term, but a key issue is whether a patient who experiences chronic pain can be considered to have reached MMI when he or she has not had the opportunity to undergo a vigorous pain rehabilitation program. More generally, a patient who has failed to benefit from curative therapies such as surgery might still benefit from a structured physical restoration program. To certify a patient as disabled before any attempt at rehabilitation is not an adequate standard of either health care or disability determination.
7. *What are the patient's physical capacities and physical limitations?* Most clinicians realize that it is difficult to assess a patient's activity limitations on the basis of a medical examination only. At best, such an examination leads to a diagnosis and broadly identifies the types of limitations that might be expected. Medical examinations, however, are not well suited to determining a patient's activity limitations in detail. One way for a clinician to obtain more detailed information is to refer his or her patient for a functional capacity evaluation (sometimes called a *physical capacities evaluation*) (85). Even a physical capacities evaluation is not totally objective, however. If even more detailed behavioral data are needed, the clinician can refer a patient to various programs that provide ongoing assessments of patients over weeks, along with attempts to increase the patient's activity capacities. Even a physical capacities evaluation is not totally objective, however. For example, pain rehabilitation programs (86), functional restoration programs (87), and work hardening programs (88) all provide extensive observational data on the capacities of chronic pain patients.
8. *How does the patient's medical condition affect his or her ability to work?* This is a key question in disability evaluations but an extremely difficult one for physicians to answer. At the very least, an intelligent answer requires a physician to match the activity limitations imposed by a patient's medical condition to the activity demands of various potential jobs. This is difficult to do for several reasons. First, as discussed throughout this chapter, activity limitations secondary to pain are difficult to quantify. Second, physicians rarely have detailed information about the physical demands of various jobs. Third, the workplace factors that influence pain patients' ability to function are often subtle. For example, Yelin (89) found that patients with rheumatoid arthritis are more likely to maintain employment if they have significant control over the pace of their work activities. Thus, even if a physician has information about the physical demands of a job, he or she may be uncertain about subtle aspects of the job that are likely to influence the ability of a patient to meet these demands.

   Some disability agencies assist physicians by hiring vocational rehabilitation counselors and providing treating physicians with job analyses—that is, detailed descriptions of various jobs for which a patient is being considered. But even with this help, physicians face ambiguity when they render opinions about the ability of patients to work.

Interfacing with Disability Agencies

Even after a physician has done the kind of detailed assessment discussed above, he or she may not be ready to respond to the questions raised by a disability agency. There are several reasons for this.

1. The specific questions addressed to physicians vary widely from one agency to another. Sometimes physicians are asked to state the physical limitations of a patient (e.g., to state how many hours the patient can sit during a day, how many pounds he or she can lift, and so forth). In other situations, they are given detailed information about specific jobs and are asked whether their patient can perform the essential functions of the jobs. These job analyses typically request much more than a simple yes or no answer by the physician. For example, they often ask whether the worker can do the job on a full-time versus a part-time basis, whether modifications in the job would help, what these modifications should be, and so forth. Other agencies ask the physician to state in broad terms the category of work in which a patient can engage—from sedentary to heavy. In still other situations, physicians are asked whether their patients can go back to their usual line of work and, if not, whether they can perform any kind of work. In essence, physicians who have completed a detailed assessment of their patients must still carefully study the questions posed to them by a disability agency and see whether the medical information they have obtained permits them to answer these questions.
2. More generally, the rules of different disability systems differ so dramatically from each other that a physician is unlikely to be able to interface with a particular one unless he or she understands it in some detail. The following discussion considers two systems—the Department of Labor and Industries (DLI) (the main workers' compensation carrier in Washington state) and the SSA. The SSA follows the same rules throughout the United States, so the following information is relevant regardless of where a physician practices. The procedures followed by workers' compensation systems vary widely from state to state, however. The following information about DLI may be relevant in states other than Washington, but the only way physicians can be sure is to study the rules in their state carefully.

Disability Evaluation in the Washington State Department of Labor and Industries

A key feature of the Washington State DLI is that it requires treating physicians to make sequential disability judgments regarding injured workers. The physician who initially evaluates an injured worker is required to complete an accident report, as shown in Figure 17-6. The form includes several items about disability. Item 45 requires the physician to list objective findings that support his or her diagnosis. It thus raises the issue of subjective versus objective perspectives on incapacitation. Item 47 asks about causation—that is, whether the patient's condition was caused by an exposure at work. Item 48 asks the physician to assess the effect of the work injury or illness on the patient's ability to work.

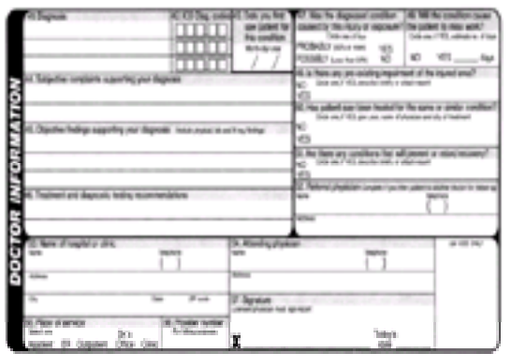

Figure 17-6. Selected questions from the Washington State Department of Labor and Industries accident report.

It is typical for physicians in emergency rooms and other immediate care facilities to address disability issues during their first encounter with a patient. If the worker remains off work for an extended period, the treating physician is asked to make a series of judgments that bear on the worker's disability status. The judgments include the following:

1. Responses to job analyses submitted by vocational rehabilitation counselors. If a treating physician indicates that the patient can perform the essential activities for one of these jobs, the patient's time-loss benefits are terminated.
2. Responses to physical capacities evaluations.
3. Judgments about whether a patient has reached MMI from treatment.

4. Comments on independent medical examinations commissioned by the DLI.

In addition, the treating physician is invited to conduct a formal closing examination on a worker who is thought to have reached maximal medical benefit from treatment. In such an examination, the physician is asked to comment on the causation of any medical condition diagnosed, to indicate whether the patient has achieved MMI, to rate the impairment associated with each condition, and to indicate whether the patient is employable.

Disability Evaluation for Social Security Disability Insurance and Supplemental Security Income Applicants

Rules and procedures governing the SSD and SSI programs have been described (under Pain and the Social Security Administration Disability Evaluation Process). The demands on the treating physician imposed by these programs are entirely different from those imposed by workers' compensation systems. In particular, the SSD/SSI programs are designed only for individuals who have reached MMI and are severely disabled. The concepts of temporary disability or partial disability do not exist in the SSD/SSI programs. One consequence is that the treating physician is typically contacted only once for information about an SSD/SSI applicant. Typically, physicians are sent letters requesting that they address the issues listed in Table 17-2.

History and physical examination findings
Progress notes
X-ray reports
Description of joints to include deformities and inflammation
Range of motion
Gait and station
Evidence of muscle spasms
Neurologic findings
Pertinent lab work
Operative reports
Description of pain (what causes it; what relieves it)
Type and duration of treatment
Prognosis

TABLE 17-2. Information typically requested from treating physicians regarding applicants for Social Security Disability Insurance or Supplemental Security Income

The SSA takes the perspective that treating physicians should provide objective information about the medical status of disability applicants but that it is the job of adjudicators with a DDS to make the final decision about whether an applicant is really disabled. Thus, in theory the role of the treating physician is limited. In practice, however, a treating physician can influence the disability determination process in several ways (58). For example, one step of the sequential evaluation process used for SSD/SSI applicants is the determination about whether their problems meet a “listing.” A treating physician who is familiar with the criteria for various listings (10) can provide information about whether a patient has the findings that qualify him or her for a listing.

It is common for workers with prolonged disability from work injuries to apply for SSD while their industrial compensation claims are still open. In that instance, the treating physician ends up interacting with two disability systems simultaneously.

Practical Suggestions for Interfacing with Disability Systems

No simple “cookbook” exists that treating physicians can follow when they address issues related to the disability of patients they are treating; however, a few general guidelines are provided:

1. An enormous difference exists between temporary, short-term disability and permanent or long-term disability. For example, a person with a low back strain might well be incapacitated for several days, and it is entirely reasonable for a treating physician to support the individual's statement that he or she cannot work. Workers' compensation systems generally acknowledge this reality by accepting more or less at face value a physician's assertion that the patient is temporarily disabled from work. Problems arise when the patient's apparent work incapacity continues for weeks or months or when the patient applies for permanent disability. The following discussion focuses mainly on permanent or long-term disability.
2. The disability evaluations that physicians make on their patients permit them not only to respond to questions posed by a disability agency, but also to manage the patients more effectively. The reason for this is that treating physicians have the potential to alter the disability status of their patients rather than simply to assess it. This is particularly important in the treatment of recently injured patients who are on short-term disability (e.g., through a workers' compensation claim). In that setting, physicians can use management strategies to reduce the likelihood of long-term disability. No proven set of strategies exists, but informal experience suggests the following:
   a. “Watching the clock.” Disability seems to feed on itself. Once a patient has been on disability for a long time, the probability of going off disability drops, as does the probability of the patient's responding positively to treatment.
   b. Protecting the worker's job. Long-term follow-up studies indicate that workers are more likely to reintegrate into the workforce if they return to the job where they were injured (90,91). A treating physician can sometimes take steps to foster constructive interaction between an injured worker and his or her employer.
   c. Knowing risk factors for chronicity. No single, definitive list of factors exists that predicts the probability that a patient will become chronically disabled; however, several tentative “red flag” lists have been developed on the basis of expert consensus (92,93) or literature reviews (94).
   d. Intensifying treatment for high-risk patients. If a patient seems likely to fail conventional treatment approaches and remain disabled, the treating physician can attempt to direct the patient toward a variety of more intensive rehabilitative interventions, including psychological evaluation and treatment, work hardening, and pain center treatment.
   e. Assessing the credibility of patients. These assessments are crucial because treating physicians typically make key management decisions on the basis of statements made by patients. Credibility assessment is a difficult area, and there are no proven guidelines. In the area of low back pain, the nonorganic signs and symptoms developed by Waddell (17) can be extremely helpful. The lists of “red flags” for chronicity that various investigators have developed (92,93) may be relevant to the assessment of patient credibility, although the set of factors thought to represent red flags for chronicity is broader than the set of factors that suggest low patient credibility (e.g., poor educational background and history of multiple surgeries are thought to predict chronicity but do not necessarily imply poor patient credibility).

   Sometimes it is useful to turn the issue around and identify a “green flags” list—that is, a set of factors associated with high patient credibility (Table 17-3). Physicians should be concerned when they see a patient who fails to match several of the factors on this list. Remember, however, that this list has not been subjected to validation research.

No preexisting condition
No medical co-morbidities
Definite stimulus (e.g., crushed by a tree)
Definite tissue damage (e.g., fracture)
Symptoms, signs, activity limitations fit expectations for the medical problem
Consistent findings over repeated examinations
No exaggerated pain behavior
No inconsistencies between symptoms and signs noted in the physician's office and behavior outside the office
No chronic psychiatric disorders or long-term psychosocial risk factors
No reactive psychiatric problems (e.g., anxiety disorder, depression)
Patient motivated to return to productivity
Job opportunities exist
No incentives for disability

TABLE 17-3. Characteristics associated with high patient credibility

3. Treating physicians are likely to assume that when they support disability applications of their patients, they are acting in the patients' interests. It is therefore

important to highlight the fact that the long-term interests of patients might actually be harmed when their treating physicians support disability rather than return to productivity. At least two considerations are relevant:

   a. Most patients are not well served by long-term disability systems. For example, the payment levels for SSD recipients are low (95) so that beneficiaries face the strong possibility of financial hardship. In general, the economic needs of an injured person are much more likely to be met if he or she remains in the workforce than if he or she remains in a disability system for an extended period (96).
   b. As discussed under Changes over Time, many injured workers seem to become more dysfunctional as they interact with the industrial compensation system (43). The dehumanizing effects of interacting with the bureaucracy are pervasive. Thus, physicians generally serve the long-term needs of their patients best when they encourage the patients to extract themselves from the system as soon as possible.

4. For physicians to interact successfully with a disability system, they should understand its rules and policies in detail. These differ sharply from one system to another. No substitute exists for spending the time needed to become familiar with some of the common ones.

   It can be particularly enlightening to learn what attorneys say about disability systems. For example, Ruskell (97) has written a book for attorneys who represent SSD/SSI applicants that provides detailed, practical information about the SSD/SSI application process.
5. A treating physician sometimes feels overwhelmed by the bureaucratic machinery of a disability system. This sense may be heightened when a group of independent medical examiners renders opinions different from the ones he or she has expressed. It is therefore important to understand that courts have required disability agencies to weigh the opinions of treating physicians heavily. Thus, if a treating physician forcefully communicates opinions about his or her patient, it will have an impact on the decision that a disability agency makes.
6. Patients who are actively seeking disability benefits often see support from their treating physicians as crucial to their disability applications. A physician who does not support such an application should discuss this issue openly with his or her patient. In many instances, conflict about a disability application will cause serious strains in a doctor-patient relationship that is otherwise entirely positive.
7. Many patients seek legal representation when they are applying for disability. A treating physician thus should consider how to interact not only with the patient and the disability system, but also with the patient's attorney.

IDEAS FOR CHANGE

There is no dearth of scientific literature on the general issue of disability evaluation. A MEDLINE search done in April 1998 with “disability evaluation” as key words yielded 2,323 articles published in English since 1990. However, virtually all of them are irrelevant to the present discussion because “disability” is generally defined in terms of self-reported activity limitations. The literature on individuals who have applied for or have been awarded SSD, or both, is much smaller, and the literature on pain and SSD is virtually nonexistent. However, new ideas that warrant discussion are on the table.

1. Numerous discussions about the assessment of pain exist in the medical literature and in other chapters of this book. I have not included an assessment protocol because essentially none of the ones in current use has been validated for the problem under discussion here—the determination of disability in chronic pain patients. The only exception is the work of Rucker and colleagues (76). As noted, they have developed reliable and valid tools for the assessment of disability applicants with pain problems. The project is a model for the approach that is needed if scientific progress is to be made in the processes by which SSD/SSI applicants are evaluated. Rucker's team did the basic work of developing an assessment battery, determining its metric properties, and assessing its validity on a cohort of disability applicants. At this point, their work stands alone as the one systematic attempt to answer questions about pain and the SSA rigorously. More studies of a comparable character are needed to address the assessment of pain as a cause of disability.
2. The National Center for Health Statistics conducts an annual national survey (the National Health Interview Survey) dealing with health problems of U.S. citizens. One of the areas covered in depth is self-reported activity limitations. The surveys provide a rich picture of the distribution of various disabling problems in the United States (98). However, the survey format to date does not include any questions about whether respondents are receiving disability benefits. In future surveys, these questions will be included (M. LaPlante, personal communication, March 1998). This will permit the National Health Interview Survey to collect population-based data on the self-reported activity limitations of individuals who are, versus ones who are not, receiving disability benefits.
3. Physicians with expertise in fibromyalgia have been involved for several years in a vigorous and sometimes rancorous debate about disability among fibromyalgia patients (42,99,100,101,102,103,104,105,106,107,108,109,110,111,112,113,114,115,116,117,118,119,120,121,122,123,124,125,126,127,128,129,130,131,132,133,134,135,136,137,138,139 and 140). The debate has been wide ranging, dealing not only with the assessment of disability in fibromyalgia, but also with the question of how causation of fibromyalgia can be assessed and with the issue of the nature and reality of the condition. Although this debate has not led to any obvious resolution, it has at least brought critical issues related to pain and disability to the attention of physicians. In essence, fibromyalgia raises questions about pain and disability in pure form because patients often complain of overwhelming incapacity but have no conclusive evidence of a disease process that can be assessed objectively by a physician. At this point, the dialog on disability in fibromyalgia represents the best discussion in the medical literature about how disability agencies and individual physicians might respond to alleged disability in painful conditions.
4. The fourth edition of the AMA *Guides to the Evaluation of Permanent Impairment* has a chapter on the evaluation of disability secondary to chronic pain. It includes important concepts about chronic pain and some guidelines about how to evaluate the impact of pain systematically. However, the chapter does not provide any method for quantifying the impairment associated with pain, and the information in it is not integrated into the entire AMA system for impairment rating. In essence, the chapter on impairment from pain is rather redundant with other chapters in the AMA *Guides* and is generally ignored by disability examiners. As a practical example, an examiner evaluating a patient with a chronic lumbar spine condition would almost certainly ignore the chapter on pain and instead use the impairment ratings given in the chapter on the musculoskeletal system.

   On the positive side, however, the AMA is committed to upgrading its system of evaluating pain-related impairment. The editor of the upcoming fifth edition of the *Guides* has contacted the American Pain Society, the American Academy of Pain Medicine, and various experts in disability in an attempt to strengthen its discussion of pain-related impairment (L. Cocchiarella, personal communication, February 1998).
5. A monograph edited by Fordyce et al. (45) focuses on problems associated with the current concepts regarding low back pain and work disability. In essence, this group argues that impairment cannot be assessed validly in nonspecific low back pain, because (a) an examiner's assessment of impairment from low back pain depends on the performance of a patient during an examination and (b) a back pain patient's performance during an examination is determined not only by the severity of the anatomic and physiologic functional loss he or she has sustained, but also by a variety of psychosocial factors. In their words, “Not all potential impairments can be confirmed by verifiable measures of their presence independent of performance by the person purported to be impaired. Because performance is also 'effort-related' as well as related to anatomical or physiological capabilities, it is inevitably linked to and influenced by such factors as attitudes, motivation and personality” (45).

Fordyce promotes the idea that patients with nonspecific low back pain should be classified as “unemployed” rather than disabled if they “persist . . . in activity intolerance beyond the allotted time for medical treatment and temporary disability status” (45). Thus, patients with persistent nonspecific low back pain would, for benefits purposes, be classified with people who are unable to find work who do not have a rated disability.

It is important to note that Fordyce makes recommendations for disability policy only in relation to nonspecific low back pain; they do not consider any other chronic pain conditions. Also, although their recommendations about disability policy rest on their pessimistic view of the ability of physicians to determine impairment accurately in patients with nonspecific low back pain, they do not provide any data to buttress this view. In essence, their monograph is a consensus document rather than a presentation of empiric data. However, in view of the eminence of its authors, *Back Pain in the Workplace* is a provocative work that should be read carefully. It clearly identifies the need to separate the availability of health care from disability status and to recognize the “moral hazard” of disability insurance.

WHERE DO WE GO FROM HERE?

This chapter was meant to have a sober tone. It is common knowledge that many people seek disability because of painful conditions; however, the societal responses to these requests are incoherent for many reasons:

1. No accepted system exists for classifying painful conditions in a way that is relevant to disability evaluation.
2. Partly as a result of the preceding reason, there are virtually no useful data on how many patients seek disability because of pain and how many actually receive benefits.
3. Similarly, little is known about the long-term activity limitations and workplace disadvantage of people who perceive themselves as disabled by pain.
4. There has been no agreed-on solution to the problem of integrating subjective information and objective information in the evaluation of patients who claim work incapacity.
5. The scientific study of disability evaluation is woefully lacking. Only fragmentary information is available about the reliability with which physicians evaluate patients claiming work incapacity. Studies on the validity of these judgments are virtually nonexistent, and there are significant problems in determining, even at

a theoretical level, how such studies should be designed.

6. The process of disability determination is entangled in the insurance and legal systems. The effects of these entanglements are difficult to assess, but, in a general way, they act as barriers to information exchange and scientific research (141).

Given the preceding, there is a real risk that the chapter on pain and disability in the next edition of *Bonica's Management of Pain* will be as inconclusive as the present chapter has been. If we are to move forward, we have to start by acknowledging the holes that exist in our present approaches to pain-related disability and work toward a set of concepts and empiric research that could properly be called *disability evaluation science*. This will be hard work, and there will be no "quick fix." A short list of the issues that should be addressed includes the following:

1. *Break the problem down.* It is quite possible that impairment rating systems currently in use are adequate for assessing patients with "expected" pain. In contrast, there is no good method available for rating unverifiable pain or psychogenic pain. These important distinctions are lost if statements about pain and disability are framed in global terms.
2. *Clarify the meaning of psychogenic pain and the manner in which impairment associated with psychogenic pain should be assessed.* Psychogenic pain is probably the most ambiguous category of pain (142). It involves philosophic conundrums (143,144) and conceptual leaps whose implications have not been carefully explored. When physicians evaluate most pain patients, they start with the assumption that the patient's pain is somehow "grounded" in a pathophysiologic process that can be understood in traditional medical terms. In psychogenic pain, pathophysiology (in the sense of injury or disease of a body part) is irrelevant. Thus, it is not clear what clinical evaluation tools are relevant to psychogenic pain. Also, it is not clear how psychogenic pain differs from abnormal illness behavior (145). In the extreme, a paradox is encountered in which it is concluded that every patient (other than a malingerer) who reports incapacitating pain must be severely impaired. If the patient has objective evidence of a medical condition that explains his or her symptoms, the impairment is attributed to that condition. If no such objective evidence is found, it is concluded that the patient must be severely impaired because of psychogenic pain. This syllogism is obviously specious, but it highlights the conceptual confusion that surrounds psychogenic pain.
3. *Develop methods for aggregating patients into large groups without losing critical clinical information.* Many problems exist in this area. The *ICD-9*, the most widely used diagnostic system, is difficult to use in studies on large groups of patients, in part because a condition such as low back pain is compatible with multiple *ICD-9* diagnoses. Ambiguities associated with *ICD-9* diagnoses are magnified by the fact that physicians and disability agencies often choose diagnoses on the basis of factors other than accuracy. Physicians tend to choose diagnoses that maximize their chance of being reimbursed by insurance companies; disability agencies tend to choose diagnoses based on their congruence with eligibility criteria for benefits [e.g., workers' compensation systems tend to code all noncatastrophic low back conditions as lumbar strains (847.2), whereas the SSA is more likely to diagnose lumbar degenerative disc disease (722.52) or displacement of lumbar intervertebral disc dislocation (722.10)]. A further complication arises when survey methods are used to obtain self-reported health data (98). Interviewers in surveys are not medically trained and typically do not have access to physical examination findings or laboratory data. As a result, the "diagnoses" made in the course of health surveys are not necessarily comparable to diagnoses made by physicians. The general point is that research on pain-related disability should deal with a paradox: Large patient cohorts are needed to identify statistical trends, but information vital to the clinician may be lost when patients are aggregated into large groups.
4. *Develop strategies for making inferences about pain on the basis of diagnostic information.* Assuming that one has access to *ICD-9* diagnoses for a group of patients, one still has to determine whether pain is a major component of the problems with which the patients presented. This requires a careful consideration of the role that pain is likely to play in various medical conditions. For example, paraplegia is a condition associated with substantial impairment even when pain is not a problem. In contrast, for most patients with lumbar disc conditions and for all patients with fibromyalgia, pain is essential to the impairment.
5. *The SSA should keep more detailed medical records on beneficiaries.* As noted previously, the SSA uses such broad medical categories in its research and statistical reports on beneficiaries that the role of pain in SSD or SSI awards is difficult to determine.
6. *Study correlations between reported incapacity from pain and objective measures of organ dysfunction or activity restriction*. Some research in this area has already been done (24,146). The broad question is whether the statements that patients make about their abilities and restrictions match objective assessments that external observers make. If the match is close, then it might be reasonable to weigh subjective estimates of incapacitation heavily in disability evaluations.
7. *Study long-term functional outcomes among patients who seek disability benefits because of pain.* This would include follow-up research both on individuals who receive disability benefits and ones whose benefit applications are denied. The research of Rucker et al. (76,78) provides an example of the kind of work that is needed in this area.
8. *Study the effect of social policies on the apparent incidence and prevalence of painful conditions*. As previously noted, many experts are concerned that if disability programs dispense benefits liberally on the basis of subjectively determined incapacity, the result will be a sharp increase in the number of people who request benefits because of pain and other symptoms. This hypothesis can and should be tested.
9. *Evaluate the hypothesis that patients with chronic pain become more incapacitated as a result of interactions with agencies that administer disability programs* (39,40,41,42 and 43).
10. .*Consider methods for determining disability in the face of uncertainty*. Statisticians deal with uncertainty on a regular basis, and statistical methods, such as regression analysis, have been developed to optimize decision making when data are incomplete. It might be possible to apply some of these methods to decisions about disability—that is, to use "statistical" rather than "clinical" decision making (147). This would require a paradigm shift because disability systems seem to operate on the assumption that detailed clinical evaluation of an individual applicant will permit an optimal decision to be made regarding that applicant.
11. .*Do validity research on pain assessment systems that have already been developed*. It is possible that multidimensional pain assessment systems, such as the one developed by Rucker et al., will turn out to have construct and predictive validity in the evaluation of patients seeking disability because of pain. Research is needed to determine whether this is so.
12. *Examine the extent to which findings about pain-related disability can be generalized across disability systems and across cultures*. Some investigators have suggested that the apparent incapacitation associated with painful conditions varies widely from one culture to another (148,149). Within the United States, there is evidence that patients receiving workers' compensation are more likely than noncompensation patients to remain disabled despite seemingly appropriate treatment (150,151,152,153,154,155,156,157 and 158). In a general way, a detailed understanding of the ways in which biological, psychological, and social factors interact to produce pain- related disability is lacking (43). As a practical matter, findings from research on any single disability system or culture will need to be replicated in other settings before they can be considered firmly established.

The preceding points provide a flavor of the work that should be done if there is going to be movement toward a well-developed science of disability evaluation for patients with chronic pain. At this point, so little work has been done that it is not known how difficult the project may be; however, the problem of pain and disability is important. At one extreme, the risk is run of abandoning citizens who, by any reasonable standard, are incapable of competing effectively in the workplace. At the opposite extreme, the risk is run of driving social support systems into insolvency by granting disability awards to individuals who are not really needy. To find some middle ground between these two extremes, research is needed to provide answers to the questions that have been raised in this chapter.

CHAPTER 18

Multidisciplinary Pain Assessment

John D. Loeser

The growing awareness that reports of chronic pain and subsequent disability are influenced by psychosocial and environmental factors as well as physical changes within the patient's body has led to the continued development of multidisciplinary/interdisciplinary (M/I) pain treatment facilities. In this section I will describe the M/I process of screening patients with chronic pain as it is implemented at the Multidisciplinary Pain Center of the University of Washington (1). Different types of evaluation are presented and the roles of a variety of health care providers in the evaluation process are discussed. I emphasize the importance of the sharing of information by the assessment team and how an integrated treatment recommendation is generated by the assessment team. The conceptual framework discussed in the Introduction to Part II of this book determines the type of assessment that is used. These diagnostic strategies have been developed from the pioneering work of W. E. Fordyce and by our physicians and psychologists since 1970 and provide us with a rational basis for assessing and treating patients disabled by chronic pain. Other authors have described evaluation strategies at their institutions; often these are based on the concepts that evolved at the University of Washington (2,3,4,5 and 6). The objectives of this type of assessment are to identify those patients who could benefit from a physical and psychological rehabilitation program based on cognitive-behavioral principles of effecting behavior change and pain reduction; to rule out those patients who have a medical or psychological contraindication to such a program; to identify other, perhaps more effective, methods of treatment; and to help establish appropriate therapeutic goals.

REFERRAL TRIAGE

Pain centers should maintain their position as referral and not as primary care institutions. The first contact in reference to a patient is usually made by either a letter or a telephone call from another physician or, on occasion, from another type of health care provider. Rarely is a referral made by a claims manager, but when this occurs, we immediately contact the primary care physician to make sure that he or she supports such a referral and wishes to have the pain center involved in the care of the patient. A pain center physician reviews each referral letter or speaks to the referring physician to ascertain the nature of the patient's problem and the type of assessment required. At times, a nurse or another highly trained staff member may participate in the preliminary triage of incoming referrals. The processes described below can apply equally well to an inpatient or an outpatient treatment service. One of six options is chosen (Table 18-1):

Screening evaluation
Consultation
Rejection of referral
More information needed
Emergent treatment required
Unresolved medical issues must be addressed

TABLE 18-1. Triage outcomes

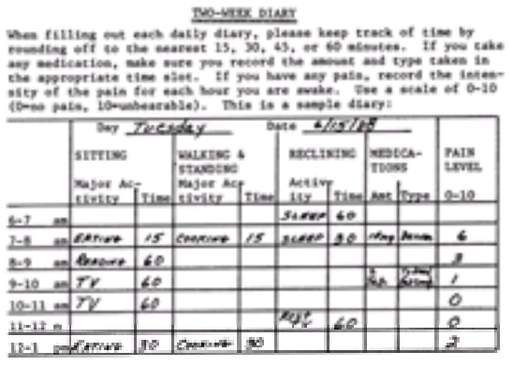
1. M/I evaluation: The patient has a complex chronic pain problem requiring comprehensive evaluation. These are most often patients with long-standing pain problems that have failed to respond to traditional health care interventions. They are often inappropriately using medications. Approximately one-half of these patients have experienced low back and leg pain. We have used the term *screener* to describe this type of patient.
2. Consult: The patient has a straightforward pain problem that one of our physicians or psychologists can handle, at least initially.
3. Reject: The patient is not suitable for further assessment or treatment at our facility.
4. Additional information required: Further information is required before a decision can be made by our staff as to the suitability of the patient for our center. Usually this means that the referring physician did not forward the appropriate medical and psychological records, which must be reviewed before any decision can be made. Sometimes the issue is the lack of current imaging studies in a patient who has had prior surgical procedures or whose clinical status has changed since his or her most recent evaluations.
5. Emergent treatment required: The patient has a severe chronic pain problem that cannot await outpatient diagnostic evaluation and requires direct admission to our inpatient service for both assessment and pain control. This is an uncommon scenario. It often relates to problems with medication. Some cancer pain patients present in this group.
6. Unresolved medical issues: The patient clearly has unresolved medical issues that must be addressed before referral. Attempts should be made to assist the referring physician to place the patient in the appropriate treatment facility. These patients should be reconsidered when their medical status has been resolved. Common examples include inadequately treated chronic diseases or new findings in the patient with cancer. At issue here is the presence of medical issues that must be addressed in parallel with or before pain management.

SCREENING, CONSULTATION, AND REJECTION OPTIONS

Screening Evaluation

Screening is the usual evaluation format for a patient with chronic pain caused by a nonmalignant disease who has failed routine health care and who does not have a specific pain syndrome such as tic douloureux or peripheral neuropathy. Few patients with pain caused by cancer are initially scheduled as screeners, but many are eventually seen both by our physicians and our psychologists. As we can screen only two patients each working day, efforts are made to avoid stacking up a long waiting list for these limited slots. Consultations are therefore the first encounter with the pain center for the majority of patients.

Most referrals to M/I pain centers concern patients with long-standing disability resulting from pain caused by nonmalignant disease. They have complex medical and psychological histories, and the pain center must first sort out the facts. When the reviewing physician determines that the patient needs an M/I evaluation, a letter is sent to the referring physician requesting the transmittal of all relevant records and imaging studies. The patient is contacted by telephone, and the names and addresses of any other treating physicians or psychologists are requested. Every effort is made to assemble the most complete documentation available before the patient's initial visit. Once the relevant information is obtained and the patient is deemed appropriate for a screening evaluation, the patient is scheduled for an appointment. At that time he or she is sent a demographic and history questionnaire and 2 weeks of pain, activity, and medication diaries, which are to be completed and brought to the initial visit (Fig. 18-1). Patients are informed of the importance of the completion of these forms in detail to ensure the appropriate evaluation of their pain problem. Failure to complete the diaries or forms often results in a partial evaluation and the rescheduling of the clinic visit for a later date.



TWO-WEEK DIARY

When filling out each daily diary, please keep track of time by rounding off to the nearest 15, 30, 45, or 60 minutes. If you take any medication, make sure you record the amount and type taken in the appropriate time slot. If you have any pain, record the intensity of the pain for each hour you are awake. Use a scale of 0-10 (0=no pain, 10=unbearable). This is a sample diary:

Day Tuesday Date 4/15/85

	SITTING Major Activity	Time	WALKING & STANDING Major Activity	Time	RECLINING Activity	Time	MEDICATIONS Amt	Type	PAIN LEVEL 0-10
6-7 am					SLEEP	60			
7-8 am	EATING	15	COOKING	15	SLEEP	30	1Tsp	Bran	6
8-9 am	READING	60					1	Tylenol	3
9-10 am	TV	60					2	Tylenol	1
10-11 am	TV	60							0
11-12 n					REST	60			0
12-1 pm	EATING	30	COOKING	30					2

Figure 18-1. Part of a completed pain clinic diary.

Patients are informed that they must be accompanied to the initial pain center appointment by the spouse or significant other. This individual is an important part of our evaluation process. We have learned that the evaluation of a patient with chronic pain requires assessment of the family and home situation and information about the patient that only another person can provide. Thus, we will not schedule an appointment for screening unless a significant other will be accompanying the patient. It is also important that patients be informed of the nature of the assessment and that more than just medical issues will be explored. Patients should be prepared, both on the basis of what the pain center provides in written and oral information for prospective patients and by their referring physician, for the thorough medical, psychological, and vocational assessment that they will undergo. The mere presence of a psychological evaluation makes many patients feel that their symptoms are not accepted as valid and that they are thought to harbor a mental illness. It is imperative that this belief be dispelled quickly by all members of the assessment team.

The screening evaluation occupies an entire morning for the patient and significant other (Fig. 18-2). The patient is seen by a physician and a complete history and physical examination are obtained using the patient-completed survey form as a starting point. The patient and the patient's family member are interviewed separately by the psychologist. The patient completes the Minnesota Multiphasic Personality Inventory (MMPI), that is immediately scored by a medical assistant and interpreted by the psychologist. The vocational counselor is also part of the initial assessment team when there are any work-related issues. The information gleaned from the patient's survey forms, MMPI, physician evaluation, psychologist evaluation, and vocational counselor evaluation is then used in a face-to-face meeting of the evaluation team.

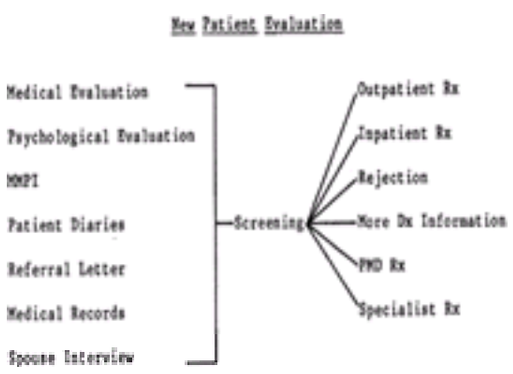


Figure 18-2. Diagrammatic representation of screening process. See text for details. (Dx, diagnostic; MMPI, Minnesota Multiphasic Personality Inventory; PMD, private medical doctor; Rx, treatment.)

Types of Screenings

We have two types of screening patients—long-distance screeners (LDSs) (the patient resides more than a 3-hour drive from our clinic) and local screeners. LDSs are individuals who live far enough from Seattle so that coming in for a screening evaluation and returning home again only to come back shortly thereafter for treatment is a hardship. The University of Washington Multidisciplinary Pain Center attracts patients from the entire Pacific Northwest region, including Alaska; long travel distances are common for its patients. Their records and letters from referring physicians have been carefully reviewed, and they appear to be patients who are candidates for our 3-week structured program treatment. If they are suitable candidates and agree to participate, they are entered into a treatment group immediately after screening. Preauthorization for their assessment must be obtained by our patient care coordinator before scheduling the patient for screening.

Local screeners reside within easy commuting distance of the University of Washington. If they are accepted for treatment, they are scheduled into the next available opening in the structured program after authorization for care has been obtained. If more appropriate, both LDSs and local screeners may be entered into other treatment programs in the pain center or in other clinical departments, whether within the University of Washington or closer to their homes.

Role of the Physician

The physician and the psychologist have complementary roles in the screening process. The physicians function as pain patient managers. Currently, five anesthesiologists, a neurologist, two neurosurgeons, a psychiatrist, and three physiatrists comprise the medical staff. In our experience, the discipline of the physician has proven irrelevant; rather, an appropriate philosophical approach and certain specialized knowledge and skills are required. The primary tasks of the physicians are the following:

1. To unravel the patient's history and document how the patient has achieved his or her present status as a chronic pain patient
2. To evaluate past medical treatments and their sequelae
3. To describe the current physical condition accurately
4. To determine whether any additional diagnostic studies are necessary
5. To identify any medical limitations on treatment

This requires that the prior medical records be carefully reviewed to reconstruct the medical events that have led the patient to the present state. Imaging and electrodiagnostic studies and other laboratory tests must be examined, often with the assistance of the specialist in these areas. Judgment must be used in identifying a real need for additional diagnostic studies. Needless repetition of tests must be avoided. The medical evaluation of the chronic pain patient is carried out by the physician as described previously in Chapter 12.

Role of the Psychologist

The task of the psychologist is to ascertain the role of cognitive, affective, and environmental factors in the genesis, exacerbation, or maintenance of the patient's pain behavior and disability. As previously noted, we use 2 weeks of diary information completed by the patient to obtain information about pain levels, medication consumption, the amount of time the patient spends up and about and sitting and lying down, and the types of activities engaged in. A patient whose days are filled with activities such as woodwork, needlework, watching television, reading, and visiting friends, all identified by the patient as positive and pleasurable, is viewed somewhat differently from a patient who has had to eliminate pleasurable hobbies and activities. The McGill Pain Questionnaire is also part of our diagnostic array, as are pain drawings, the Beck Depression Inventory, and a structured questionnaire for collecting additional information. The MMPI is used to describe the likelihood that the patient is responding to environmental or affective factors with pain behaviors, as well as in helping to assess level of depression; covert expressions of suffering, pain, and distress; possible cognitive impairment; and other serious mental disorders. Most important, however, is the psychologist's assessment of the

patient and spouse based on the interviews in the screening evaluation. Observation of the patient's behavior and the responses of the significant other during the interview are particularly important. The psychologist also attempts to identify the antecedents and consequences of pain behaviors. Data from all of these sources are considered by the psychologist when determining what are the appropriate diagnoses, what form of treatment is most likely to succeed, and whether there are impediments to participation in a pain management program.

Role of the Vocational Counselor

The role of the vocational counselor is to ascertain the contributions of workplace factors to the patient's pain behavior and to evaluate outcome potentials in the employment sphere. In other pain treatment facilities, occupational therapists or rehabilitation nurses may undertake some aspects of this role. The current workplace environment as well as prior work experiences and the opportunities for future job modifications are investigated. The vocational counselor also communicates with claims managers and outside vocational counselors to glean further information about the patient and address administrative issues.

In effect, our screening process asks the physician to identify the roles of tissue damage or injuries to the nervous system; the roles of the patient's appraisals, beliefs, expectations, affective disturbances, and environmental factors are assessed by the psychologist and workplace factors by the vocational counselor. Consistent with the literature, we have not found any single test or scheme to be highly reliable either for diagnosis or treatment outcomes (7,8,9 and 10). The professional judgments of our physicians, psychologists, and vocational counselors are not infallible, either. The assessment process does yield information that predicts likelihood of treatment success, probably by identifying those who are likely to fail (2).

Management Conference

The management conference that follows the patient's assessment by the physician and vocational counselor and the patient and the spouse assessment by the psychologist are critical to our evaluation and to the establishment of treatment goals. This conference usually lasts 30 to 45 minutes. The physician presents the medical history and physical findings, the psychologist presents the psychological and social history and the MMPI interpretation, and the vocational counselor reports work-related findings and issues. A consensus is reached regarding both diagnosis and treatment options. The process of obtaining a consensus is one of the most important aspects of the M/I evaluation. It requires that the team members be able to break through their disciplinary approaches and share in the give and take of a problem-solving exercise.

The patient and the family member or significant other are then brought into the room for the feedback portion of the management conference. The process of evaluating and meeting with the patient and significant other is labor intensive, but it seems to be required both for diagnosis and the establishment of meaningful treatment plans. Chronic pain patients have been a puzzle to their prior health care providers. We attempt to fit the pieces of this puzzle together. The face-to-face meeting of health care providers to formulate a single, mutually acceptable diagnosis and treatment plan is a critical part of multidisciplinary pain management. The feedback component is also an important educational experience for the patient and the significant other. After this feedback conference, a written report is generated, and the referring physician is informed of our diagnosis and treatment recommendations.

Other Issues in the Screening Process

At times, the screening evaluation is inconclusive because of unresolved medical or psychological issues and because additional information is needed before diagnosis and treatment can be determined. In such cases, the patient is asked to undergo the appropriate diagnostic tests and is brought back for another conference when the necessary information has been obtained. If the patient has pending litigation that is relevant to the pain problem, we always ask the patient's permission to contact the attorney before embarking on a treatment program. Litigation is not by itself an exclusionary factor. Although a number of studies have reported that compensation and litigation status are impediments to rehabilitation, they are not primary determinants of treatment eligibility, but rather are viewed as important pieces of information that are included in the determination of the appropriate treatment (11,12 and 13).

In the event patients manifest drug toxicity (from multiple medications) such as impaired mentation and confusion, they are placed on the “drug detoxification” program (described in detail in Chapter 88) and then reevaluated. Experience has impressively demonstrated that after they are detoxified, such patients have been able to provide more precise information, are able to better cooperate, and frequently state that they have less pain.

Purpose of Screening

The purpose of our screening evaluation is to identify those patients for whom a structured, 3-week, intensive program of physical, psychological, and vocational rehabilitation will launch a return to functional existence both at home and in the workplace. The goals of this program include the following:

1. Reduction of pain level
2. Improvement of physical conditioning, strength, and flexibility
3. Management of medications
4. Improvement of psychological well-being
5. Identification of reasonable vocational goals and movement toward them
6. Education about mind and body function
7. Education about prudent health care consumption
8. Alleviation of depression

The actual treatment program is discussed in detail in Chapter 109. It has been our experience that approximately 50% to 70% of the patients who are accepted for screening are referred to our structured rehabilitation program. The “hit” rate is a function of the type of patient as well as the source of funding for health care. Ideally, we would like to have a higher “hit” rate, but our triage system has been biased toward evaluating the maximum number of referrals for humane reasons and to try to assist physicians in the community.

Consultation

When the referral letter indicates a chronic pain problem that appears to have a specific diagnostic or treatment requirement, we schedule the patient for a consultation with a physician or psychologist at the pain center. Some patients are referred by other physicians in our pain center for psychological assessment only. The special training and interests of our physicians dictate the referral of patients for consultations. Thus, in our pain center, headache and peripheral neuropathy problems are referred to our neurologist, our neurosurgeon sees patients with tic douloureux and other neuropathic states, physiatrists see patients with musculoskeletal problems, and so forth. All of our physicians participate in the assessment of chronic pain patients referred as candidates for our structured 3-week rehabilitative program. Some patients with specific physical issues may be referred to physical therapy or occupational therapy for additional evaluation.

Sometimes what appeared on referral to be a straightforward problem turns out to be a complex issue requiring additional study. The consulting physician may then refer the patient to a psychologist. Conjointly they plan the patient's evaluation and subsequent treatment. Such a patient may eventually be admitted into our structured program. Patients who are seen in consultation may be managed by the consulting physician or may be returned to the care of their primary physician, with treatment recommendations from our consultant.

Rejection

Certain factors can lead to refusal to evaluate a patient. Many physicians consider the phrase *pain clinic* to be synonymous with *garbage pail* and cannot understand why every referral should not be seen. It is important for a pain center to be able to control the types and numbers of patients that it sees; otherwise a considerable amount of time can be wasted evaluating patients for whom the pain center has little to offer.

We have learned that our pain center strategies are ineffective in the management of addiction based on illegal (“street”) drugs. It is easy to taper patients off their medicine using the “pain cocktail” technique (see Chapter 88), but such patients are almost certain to resume their drug-seeking behavior immediately after discharge from the pain center. The factors that lead to addiction appear to be quite different from those that lead to tolerance and habituation because the chronic pain patient is not likely to return to medication usage after the treatment program has been completed. The factors that lead to addiction, both biological and psychological, are not present in the vast majority of chronic pain patients who have been prescribed opioids to alleviate pain and suffering. Chronic pain patients, if their pain is relieved

by some other means, can be rapidly tapered off opioids and do not engage in subsequent drug-seeking behaviors.

Patients who have already failed to benefit from similar pain rehabilitation programs are usually not accepted for evaluation or treatment. Their acceptance must be based on a significant change in the patient's physical condition or the affective and environmental factors. We have learned that pain management strategies are not effective with severely emotionally disturbed patients. Moreover, the group treatment program may be disrupted by the inclusion of such patients, thereby impairing other patients' treatment. When the referral letter indicates that the patient has long-standing major psychopathology that antedates the pain problem, we do not evaluate the patient. Although many patients have a history of excessive alcohol usage, patients currently abusing significant amounts of alcohol should be referred for the treatment of alcoholism before acceptance to our pain rehabilitation program.

Different pain management programs have evolved their own evaluation strategies that can make use of the services of a wide array of health care providers and include different physical and psychological strategies for patient assessment. Comparative data are lacking on relative efficacy and costs. Thus, there is no empiric basis for the determination of optimal inclusion or exclusion criteria.

Basic Requirements for Patient Assessment

It is certainly true that many pain practitioners desire to practice M/I pain management but lack the resources of a university center or a large, multispecialty hospital. The minimal resources required to provide an M/I service include a physician, a psychologist or psychiatrist, and someone to undertake the assessment of vocational issues. As is true for M/I pain centers, the role of the physician is to ascertain medical diagnoses and the suitability from the physical perspective for a rehabilitation program. The role of the psychologist or psychiatrist is to determine the contribution of cognitive, affective, and environmental factors in the patient's symptoms. A vocational counselor or someone competent to assess vocational issues must also be available. The physician and the psychologist and other team members should all participate in the decision of whether to treat a particular patient. The entire team must also share in the design of a treatment program that addresses the physical, psychosocial, and behavioral factors associated with the patient's suffering, emotional distress, maladaptive attitudes and beliefs, and the maintenance of inappropriate pain behaviors, all of which may interfere with effective rehabilitation. The assessment team must meet face to face to discuss their findings and agree on treatment recommendations. Finally, a feedback conference for the patient and his or her significant other must complete the assessment process. The interactions between the providers and the interaction with the patient are essential components of this assessment process. It is preferable that the physician and the psychologist have some experience with and understanding of chronic pain patients. It is not safe to assume that the necessary knowledge base or implementation skills are imparted in standard training programs for the education of physicians, psychologists, or vocational counselors.

An essential product of a pain center evaluation is the letter that is sent to the referring physician and the sponsoring agency. Such a document needs to state clearly but concisely the patient's medical, psychological, and vocational history and the diagnoses that have been established by the evaluation. It should also state the prognosis if no further treatment is offered. The treatment recommendation section should indicate the reasonable treatment options, their relative likelihood of success, and how the patient's status will be altered by successful treatment (outcome goals). In the managed care environment of the United States, this letter must contain all of the information that is required to obtain authorization for care.

Evaluation for Nonmedical Purposes

Pain centers are often asked to perform a variety of administrative evaluations that have little to do with patient care. These include such things as a physical capacities evaluation and a medical evaluation to ascertain disability status. Such activities may be a method of generating revenue for individual health care providers, but they have little to do with improving the patient's well-being. Whereas there is no violation of the doctor-patient relationship when such an evaluation is performed on an individual who is not receiving care in an institution or from the evaluating physician, there are many reasons to be cautious about providing such administrative ratings on someone who has confided in his or her physician for reasons of health care. Indeed, such rating activities could easily be a violation of the doctor-patient relationship (14). In addition, there is very little evidence to support the validity of either a physical capacities evaluation or a medical evaluation. When the matter arrives in a court of law, each side is able to produce expert witnesses who solemnly swear that the individual is either fully disabled or not disabled at all. The time is long overdue for such trials by combat to be eliminated from the disability determination system. Pain centers should have a circumspect viewpoint on participating in such administrative charades (see Chapter 17).

CHAPTER 19

Painful Neuropathies

Misha-Miroslav Backonja

Injuries and diseases of the peripheral nerves are relatively uncommon among the large numbers of patients with chronic pain, but pain is a frequent symptom of injuries to and diseases of peripheral nerves. Painful neuropathies are not too rare in general medical practice and, of course, they are concentrated in pain management practice. They have diverse etiologies and, as a consequence, their clinical course varies from disease to disease. However, many symptoms and signs are common to all painful neuropathies, and it has been postulated that they share many similar, if not the same, pathophysiologic mechanisms. Painful neuropathies are classified under the rubric of neuropathic pain syndromes.

Painful neuropathies can be classified by major etiologic categories: toxic-metabolic (endocrine, chemotherapy and chemical exposure associated, nutritional), posttraumatic (complex regional pain syndrome types I and II), compressive (nerve entrapment syndromes), autoimmune (vasculitic, paraneoplastic, parainfectious), infectious, and hereditary (1,2). Nerve entrapment painful neuropathies and posttraumatic neuropathies are discussed in many other chapters of this textbook, so they are not treated here. Complex regional pain syndrome is presented in Chapter 20. One of the infectious neuropathies, herpes zoster, is also discussed in Chapter 22. This chapter concentrates on painful neuropathies with the other common etiologies.

General issues that are common to all neuropathic disorders are discussed first. Among these are the pathophysiologic mechanisms underlying the pain of painful neuropathies, pain and other symptoms assessment, approaches to diagnostic evaluation and testing, treatment principles, and a review of the frequently used pharmacologic therapies. When discussing pathophysiology, the emphasis is on how an understanding of these common issues affect pain assessment and therapy. This chapter then reviews a few examples of painful neuropathies related to diabetes, human immunodeficiency virus (HIV) infection, Guillain-Barré syndrome (GBS), and vasculitis, with the accent on specific issues in diagnosis and therapy for these neuropathies.

Because of limited space, rarer types of painful neuropathies cannot be covered in this chapter. The textbooks edited by Dyck and colleagues (1) and Schaumburg and colleagues (3) and the issue of *Seminars in Neurology* devoted to diabetic neuropathies (4) are excellent sources of additional information. Table 19-1 lists painful neuropathies according to etiology.

Toxic-metabolic	Endocrine (e.g., diabetic)
	Chemotherapy (e.g., isoniazid)
	Chemical exposure associated
	Nutritional (e.g., beriberi)
Posttraumatic	Complex regional pain syndrome types I and II
Compressive	Nerve entrapment syndromes (e.g., carpal tunnel syndrome)
Autoimmune	Vasculitic
	Demyelinating
	Paraneoplastic
	Parainfectious
Infectious	Viral (e.g., human immunodeficiency syndrome, herpes zoster)
	Spirochetal (e.g., Lyme)
	Guillain-Barré disease
Hereditary	Fabry's
	Amyloid

TABLE 19-1. Etiology of painful neuropathies: major categories

EPIDEMIOLOGY

The epidemiology of painful neuropathies is not well known for many reasons. Diverse etiologies prevent systematic epidemiologic study of painful neuropathies as an entity (Fig. 19-1). The epidemiology of painful neuropathic disorders varies greatly from country to country depending on the socioeconomic status and the disease incidence and prevalence for any given country. In poor countries, one would expect to see more painful neuropathies caused by nutritional deficits, whereas in industrial countries one sees more toxic and metabolic disorders, such as diabetes-related neuropathies. With more and more patients surviving cancer and acquired immunodeficiency syndrome (AIDS), chemotherapy-related painful neuropathies have increased in incidence. The emergence of new diseases, such as AIDS and Lyme disease, and their spread in the population have been associated with increasing numbers of painful neuropathies associated with these disorders. With the exception of diabetes, which has been well studied in Western countries, data for most other types of painful neuropathies are not available. We have learned from observing the course of diabetes that with the progression of the disease an increase occurs in the prevalence of neuropathy, from approximately 8% at the time of diagnosis up to 50% after 25 years of the disease (5). However, the severity of painful symptoms and the associated morbidity are not known (6).

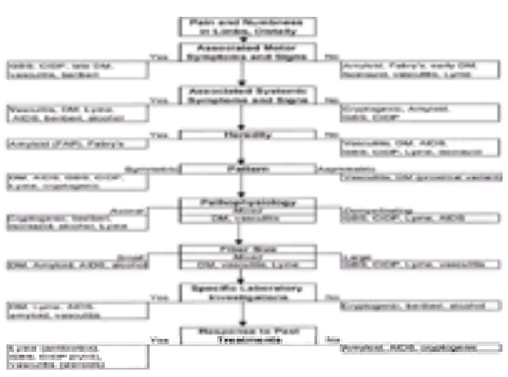

Figure 19-1. This algorithm is provided as a guide to consider major steps in diagnosis of painful neuropathies. It should be kept in mind that these are only suggestions for categorization for each diagnostic step; the designation into each category is likely but not exclusive categorization. For example, Guillain-Barré syndrome (GBS) and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) present most commonly in their idiopathic form and are not necessarily associated with systemic symptoms, but on the other hand, GBS is frequently preceded by a viral and most often systemic illness, whereas CIDP can be associated with many systemic illnesses. It should be also noted that the designation into any category is tentative, because many neuropathies change their characteristics as the disease process progresses or the same disease can have several presentations. For example, diabetic neuropathy can present with or without motor involvement. (AIDS, acquired immunodeficiency syndrome; DM, diabetes mellitus; FAP, familial amyloid polyneuropathy; IVIG, intravenous immunoglobulin.)

PATHOPHYSIOLOGY OF NEUROPATHIC PAIN IN PAINFUL NEUROPATHIES

Advances in the neuroscience of pain have significantly helped our understanding of the mechanisms underlying symptoms and signs of neuropathic pain. Descriptions of pain after nerve injury and dysfunction date as far back as the late eighteenth century and have been described in greater detail in the late nineteenth century (7). Pathologic studies of human peripheral nerves demonstrating preferential loss of nerve fibers in certain painful neuropathies, such as postherpetic neuralgia (8), laid the groundwork for theories postulating the loss of myelinated fibers as the precursor of neuropathic pain. These ideas subsequently formed the basis for the gate- control theory of pain (9). However, pathologic studies demonstrating the loss of other fiber types as well, including small unmyelinated fibers, called for additional explanations for the underlying pathophysiology of neuropathic pain. After an extensive review of this topic, Scadding concluded that the loss of a particular fiber size did not predispose patients to develop pain, nor did it prevent them from developing pain as part of peripheral neuropathy (10).

Human psychophysical studies performed in the first half of the twentieth century set the stage for the developing concept of sensitization of neurons in the peripheral and central nervous system (CNS) (11,12). It was, however, the introduction of animal models (13,14) that dramatically enhanced our understanding of the pathophysiologic mechanisms of such abnormal phenomena as allodynia and hyperalgesia (15), both of which are common symptoms of neuropathic pain. This topic is discussed in detail in Chapter 3.

Pathophysiologic Mechanisms Underlying Abnormal Sensations

The primary pathology in peripheral neuropathies is in the peripheral nervous system, so that primary pathophysiologic mechanisms are those of the peripheral nervous system. However, it is overwhelmingly clear from basic science research that the CNS undergoes changes when the peripheral nervous system is injured and dysfunctional (16). The concept that has been evolving is that peripheral generators of abnormal activity are responsible for chronic pain symptoms (17,18 and 19). Consequently, efforts should be made to correct the abnormalities in the peripheral nervous system to improve overall symptomatology.

A large number of human laboratory and clinical studies, as well as animal research on sensory symptoms and signs of neuropathic pain syndromes, point to the many peripheral and central mechanisms whose interactions lead to the manifestation of neuropathic pain. Enough experimental and clinical evidence exists from peripheral nervous system research to suggest some common mechanisms as a cause for neuropathic pain (20). These mechanisms include receptor sensitization and spontaneous afferent activation (17,20). On the other hand, all symptoms cannot be explained by peripheral pathophysiology. An increasing body of basic science information suggests that CNS mechanisms play a significant role, and central sensitization is the best example of how CNS mechanisms lead to the development of chronic neuropathic pain (19). An exciting development has been the realization that peripheral sensitization can initiate and maintain central mechanisms of neuropathic pain (17,18,21).

A large body of research exists on peripheral mechanisms of neuropathic pain and associated phenomena. Sensitization of nociceptors (20) has been documented even in a human patient (22), and it is probable that this sensitization occurs as a result of the release of many chemical mediators of inflammation, the so-called inflammatory soup (20,23). Sensitization of primary afferents has been documented in animal and human research and it presents with ectopic generation of nerve impulses at the site of injury caused by increased sensitivity of adrenergic receptors (20,24,25 and 26). Continuous spontaneous activity of sensitized primary afferents is the probable mechanism of ongoing pain (23,27,28 and 29). Upregulation of sodium channels is possibly a more specific explanation of mechanical allodynia and hyperalgesia (24). Hyperalgesia to heat appears to be mediated by sensitized small fiber nociceptors (22,30,31). Sympathetic catecholamine sensitization of the primary afferents may be the mechanism by which the sympathetic nervous system adversely affects primary afferents resulting in hyperalgesia and allodynia (32,33,34 and 35). Ephaptic transmission between the sympathetic nervous system and primary afferents has been suggested (36). Activation of *silent* nociceptors could explain ongoing pain and pressure pain (20,37). Ectopic discharges of dorsal root ganglion cells have been documented in animal models of neuropathic pain (38,39 and 40) and could also explain ongoing pain.

CNS plasticity changes, particularly in neuropathic pain, play a significant part in the development and maintenance of chronic pain syndromes and their symptoms and signs. The symptoms and signs related to the phenomenon of central sensitization were recognized in the late 1930s (11,12) and have been well characterized in human laboratory models (41,42). Clinical research has confirmed what the laboratory models had demonstrated: Neuropathic pain phenomena, such as ongoing pain, allodynia, and hyperalgesia, are to a significant degree the result of central mechanisms. Research in animal models contributed significantly to the understanding of some of the basic mechanisms. The phenomenon of *wind-up* at the dorsal horn level was recognized as early as 1966 (43), but received much deserved attention only over the 1990s. Physiologic and pharmacologic studies of spinal cord neuroplasticity changes after neuropathic injuries have contributed to a better understanding of wind-up and central sensitization (19,44). It was found that excitatory amino acid neurotransmitters, in particular *N*-methyl-d-aspartate (NMDA) receptor-related activity, play a crucial role in the genesis and maintenance of chronic neuropathic pain and associated symptoms and signs (45,46). Our understanding of pathophysiologic mechanisms underlying neuropathic pain has advanced considerably, and it is becoming clear that neuropathic pain is a complex biological phenomenon with many components. A better understanding of the pathologic mechanisms of neuropathic pain and its components should contribute to a better evaluation and treatment of patients with neuropathic pain, including painful neuropathies (see Chapter 3).

PHYSICAL EXAMINATION

Physical Examination in General

Traditionally, different specialists examine pain patients by a method that is centered on the skills that define their specialty. However, the evaluation of patients with neuropathic pain also requires a systemic examination, particularly an examination of the nervous and musculoskeletal systems. A general neurologic examination should be performed on all patients with chronic pain, but is not discussed in great detail here (see Chapter 12). The emphasis in this chapter is on those aspects of the neurologic examination that are related to pain evaluation that lead to a more specific neuropathic pain diagnosis. A thorough documentation of the patient's history is the first step (Table 19-2).

Onset	When and how did the pain start?
Location/site	Where is the pain located?
Temporal profile	What has happened since onset?
Characteristic/quality of pain	Describe the pain.
Severity	How severe is the pain?
Unpleasantness/distress	How unpleasant is the pain?
Associated symptoms	Are there any other symptoms, such as numbness, weakness, uncontrollable movements, bowel/bladder dysfunction, or insomnia?
Psychological factors	Does the patient suffer from depression? Anxiety? Posttraumatic stress disorder?
Aggravating factors	What makes the pain worse?
Alleviating factors	What makes the pain feel better?
Effect on function and activities	How are work, daily activities? Is the patient engaged in recreational activities? Workers' compensation? Family responsibilities affected? System adding barriers to return to enjoyable pain/employment?
Response to past treatments	What prior treatments have been used?
Habits	Does the patient smoke? Drink? Use illegal drugs? If yes, how much and how often?
Coping skills	How is the patient coping with pain?
Chronic regional pain syndrome-specific symptoms and signs	In the painful region, are there abnormal skin color changes? Skin temperature changes? Abnormal swelling? Abnormal sweating or skin dryness?

TABLE 19-2. Neuropathic pain and symptoms assessment

Neurologic Examination

Several aspects of the examination specific to neuropathic pain should be attended to while performing the standard neurologic examination of the patient whose history suggests possible neuropathic pain. These specific tests are part of the sensory examination and are helpful in confirming the presence or absence of a neuropathic pain disorder. It must be noted that the lack of significant physical findings, including those discussed here, does not rule out the possibility of neuropathic pain, nor should their absence be interpreted as psychogenic pain or malingering (see Chapter 26).

Sensory Examination

Sensory signs are obtained by the patient's report during sensory examination. Indeed, it cannot be emphasized enough that the patient with neuropathic pain, like the patient with any kind of pain, is still the only and the best judge of his or her pain symptoms (47). The examination itself is carefully described beforehand to the patient, and the patient is reassured that the limits of the examination are set by the patient himself or herself.

The sensory examination consists of three steps that, when undertaken sequentially, help to better differentiate between sensory signs in patients with possible neuropathic pain. The first step is to establish whether a stimulus is perceived as normal. The second step is to establish whether a stimulus is a negative phenomenon (i.e., felt as less) or a positive phenomenon (i.e., felt as more). Third, if a stimulus is perceived as a positive phenomenon then the patient's own description is obtained, and these descriptions should help in differentiating between types of sensory abnormalities.

When performing the sensory examination, there are many ways of communicating with the patient to obtain information regarding sensory phenomena. When performing the first two steps, the patient is asked to answer whether the stimulus is normal or different, increased or decreased. Questions are simply phrased, requiring a simple answer: *yes, no*, or *do not know*. This is the basic rule of psychophysical testing. The stimulus should first be applied to the normal body part. This introduces the stimulus to the patient and establishes how the examination is to be conducted. During the application of the stimulus, the examiner should ask the patient to describe the perceived sensation. The questions are simple, unambiguous, and should ask only if the perceived sensation is normal or abnormal, uncomfortable, unpleasant, or painful. The area of abnormal sensation determined by application of stimuli is then mapped.

Sensory signs can manifest as negative or positive sensory phenomena (48). When the patient has negative sensory phenomena, this means that a stimulus such as light touch, pinprick, cold, warm, vibration, joint position sensation, two-point discrimination, or sensory neglect is perceived as decreased or less. Sensory signs can also manifest as positive sensory phenomena. Positive sensory findings include allodynia, hyperalgesia, and hyperpathia, and application of any of the earlier named stimuli is perceived as increased or more. Positive sensory signs can be caused by mechanical or thermal stimulation. Positive sensory signs are associated with additional sensory phenomena, such as stimulation-induced paresthesia, dysesthesia, summation, and aftersensation. Neglect of the pain-affected area or a body part was described in 1995. The patient's perception is that the pain-affected body part or a limb does not belong to him or her (49).

The following paragraphs review sensory abnormalities (50) that may be observed in patients with neuropathic pain disorders and should be tested for during the neurologic examination. These terms are briefly defined in Chapter 2. Proposed pathophysiologic mechanisms underlying each phenomenon are discussed as well.

Mechanical allodynia is the abnormal sensation of pain from usually nonpainful mechanical stimulation and is elicited by lightly touching the painful region with a fingertip, cotton swab, or paint brush. Mechanical allodynia may be one of the most disabling physical symptoms, forcing the patient not to wear clothing, rendering the patient homebound. The pathophysiologic mechanism underlying this sensory phenomenon is central sensitization and activation by fast conducting A-b afferents (20,51). Mechanical allodynia can be static when a single stimulus is applied, such as light pressure. Dynamic allodynia is the pain from repeated innocuous stimuli such as when the area being examined is repeatedly stroked with a cotton swab (19,20,51).

Thermal cold and warm allodynia is the abnormal sensation of pain from usually nonpainful thermal stimulation, such as cold or warmth. For example, a patient may describe a worsening of pain when the painful region is exposed to a cold or warm external environment. Examining the patient for thermal allodynia entails placing a cool stimulus, such as a cool tuning fork, and a warm stimulus, such as a warm test tube of water or warm tuning fork, directly on the painful region for a few seconds. Patients with thermal allodynia report that thermal stimulus, although innocuous, is irritating and painful and frequently continues longer than stimulus application. Thermal warm allodynia is the result of C nociceptor sensitization (22), and cold allodynia comes as a result of central plasticity changes (20).

Summation refers to an abnormally increasing painful sensation to a repeated stimulus although the actual stimulus remains constant. The patient describes the pain as growing and growing as the same intensity stimulus continues. Summation is frequently seen as a part of hyperalgesia and hyperpathia (see following discussion), although it could be seen in mechanical allodynia from repeated light touch stimulation or from vibration. Summation is a sign of central sensitization (20,52), and it is a clinical equivalent of what has been described in electrophysiologic laboratory studies as the *wind-up phenomenon* (43).

Aftersensation refers to the abnormal persistence of a sensory perception provoked by a stimulus even though the stimulus has ceased. After nonpainful and painful stimuli, neuropathic pain patients may report that the pain, dysesthesia, or paresthesia lingers and continues for seconds or minutes after mechanical, thermal, or painful stimuli. Aftersensation could be the result of stimulus-evoked exaggeration of ongoing primary afferents' ectopic generators (19,22,53) or could be caused by a wind-up phenomenon (43) as a manifestation of central sensitization.

Hyperalgesia is an exaggerated pain response from a usually painful stimulation, either mechanical or thermal. Hyperalgesia does not have a symptom analogue and can only be determined by physical examination. Hyperalgesia can also be mechanical or thermal. Examining the patient for mechanical hyperalgesia entails stimulating the painful region with a sharp object, such as a safety pin, using a single pinprick stimulus and multiple pin-prick stimuli. Repeated stimuli are applied to the same area for a few seconds or as long as it is tolerated by the patient. At the bedside, the simplest way to test for thermal hyperalgesia is by using a glass tube filled with ice cold water. A variety of responses may be seen in neuropathic pain patients. Hyperalgesia is present if an exaggerated pain response is observed and reported by the patient. Summation and aftersensation are frequently present. Often areas of hyperalgesia are adjacent to areas of sensory deficits within the region of neuropathic pain (i.e., sensory changes may be patchy within the neuropathic pain-affected region). Mechanical hyperalgesia is a result of activation of myelinated afferents (19,20,54).

Hyperpathia is the most complex abnormal sensation. Hyperpathia refers to an abnormally painful and exaggerated reaction to a stimulus, especially to repetitive stimuli, in a patient who at first perceives the stimulus as less intense. Then the patient experiences explosive pain and usually cries out. Summation and aftersensation are usually present. For example, during repetitive stimulation with a pin the patient may at first perceive little, but after a few seconds the patient reports a great deal of pain and responds with an increased reaction.

Paresthesiae are abnormal and unusual sensations that are described by the patient as neither unpleasant nor painful. Paresthesia can be a spontaneous sensation, such as the report of pins and needles perceived at rest, or it can be evoked on physical examination by nonpainful or painful stimulation, such as light touch, thermal stimuli, or pinprick.

Dysesthesiae are abnormal sensations described as unpleasant and disturbing. As with paresthesiae, dysesthesiae may be spontaneous or provoked by maneuvers on physical examination. Once the patient reports the provoked sensations as painful they should be considered to be allodynia or hyperalgesia.

These abnormal positive sensory signs are most often indicative of a neuropathic pain process. However, allodynia and hyperalgesia may be seen in cases of acute injury and pain, such as burns, but their natural history is one of a gradual resolution of pain, allodynia, and hyperalgesia. On the other hand, in instances of neuropathic pain, allodynia and hyperalgesia persist after the initial injury or disease process has healed. Any or all of the sensory symptoms and signs are considered diagnostic for a dysfunctional sensory nervous system and are, therefore, likely to signify neuropathic pain if pain is part of the clinical presentation.

Motor System

Patients with neuropathic pain experience motor symptoms and signs that could also be viewed as negative and positive. On the level of the motor system, negative signs include hypotonia, decreased muscle strength, and decreased endurance (55). Positive motor signs include increased muscle tone, tremor, dystonia, and dyskinesiae (56,57). Incoordination, ataxia, and apraxia can be seen on examining patients with neuropathic pain syndromes as well. The type and the degree of motor abnormalities vary from syndrome to syndrome depending on how much the motor system is affected, either directly or indirectly. Motor symptoms and signs are

frequently overlooked during the pain evaluation, although they are significant indicators that the nervous system is affected beyond the pain-transmitting fiber.

LABORATORY STUDIES AND INVESTIGATIONS

Blood and serum studies for specific agents are performed any time a specific condition, such as HIV or diabetes, is suspected. Additional laboratory studies to confirm a specific diagnosis, such as cerebrospinal fluid (CSF) for the diagnosis of GBS, may be necessary. Their use with specific pain symptoms is discussed later in this chapter.

Neurophysiologic investigations of nerve conduction velocity (NCV) study and electromyography (EMG) are performed to confirm the presence of neuropathy and to help provide additional information that can help in differentiating different types of neuropathies (58) (see Chapter 13). For example, NCV and EMG can specifically diagnose entrapment neuropathies and can help differentiate neuropathies caused by demyelination versus axonal loss. The role in the early diagnosis of GBS is especially important. However, like every test, NCV and EMG have a number of limitations, and these include false-negative results. More specifically, these studies can show normal results in neuropathies of recent onset and in neuropathies affecting predominantly the small fibers.

In contrast, quantitative sensory testing provides a sensitive measure of large and small diameter fiber function (59,60). The quantitative sensory testing provides quantitative values for many sensory modalities, including thresholds for vibration, touch, pinprick, two- point discrimination, warm, cold, heat pain, and cold pain. Values can be obtained for individual patients and compared with control values. Based on functional properties of the different nerve fibers and their associated pathways, the abnormal values of quantitative sensory testing for a particular patient would suggest a type of sensory nerve dysfunction as the cause of the neuropathy. However, this method of investigation also has limitations, primarily its susceptibility to the patient's cognitive status and other neuropsychological dysfunctions.

More invasive evaluations such as nerve biopsy can be done to confirm the diagnosis and delineate the pathology. Nerve biopsy may be helpful in the investigation for the presence of chronic demyelination, amyloidosis, vasculitis, and hereditary neuropathies. Nerve biopsy for cryptogenic polyneuropathies, those without clear-cut etiology, has the most utility if one wants to rule out amyloid polyneuropathy. The value of this method in metabolic disorders and alcoholic and nutritional neuropathies is limited because findings are nonspecific. Genetic analysis using recombinant DNA technology is rapidly gaining wide use (61) for the diagnosis of hereditary neuropathies. Skin punch biopsy is a novel method for staining small nerve fibers; it is still in development, but it holds the promise of being useful in diagnosing small fiber neuropathies, including painful neuropathies. Microneuronography is a novel electrophysiologic method that can be used to record from individual nerve fibers and to study the generation and maintenance of pain, but it remains strictly a research tool without practical clinical applications.

The diagnosis of the majority of neuropathies is easily made based on the history and physical examination and confirmed with appropriate laboratory and electrophysiologic tests (see Cryptogenic Polyneuropathies and Neuropathies Caused by Undetermined Causes , later in this chapter). Differential diagnosis becomes more challenging when two neurologic conditions coexist (e.g., a patient with diabetic neuropathy can have compression neuropathies, such as carpal tunnel syndrome in the upper extremities and tarsal tunnel syndrome in the lower extremities).

TREATMENT OF PAINFUL NEUROPATHIES

General Principles of Therapy

Therapy for painful neuropathies can be viewed at two levels. At the primary level, therapy is targeted at the underlying disease process (e.g., nutritional supplementation for neuropathies caused by nutritional deficiencies). Whenever practical, such therapy should be administered as soon as possible, because it is most likely to control and even reverse the process that initiated the disease in the first place. With reversal of the disease, the pain is highly likely to be alleviated. At the secondary level is symptomatic therapy, such as analgesia and symptom control, which should also be administered as soon as possible and parallel to the treatment of the underlying disease. One does not exclude the other. This chapter concentrates on analgesia and symptom control.

Guidelines for Pharmacotherapy

The general principles of pharmacologic treatment are individualization of therapy and titration of pharmacologic agents with close attention paid to effect on the one hand and side effects on the other (62,63 and 64). *No response* should not be accepted as an outcome until a sufficient period of time has passed to judge the efficacy of the drug. The pharmacologic agents best studied and longest used for pain relief in painful neuropathies are tricyclic antidepressants (TCAs) and antiepileptics. With advances in the neuroscience of pain, however, other agents are being introduced, such as systemically administered local anesthetics and NMDA blockers. Opioids may be useful, although their efficacy in the treatment of neuropathic pain has been questioned (65). Causes of and possible strategies to overcome opioid resistance in neuropathic pain states are under investigation (44,66,67). Controlled data for long-term use of opioids for chronic neuropathic pain are lacking, and consequently the medical literature generally does not advocate their use. The confusion regarding definitions of tolerance, dependence, and addiction, and the consequent fear of addiction, has been the ultimate barrier for use of opioids for chronic pain (68). However, the marked improvement in pain assessment and the utility of multidisciplinary and interdisciplinary approaches to pain management are leading to reconsideration of opioids for neuropathic pain. Destructive surgery on the peripheral or central afferent nervous system in the case of neuropathic pain always implicates further deafferentation and thereby provides an increased risk for a persistent deafferentation type of pain. For that reason, stimulation methods are favored over destructive procedures whenever surgical therapies are contemplated (69).

Frequently, patients are labeled as *treatment failures* because of inadequate medication trials. Many patients are subsequently successfully treated with drugs that were in the past deemed as failures, once those drugs are appropriately prescribed and administered. Two common reasons exist why patients do not respond to a particular medication. One is inadequate dose titration, often seen when a patient does not achieve pain relief or side effects. The second reason is the initiation of polypharmacy at the onset of the treatment trial; it is then not possible to ascribe either effects or side effects to any particular medication.

Guidelines for the treatment of painful polyneuropathies suggest that (a) one drug is titrated at any give time; (b) the dose of each drug is started at the lowest possible level; (c) titration is performed slowly by increasing the dose by one additional unit dose every 3 to 7 days, as determined by the patient's characteristics (i.e., age, prior medication experience, comorbidities, other medications patient is using at the time); and (d) titration is continued and the dose is further increased until one of the following endpoints is attained: significant pain relief, intolerable side effects, or *toxic* serum levels. The last applies only to antiepileptics and mexiletine. A medication is continued for the foreseeable future if all of the following criteria are met: significant pain relief, tolerable side effects, and improved patient activity and function.

The examination and pain assessment should lead to a specific neuropathic pain syndrome diagnosis, or in some cases, to more than one pain diagnosis. The treatment plan is based on the severity of pain, associated symptoms and comorbidity, and the complexity of the patient's medical presentation. The patient is apprised of the possible analgesic treatment goals, which should be modest, because most of the neuropathic pain syndromes are difficult, if not impossible, to cure and relieve completely.

Role of Polypharmacy and Duration of Treatment

Many patients require more than one drug to obtain satisfactory pain relief; it appears that more than one pathophysiologic mechanism may be causing the pain (70,71). As a practical guideline, one drug should be continued and another drug added only if the first drug produces only partial but still unsatisfactory pain relief. It should be kept in mind that only one drug should be titrated at any given time. No controlled studies demonstrate the efficacy of this treatment model, but data from basic science strongly support this concept.

A similar lack of clinical trial data exists to answer how long any given therapy, including pharmacologic treatments, should be administered. No attempts have been made to evaluate whether successful treatment with an analgesic medication alters the natural history of pain. Do patients who report significant pain relief with a certain medication need to be treated with that particular medication at that dose for the rest of their lives? One suggestion is to taper the medication every 6 to 12 months for the reassessment of the patient's pain level without the medication and basing the need for therapy on that *no medication trial*. Most of the medications have been used on a long-term basis for treatment of other disorders (e.g., for epilepsy and depression) so that long-term use for pain relief would be justified as safe as long as the treatment is monitored and the medications provide satisfactory pain relief.

Pharmacologic Agents Used for Treatment of Neuropathic Pain

Neuropathic pain in general has always presented a challenge because it does not respond to standard doses of opioids (65). The first class of pharmacologic agents demonstrated to be effective in the treatment of neuropathic pain were TCAs, but their effect is modest. With advances in the neurobiology of chronic neuropathic pain, new options for treatment could be considered, and with the development of novel pharmacologic agents these possibilities have been realized. The group of pharmacologic agents that provides relief of pain in neuropathic pain through mechanisms other than mu-opioid receptors is termed adjuvant analgesics (see Chapter 85 and Chapter 86). Categories of pharmacologic agents used for treatment of neuropathic pain include TCAs, antiepileptics, a-adrenergic agents, systemically administered local anesthetics, gamma-aminobutyric acid agonists, and NMDA blockers (Table 19-3). In addition, opioids have been reconsidered and have been found to be effective in some patients with neuropathic pain but at doses that are often higher than for those used for patients with nociceptive pain.

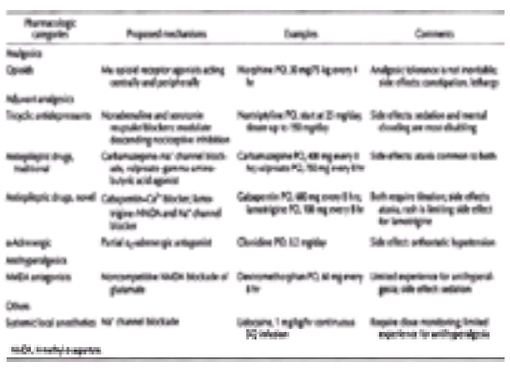

TABLE 19-3. Pharmacologic therapeutic agents used in treatment of neuropathic pain syndromes including neuropathies

Analgesics

Opioids. Opioids are still the drugs of choice for the treatment of acute episodes and acute exacerbations of neuropathic pain. Opioids strongly inhibit central nociceptive neurons mainly through interaction with mu-opioid receptors producing neuronal membrane hyperpolarization. Opioids are clearly effective in postoperative, inflammatory, and cancer pain. In some neuropathic pain syndromes, intravenous morphine is clearly analgesic when compared with placebo. However, no long-term studies have been performed on oral opioids used in the treatment of neuropathic pain. Surveys and uncontrolled studies indicate that a small fraction of the patients suffering from postherpetic neuralgia (72,73 and 74) or other neuropathic pain syndromes (75) can obtain and maintain adequate pain relief with oral opioids. Even without solid scientific evidence, the opinion of many pain clinicians is that opioids can and should be used as a part of comprehensive pain treatment program. Given that some patients with neuropathic pain may obtain considerable pain relief, opioids should be tested early in the treatment of neuropathic pains and a trial of opioids should not be delayed as a last resort. Administration of opioids requires specific treatment programs for patients with a history of chemical dependence and caution in patients with pulmonary disease. Prophylactic treatment of common side effects, notably nausea or constipation, can improve patient compliance and satisfaction with opioid therapy.

Adjuvant Analgesics

Tricyclic Antidepressants. TCAs are the best-studied group of pharmacologic agents and the most widely prescribed drugs for the treatment of neuropathic pain disorders (see Chapter 85). They have been shown to have analgesic effects, although often modest and not in all patients. Controlled studies have demonstrated their efficacy in painful diabetic neuropathy independent of their effect on depression (76). Solid evidence suggests that the serotonin and noradrenaline reuptake blocker amitriptyline and the selective noradrenaline blocker desipramine produce pain relief in diabetic or postherpetic neuropathy (24,25,26 and 27,76,77,78,79,80,81 and 82). A systematic review of antidepressants for the treatment of neuropathic pain concluded that these drugs are effective: “of 100 patients …30 will obtain more than 50% pain relief” (83). Contrary to prior teaching, when these agents are effective, they may relieve the constant burning and deep pains, as well as lancinating pains.

TCAs inhibit reuptake of monoaminergic transmitter peptides. Selective serotonin reuptake blockers are no more effective than placebo (84); this would suggest that efficacy of TCAs for neuropathic pain depends in a significant part on a noradrenergic component (79). It has been postulated that the site of analgesic activity is the CNS brainstem–dorsal horn nociceptive modulating system, in which the drug may alter serotonin and norepinephrine activity (85).

The TCA drugs bind to a variety of receptor sites, not only serotonin and norepinephrine, but also histaminergic, cholinergic, and adrenergic neurotransmitter sites. The significant variability in pain relief and side effects experienced by patients among the different TCAs may be explained by the fact that each tricyclic possesses a distinct profile of activity at each of these neurotransmitter sites. TCAs also have sodium channel blocking characteristics, and this could contribute to their efficacy.

Treatment with a tricyclic should be initiated with a dose of 10 or 25 mg in the evening, a few hours before bedtime to avoid early morning sedation. The lower 10-mg dose should be prescribed for the elderly, frail, or side effect–prone patient. The dose is titrated by one tablet, 10 or 25 mg, every 5 to 7 days if the patient has poor pain relief and does not complain of intolerable side effects. If effective, the majority of patients report significant pain relief or intolerable side effects within the dose range of 30 to 150 mg. The mean dose that results in pain reduction for amitriptyline is 75 to 150 mg per day, and that dose is smaller than doses necessary to achieve antidepressant effects. Onset of the analgesic effect occurs within 1 to 2 weeks and peaks around 4 to 6 weeks (76,80). Improvement in sleep, mood, and anxiety can further add to the improvement of pain control.

The most common side effects of the tricyclics are caused by their anticholinergic activity: constipation, dry mouth, blurred vision, slight cognitive changes, tachycardia, and urinary hesitancy. a-Adrenergic receptor blockade may result in orthostatic hypotension. Importantly, all of these potential side effects can be minimized by following the guideline of slow titration. Contraindications to the tricyclics include closed-angle glaucoma, benign prostatic hypertrophy, and acute myocardial infarction. Sedation and weight gain may occur from histaminic activity. The tricyclics are often prescribed solely for their positive effects on sleep. Sedation without weight gain is not possible, as both result from histaminergic activity.

The clinical experience with the TCAs for pain relief is poor to fair. Many patients obtain clinically insignificant pain relief and more often than not they report intolerable side effects. Although TCAs have been important in the field of neuropathic pain, their clinical utility is marginal and more effective agents are needed.

Antiepileptic Drugs. Antiepileptic drugs (AEDs) have garnered significant interest as agents for the treatment of neuropathic pain, because they have therapeutic effects on many neurotransmitter and ion channel systems that are implicated in the genesis and maintenance of neuropathic pain (86). Although they all have different mechanisms, they are grouped together because of their clinical utility for control of seizure and epileptic disorders.

As with all drugs used to treat neuropathic pain, significant variability exists with regards to efficacy, dose, and serum level of antiepileptics. Some patients may report significant relief with serum levels that are far below the *therapeutic* range for epilepsy, whereas other patients require *toxic* serum levels before pain relief is obtained and still remain without intolerable side effects. Therefore, a medication should, as a rule, be started at the small dose and slow titration should be initiated, as with all other medications for pain control.

Phenytoin and Carbamazepine. Phenytoin and carbamazepine act primarily by having an effect on sodium channels. Phenytoin and carbamazepine as pain relievers are deemed effective, but “minor adverse effects occurred as often as benefit” (86). Several controlled trials have reported benefit using these classic anticonvulsants. Phenytoin has been shown to be effective in well- controlled trials of diabetic polyneuropathy (87) and pain in Fabry's disease (88). Carbamazepine was found to be effective in two double-blind placebo-controlled studies for control of pain in diabetic neuropathy (89,90). The clinical experience with these two older anticonvulsants has been unsatisfactory. Many, if not most, patients when treated with these older anticonvulsant drugs either do not experience significant pain relief or develop intolerable side effects.

Gabapentin (Neurontin). Gabapentin is a novel antiepileptic with an unknown mechanism of action. A multicenter placebo- controlled study demonstrated significant pain reduction with gabapentin for the treatment of painful diabetic polyneuropathy (91). Gabapentin has also demonstrated analgesic efficacy in control of other neuropathic pain syndromes, such as postherpetic neuralgia (92). Even before these reports were presented, gabapentin had been extensively prescribed for the treatment of many neuropathic pain syndromes, based on the drug's excellent efficacy, side-effect ratio, remarkably low incidence of intolerable side effects, and the ease with which it may be prescribed, with no need to monitor any blood and serum parameters (93). Another added benefit of gabapentin is that the drug is not metabolized, and thus there are no drug–drug interactions.

The starting dose is 300 mg every 8 hours and is titrated by 300 mg per dose every 3 to 7 days until the patient reports pain relief, intolerable side effects, or a dose of 4,500 mg per day has been reached. Clinical experience has shown that a majority of the responders obtain relief at doses in the range of 1,800 to 3,600 mg. Gabapentin is much more expensive than the older anticonvulsants.

Lamotrigine. Lamotrigine is a novel antiepileptic agent that blocks voltage-sensitive sodium channels and inhibits the release of glutamate. An open-label survey revealed that this drug provided significant pain relief in most patients with painful diabetic neuropathy (94). To date, however, the clinical experience of the treatment of painful polyneuropathies with lamotrigine is limited.

Other Antiepileptics. Clonazepam and valproic acid have an effect on gamma-aminobutyric acid and could potentially help control neuropathic pain, but they have not been formally studied for that indication. However, the clinical experience is limited for both agents. A couple of novel AEDs, topiramate and vigabatrin, could potentially have analgesic effects similar to other AEDs, but data are not available, and these medications are frequently associated with bothersome side effects that could limit their usefulness.

Systemically Administered Local Anesthetics. Systemically administered local anesthetics block ectopic discharges caused by experimental injury and in axotomized dorsal root ganglion cells of the peripheral nerves (38), probably by blocking sodium channels (23), although central effects have been proposed (95). Local anesthetics have been administered systemically also for the control of cardiac arrhythmias and they are categorized as type Ib antiarrhythmic drugs. Systemically administered lidocaine, mexiletine, and tocainide were demonstrated to have analgesic effect for control of neuropathic pain in diabetic or postherpetic neuropathy (73,96,97 and 98). Reviews of the experience with use of these drugs revealed success for treatment of various neuropathic pain syndromes (99); no well-controlled studies and accepted standards exist for their long-term administration. Therefore, care needs to be taken when administering them. In the first edition of this text, Bonica championed the use of intravenous procaine for the treatment of neuropathic pain, based on his clinical experience. Contraindications include cardiac electric conduction abnormalities, reduced left ventricular function, and severe liver and renal disease. Properly conducted clinical trials cannot be identified.

Antihyperalgesics: N-*Methyl-D-Aspartate–Receptor Antagonists.* NMDA receptors have been demonstrated to play an important role in the genesis of neuropathic pain (see previous discussion). Clinically available compounds that are demonstrated to have NMDA-receptor–blocking properties include ketamine and dextromethorphan. Memantine is available outside the United States. NMDA-receptor antagonists have demonstrated analgesic effects in human laboratory and clinical studies (100,101,102 and 103), including in a long-term trial with diabetic neuropathy (104). Toxicity and side effects of these agents at analgesic doses are limiting factors for their wider use, but advances in neuropharmacology hold promise and hope for more effective and less side-effect–prone agents.

CLINICAL SYNDROMES

Polyneuropathies can be diagnosed only by the patient's history, metabolic findings, and diseases in other organs; their clinical manifestations are not distinctive (Table 19-4).

Type of fiber loss	Neuropathy
Selective large fiber loss	Isoniazid neuropathy
	Pellagra neuropathy
Selective small fiber loss	Fabry's disease
	Dominantly inherited sensory neuropathy
	Diabetic neuropathy
	Amyloid neuropathy
Nonselective fiber loss	Alcoholic neuropathy
	Myeloma neuropathy
Unknown	Guillain-Barré neuropathy (acute inflammatory)
	Beriberi neuropathy
	Strachan's syndrome
	Burning feet syndrome
	Arsenic neuropathy
	Chloramphenicol neuropathy
	Metronidazole neuropathy
	Misonidazole neuropathy
	Organophosphorus neuropathy
	Thallium neuropathy

TABLE 19-4. Painful polyneuropathies

Diabetic Painful Neuropathy

Patients with diabetes develop a variety of peripheral neuropathies as their disease progresses. One of the presenting features of diabetes is symmetric distal polyneuropathy, which can affect predominantly either small or large fibers. Small fiber neuropathy manifests most commonly with pain and paresthesiae, whereas large fiber neuropathy presents with sensory ataxia. Polyneuropathy is seen in insulin-dependent and noninsulin-dependent forms of diabetes. Focal diabetic neuropathies are common as well. Two possible mechanisms lead to focal neuropathies. One is focal ischemia, and the other is an abnormal susceptibility to compression injuries. At times, focal neuropathies present with involvement of multiple nerves as mononeuritis multiplex, and this presentation then makes the differentiation from polyneuropathy more important. Any and all of the diabetic neuropathies might be associated with pain or dysesthesiae, but most commonly small fiber distal neuropathy and ischemic mononeuropathy are painful. In a few patients presenting with primarily proximal pain and weakness, termed *diabetic amyotrophy*, evidence exists of autoimmune inflammatory neuropathy resembling vasculitis (105,106 and 107), and on pathologic review of nerve biopsy, evidence of demyelination and axonopathy exists (105).

The cause of common distal neuropathy is likely to be multifactorial. Pathologically, evidence exists of demyelination and axonal degeneration in most patients. The pathogenesis is uncertain, but direct injury of axons and their supporting structures caused by either metabolic abnormalities or affliction of nerve microvasculature remains the most readily accepted hypothesis (108,109 and 110). The putative pathologic mechanisms include accumulation of sorbitol, formation of glycosylation end products, free radical–mediated oxidative stress, abnormalities in essential fatty acids, and deprivation of nerve-growth factors (6). No differences existed in morphometric studies of the sural nerve biopsy from patients with and without neuropathic pain (111). However, based on the clinical examination and according to neurophysiologic studies, patients with diabetic neuropathy who experience pain have evidence of small fiber dysfunction (112).

Differentiation of two forms of distal painful polyneuropathy syndromes in patients with diabetes is possible. One is acute and the other is chronic. Acute painful polyneuropathy is most frequently precipitated by the initial administration of insulin. The syndrome manifests with many severe pains distally in feet and legs and is associated with marked allodynia and hyperpathia (113). Pain in the hands is less common. Sensory and motor findings are usually slight, although clear evidence exists of abnormal thermal perception. Acute polyneuropathy, and many focal neuropathies as well, run a more benign course, with pain abating spontaneously after months to years. Pathophysiologic mechanisms are not well known, but observations suggest that insulin has a vasoactive hypoxic effect, and this may offer an explanation (114). Chronic painful neuropathy has an insidious onset of symptoms, such as numbness, leg weakness, ataxia, and paresthesiae. Symptoms and signs of autonomic dysfunction are present in varying degrees. Most commonly, patients experience aching pain with superimposed shooting pains. Improvement of glucose control can slow down the progression of polyneuropathy, but this improvement has little effect on manifestations of pain.

Diagnosis

Diagnosis of painful diabetic neuropathy is usually straightforward. It is made on the basis of painful neuropathy in patients with known diabetes. Because diabetes is one of the most common causes of distal painful neuropathies in the Western countries, any patient presenting with painful neuropathy deserves diagnostic evaluation for diabetes. In addition to serologic studies performed to corroborate the diagnosis, electrophysiologic studies of NCV and EMG can be performed for

better definition of the type of neuropathy. Quantitative sensory and autonomic testing could also bring additional information regarding the type and the extent of neuropathy.

Therapy

Recommendations for tight blood sugar control are the standard of care for all diabetics, and it has been repeatedly shown that the onset and progression of diabetic neuropathy are delayed with normoglycemia (115,116). More advanced therapies with combined pancreatic transplantation and kidney transplant can lead to clinical improvement and substantial recovery of mean motor and sensory conduction velocities, although no improvement in sensory thresholds or autonomic function have been shown (117). Patients with autoimmune painful diabetic amyotrophy should be considered for treatment with immunosuppression (107).

Any therapy for diabetic neuropathy should start with general medical care, such as striving for as rigorous blood sugar control as possible, good skin care, and particularly good foot care. Symptomatic pain treatment for diabetic neuropathy is in general similar to other painful neuropathic disorders. Pain assessment and the examination should lead to a specific diabetic pain syndrome diagnosis or, in some cases, more than one pain diagnosis, as discussed earlier. Treatment plans are based on the appreciation of the severity of pain, associated symptoms and comorbidity, and the complexity of the patient's medical presentation. The patient is apprised of the possible analgesic treatment goal, which should be modest. The patient with acute polyneuropathy can be reassured that eventually a good outcome exists regarding spontaneous resolution of pains. TCAs have been best studied for treating pain in patients with diabetic neuropathies (76,80,118,119). Although in clinical trials up to 60% to 70% of patients receive satisfactory or good relief of pain, clinical experience has not been as favorable. Most patients cannot titrate the dose because of the side effect of sedation and other anticholinergic side effects. Antiepileptics, carbamazepine and phenytoin have been studied and used as adjuvant analgesic therapy with modest effect (6). The newer antiepileptic, gabapentin, has demonstrated good analgesic efficacy in a multicenter study, and with its benign side-effect profile it is a welcome addition (91). Other antiepileptics, such as valproate and lamotrigine, are considered for treatment of pain in diabetic neuropathy, although controlled studies are lacking. Long-term use of opioids for chronic neuropathic pain may be considered in patients with well-defined pain syndromes who show good response to a trial of opioids. New and exciting possibilities suggested by the preliminary studies of nerve growth factors that might help regeneration of nerves damaged in diabetes (120) may have an important effect on pain control and diabetic care in general (121).

Topical capsaicin has been widely used, although evidence regarding efficacy is conflicting. Its application is frequently reported as messy and requires great skill and diligence in how it is applied. Vitamins and gangliosides are widely prescribed, but only a few controlled studies have assessed their efficacy. At best, the results are conflicting (116).

Physical therapy modalities are an important part of any chronic pain treatment, and this also applies to painful diabetic neuropathy. This is especially important for those with diagnosed musculoskeletal problems and with significant muscle pain. Psychological methods of pain control are used at all times and are an integral part of pain management in general. Another important aspect of psychological therapy is the establishment of realistic treatment goals.

A more challenging situation is the treatment of the patient who has more than one type of pain. For example, burning and stabbing pain caused by distal neuropathy, localized ache and sharp pain caused by entrapment neuropathy, and severe cramping deep pain caused by vascular insufficiency can present in the same patient. That patient would need, in addition to pharmacologic therapy for neuropathic pain, therapy for vascular insufficiency and would need to be considered for decompressive surgery.

Stimulation therapies may be used as well. Transcutaneous electrical nerve stimulation can help some patients with neuropathic pain. Spinal cord stimulation has been used with increasing frequency and success and may ameliorate pain even in those refractory to all other medical intervention (122). However, controlled clinical trials still have to confirm these preliminary observations before this invasive method of therapy could be routinely recommended.

In addition to analgesia, other symptoms are treated in parallel. Insomnia is one of the most disabling results of unrelieved pain; once pain is relieved, it is easier to aid sleep by introducing small doses of TCAs, which themselves have analgesic action. Nausea, diarrhea, constipation, itching, and fatigue could be part of diabetes and should be treated specifically. It should, however, be kept in mind that these symptoms are also frequently seen as side effects of many analgesic medications, so careful monitoring of any therapy is necessary.

Neuropathies Caused by Connective Tissue Disorders and Vasculitis

Vasculitis syndromes are autoimmune disorders characterized by inflammation and necrosis of blood vessel walls. Vasculitis syndromes are a heterogeneous group of disorders, and they can be classified as falling into several groups depending on their relationship to the neuropathies: systemic necrotizing, hypersensitivity vasculitis, giant cell arteritis, and localized vasculitis. This classification is particularly important for the planning of therapy (123).

Peripheral neuropathy is a common component of the vasculitis syndromes in systemic and localized vasculitis. Localized vasculitis is more frequently associated with peripheral neuropathy, which is usually painful. Vasculitis is frequently insidious at the time of presentation, and for that reason is difficult to diagnose, leading to long delays from initial presentation until the time of diagnosis (124). Most patients with neuropathy caused by vasculitis experience varying degrees of numbness and weakness in addition to severe pain, depending on the extent and the severity of vasculitis. The pain usually has characteristics of acute neuropathic pain with severe ongoing pain and frequent spontaneous paroxysms of pain and hyperalgesia. Involvement of other organs varies from one vasculopathy syndrome to another and may include skin, kidneys, gastrointestinal, sinuses, and joints.

When the diagnosis of vasculitis is suspected, a comprehensive workup is necessary, starting with serologic studies, such as sedimentation rate, antinuclear antibody panel, and other more specialized autoimmune tests. The suspicion of this diagnosis may make obtaining combined muscle and nerve biopsies necessary (125). The diagnostic histologic finding is inflammation of the medium-sized arteries in the epineurium, multiple areas of demyelination, and patchy destruction of axons. The lymphocytic infiltration of the arterial wall and the thrombotic occlusions of inflamed arteries are diagnostic findings. Occlusion of medium and small vessels leads to interruption of the blood supply to the nerves through their nutrient vessels. The extent of the occlusive disease determines whether distal polyneuropathy or mononeuritis multiplex occurs. Frequently, electrophysiologic investigation with NCV and EMG can help in the differential diagnosis of these two syndromes that can be difficult to distinguish on clinical grounds alone.

The primary treatment goal in case of neuropathy caused by vasculitis is the control of the underlying disease process. Treatment is based on high-dose immunosuppressive therapy that typically includes corticosteroids, cyclophosphamide, azathioprine, and chlorambucil. Specific treatment guidelines regarding the specific agents and duration of therapy are established for different types of vasculitis (123). For example, the simplest is the treatment for giant cell arteritis with prednisone for up to 5 months, and the most complex therapy is for peripheral nerve vasculitis with systemic necrotizing vasculitis, and consists of prednisone and cyclophosphamide for at least 1 year, depending on the response. Immunosuppressive therapy can control motor as well as painful sensory symptoms. Neuropathic pain should be treated with opioid and adjuvant analgesics, as discussed earlier in this chapter in the section Treatment of Painful Neuropathies (see Table 19-3).

Autoimmune Demyelinating Neuropathies: Acute Inflammatory Demyelinating Polyneuropathy or Guillain-Barré Syndrome and Chronic Inflammatory Demyelinating Polyneuropathy

Acute Inflammatory Demyelinating Polyneuropathy (Guillain-Barré Syndrome)

GBS is an inflammatory polyneuropathy with an estimated crude average annual incidence rate of 0.4 to 1.7 per 100,000 (126), which means that a large hospital is likely to receive several patients with GBS each year. GBS is an immunologically mediated disorder, usually triggered by cytomegalovirus or Epstein-Barr virus, and reports exist of GBS occurring after vaccination and surgery. The syndrome is characterized by ascending motor weakness; approximately 10% of patients develop disease severe enough to require ventilatory support that leads to admission to the intensive care unit for weeks. Pathologic studies show an inflammatory process affecting the peripheral nerves and nerve roots, consisting of lymphocytic and macrophage infiltration and demyelination. GBS can last for a number of months, but eventual spontaneous recovery takes place in 90% of patients. Developments in intensive neurologic care and advanced critical care facilities have resulted in low mortality of approximately 1%. Therapy targeted toward the underlying mechanisms is based on the removal of the antigen and consists of plasma exchange and intravenous immunoglobulins. Once the patient begins recovery, the treatment focus is physical therapy and rehabilitation.

Pain and dysesthesia are relatively common in GBS, found in 40% to 75% of patients in one series (127). In most cases, however, they do not constitute a major source of inconvenience to the patient, to whom the loss of motor function of legs and arms is usually far more distressing. However, pain can be severe, often of a burning quality and associated with allodynia and hyperpathia. In this situation, prompt amelioration of pain is of paramount importance. Sensory changes are usually

mild but detectable in 25% to 50% of patients, especially affecting the functions subserved by large-diameter fibers. It is obvious from a number of clinical and neurophysiologic observations that most pain in GBS is neurogenic in origin. Other types of pain may occur as well, perhaps secondary to prolonged immobility and neuritis-induced myofascial mechanisms. One review lists several types of pain: backache, meningism, muscle pain, joint pain, and visceral pain (127).

Moulin and colleagues reported that pain is a presenting symptom in more than three-fourths of patients with GBS, and in many it precedes weakness. Pain is present throughout the course of GBS; in one-half of those patients, it is rated as severe. Pain intensity on admission correlated poorly with neurologic disability on admission and throughout the period of the study. Patients who present with severe pain do not necessarily progress to severe paralysis or have a poor prognosis (128).

The major pain syndromes observed in GBS are back and leg pain, dysesthetic extremity pain, and myalgic-rheumatic extremity pain, which are most directly related to the GBS, and visceral pain, headache caused by dysautonomia, pressure palsies, and sacral decubiti as an indirect consequence of GBS.

Approximately two-thirds of patients experience back and leg pain at some time during the course of the GBS. Pain is usually described as a deep, aching, or throbbing pain in the low back, frequently radiating to the buttocks, thighs, and occasionally to the calves. These symptoms are the most frequent cause of what patients describe as horrible or excruciating pain. Back and leg pain is exacerbated with straight leg raising, and this phenomenon would suggest that traction on inflamed nerve roots could be responsible for this pain. Pain exacerbation by nerve root traction maneuvers could be mistakenly diagnosed as an acute radiculopathy caused by herniated disk. A strong component of muscular pain occurs as a mechanism for back and leg pain in the acute phase of GBS. Acutely paralyzed large muscles are commonly painful, and this parallels the elevation of serum creatinine kinase (129). Muscle calf pain can be difficult at times to differentiate from deep venous thrombosis, so a number of patients are subjected to venous studies.

Dysesthetic extremity pain, described as burning, tingling, or shocklike, involves the legs more frequently than the arms and is also common in GBS. This type of pain is present in a minority of patients on admission, although approximately one-half experience dysesthetic pain sometime during the course of the illness. It may persist indefinitely in 5% to 10% (128). It is postulated that neuropathic pain of this type is likely caused by ectopic impulse formation at sites of demyelination and axonal degeneration and regeneration along the peripheral nerve (53).

Myalgic and rheumatic extremity pain, described as an aching or cramping type of pain, is less frequent than radicular low back pain. This pain is usually associated with the complaint of joint stiffness. This pain is most notable during the passive and active- assisted exercises associated with physical therapy.

Visceral pain is often related to constipation and usually responds to an aggressive bowel regimen. Headache caused by malignant hypertension can also occur as a result of dysautonomia. Bedridden patients are prone to sacral ulcers and painful pressure palsies; they can be prevented with the use of air mattresses, careful turning of patients, and positioning of limbs. The use of padding over elbows and knees can prevent pressure palsies.

Pain Management in Guillain-Barré Syndrome A wide range of pharmacologic agents can be used for management of pain in GBS. It is most efficient to attempt to match the underlying pathophysiologic mechanisms with a class of pharmacologic agent. For example, nociceptive pain of the low back type is best treated with nonsteroidal antiinflammatory agents and opioids, depending on the severity of pain, and dysesthetic pain is best treated with anticonvulsants.

In a prospective study (128), 75% of patients required oral or parenteral opioids to provide adequate pain relief. Patients with severe pain who are in the intensive care unit on ventilatory support are best managed with a continuous intravenous opioid infusion using either morphine or hydromorphone. Starting doses of an intravenous morphine infusion are usually in the range of 1 to 3 mg per hour. Epidural morphine is an acceptable alternative to systemic opioids in ventilated patients with primarily low back and leg pain (130). In nonventilated patients in the acute stage of illness, opioid analgesics must be titrated carefully because of increased risk of respiratory depression. However, starting doses of sustained-release morphine in the range of 15 to 30 mg twice a day with dose titration to 60 to 90 mg twice a day are usually well tolerated (128). During the recovery phase, when muscle and joint pain are routinely precipitated by passive and active exercises, immediate-release codeine or morphine can be given an hour or two before treatment to facilitate compliance with physiotherapy. Most patients do not require opioid analgesics beyond the first 8 weeks of illness.

Corticosteroids, including methylprednisolone, may relieve severe pain in GBS (131), and this may be caused by its antiinflammatory effects at the nerve root level.

A tricyclic antidepressant such as amitriptyline or nortriptyline represents the first line of treatment for dysesthetic extremity pain seen in GBS. If a tricyclic antidepressant is intolerable or does not control the pain, mexiletine (132) or clonidine (133) may be useful. Mexiletine is usually prescribed in gradually increasing doses to 200 mg orally three times a day. Clonidine can be given orally or transdermally in a total daily dose of 0.3 mg daily. Gabapentin, a newer anticonvulsant, has shown promise in the management of chronic neuropathic pain states (134). Gabapentin can be rapidly titrated to 300 mg three times a day orally to a maintenance dose of 900 mg three times a day.

Studies on the efficacy of plasma exchange and immunoglobulins concentrate on improvement in motor weakness and overall disability. It is not clear whether these therapies relieve pain or help to prevent it from occurring in prolonged cases.

No controlled studies exist on the efficacy of any treatment of pain associated with GBS. Most authors have adopted a common-sense approach, recognizing the neurogenic nature of most pains in this condition and adopting well-known pain-relieving methods, including TCAs and anticonvulsants.

Occasionally, pain becomes a major problem in those patients treated in the intensive care unit for weeks or months. It should be noted that as the patients in this setting are disabled for a long time, without exception they need some type of psychological support. Because of the inflammatory nature of this pain, nonsteroidal antiinflammatory agents are occasionally effective. However, the patients are at an increased risk for developing peptic ulcers, and the prolonged use of nonsteroidal antiinflammatory agents cannot be advocated. Similarly, although corticosteroids seem to provide temporary alleviation (131), their long-term use is not recommended.

In summary, GBS is an acute and often frightening paralytic disease that commonly has a significant pain component. Accurate diagnosis, careful monitoring, early therapeutic intervention with intravenous immunoglobulin or plasma exchange, good intensive care unit care, active pain management, and active rehabilitation are all essential in the treatment of GBS.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is a chronic peripheral nervous system disorder that can have progressive, relapsing-remitting, and monophasic courses. The incidence is probably less than GBS, but, because of its prolonged course, its prevalence is greater than GBS. Association with preceding viral illnesses is less common, at 20% to 30% of patients, in contrast to GBS, in which the incidence is close to 70%. Many autoimmune and infectious disorders, such as lupus, HIV, paraproteinemias, and diabetes mellitus, are associated with CIDP. Malignant cell dyscrasias and monoclonal gammopathies can also lead to CIDP. Presenting symptoms are the insidious onset of numbness and weakness, primarily affecting distal limbs first, but a great variability occurs. Pain may or may not occur, and it has all of the features of neuropathic pain. Pain in CIDP is probably more prevalent than previously reported (135). A notable sparing of cranial nerves takes place, which contrasts with GBS (136). Therapy is aimed at treating the underlying disease process with intravenous immunoglobulin, plasmapheresis, and oral corticosteroids. Pain management should follow the basic principles of neuropathic pain pharmacologic therapy.

Brachial Plexopathy

Idiopathic brachial plexopathy (Parsonage-Turner syndrome) is an infrequent peripheral neuropathy syndrome that occurs primarily in younger adults, usually 20 to 40 years of age. The etiology of this syndrome is not well established, although cases with a preceding viral illness would suggest the possibility that this disorder results from an autoimmune process similar to GBS. Idiopathic brachial plexopathy is usually a self-limited disease with good recovery. On the other hand, prognosis of symptomatic brachial plexopathy depends on the underlying disease process.

Predominant symptoms are pain in the affected shoulder and weakness of the shoulder girdle muscles. The weak muscles are usually serratus anterior, deltoid, supraspinatus and infraspinatus, and triceps, in isolation or various combinations. Muscle atrophy develops 2 to 3 weeks from the onset of pain and weakness. If the long thoracic nerve is affected, the diaphragm may be partially paralyzed. Pain is usually described as deep and aching. It is made worse with movements of the affected limb. Pain is not made worse by coughing or sneezing, which helps to differentiate this syndrome from cervical radiculopathy. Despite the pain and weakness, minimal sensory deficits occur. EMG is useful in documenting the extent of nerve involvement. Differential diagnosis includes traumatic causes of brachial

plexus, invasion of brachial plexus by lung or breast malignancies, postradiation brachial plexopathy, cervical radiculopathy, and a number of rheumatologic syndromes affecting the shoulder joint. Differential diagnosis also includes hereditary liability to brachial plexopathy, which can be diagnosed from an adequate family history.

Because most cases of brachial plexopathy are idiopathic, no specific therapy exists for this disorder. Treatment of pain may require mild to strong analgesics, and in chronic forms of brachial plexopathy other treatments such as TCAs, antiepileptic drugs, or systemically administered local anesthetics are used. Early rehabilitation is important to prevent capsulitis (frozen shoulder).

Hereditary Neuropathies

Hereditary neuropathies present a wide spectrum of peripheral nerve disorders and syndromes, but only a few of them are painful. Some of the hereditary sensory-motor neuropathies and porphyria may have pain as one of the presenting symptoms, but pain is always overshadowed by symptoms of sensory and motor deficits. However, in the presentation of Fabry's disease, pain is the cardinal symptom.

Fabry's Disease

Fabry's disease is a multisystem disorder, affecting peripheral nerves, kidneys, heart, and skin. It is caused by an X-linked recessive gene and the symptoms start in childhood or adolescence. The biochemical abnormality in this disorder is deficiency of a-galactosidase, a lysosomal enzyme.

The clinical features include red punctate skin lesions in lower body and thighs, corneal opacifications, cardiac and renal failure, and polyneuropathy. Renal and cardiac failure usually requires intensive care treatment, and can be terminal for these patients. Constant burning pain in hands and feet is the prominent feature of this neuropathy. Another type of pain these patients can experience is spontaneous paroxysms of severe excruciating burning pain. On examination, surprisingly minimal abnormalities are evident. Sensory and motor function and stretch reflexes are usually preserved. Electrophysiologic studies of NCVs and EMG are almost always normal. Antiepileptic medications, such as carbamazepine (137) and phenytoin (88), can be used for control of pain. In addition to pain, patients with Fabry's disease have marked autonomic abnormalities manifested by episodic diarrhea, vomiting, urinary retention, and diminished sweating. These have been reported to be exacerbated by carbamazepine (137), so this medication should be used with caution. Gastrointestinal symptoms can be relieved with metoclopramide.

Amyloid Neuropathy

Peripheral neuropathy is a common, early, and often most prominent manifestation of amyloidosis (138). Most of the cases of amyloid neuropathy belong to the hereditary (familial) form, although some cases are of sporadic type. Several distinct clinical groups of hereditary amyloidosis exist, but all of them have an autosomal dominant pattern. The initial symptoms are numbness, paresthesiae, and pain in the feet and lower legs. Autonomic involvement is also important, manifested by abnormal pupillary reflexes and myosis, anhidrosis, orthostatic hypotension, diarrhea alternating with constipation, and impotence. Cranial nerve involvement is seen late in the disease. Primary (nonfamilial) systemic amyloidosis has a similar neuropathic presentation as does hereditary (familial) amyloidosis. Approximately one-half of the patients have at the onset predominantly neuropathic symptoms, and one-half have systemic disorders of cardiac, hematologic, and renal function (138). Patients with familial amyloid polyneuropathy can benefit from liver transplantation (139). Most of the patients with systemic (nonfamilial) amyloidosis die because of major organ failures within 6 to 12 months after the diagnosis (3).

Toxic and Nutritional Neuropathies

Neurotoxic substances impair a number of neural processes, such as protein synthesis, axonal transport, and myelin maintenance. Exposure to several industrial toxins is known to lead to polyneuropathy. These usually cause motor symptoms and signs, although painful and dysesthetic symptoms may ensue in a minority of patients. Few pathologic studies have been conducted in humans. *N*-hexane, a common ingredient in household glue, and methyl-*n*-butyl ketone, used as an industrial solvent, are known to cause focal swelling of axons to two to three times their normal diameter and can result in painful neuropathies (3).

Several drugs may cause painful polyneuropathy. Cytotoxic and immunosuppressant drugs are especially important in this respect because of the rapid onset of polyneuropathy and its dose-limiting influence on treatment. Vincristine, cisplatin, paclitaxel (Taxol), paxitaxel, and docetaxel all cause polyneuropathy with pain and dysesthesia. These are reversible if the drug is discontinued, and preventable to a certain extent if low doses are used. Concomitant adrenocorticotropic hormone may help to reduce, but not prevent, cisplatin neuropathy (140). A potent immunosuppressant FK506 or tacrolimus causes CNS and painful sensory-motor demyelinating multifocal neuropathy. The latter improves after plasma exchange or intravenous immunoglobulins (141).

Many other drugs are known to cause polyneuropathy, which is usually but not always painful. Among these are isoniazid, gold, disulfiram, nitrofurantoin, amiodarone, and bezafibrate. In the category of toxic-metabolic neuropathies are included neuropathies that are related to nutritional deficiencies, primarily caused by vitamins from the B family.

Isoniazid-Related Polyneuropathy

Isoniazid is an effective and the least expensive antituberculosis drug, but it is associated with distal neuropathy when administered in higher doses (3). Patients with genetic predisposition for slow metabolism of isoniazid are more susceptible to this adverse effect. Isoniazid interferes with enzymes related to vitamins from the B_6 group leading to axonal damage. This axonopathy affects small and large fibers, causing sensory and motor deficits and pain. Physical examination confirms these deficits as well as positive sensory phenomena. Pain is described as deep aching pain in calf muscles and burning paresthesiae in upper and lower extremities. The treatment consists of administering pyridoxine in doses of 30 to 100 mg per day; doing so can prevent development or reverse existing isoniazid neuropathy. When administering pyridoxine, excessive doses should be avoided because pyridoxine itself can cause neuropathy if given in excess (3).

Beriberi Neuropathy

Beriberi is the most widely recognized nutritional neuropathy; it is a disease of peripheral nerves and heart (138,142). If the heart is affected, patients present with heart failure (wet beriberi). The majority of patients present with neuropathy with or without heart disease (dry beriberi). Presenting symptoms are slowly progressive weakness, paresthesiae, and pain in distal limbs, worse in lower than upper limbs. On rare occasions, there could be a rapid progression of symptoms over a period of only a few days. Multiple pain symptoms occur, including dull, constant ache, lancinating brief pain similar to tabes dorsalis, tightness in calves, bandlike sensation in the legs, and burning. Because burning in the feet could be a presenting symptom of beriberi, it could be mistakenly diagnosed as *burning feet syndrome*. In beriberi, burning usually involves hands early in the disease. Physical examination reveals symmetric sensory loss in all modalities as well as positive phenomena of allodynia, hyperalgesia, and hyperpathia, all of which are worse distally. Also, distal muscle weakness and absent reflexes occur, as beriberi can be documented on nerve conduction study (143). The emphasis of therapy is nutritional supplementation with thiamine and all other B vitamins, but pain and symptom control have an important part. The prognosis in treated beriberi neuropathy is good, but recovery takes a long time because regrowth of nerves is slow (138).

Pellagra Neuropathy

Pellagra is a nutritional disorder that, when fully developed, affects skin, gastrointestinal tract, hematopoietic, and nervous systems. Nervous system manifestations include encephalopathy, myelopathy, and neuropathy. Neuropathy is infrequent, but it can be disabling. Neuropathy symptoms and physical findings are indistinguishable from other nutritional neuropathies (138).

Alcohol-Related Painful Neuropathy

Chronic alcohol intoxication is associated with many disorders of liver, heart, muscles, and nervous system. The neurologic complications of chronic alcoholism include dementia, cerebellar ataxia, and polyneuropathy. Alcohol polyneuropathy is probably caused by multiple nutritional deficiencies, and the clinical presentation is similar to any other nutritional deficiency disorder (138). Treatment of alcoholic neuropathy should be given as a part of a comprehensive treatment program, which includes alcohol abstinence and psychological alcohol addiction therapy, improved nutrition, and vitamin supplementation. Pain relief may be attempted with antidepressants and anticonvulsants; opioids should be used cautiously.

Human Immunodeficiency Virus Infection–Related Neuropathies

Peripheral neuropathies are among the most frequent neurologic complications in HIV infection (see Chapter 39). A few peripheral neuropathic pain syndromes occur in patients with HIV infection, and they tend to be specific to the stage of HIV infection. Inflammatory demyelinating polyneuropathies occur early in the course of HIV infection; distal sensory neuropathy occurs late in the disease; vasculitis-related neuropathies occur midcourse in the disease. Incidence and prevalence of neuropathies in HIV patients are as low as 2.6% in Japan (144) and as high as 44% in a cohort from Zimbabwe (145). In the study by Parry and colleagues (145), in a randomly selected group of HIV-positive subjects in Africa, with clinical manifestations ranging from asymptomatic to AIDS, 44% had evidence of neuropathy based on history, clinical examination, and electrophysiologic abnormalities. Major categories of neuropathies included subclinical (56%), acute inflammatory demyelinating polyneuropathies (acute inflammatory demyelinating polyneuropathy) (15%), and distal symmetric polyneuropathies (22%). Subclinical neuropathy was found in all categories, whereas acute inflammatory demyelinating polyneuropathy predominated in the symptomatic category and distal symmetric polyneuropathies in individuals with AIDS. The pattern and frequency of neuropathies seen in the African-American population are similar to those reported for other continents. In the late stages of the disease, as documented in biopsy and autopsy series, the incidence of neuropathy is 100%.

Acute demyelinating polyneuropathies occur in early stages of HIV infection, and often may be a presenting syndrome in patients who are otherwise asymptomatic for any other HIV symptoms (146). Chronic demyelinating polyneuropathies also develop as one of the early manifestations. Demyelinating polyneuropathy is assumed to be on an autoimmune basis. Brachial plexopathy and focal neuropathies also occur during early stages of HIV infection (147). Neuropathies caused by vasculitis may develop in the course of HIV, and this diagnosis should be suspected, especially in patients who develop multiple mononeuropathies (mononeuritis multiplex).

The pathologic mechanisms in neuropathy caused by HIV are not well understood, and it has been argued that it is not from the direct effect of the virus itself (146). The virus, which is not found within ganglionic neurons or Schwann cells but only within the endoneurial macrophages, may generate a tissue-specific autoimmune attack by secretion of cytokines that promote trafficking of activated T cells and macrophages within the endoneurial parenchyma (148). Antisulfatide antibodies are therefore one of the humoral factors responsible for demyelinating diseases in AIDS patients (149).

Distal symmetric predominantly sensory polyneuropathy is commonly seen in the late stage of the disease in full-blown AIDS. Patients frequently suffer from severe painful burning dysesthesiae, especially in the feet.

Differential diagnosis is complicated by the fact that anti-HIV medications such as ddI (Didanosine) and ddC (Zalcitabine) can themselves cause neuropathies. The wide use of the neurotoxic antiretroviral nucleoside analogues ddC, ddI, d4T (Stavudine), and 3TC (Lamivudine) exacerbate or trigger subclinical neuropathy in many of these patients. Like HIV-associated sensory neuropathy, ddC- related toxic neuropathy is a predominantly sensory, length-dependent, symmetric, painful neuropathy. Dose reduction has lessened the severity of symptoms, although objective signs of neuropathy persisted. Patients with subclinical neuropathies or who are at significant risk, such as diabetics, may be poor candidates for ddC therapy (150). Patients who developed peripheral neuropathy while continuing treatment with ddI, ddC, and d4T had acetyl-carnitine deficiency. The normal levels of total carnitine in the study group appear to indicate the specificity of the defect and rule out coexisting relevant nutritional problems. The critical role of acetyl-carnitine for the metabolism and function of the peripheral nerves supports the view that the acetyl-carnitine deficiency found in these subjects may contribute to the neurotoxicity of ddI, ddC, and d4T, even though the interference with mitochondrial DNA synthesis is regarded as the main cause of their toxicity.

Opportunistic infections are a serious possibility in HIV patients and may lead to neuropathies; cytomegalovirus polyradiculoneuritis and herpes zoster neuropathy should be kept in mind. Differential diagnosis of painful neuropathy in the HIV patient also must include cytomegalovirus infection of the dorsal root ganglia with polyradiculoneuritis, especially in patients who present with cauda equina syndrome.

Treatment of neuropathic pain syndromes in HIV patients is complicated by the fact that pain in HIV patients in general is underdiagnosed and undertreated. Pharmacologic treatment of neuropathic pains in this condition is analogous to that of neuropathies caused by cancer (151). The specific issues are the multiple diagnostic possibilities that may require specific considerations such as cytomegalovirus treatment with acyclovir or treatment of demyelinating neuropathy with plasmapheresis or intravenous immunoglobulin.

Lyme Neuropathy

Neuropathies were documented early, when Lyme disease was initially described. This spirochetal infection, which is transmitted to humans by deer ticks, causes multisystem disease including dermatologic, rheumatologic, cardiac, and neurologic symptoms and signs. Neurologic manifestations include neuropathy, polyradiculoneuropathy, myelopathy, multiple cranial nerve dysfunction, and encephalomeningitis (152). Presenting neuropathy symptoms are paresthesiae and dysesthesiae (153), but later, in the chronic phase of the disease, distal painful sensations predominate (154). The Lyme neuropathy is reversible if the patient is treated with systemic antibiotics such as oral doxyxicycline. If symptoms are severe with positive cerebrospinal fluid findings, intravenous ceftriaxone, 2 g per day for 2 weeks, should be used. Symptomatic pain control should be administered as long as symptoms interfere with the patient's function.

Cryptogenic Polyneuropathies and Neuropathies Caused by Undetermined Causes

Surveys that looked for causes of neuropathies have concluded that, for a number of patients with neuropathy, 32% to 70% cannot be accurately diagnosed (155,156). A number of these patients have sensory disturbances, including pain, paresthesiae and dysesthesiae, and muscle cramps (157,158 and 159). However, as suggested by a few authors, intensive reevaluation with comprehensive techniques leads to improvement in diagnostic rates (157). According to a large series by Dyck and Lambert (157), of the 205 patients who were originally unclassified, most (42%) had inherited disorders, followed by autoimmune disorders in 21% of patients, inflammatory demyelinating polyradiculoneuropathy in 13%, and other causes accounting for 13%. Even after comprehensive reevaluation, 24% of patients remained without diagnosis. In the series of 519 patients reported by McLeod and colleagues (158), approximately 13% of patients were without a specific diagnosis. Consequently, the possibility exists that patients presenting with pain and paresthesiae in distal limbs could not be diagnosed with a specific polyneuropathy at initial workup, but reevaluation is recommended because it is likely to provide a specific diagnosis that permits the administration of more specific therapy. In the interim, symptomatic treatment should be administered.

CONCLUSIONS

Painful neuropathies are a diverse group of disorders with many clinical similarities. The natural course of the disease for each disease entity is determined by the underlying etiology. The approach to pain and symptoms assessment and the treatment strategies are similar, although the treatment of each clinical entity should be based on the underlying etiology. A growing number of adjuvant analgesics offer an opportunity for control of pain in these disorders.

CHAPTER 20

Complex Regional Pain Syndromes—Type I: Reflex Sympathetic Dystrophy, and Type II: Causalgia

Bradley S. Galer, Lauren Schwartz, and Roger J. Allen

Of all the chronic neuropathic pain syndromes, none has perplexed patient, clinician, and scientist more than the complex regional pain syndromes (CRPS), heretofore known as *reflex sympathetic dystrophy* (RSD) and *causalgia*. Although much has been written about these disorders, unknowns include the pathophysiology, natural history, and useful therapies for these syndromes. Much of the past literature was descriptive, based on authorities' personal clinical experience, which most likely does not adequately reflect the true clinical spectrum of these disorders and also suffers from selection bias. Thus, writings that have been accepted more or less on faith as clinical fact are being reanalyzed and scientifically evaluated to assess whether they are scientifically sound or rather merely clinical folklore. Several task forces of the International Association for the Study of Pain (IASP) have been formed to try to answer many crucial questions in the quest for a better understanding and improving the treatment of the CRPS disorders.

Throughout this chapter the currently accepted taxonomy, *CRPS*, is used when CRPS and RSD or causalgia can be used interchangeably. However, when older writings and studies have described or assessed patients with *RSD* or *causalgia*, these older terms are used to be true to these reports.

HISTORICAL PERSPECTIVE

Causalgia

The initial reports of causalgia stem from descriptive writings of wartime injuries. In 1862, Paget described patients with “distressing” pains in the fingers after nerve injury that had associated “nutritional changes” (1). The term *causalgia* was first used by Silas Weir Mitchell in an 1867 monograph, *United States Sanitary Commission Memoirs* (2):

> Causalgia—There is, however, one species of pain arising out of nerve wounds which had never been described except by my colleagues and myself, although the state of skin which is usually found with it had been spoken of by Mr. Paget, who seems to have seen it only in association with common neuralgic pains. In writing this peculiar kind of suffering, I felt that it would be well to give it some more convenient name than merely “burning pain,” and in accordance with the suggestion of my friend, Professor Robley Dunglison, I have therefore adopted the term Causalgia as being both descriptive and convenient.

Mitchell also described localized skin changes, “glossy skin,” and increases in skin temperature, which he stated may or may not accompany causalgia (3). In 1920, the Nerve Injuries Committee of the British Medical Research Council defined *causalgia pain* as: (a) spontaneous; (b) hot and burning in character, intense, diffuse, persistent, but subject to exacerbations; (c) excited by stimuli that do not necessarily produce a physical effect on the limb; and (d) tending to lead to profound

changes in the mental health of the patient (4).

During World War II, nerve injuries were also noted at times to result in causalgia pain that may be associated with other focal changes. At that time, it was thought that the intermittently occurring temperature changes, skin color changes, and bone changes developed as an independent problem, and perhaps were related to disuse of the limb secondary to the severe pain and were not necessarily caused by a distinct pathophysiologic event (5).

Reflex Sympathetic Dystrophy

The first reported descriptions of a nonneuralgic chronic pain disorder associated with localized vasomotor changes were in 1877 by Wolff (6) and in 1895 by Kummell (7). Similar case descriptions were published by Sudeck in 1900 (8), Fontaine and Herrmann in 1933 (9), Detakats in 1937 (10), Livingston in 1938 (11), and Homans in 1940 (12). Evans was the first to use the term *RSD* in 1946 to describe a group of patients with chronic pain and skin changes (13).

In the 1953 first edition of this text, Bonica suggested that all conditions with pain and associated focal vasomotor abnormalities should be “consider[ed] …under one all-inclusive term …reflex sympathetic dystrophy” (14). Before this time, many differently named syndromes had been described by different medical specialists for apparently the same disorder, such as *minor causalgia, posttraumatic spreading neuralgia, posttraumatic vasomotor disorders, Sudeck's atrophy, sympathalgia, algodystrophy*, and *shoulder-hand syndrome*. All of these disorders reflected a similar symptom complex characterized by pain, vasomotor skin changes, functional impairment, and various degrees of trophic changes that usually followed a musculoskeletal trauma, although certain characteristics may have been more prominent in certain of these conditions. Thus, because of these similarities, Bonica suggested that “all of them be considered under the generic term ‘reflex sympathetic dystrophy’” (14).

Bonica and many of his colleagues believed that the major underlying etiology of RSD was a disturbance in the sympathetic nervous system. This belief stemmed from their own clinical experience that most of their patients with RSD reported pain relief with sympathetic nerve block. In addition, it was thought that the unusual associated vasomotor changes associated with RSD, such as the focal skin color and temperature changes, had to be caused by abnormal sympathetic tone in the involved limb, hence the term *dysautonomic signs*.

Complex Regional Pain Syndrome

Many medical disorders have no clear single diagnostic “gold standard” (e.g., known measurable etiologic process or laboratory test result) that unequivocally indicates the presence or absence of the disorder. Most disease states reflect a spectrum of associated signs and symptoms. Often no prototypic signs and symptoms define the presentation of a given disorder across all cases. Thus, development of standardized, reliable diagnostic criteria and decision rules to identify disorders is the only way to allow adequate generalizability for appropriate treatment selection and identification of reproducible research samples. Medicine continually attempts to classify symptoms and signs into distinct categories with the goal of achieving standardized diagnostic criteria and hence leading to improved understanding of symptom/sign pathophysiology and eventually to improved treatment (15).

Why Rename the Clinical Syndrome?

Even though Bonica's intent was that the “all-inclusive term (reflex sympathetic dystrophy) serve the very purpose of coordinating and crystallizing our thoughts about the general subject, and in this manner helps to avoid confusion” (14), over the ensuing decades confusion continued because no single diagnostic criterion had been widely accepted by clinicians and researchers worldwide. Hence, patients evaluated by one physician or researcher diagnosed with RSD (or causalgia) may or may not have obtained the same diagnosis from another evaluating physician. This lack of consensus and the confusion with regard to RSD and causalgia diagnostic criteria have retarded clinical research. Little progress has been made regarding these disorders' pathophysiology. Therapy and patient outcomes continue to be poor.

In 1993, a consensus group of pain medicine experts (a Special Consensus Workshop of the IASP) gathered with the defined task of reevaluating the clinical syndromes of RSD and causalgia (16). It was agreed by this group that these disorders were characterized by controversy and confusion with regard to diagnostic criteria, pathophysiologic mechanisms, and effective therapies. Therefore, this international consensus group agreed to dismantle the terms *RSD* and *causalgia*, to admit the field's ignorance, and to think anew about patients who present with severe disabling pain after soft tissue injury or nerve injury associated with regional abnormalities in skin color, skin temperature, abnormal sudomotor activity, skin sensitivity, and motor difficulties. Additionally, it was increasingly apparent, with increased worldwide clinical experience, that many, if not most, patients with this clinical syndrome did not obtain cures or even significant long-term benefit from sympathetic nerve blocks. This feature was an important tenet to Bonica's and others' writings. As Boas, a participant in the 1993 conference, wrote:

> …there was agreement that not all patients referred under this RSD banner met the classical case scenario, and many of those who met diagnostic criteria responded poorly to long-term treatment. Variability in symptoms and signs over time, a lack of consistency in supportive diagnostic testing, and lack of responsiveness to sympathetic blockade belied the simplistic elements inherent in the mechanistic label of RSD. Participants agreed that the use of the term RSD had lost its usefulness as a clinical designation and had also become an indiscriminate diagnosis for patients showing elements of neuropathic pain or resistance to therapy. Therefore, the need to develop alternative concepts and nomenclature was accepted (17).

Thus, at the historic meeting of 1993 it was decided to rename these syndromes as CRPS for several reasons. First, little agreement existed among those from different medical fields and among those from different parts of the world as to the diagnostic criteria and appropriate therapies for RSD and causalgia. Second, much medical folklore exists with reference to RSD and causalgia based on early anecdotal personal physician experiences that have either not been proven in a scientific manner or are not consistent with a more extensive worldwide clinical experience. Last, most authorities agree that many patients do not demonstrate the classically described *dystrophic signs*, such as atrophy and changes in skin, nails, and hair.

Complex Regional Pain Syndrome Criteria

The diagnostic criteria for CRPS as defined in 1993 were accepted by the IASP classification committee and published in 1994 (18). These diagnostic criteria were meant to be a starting point, not to be written in stone. The criteria should and must evolve and change after the results of scientifically performed validation studies, something that had not been done with RSD and causalgia.

Unlike the prior criteria of RSD and causalgia, the diagnostic criteria for CRPS are purely clinical (i.e., no need exists for laboratory testing or sympathetic block). All that is needed is a history, pain and symptom description, and physical signs meeting the needed diagnostic criteria. [Clinically based diagnostic criteria without laboratory testing have been successfully used in psychiatry (i.e., *Diagnostic and Statistical Manual*) and headache (i.e., International Headache Society Criteria).]

The consensus group divided the disorders based on the type of injury that apparently initiated the disorder: Type I follows a soft tissue injury, akin to RSD, whereas type II follows a well-defined nerve injury, akin to causalgia. Types I and II are otherwise identical, with the exact same diagnostic symptoms and signs. Although the two types of CRPS differ in the type of inciting injury, different pathophysiologic events that follow their respective trauma and result in CRPS I or II have not been identified. In addition, as noted later, differences in responsiveness to therapeutic interventions also have not been noted. Furthermore, at times, it is not possible to state whether a patient's CRPS followed injury to nerve, soft tissue, or both, such as CRPS that develops after carpal tunnel surgery.

Complex Regional Pain Syndrome Type I

- The presence of an initiating noxious event, or a cause of immobilization
- Continuing pain, allodynia, or hyperalgesia with which the pain is disproportionate to any inciting event
- Evidence at some time of edema, changes in skin blood flow (skin color changes, skin temperature changes more than 1.1°C difference from the homologous body part), or abnormal sudomotor activity in the region of pain
- This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction

Complex Regional Pain Syndrome Type II

- The presence of continuing pain, allodynia, or hyperalgesia after a nerve injury, not necessarily limited to the distribution of the injured nerve
- Evidence at some time of edema, changes in skin blood flow (skin color changes, skin temperature changes more than 1.1°C), or abnormal sudomotor activity in the region of pain

- This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.

Acceptance of the Complex Regional Pain Syndrome Criteria

Since its inception, the CRPS criteria have been criticized by some as being too vague and perhaps allowing for the overdiagnosis of this syndrome. For instance, as it is currently written, it is unclear how many symptoms and signs are necessary to make the diagnosis. The phrase “at some point in time there must be evidence of” is ambiguous. How many symptoms are necessary? How many signs must be documented on physical examination? The current criteria do not adequately define the minimal requirements for diagnosis.

Another issue with the CRPS diagnostic criteria is that these empiric criteria discarded several symptoms and signs that had been used in prior diagnostic constructs, including burning pain, dystrophic symptoms and signs, and motor abnormalities. Was it correct not to include these abnormalities in the new diagnostic criteria?

Complex Regional Pain Syndrome Validation Studies

The CRPS criteria are plastic and were written with the intent of performing validation studies, the results of which should refine the criteria. Thus, it was acknowledged that part of the process must be to study the consensus-written CRPS criteria and then reshape them as the data dictate.

Thus, to address these issues and to validate the new criteria, the IASP has formed a multicenter CRPS research group. Several members of this group first reported a small single-center empirical validation study that concluded that the 1994 CRPS criteria overdiagnose the disorder and that patient-reported symptoms can be useful diagnostically without confirmatory physical signs (15). Data from this small study confirmed that several of the classic symptoms and signs that had been discarded in the CRPS criteria, such as burning pain and dystrophic symptoms and signs, were not useful, but that the addition of motor neglect signs to diagnostic criteria may improve diagnostic accuracy (15). This study also demonstrated an extremely high false-positive percentage using the criteria as currently written, noting that nearly 40% of painful diabetic neuropathy patients met the sign and symptom diagnostic criteria for CRPS.

An extensive six-center study of 123 patients meeting IASP criteria for CRPS also analyzed the signs and symptoms of CRPS for internal validity (19). Based on the results of this comprehensive analysis, the authors proposed the following as a first revision of the CRPS criteria: (a) criterion 1 (presence of an initiating event) should be dropped; (b) the presence of symptoms and signs should be divided into distinct necessary criteria; (c) patients must have at least two of the following *symptoms*: sensory (hyperesthesia), vasomotor (temperature, skin color abnormalities, or both), sudomotor/fluid balance (edema, sweating abnormalities, or both), and motor (decreased range of motion, weakness, tremor, neglect, or all); (d) patients must have at least two of the following *signs*: sensory (allodynia, hyperalgesia, or both), vasomotor (objective temperature, skin color abnormalities, or both), sudomotor/fluid balance (objective edema, sweating abnormalities, or both), and motor (objective decreased range of motion, weakness, tremor, neglect, or all). These newly recommended CRPS criteria will be evaluated and validated as the process continues.

Sympathetically Maintained Pain

Definition

The term *sympathetically maintained pain* (SMP) is commonly used by clinicians to describe patients who have CRPS (Fig. 20-1). However, all too frequently the term is used incorrectly. SMP is defined as “pain that is maintained by sympathetic efferent innervation or by circulating catecholamines” (16). Thus, SMP is not a clinical diagnosis, but rather an assumed pain mechanism. The term SMP should only be used in clinical practice to describe a patient's report of pain relief after a sympatholytic procedure (i.e., if a patient reports good pain relief after a sympathetic block, then that patient can be said to have SMP).

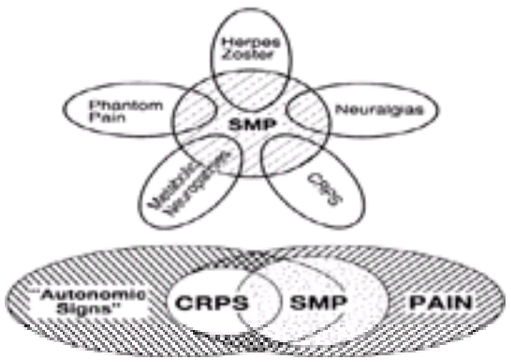

Figure 20-1. Relationship between sympathetically maintained pain (SMP) and selected painful conditions. This is meant to be a conceptual framework and the magnitude of the intersection between sets is not intended to represent a quantitative relationship. Sympathetically maintained pain may exist as an entity not associated with any other condition. The list of associated conditions is not meant to be exhaustive. (CRPS, complex regional pain syndrome.) (From Stanton-Hicks M, Janig W, Hassenbusch S, et al. Reflex sympathetic dystrophy: changing concepts and taxonomy. *Pain* 1995;63:127–133, with permission.)

Complex Regional Pain Syndrome and Sympathetically Maintained Pain

SMP cannot be used interchangeably with CRPS. SMP is a pain mechanism, whereas CRPS is a clinical diagnosis. By definition, SMP cannot be established by the presence of *dysautonomic* symptoms and signs, such as skin color changes, skin temperature changes, and sudomotor abnormalities. Patients with CRPS may or may not have SMP. In fact, it is believed that the majority of CRPS patients do not have SMP, but instead have sympathetically independent pain. Moreover, response to sympathetic block may be partial and thus, at least theoretically, a CRPS patient may have components of SMP and sympathetically independent pain.

Additionally, patients with other distinct chronic neuropathic pain syndromes without these symptoms or signs, such as peripheral neuropathies and postherpetic neuralgia, may also report significant pain and symptom relief with sympathetic blockade, and thus could be said to have SMP as well (17,20,21 and 22).

Flawed Sympathetically Maintained Pain Assumptions

If a patient reports pain and symptom relief after a sympathetic block, it has been assumed that the mechanism of relief is caused by the anesthetic effect on the sympathetic fibers (i.e., a reduction in focal sympathetic hyperactivity) (14,23). However, such simplistic thinking may be faulty based on several lines of evidence: (a) after selective sympathetic blockade (with normal volume), systemic absorption of local anesthetic results in local anesthetic serum concentrations similar to those obtained with intravenous lidocaine infusion, thereby potentially altering activity in other regions of the nervous system besides the sympathetic nervous system (22,24,25); (b) spillage of local anesthetic onto adjacent nonsympathetic nerve fibers has been documented after selective sympathetic blockade (26); (c) degree of sympathetic dysfunction does not correlate with degree of pain relief obtained from sympathetic blockade (20,27,28); (d) time of onset and duration of pain relief do not correlate with the timing of sympathetic block (22,29); and (e) no correlation has been reported between RSD affected limbs' catecholamine concentration and pain relief after sympathetic blockade (30).

Thus, a CRPS patient who reports pain relief after a sympathetic block by current definition has SMP. Yet whether this patient's pain is generated by abnormal hyperactivity in the regional sympathetic nervous system innervating the CRPS body region is not known (22,31). Therefore, stating that a patient's pain is being generated by abnormal activity in the autonomic nervous system based on a report of pain relief from sympathetic blockade can only be considered a hypothetical assumption.

EPIDEMIOLOGY

No well-designed prospective study has assessed the epidemiology of CRPS, RSD, or causalgia in the general nonmilitary population. Although several studies have reported some epidemiologic data, they suffer from selection bias and therefore cannot be generalized to the CRPS population as a whole. Only a few published reports have obtained even basic demographic data.

Age

A prospective study of RSD patients from a tertiary referral surgical clinic in the Netherlands reported a median age of 41 years (range, 4 to 84 years old), with a mean duration of RSD of 405 days (range, days to 20 years) (32). A retrospective study of 134 patients referred to a tertiary university pain center in the United States reported a mean age of 41.8 years (range, 18 to 71 years), mean age at time of injury of 37.7 years (range, 14 to 64 years), and a mean duration of CRPS symptoms before pain center evaluation of 30 months (range, 2 to 168 months) (33).

Gender

The large study from the Netherlands found a female to male ratio of 3:1 (32), and a 2.3:1 ratio was found in the U.S. pain clinic study (33).

Location

Most patients have CRPS involving a single limb. Involvement of the upper versus lower limb has been reported fairly equally, with one study observing 59% upper extremity and 41% lower extremity involvement (34) and another 44% upper extremity and 48% lower extremity involvement (33). This latter study reported CRPS occurred in 38% on the left and 46% on the right. Bilateral limb involvement has been reported to occur in 11% to 16% of patients (33,34).

Inciting Injury

The large prospective study from the tertiary surgical clinic reported 65% followed trauma, usually a fracture, 19% an “operation,” 2% an inflammatory process, and 4% “after various other precipitants, such as injection or intravenous infusion” (32). The United States study from a chronic pain clinic reported 77% of their patients had a known event that resulted in the development of CRPS, 29% strain or sprain, 24% postsurgical, and 11% contusion or crush injury (33). Additionally, both studies identified patients with no known precipitating cause, ranging from 10% to 23% (32,33).

Direct damage to central nervous system structures has also been reported to be an initiating cause of RSD, including spinal cord injury (35) and brain injury (36).

Legal and Workers' Compensation Issues

As most cases of CRPS develop after a traumatic event, it is reasonable to expect issues regarding on-the-job injury and other potential litigious issues to arise. Of a group of patients evaluated in a United States chronic pain clinic, only 17% had a lawsuit, whereas 54% had a workers' compensation claim related to their CRPS (33) (this clinic had a contract with the state workers' compensation system and thus biases these data).

Only one study has assessed the type of job in which the injury occurred that resulted in the development of CRPS. This chart review study found that of the work-related injuries, 14% occurred in service occupations, such as restaurant workers, bakers, and police officers; 8% in clerical and sales professions; 7.4% in manual labor workers such as construction workers; 5.2% in professional, technical, or managerial; 5.2% in agricultural, fishing, or forestry occupations; 4.4% in benchwork occupations, such as assembly workers; 2.2% in machine trades, such as mechanics; and 4.4% in miscellaneous occupations, such as bus drivers and truck drivers; in 5% of the cases, the occupation could not be determined from the chart (33).

Health Care Use

Of patients referred to a university-based chronic pain clinic in the United States, the mean number of physician evaluations before the pain clinic evaluation was 4.8 (range, 1 to 20) (33). Before and during treatment in this multidisciplinary pain center from 1992 through 1997, the majority of CRPS patients were given medication trials, including 78% tricyclic antidepressants (whether these drugs were prescribed for pain, sleep, a psychological disorder, or all is unclear), 38% selective serotonin reuptake inhibitor antidepressants, 60% anticonvulsants, and 70% opiates (33). This study also noted 88% obtained physical therapy, 45% occupational therapy, 82% nerve blocks (mean of six blocks per patient; range, 0 to 20), 50% psychological treatment, and 6% spinal cord stimulation. Whether these data can be generalized is unclear, because treatment of CRPS most likely varies tremendously between individual providers, different medical specialties, types of clinics, and region of the world in which treatment is obtained.

Risk Factors to Developing Complex Regional Pain Syndrome Do Exist

No definitive risk factors have been identified that predispose individuals to developing CRPS. Factors that have been postulated include extensive immobilization (and disuse), cigarette smoking, genetic predisposition, and psychological factors.

Immobilization

Although not well studied, available clinical data suggest that immobilizing an injured limb for an extended period of time may be a risk factor for the development of CRPS. A prospective study demonstrated CRPS symptoms and signs in normal individuals casted after an orthopedic procedure; however, these patients immediately participated in an active physical therapy program and did not develop CRPS or any other chronic pain syndrome (37). Similar findings of abnormal symptoms and signs akin to CRPS have been documented in animal models of limb immobilization (38,39). Retrospective chart review studies have reported rates of prior immobilization in established CRPS patients of 42% to 47% (33,40).

Smoking

One retrospective survey of refractory RSD patients identified smoking as a possible risk factor for the development of RSD (41). However, a similar retrospective survey did not confirm this association (42). Clinical experience minimizes this finding, because many CRPS patients do not smoke, many who do smoke can show improvement, and some nonsmoking patients may be refractory to treatment. Neither study performed relevant multifactorial analysis or used chronic pain patients as controls.

Genetic Factors

One small pilot study reported a possible genetic predisposition to the development of CRPS (43). Also, a retrospective clinical study hypothesized that rare individuals afflicted with RSD may then be predisposed to recurrences (34). These studies are preliminary and are based on an extremely small number of patients; therefore, definitive conclusions should not be drawn from these data.

Psychological Factors

It is important to note that the mind plays a role in all forms of suffering and dysfunction, and it is the mind that copes and adapts or fails to do so (44).

Researchers and clinicians have posed the question as to whether specific psychological factors may predispose certain individuals to develop RSD (45,46 and 47). Many claims have been made, most in the clinical literature, that certain long-standing psychological factors or issues predispose individuals to develop RSD, such as history of psychological or psychiatric disorders or childhood abuse. In addition, some authors have proposed the existence of psychological characteristics of patients may be etiologic risk factors for the development of RSD. For instance, Lankford stated, “It has long been recognized, but seldom discussed in the literature, that only a certain type of patient develops RSD” (48). However, it must be stressed that the research has not borne out this claim. Models that consider multiple etiologic factors are more appropriate conceptually for this disorder, especially when considering the role of psychological, psychiatric, and behavioral factors.

Most research studies have not shown evidence for an *RSD personality* or specific personality factors that predispose a person to develop CRPS. A thorough review of the literature concluded that these concepts do not hold up to scientific scrutiny (49). Other studies have found that anomalies in personality and behavior decreased after relief of the pain, suggesting that such abnormalities were likely the sequelae of causalgia or RSD rather than the cause (47,50). A few studies have attempted to evaluate premorbid personality characteristics retrospectively. One such study found that 12 of 19 active duty servicemen with RSD had records indicating conflict with authority and slow promotion rates (51), whereas another study reported that 6 of 11 patients who developed RSD as a procedural complication had evidence of premorbid dependent personality characteristics (52). Interpretation of these studies is limited by their small sample size and by the lack of appropriate comparison groups.

Regarding major psychological or psychiatric illness, most studies have focused on a history of depression, anxiety disorders, or substance abuse in this population, as with other chronic pain conditions. It has been proposed that a history of psychological difficulties may be evidence of a vulnerability that may limit adaptive coping with an injury, thus promoting more intractable pain, disability, and unusual somatic symptoms. Another interpretation has been that the RSD symptoms and disability may be a mask for more serious underlying psychiatric disorder. This latter theory has received more attention in the literature.

A long history of discussion exists in the general chronic pain literature regarding the intimate relationship between chronic pain and depression (53). It is well known that individuals with all types of chronic pain have higher rates of depression, and individuals with depression have higher rates of chronic pain. Clinical lore and research suggest that although treatment of psychological and psychiatric symptoms is often significantly helpful in decreasing pain, disability, and improving response to pain treatment (54,55), it is rarely the magic cure for chronic pain. The current belief is that for the majority of patients, chronic pain is not a mask for depression or other psychiatric disorder, although a high rate of co-occurrence exists, and both warrant clinical attention and treatment. A specific study evaluating this issue for individuals with CRPS has not been conducted.

In a retrospective chart review of 134 CRPS patients evaluated at a chronic pain clinic in the United States, 26% had a premorbid history of depression and 24% had a history of problems with anxiety, based on a clinical interview using *Diagnostic and Statistical Manual*, third edition, criteria conducted by a licensed psychologist (56). Another study reported that 37% of RSD patients had a history of psychiatric problems or *emotional disturbances* before the onset of RSD (57); specifics regarding the nature of these psychological difficulties were not detailed in this report. As with other chronic pain conditions, no study has been able to determine the role of psychiatric disorders in the development of CRPS. More likely, psychological disorders are comorbid conditions that develop because of the pain, disability, and poor coping abilities associated with CRPS.

The literature suggests wide variance in substance abuse rates among individuals with chronic pain that may not be significantly higher than the general population. A study of CRPS patients evaluated in a pain clinic observed that 30% of patients with CRPS had a history of substance abuse, as defined by *Diagnostic and Statistical Manual*, third edition, criteria (56). The reported prevalence of drug and alcohol abuse or dependence in general chronic pain patients ranges from 3% to 19% (58). The national alcoholism prevalence is thought to be 14% to 18%. Thus, preliminary research suggests that CRPS patients may have slightly higher rates of substance abuse history than patients with other chronic pain disorders. However, this finding needs to be verified by other studies. Furthermore, clinical experience suggests that a small minority of patients presenting to a pain clinic with CRPS have a true addictive disorder.

As with many other chronic pain conditions, the issue of child abuse history among patients with CRPS has been raised (44,59). However, only one study has systematically evaluated reported histories of child abuse among patients with RSD. This study reported that sexual, physical, and emotional abuse, as well as cumulative trauma experiences, were equally distributed among all three of the chronic pain groups studied, RSD, chronic local neuropathy, and back pain (60).

Thus, although some studies have found higher rates of psychological difficulties among RSD patients as compared with non-RSD chronic pain patients (61,62), the findings are far from consistent (63,64). In any chronic disorder, failures of coping and adaptation among patients frequently occur, especially among specialty (pain) clinic samples. The data suggest that psychological and psychiatric difficulties occur in CRPS patients as frequently as in other chronic pain disorders, and that such difficulties exacerbate the patient's overall suffering and impair coping efforts. Additionally, the prevalence of psychiatric disorders and psychological difficulties is highest in the most refractory cases, such as those patients seen in specialty pain clinics. As Ciccone and colleagues have stated, “[data] raises further doubt about supposed psychological origins of RSD …and the burden of proof is upon those who advocate the non-organic hypothesis” to provide credible evidence of primary psychological factors in the etiology of RSD (60).

PATHOPHYSIOLOGY

The pathophysiology of CRPS is not known. Although much has been learned with regard to the mechanisms underlying pain after peripheral nerve injury, minimal progress has been made in understanding the pathophysiologic events that result in the evolution of CRPS, whether after a well-defined nerve injury or soft tissue trauma. Most likely, CRPS develops and is maintained by abnormalities throughout the neuraxis, including peripheral nervous system, central nervous system, and autonomic nervous system. In addition, at least in some patients, the involvement of regional myofascial dysfunction may play an important role in CRPS development. The degree to which each system is involved probably varies from patient to patient (Fig. 20-2). Furthermore, the entire nervous system and musculoskeletal system are further altered by psychological factors, ongoing stress, and disuse that occur after the development of CRPS. Thus, CRPS is most likely not reflective of a single pathophysiologic event, but rather is a heterogeneous disorder with several different underlying pathophysiologic mechanisms that result in similar clinical symptoms and signs.

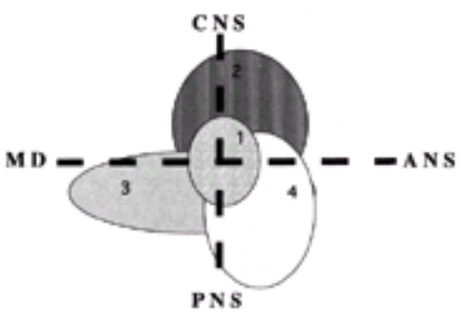

Figure 20-2. A model for understanding the heterogeneity among pathophysiologic processes and sites involved in the development and maintenance of complex regional pain syndrome (CRPS). Potential sites of abnormality among CRPS patients include the peripheral somatic nerves (PNS), the central nervous system (CNS), which includes spinal cord and all supratentorial events, such as psychological processes, the autonomic nervous system (ANS), both its peripheral and central components, and myofascial dysfunction (MD), which may be primary or secondary. Four theoretical CRPS patients are depicted: Patient 1 has an equal degree of PNS, CNS, ANS, and MD abnormal function responsible for CRPS symptoms; patient 2 has mostly CNS, ANS, and MD dysfunction; patient 3's symptoms derive mostly from ANS and MD; and patient 4's CRPS symptoms develop from PNS and ANS pathophysiologic processes.

More Questions Than Answers

Some basic questions regarding the pathogenesis of CRPS remain to be answered:

- Why do only a small minority of patients develop CRPS after a simple soft tissue injury, such as strain, sprain, or contusion? Quite often, these patients have had similar injuries in the past and did not develop the symptoms of CRPS.
- Why do only a small minority of patients with a well-defined nerve injury develop CRPS? Some patients with apparently the same injury do not develop chronic pain, others only develop a chronic neuropathic pain without *dysautonomic signs*, and a rare few develop a chronic neuropathic pain associated with CRPS signs and symptoms.
- Are there structural differences in the injuries to soft tissue or nerve that cause CRPS?
- Does the nervous system react to the injury aberrantly, causing CRPS?

- Was the patient's internal or external environment different at the time of injury, thus resulting in an altered physiologic response to the injury resulting in CRPS?
- Is the sympathetic nervous system involved in the development or maintenance of CRPS?
- Can some or all of the symptoms and signs of CRPS be explained by disuse alone?
- Is there a genetic predisposition to CRPS?
- Why do patients with CRPS vary significantly with regard to the type and degrees of vasomotor, sudomotor, and motor abnormalities?
- Is there only one pathophysiologic mechanism? Or could there be several different possible initiating mechanisms that resemble one another in their clinical presentation? Thus, could subtypes of CRPS exist with distinct pathophysiologic mechanisms that respond differentially to different therapies?

Postulated Mechanisms

Many authorities have hypothesized potential pathophysiologic mechanisms that result in the development of CRPS. Some of these postulated mechanisms are based on animal data, others on clinical experience, and others on pure speculation. No mechanism has definitive evidence proving its involvement in CRPS.

Aberrant Healing Response

After tissue injury, the body responds in such a way so as to promote healing, prevent complications, and thereby ensure survival. Thus, all aspects of healing should aim to improve the organism's odds of efficiently regaining full use of the injured body. Healing is promoted by the inflammatory response. Further bodily injury is prevented by guarding and protecting the damaged bodily region. CRPS has been hypothesized to be caused by an aberrant healing response, including exaggerated and persistent inflammation and guarding.

Exaggerated Inflammatory Response

Sudeck first hypothesized that RSD may be caused by the inflammatory reaction (65). Rubor, calor, dolor, tumor and functio laesa, the classic signs and symptoms of the inflammatory response, are all present in CRPS. Inflammation is a complex neuroimmunologic reaction. At the site of injury, peripheral A-d and C-fiber nociceptors transmit signals interpreted as pain in the brain and also release substance P and calcitonin gene–related peptide (CGRP) into the damaged tissues, which result in vasodilatation and increased vascular permeability (66). These neuropeptides cause the physical findings associated with inflammation, redness, warmth, and swelling. Also released into the injured tissues are bradykinin, leukotrienes, histamine, prostaglandins, and serotonin, all of which heighten these vascular changes in the local environment and cause nociceptor sensitization (66).

As part of the normal inflammatory response, the area of pain, skin sensitivity, and tenderness spreads into adjacent regions after a bodily injury. This spread of pain is thought to be caused by *secondary hyperalgesia*, central nervous system alterations resulting from the abnormal ectopic input from the periphery. These changes in the central nervous system have been hypothesized to involve *N*-methyl-D-aspartate receptors, substance P, CGRP, and nitric oxide (67,68). Thus, many of the hallmark signs and symptoms of CRPS are present in the normal postinjury setting, including skin color change, abnormal skin temperature, edema, and spreading pain and skin sensitivity. However, this symptom and sign complex normally remits spontaneously within several weeks of the injury, whereas in the CRPS patient these symptoms and signs continue and even progress seemingly inexplicably.

The authors of a large prospective study of 829 RSD patients concluded that their data support the concept of “an exaggerated regional inflammatory response” (32). Data also supporting this hypothesis include the observation of increased microvascular permeability for high-molecular-weight proteins in early RSD (69) and high-energy phosphate metabolism impairments in affected RSD limbs (70). Several studies, however, have demonstrated that bone-scan changes thought to be associated with an inflammatory response that subside with time in chronic RSD patients (69,71).

Protective Disuse

Another normal part of the postinjury reaction may explain some of the maintenance and progression of the CRPS symptom and sign complex: protection and decreased use of the injured body part. After injury, the organism naturally protects and guards the injured body part to optimize healing and prevent reinjury. With normal healing, the organism gradually increases the use of the injured region, which then aids in the eventual full recovery and reintegration of the body part into the organism's normal sense of self. However, the CRPS patient continues to protect and guard the injured and painful limb either directly because of recommended medical treatment, such as casting or splinting, because of the patient's volitional disuse for fear of pain exacerbation, or because of a neurologic neglectlike syndrome.

The classic teaching has been that this prolonged guarding of the involved limb is volitional, caused by the patient's fear of heightened pain if the limb is reinjured or accidentally touched (14). A more recent hypothesis, that a neurologic neglectlike disorder may be present in some CRPS patients of this phenomenon, has been postulated (72). Similar to a stroke patient with a neglect syndrome, such CRPS patients' involved limbs are seemingly out of conscious awareness. The patient states the need to bring full attention, mental and visual, to the CRPS limb to move it proficiently, so-called motor neglect, which is confirmed on physical examination testing. In addition, the patient may state that the limb “feels like it is not part of me anymore” or “feels disconnected from my brain and body” (72). It has been postulated that this neglect may be caused by neuroplastic changes in the brain, perhaps involving the central autonomic nervous system (72).

Regardless of the reasons underlying the disuse of the limb, the lack of normal movement of the body part most likely causes further bodily dysfunction in the soft tissues and nervous system. Many of the symptoms and signs of CRPS may, at least in part, be solely caused by the patient's lack of use of the limb. For instance, by not using an extremity over an extended period of time it may become swollen (dependent edema), cold (decreased blood flow), and develop trophic changes (decreased blood flow). A small prospective study revealed that patients who have been casted after an orthopedic procedure for 4 to 6 weeks develop many of the CRPS symptoms and signs, but these resolve once the patients partake in the normally prescribed active physical therapy (37). Brain-injured patients may develop RSD in a limb that has been weakened or is part of a neurologic neglect syndrome (36).

Several animal studies have demonstrated pain and nervous system changes caused solely by disuse of a limb. One study showed that immobilizing a rodent wrist with a plastic cast for 3 to 4 weeks resulted in significant allodynia and neuroplastic changes within the dorsal horn similar to those caused by nerve injury (i.e., sensitization of dorsal horn neurons) (38). Another rodent study demonstrated the presence of mechanical and cold allodynia that persisted for several weeks after 7 days of hind paw immobilization (39).

Dysfunctional Sympathetic Nervous System

The classic teaching has been that RSD and causalgia were caused by hyperactivity of the sympathetic nervous system (14). This belief has come under serious scrutiny during the 1990s, with much scientific and clinical evidence dismissing this hypothesis. The following evidence argues against the sympathetic hypothesis:

- The majority of patients who meet diagnostic clinical criteria for RSD do not obtain significant pain relief from sympathetic blocks (73,74).
- Some patients without the signs and symptoms of RSD and causalgia report pain relief with sympathetic blocks (20,74).
- Plasma catecholamine concentrations are actually lower in RSD-affected limbs (30,75).
- Laser Doppler flowmetry results suggest that vascular disturbances in RSD are not caused by constant overactivity of sympathetic vasoconstrictor neurons (76).
- Microneurography testing shows no increase in sympathetic activity or discharge pattern in RSD patients subjected to arousal and mental stress (77).
- No histochemical evidence of an atypical distribution of sympathetic fibers is found in CRPS hyperalgesic skin (78).
- Skin temperature does not correlate with the activity of sympathetic vasoconstrictor neurons (79).

Involvement of the autonomic nervous system has been hypothesized to occur via adrenergic supersensitivity that develops in the peripheral nervous system or within the spinal cord, or both (30). Others have postulated that an upregulation of a $_1$-adrenoreceptors on nociceptor afferents results in pain and SMP (80). Further evidence for a possible role of adrenergic supersensitivity is the observation that locally infused adrenaline results in a worsening of pain in RSD patients (81). However, similar findings of a worsening of pain and allodynia with subcutaneous injections of epinephrine have been documented in a controlled study of postherpetic neuralgia patients (82).

An alternative hypothesis has been published postulating that, after a limb is injured, endogenous opioid modulation normally increases in regional sympathetic ganglia to prevent excessive autonomic activity in the limb, but that in patients with RSD this local opioid modulation does not occur, resulting in “autonomic features of opioid withdrawal” (pain, increased pilomotor activity, increased sweating, and vascular instability) in the affected limb, which are then perpetuated by disuse of the

limb (83).

Myofascial Dysfunction

Several studies have documented significant myofascial dysfunction in many CRPS patients. Evans remarked on the seemingly high occurrence of “muscle cramps and spasms” in RSD patients (13). Also, Livingston's “vicious cycle” hypothesized excessive muscle spasm resulted in hypoxia and metabolites, which were an additional source of symptoms (84). A prospective study of 41 CRPS patients referred to a chronic pain clinic reported 61% had identifiable myofascial dysfunction in the proximal musculature, in which trigger point palpation resulted in a worsening of pain and other CRPS symptoms in the CRPS body region (shoulder girdle musculature for upper extremity CRPS and gluteal and lumbar paraspinous muscles for lower extremity CRPS) (85). This study also reported a higher prevalence of myofascial dysfunction in CRPS patients with upper (70%) versus lower (47%) extremity pain, a positive correlation between the presence of myofascial dysfunction and motor neglect, but no association between duration of CRPS symptoms and myofascial dysfunction.

If present, myofascial dysfunction may be primary or secondary. Because the patients in the previously mentioned study were evaluated many months after the onset of CRPS symptoms, these patients' myofascial dysfunction could have been present at onset and possibly be primarily responsible for the development of CRPS or, on the other hand, evolved from dysfunctional disuse and overuse of soft tissues. Regardless of whether myofascial dysfunction is primary or secondary, clinical experience suggests that, if myofascial dysfunction is present, patient improvement of pain and symptoms occurs when myofascial trigger points resolve.

Central Nervous System Abnormality

It is now accepted as scientific fact that adaptive changes occur acutely and chronically in the central nervous system after injury to the nervous system (68). Thus, damaged or dysfunctional peripheral nerve and soft tissue that result in the development of CRPS must also involve abnormal processes in the spinal cord and brain. The exact sites and pathophysiologic processes within the central nervous system that result in and maintain the pain and other signs and symptoms of CRPS are unknown, yet various sites have been postulated.

Spinal Cord. Leriche first hypothesized that a vicious cycle develops initially from a peripheral source that then results in chronic changes within the spinal cord (86). Later, Livingston proposed that abnormal impulses developed in self-sustaining loops within the dorsal horn, by either small peripheral nerve endings or major nerve trunks, which also eventually involved other neuronal systems, including the motor horn cells, which resulted in abnormal muscle activity and spasm (87) (Fig. 20-3). Roberts postulated a spinal cord mechanism in which sympathetic outflow stimulates low-threshold, myelinated mechanoreceptors, resulting in sensitized wide dynamic range neuronal activity (23).

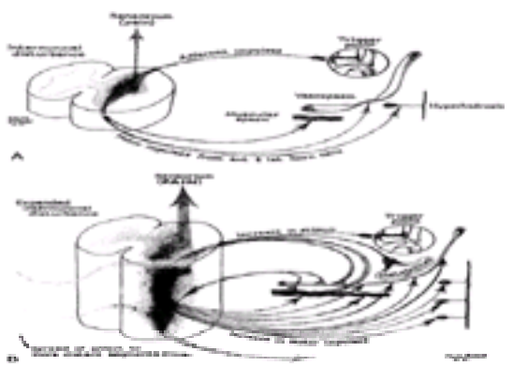

Figure 20-3. **A:** Schematic diagram to depict the physiopathologic mechanism of causalgia and other reflex sympathetic dystrophies. The early stages of the disturbances initiated by a fracture are shown. The afferent impulses from this trigger point reach the spinal cord wherein they set up disturbances of the internuncial pool. This results in increased activity of the anterior and lateral horn cells, which in turn produces increased motor activity of the affected segment. **B:** The fully established vicious circle with expansion of the internuncial disturbances and consequent involvement of other segments. (From Bonica JJ. *The management of pain*. Philadelphia: Lea & Febiger, 1953:973, with permission.)

Brain Mechanism. In 1943, deTakats and Moser each suggested that the brain may be mechanistically involved in RSD (88,89). The thalamus was hypothesized to be the primary area of dysfunction by Moser and Zikeyev (89,90). More recent evidence continues to point to the brain as being possibly involved in the development and maintenance of CRPS. After all peripheral bodily events, including peripheral nerve injury, neuroplastic changes in the brain occur (68). Data supporting the brain's involvement include the occurrence of RSD after brain injury and the anatomic distribution and spreading of CRPS symptoms and signs (91). Positron emission tomographic scanning has demonstrated altered thalamic activity in CRPS patients (92). Also, a neglectlike syndrome has been observed in CRPS patients (72), which, if present, must be the result of altered higher brain processing. Laser Doppler flowmetry results suggest that abnormal patterns of sympathetic vasoconstrictor neurons may be caused by thermoregulatory and emotional stimuli originating from the brain (76). It has been hypothesized that an important functional neuroanatomic region involved in CRPS is the central autonomic nervous system, which includes the insular cortex, amygdala, hypothalamus, and the periaqueductal gray; this central autonomic nervous system could theoretically link the complex clinical picture of CRPS, including the pain, vasomotor changes, sudomotor alterations, and motor abnormalities (72).

Psychological Factors

Similar to the discussion of proposed psychological risk factors for CRPS, several psychological and behavioral factors have been suggested as being integral in the pathophysiology of CRPS, including stress around the time of the injury and an abnormal behavioral response to the injured body part. A possible psychophysiologic mechanism that has been focused on is sympathetic nervous system hyperarousal.

An intriguing, but as yet unproven, hypothesis is that psychosocial stress at the time of injury or during the time of healing may play a role in CRPS development. It has been reported that a significant stressful event occurred before or concurrent with the inciting injury that precipitated RSD or CRPS in some patients. One study observed that 31 of 32 RSD patients referred for psychological or psychiatric evaluation reported experiencing a major life stress around the time of the onset of their RSD (46). Another observed that eight RSD patients recalled experiencing “an extraordinarily difficult period” coincident with the injury or trauma that triggered the RSD (93). A chart review study of CRPS patients referred to a chronic pain clinic found that 30 of 45 patients reported a significant stressful event 6 months before or after the inciting injury that precipitated their CRPS, with most of the patients reporting the event occurred within 6 months before the inciting injury (56).

It is well known that sympathetic arousal or stimulation can increase pain (50). Ecker suggested that RSD pain may be maintained or exacerbated by a feedback system of sympathetic arousal (94). Chronic states of hyperarousal could theoretically predispose an individual with an injury or trauma to developing CRPS. Some believe that sympathetic hyperactivity can account for certain RSD symptoms (95). It has been proposed that RSD symptoms, particularly hyperalgesia, may be related to a-adrenergic activity and that for an individual with a nerve injury, increased a-adrenergic activity associated with anxiety, life stress, or depression may contribute to the development and maintenance of RSD symptoms through sensitized receptors in the area of the injury (45). It has been demonstrated that life stress in the preceding 6 months results in disturbed a-adrenergic activity (96).

Overall, however, limited scientific data exist to support these theories beyond the seemingly high incidence of reported stress occurring before or immediately after the inciting injury or trauma. Additionally, the classic belief that RSD is primarily caused by hyperactivity of the sympathetic nervous system has come under scrutiny. Sympathetic nervous system mechanisms may only partially explain the development and maintenance of CRPS in all patients, or, more likely, may play a significant role in only a subset of CRPS patients.

It has also been hypothesized that patients' behavioral responses to an injury may be a key contributing factor in the development of RSD after a relatively minor injury (44). These responses can range from minimal guarding of the limb to complete immobility and atrophy of the affected area. Such guarding and disuse of the CRPS limb may be explained by extraordinarily high levels of fear of reinjuring the area, fear of worsening of pain with movement, neglect, or all three. Additionally, poor motivation caused by disincentives for wellness may account for at least part of the disuse phenomenon. However, it is almost impossible to assess the extent to

which a person's behavior reflects the experience of pain versus a reaction to more external factors (e.g., stress, solicitous responses from family, or compensation system demands); moreover, both factors may operate simultaneously in some patients. Patients' guarding and disuse behaviors can seem extreme and unusual to the outside observer and therefore are often misinterpreted. Further understanding of the possible roots of such behavior within the context of psychological and physical factors is crucial. Accurately evaluating the causes of such behavioral responses can be difficult, but it is critical when working clinically with these patients.

Psychogenic Factors

Finally, examining the usefulness of the dichotomy frequently discussed between *psychogenic pain* and *organic pain* is important. Ochoa and colleagues have written extensively that RSD and CRPS are primarily psychogenic in origin (97). This group bases their hypothesis on the fact that neurophysiologic testing does not show any defined abnormality and that many of their CRPS patients show *placebo responses* to their interventions. This line of reasoning is scientifically invalid and clinically dangerous for several reasons. First, by definition, a patient's electrodiagnostic testing must be normal to make the diagnosis of CRPS 1. Second, currently available electrodiagnostic and other neurophysiologic testing does not have the ability to assess many important neuropathophysiologic events that may be relevant to CRPS in humans, such as altered receptor affinity, aberrent synapse formation, altered central nervous system processing, and so forth (98). Third, most of their patient placebo responses are associated with single-blind placebo trials, in which conclusions may be biased, making such responses uninterpretable (99). Last, clinicians and scientists must realize that in all illness and disease, symptoms are most often the result of coexistent psychological and physiologic components. After all, psychological processes are actually neurophysiologic events, and physiologic processes may develop, worsen, or improve with different psychological states. These points are often forgotten, if not entirely overlooked, by Ochoa and colleagues. Thus, the schism between the psyche and the body is an artificial one that a true multidisciplinary approach replaces with a realization that a person's body, nervous system, and spirit are one.

Pathophysiology Conclusion

As outlined previously, much has been hypothesized about the possible pathogenesis and anatomic sites of dysfunction in CRPS. Although many authors of such hypotheses have discounted others' postulations, it is feasible that all hypothesized pathophysiologic sites and events may occur simultaneously or in sequence. Moreover, it may be that underlying the clinical picture of CRPS is a heterogeneous group of pathophysiologic mechanisms, which includes dysfunctional peripheral, central, and autonomic nervous systems, myofascial dysfunction, and psychological states, that result in a common set of clinical signs and symptoms. It also should be remembered that each of these *distinct* systems is integrally related to all others: One system does not act independently of all the others. Psychological distress (a neurobiological event) has direct physiologic effects on the entire neuraxis and the musculoskeletal system. Thus, each CRPS patient may differ with regard to the overall role each system plays in the development and maintenance of his or her unique set of CRPS symptoms and signs (see Fig. 20-2).

SYMPTOMATOLOGY

Few studies have prospectively evaluated RSD and CRPS patients' symptoms, signs, or both. The largest prospective study included 829 RSD patients and reported the following symptoms: paresis, 95%; pain, 93%; altered skin temperature, 92%; skin color change, 92%; limited range of motion, 88%; hyperpathy, 79%; hyperesthesia, 76%; hypoesthesia (stocking/glove), 69%; edema, 69%; altered nail or hair growth, 60%; muscle atrophy, 55%; incoordination, 54%; tremor, 49%; hyperhydrosis, 47%; and skin atrophy, 40% (32). A prospective multicenter study of 123 CRPS subjects evaluated by pain specialists reported the following frequencies of symptoms: color change, 86.9%; burning pain, 81.1%; decreased range of motion, 80.3%; edema, 79.7%; temperature asymmetry, 78.7%; weakness, 74.6%; hyperesthesia, 65.1%; sweating change, 52.9%; hypoesthesia, 44%; skin change, 24.4%; tremor, 23.7%; nail change, 21.1%; and dystonia, 20.2% (19).

Clearly, not all patients with CRPS suffer from the same constellation of symptoms or suffer to the same degree from each symptom. CRPS presents itself with a tremendous amount of variable symptoms. A spectrum of symptoms exist. It remains to be seen whether subpopulations of patients with CRPS exist within this large diagnostic category.

Correlation between Symptoms and Signs

When diagnostic criteria rely on a patient's self-reported symptoms, questions often arise about their validity. However, it should be noted that other diagnostic criteria that rely solely on patient self-reported symptomatology have undergone the rigors of validation studies, including the International Headache Society criteria for migraine and *Diagnostic and Statistical Manual* criteria for depression. Two studies have assessed the validity of using self-reported symptoms for the diagnosis of CRPS. These studies have reported that although patient self-reported symptoms are more frequent than objective signs, the pattern of frequencies is similar across signs and symptoms, suggesting that patient self-reported symptoms produce a more global assessment of the condition versus the objective signs, which reflect only a small *snapshot* of a CRPS patient's overall condition, which fluctuates from hour to hour and day to day (15,19). Thus, it appears that symptoms reported by patients have an important role in evaluating patients for CRPS.

Location of Symptoms

As with the classic descriptions of RSD and causalgia, CRPS most commonly occurs in a distal limb (i.e., foot or hand), although RSD has been reported in other body regions, such as the head, proximal limb, and genitalia (100). Applying the current diagnostic criteria, one finds that CRPS may occur in any body regions covered by skin; thus, CRPS cannot occur in the teeth, for instance, because changes in skin temperature, skin color, sudomotor activity, or all three are necessary. Why CRPS occurs more commonly in the extremities is not known, although possible reasons include the fact that limbs are involved most commonly in soft tissue injuries and, perhaps, because of the neuroanatomic and neurophysiologic uniqueness of these body regions.

Spreading and Recurrence

It has been well described that CRPS symptoms may spread proximally or to other body regions, including the contralateral limb, coined *mirror RSD* (18,84,100). However, it is important to distinguish between true spread of CRPS and the more common scenario of a spreading of symptoms apparently caused by myofascial dysfunction. For instance, most patients with upper extremity CRPS also develop shoulder girdle pain, neck pain, and often referred headache, whereas the lower extremity CRPS patient develops buttock and hip pain and low back pain.

An analysis of 1,183 consecutive RSD patients reported a recurrence incidence of 1.8% per patient per year (34). Recurrences occurred in the same or other limbs. This study noted that 53% of these recurrences were of spontaneous origin (i.e., no known precipitating injury), and that the duration between first and second RSD had a tremendous range, from 3 months to 20 years.

Pain Quality

Although the classic pain quality that has been ascribed to RSD and causalgia is burning pain, two separate CRPS validation studies have shown this not to be true (15,19). Bonica also mentioned that these patients may not describe their pain as burning (14). In fact, the pain of CRPS is typically described by its sufferers with several different pain descriptors. A prospective study using the Neuropathic Pain Scale reported that the most prevalent pain descriptors endorsed by CRPS patients were deep, sharp, sensitive, and hot (101). Many CRPS patients complain most of a deep aching pain, described by them as “like my limb has just been removed from freezing water and is thawing out.”

Pain Triggers

As with many chronic pains, the pain and other associated symptoms of CRPS may be worsened by physical contact, changes in environmental temperature, and emotional stress (14,18).

Edema

The painful body region may have mild to frank pitting edema. Not uncommonly, patients may describe a sensation of swelling or fullness without actual physical evidence of edema (“like when a dentist gives you Novocain and your lip feels big”).

Skin Temperature Changes

The involved body region may be hotter or colder than the contralateral region. Moreover, in any one patient, the same region may fluctuate from hot to cold within hours (76). Fluctuations in abnormal skin temperature have also been demonstrated in animal models of nerve injury (102). The difference in temperature between the affected and unaffected limb has been shown to be dependent on the external temperature (103).

Although not well described or differentiated in the literature, when patients admit to temperature changes, it may mean two different things: (a) the CRPS body region's skin has a palpable skin temperature difference as compared with the contralateral limb; or (b) to the patient, the body region may feel abnormally hot or cold; when actually touched, however, it feels the same temperature as the other side. The frequency of each of these has not been evaluated, and the implication of this difference has not been studied.

Skin Color Changes

The CRPS region may have observable skin color alterations, typically described as mottled, deep purple, pale, or bright red. Like skin temperature, the skin color may vary in any one patient over time (76). Frequently, patients state that the skin color changes are correlated with the temperature of the limb, coldness associated with a deep purple skin color and hotness with a red skin color. Uncommonly, patients may describe and have observable frank rashes or peeling of their skin.

Sweating

Alterations in sudomotor activity within the CRPS region may occur. Although the classic description is of profuse sweating, increased or decreased sweating may occur. Patients may describe an abnormal skin dryness in the CRPS affected region.

Motor Dysfunction

Motor abnormalities have been minimized in prior authoritative texts regarding RSD (14). Others, however, have noted that “reflex sympathetic dystrophy is as much a movement disorder as a painful condition” (83). The largest prospective study of RSD demonstrated that motor dysfunction is nearly universally present, with 95% having weakness, 54% muscular incoordination, and 49% tremor (32). In addition, this study noted that 15% of RSD patients had no active movement with normal electromyography tests and were deemed to have a *pseudoparalysis*, thought to be neurologic in nature (32). Another study described RSD patients who displayed clinically significant motor abnormalities, including “focal dystonias, weakness, spasms, tremors, difficulty initiating movement, and increased tone” (40).

CRPS patients commonly describe a vague weakness of the involved limb, even though neurologic muscle testing may be normal. Frequently, patients with CRPS of the hand complain that objects fall out of the hand suddenly, and those with the disorder in the feet may describe stumbling or tripping.

Guarding and Neglect

A classic image of the CRPS patient is one with the upper limb held tightly against the chest with minimal spontaneous and voluntary movement. The historic explanation for this abnormal body position has been that these patients *guard* the involved body region (i.e., they develop a protective posture and tend to avoid its use to minimize a worsening of their pain). Thus, it was generally assumed that this lack of movement was volitional.

However, one report has postulated that the abnormal motor weakness, abnormal posturing, and lack of spontaneous and volitional movement may be caused by a neurologic neglectlike syndrome (72). In other words, these patients do not use their limbs normally because their central nervous system has *shut off* the limb from conscious awareness. Another report noted “inability or difficulty in initiating movements” (40). These patients note that to initiate and perform volitional motor tasks with the CRPS limb they need to look directly at the limb and focus all of their conscious attention on the limb for it to move as desired. Additionally, these CRPS patients describe the involved limb as though it has been disconnected from themselves, for instance, “it's as if my arm is not connected to my brain” or “my mind tells my hand to move, but it won't” (40,72). For some patients, this motor neglect is more disabling than the pain.

Myofascial Pain

Patients with CRPS of the limb develop a secondary proximal myofascial pain caused by disuse and overuse of other musculoskeletal body regions in compensation of the functional loss of the CRPS limb. Although Bonica mentioned this anecdotally, he did not describe it as an important feature clinically (104). Evans also described “skeletal muscle cramps and spasms” (13), and Livingston described muscle spasms as a key factor in his vicious cycle model (84). The clinical relevance of the muscular component has been overlooked, if not ignored, by most clinicians.

In some CRPS patients, the proximal myofascial pain syndrome may be of primary importance (i.e., by treating the proximally involved myofascial regions, the patient's CRPS symptoms improve). During the evaluation of the CRPS patient, palpating the proximal musculature for trigger points not only may reveal their presence, but also may result in referred symptoms (i.e., an immediate worsening of the patient's CRPS pain and its other associated symptoms). At times, a patient's CRPS signs may become evident or worsen immediately on trigger point palpation (e.g., a hand may become abnormally dusky and cold in conjunction with palpation of a trapezius trigger point).

When examining the patient with CRPS of the hand and upper extremity, it is recommended that the shoulder girdle musculature be examined for myofascial trigger points and the hip, buttocks, and the lumbar paraspinous muscles be evaluated in the patient with CRPS of the foot and lower extremity. Even if the initial injury is in the distal extremity (i.e., hand, wrist, foot, or ankle), over time proximal myofascial trigger points may develop and may even become the primary source of many symptoms. A prospective study of CRPS patients revealed clinically significant myofascial dysfunction in 70% of upper extremity and 47% of lower extremity CRPS patients (85).

Therefore, all CRPS patients should be evaluated for myofascial pain in the respective proximal muscle groups, and if present, should be treated appropriately with active physical therapy and possibly trigger point therapy.

Trophic Changes

Although classically considered part of the syndrome, trophic changes, such as decreased hair growth, brittle nails, muscle wasting, and joint thickness, are less common than once thought. In fact, these are not part of the CRPS diagnostic criteria, and studies, as mentioned previously, show that only a small minority of CRPS patients have symptoms or signs of trophic changes (15,19,32).

Psychological Factors

Most CRPS patients experience significant pain, disability, and emotional suffering. Cross-sectional research studies have examined the psychological symptomatology associated with RSD and also have compared them with patients having other chronic pain conditions. Results have shown that affective disorders are common among patients with RSD and CRPS (45,56,62). A chart review study found that 62% of patients with CRPS meet criteria for major depressive disorder during their initial evaluation in a pain clinic (56). One study found that, compared with hand surgery patients, female RSD patients had higher rates of depression and male RSD patients had higher rates of anxiety (61). Compared with chronic back or non-RSD limb pain patients, RSD patients reported greater psychological distress, but the correlation between distress and pain was strongest for the RSD and non-RSD limb pain patient groups (62). This study also noted that the RSD and non-RSD limb pain patients were similar on nearly all the psychological measures used in the study (62). Elevations of scores on the Minnesota Multiphasic Personality Inventory were more frequent for RSD patients than non-RSD nerve lesion patients; however, the differences were not statistically significant, and the cut-off scores used were not clinically significant (105). Another study reported that RSD patients demonstrate higher pain levels but less psychological distress, as rated on the Symptom Checklist-90, compared with patients with chronic back pain and headache (63). Thus, most studies have concluded no consistent significant differences exist on psychological measures between RSD patients and patients with other chronic pain conditions (60,62,63 and 64).

CLINICAL SPECTRUM

Natural History

The natural history of CRPS is unknown. No long-term prospective longitudinal study has assessed the natural history of these disorders. The symptoms of RSD may begin within hours, days, weeks, or months after injury (14). The 1994 IASP taxonomy monograph states, “the onset of symptoms usually occurs within one month of the inciting event” (18). Although pain may begin fairly abruptly in relation to an injury, the other symptoms of CRPS may be delayed for several months and, in some, may be associated with prolonged decreased use of the involved body region. The progression of symptoms and signs appears to vary from patient to patient, and there appears to be a spectrum of natural histories.

Bonica reported that pain persists for more than 6 months in 85% of patients and longer than 1 year in 25%, but these data are based solely on his personal clinical experience (105). One survey reported that two-thirds of RSD patients were officially disabled, retired, or unable to return to prior employment 14 months after last treatment (106). Most reports, however, are based on observations made on patients referred to pain specialists and thus may not adequately reflect a true population-based sample. For instance, one such study observed that the average time duration between injury date and initial pain clinic consultation in the United States was 30 months (33). It may be that these patients are distinctly different (or similar to) other CRPS patients who are evaluated and treated by primary care physicians.

Does Reflex Sympathetic Dystrophy Have Stages?

Historically, it has been written that RSD progresses through certain distinct stages. Initially, Steinbocker described stages of the *shoulder-hand syndrome* (107). Bonica, in the first edition of this text (1953), described the following three stages of RSD:

> The first stage is characterized by constant pain, usually of a burning quality and of moderate severity and localized to the area of injury. The pain is aggravated by movement and is associated with hyperesthesia. There is also localized edema, muscle spasm, and tenderness. All of these factors are conducive to limitation of motion. At this stage the skin is usually warm, red, and dry (vasodilation) …in mild cases the first stage lasts a few weeks, and then subsides spontaneously or rapidly responds to treatment. In severe cases this stage may last as long as six months.
>
> The second stage is characterized by gradual decrease in pain, spread of edema, and increasing stiffness of the joints and muscular wasting. The skin is moist, cyanotic, and cold; the hair is coarse and nails show ridges and are brittle. Signs of atrophy become more prominent…. During this stage, which usually lasts three to six months, proper treatment may be effective in reversing the process.
>
> The third stage is characterized by marked trophic changes which eventually progress to an irreversible degree. The skin becomes smooth, glossy, and drawn; its temperature is lowered and it is pale or cyanotic in color. The hair is long and coarse, the nails are ridged with lateral arching and brittle. The subcutaneous tissue is very atrophic, as are the muscles …extreme weakness and limitation of motion …contractions of the flexor tendons …pain may be mild to severe, and is usually aching in character, although it may be throbbing or burning…. Hyperesthesia and paresthesia are occasionally present (14).

No long-term longitudinal prospective study has been published that follows the natural history of RSD. However, the largest prospective study of referred RSD patients did not confirm a correlation between duration of RSD and differing sets of symptoms and signs (32). One study demonstrated that increased skin temperature was correlated with a shorter duration of pain in RSD and non- RSD painful limbs, but direct autonomic testing did not support a correlation with pseudomotor activity (74). Another study that categorized patients solely by patient perception of skin temperature (stage I, stationary warmth; stage II, intermittent warmth and cold; stage III, stationary cold) reported thermoregulatory skin blood flow as measured by laser Doppler flowmetry was increased in stage I and decreased in stages II and III, perhaps reflecting an initial decrease in efferent sympathetic nerve impulses and then later an increase in skin microvessel sensitivity to circulating catecholamines (108). However, this latter study noted that the skin blood flow changes tended to correlate more with skin temperature than the duration of the syndrome. The authors of this study concluded that large interindividual differences with respect to skin blood flow “may reflect dissimilar rates with which pathophysiologic processes take place” (108). Furthermore, some of the clinical signs and symptoms described in Bonica's stages 2 and 3 may be caused by disuse of the limb and may not necessarily be caused by the underlying pathophysiologic process responsible for CRPS.

Several authorities do not recommend using a staging system (100,109). In fact, a staging system may be counterproductive in the clinical setting, because it paints a negative prognostic outlook for the later stages, adding to the patient's sense of doom and gloom when such negativity is actually not based on scientific study. Patients who would technically meet Bonica's criteria for stage 3 have been observed to make clinically significant improvement with proper long-term multidisciplinary treatment.

Is Early Intervention Important?

Most texts and reviews recommend early treatment for RSD, stating that early intervention may prevent chronicity and refractoriness. Bonica was a strong advocate for early aggressive sympathetic blockade with physical therapy (14,104). However, although early aggressive treatment makes intuitive clinical sense, no controlled prospective study has proven this clinical assumption to be true. It has also been assumed that early CRPS responds to sympathetic blockade, whereas later-stage CRPS does not. This long-standing tenet also has never been assessed in a controlled fashion and it too is based on clinical folklore rather than scientific validity. Moreover, because the natural history of the syndrome is not known, patients reported to be cured by a treatment may in fact be manifesting the natural history of their disease (10).

Regardless of when the diagnosis is made, aggressive therapies as outlined in this chapter should be immediately initiated. Even patients who are diagnosed with CRPS several years after actual CRPS onset may respond to appropriate therapies that have not been attempted in the past. To be unduly pessimistic with long-standing CRPS patients, especially those who have had inadequate treatment, is unwise and not based on any solid definitive data.

LABORATORY TESTING

Based on the CRPS criteria, no need exists for any laboratory testing for diagnostic purposes. Authors have suggested that certain laboratory testing may be helpful as diagnostic aids for RSD and causalgia. However, laboratory testing is not necessary for CRPS diagnostic purposes, nor is it useful in defining appropriate therapies or assisting in prognosticating. Thus, it is questionable as to whether any laboratory testing is ever warranted once the diagnosis of CRPS is made.

Radiologic Testing

Plain radiographic findings of bony demineralization have been noted in some patients with RSD, and this finding may aid in the diagnosis of RSD (111). However, these changes are nonspecific to CRPS, and most patients do not demonstrate this abnormality. In addition, demineralization may occur because of disuse of the limb *per se* and is therefore not specific to CRPS.

Bone Scan

Kozin and colleagues described using bone scintigraphy as a useful diagnostic laboratory tool in RSD (111,112). Bone scan changes described as consistent with RSD include distinctive patterns of radiotracer uptake, especially in the delayed phase of the test (111). Using his personal criteria for RSD, Kozin reported bone scintigraphy has a sensitivity of 67%, a specificity of 86%, and a positive predictive value of 86% (111), whereas another similar study reported a sensitivity of 44%, a specificity of 92%, and a positive predictive value of 61% (113). This latter retrospective study also demonstrated that only 21% of their RSD patients had bone scan abnormalities consistent with RSD (113). A retrospective study of patients with a proven diagnosis of CRPS referred to a chronic pain clinic observed that of the 38% of the 134 patients who had received a bone scan before referral, 53% had a positive scan result, and 47% had a negative scan result (33). Moreover, the test's ability to predict response to sympathetic block has been evaluated in a prospective study, which revealed no correlation between three phase bone scan changes and pain relief after sympathectomy (114). Thus, based on these studies, the clinical utility of bone scan in CRPS has not been demonstrated.

Thermography

Thermography can assist in documentation of abnormal skin temperature. As asymmetric skin temperature in the painful region is one of several possible signs of CRPS, thermography is of potential use but not a necessity for diagnosing CRPS. More inexpensive tools may be used to accurately document skin temperature abnormalities, such as skin temperature probes or infrared thermometers. One study assessing the validity of thermography as a diagnostic tool for RSD concluded that an asymmetry cutoff of 0.6°C provided optimal sensitivity and specificity (115).

Autonomic Testing

Quantitative sudomotor axonal reflex testing can document abnormalities in the autonomic nervous system (116). Although potentially useful in research, the extent to which quantitative sudomotor axonal reflex test is useful in the clinical setting has not been established. One retrospective study reported that resting sweating output was found to have diagnostic specificity for RSD (74). However, such autonomic testing devices are not readily available in clinical practice and therefore have limited use.

Electrodiagnostic Studies

Electrophysiologic studies, electromyography, and nerve conduction velocity testing can confirm the presence of large fiber peripheral nerve injury for the diagnosis of CRPS type II. At present, however, it is unclear whether electromyographic or nerve conduction velocity documented nerve injury evidence has any prognostic or therapeutic relevance with regard to CRPS. Another neurologic test, quantitative sensory testing, can provide information on the function of large and small peripheral nerve fibers and the central nervous system's interpretation and perception of thermal stimuli. Again, the clinical relevance of these findings is not known. However, the combination of microneurography and quantitative sensory testing may permit a classification of pain syndromes, including CRPS, on the basis of mechanisms rather than symptoms and signs.

TREATMENT

> It is probably a truism to state that most physicians and surgeons are so trained and skilled at treating organic pathology that they are unable, unskilled or disinterested in the demands imposed by a CRPS patient who has neither a focal injury nor is amenable to a disease based therapy (21).

Many claims have been made that described treatments result in CRPS/RSD/causalgia cures. The reality is that no such treatment exists. Although many treatments for RSD or causalgia have been reported and recommended, the majority are descriptive and anecdotal and are not based on the results of controlled clinical trials. The overall clinical experience with all medical and procedural treatments is poor, with the majority of patients not reporting clinically meaningful pain relief or improved function with any monotherapeutic treatment approach.

Several detailed treatment review articles have been published and are recommended reading (116,117 and 118). These extensive critical reviews of the published literature by Kingery and Tanelian clearly delineate the lack of controlled clinical trials (116,117 and 118). No scientifically established treatments exist for CRPS. Although a few treatments have some controlled trial data suggesting efficacy, no treatment has been shown to cure CRPS. In addition, good long-term efficacy data are lacking for all therapeutic interventions. A failure of all published trials to date is their lack of long-term functional outcome measures. As is described here, even the classic teaching of sympathetic nerve blockade for the treatment of these conditions has no significant supportive data suggesting long-term efficacy and thus is no longer recommended as the mainstay of CRPS treatment (109,116,117 and 118).

One potential reason for such poor outcomes overall with all treatments for CRPS is that CRPS is a heterogeneous disorder with many possible underlying mechanisms responsible for its pain and symptoms. In other words, perhaps CRPS is actually composed of multiple patient subgroups with different pathophysiologic mechanisms and environmental factors, all of which need different therapeutic approaches. Thus, it would be unrealistic to expect a single modality treatment to be beneficial for all CRPS patients.

Multidisciplinary Treatment

The key disciplines needed for the management of CRPS include medicine, psychology, and physiotherapy (Fig. 20-4). The primary goal of multidisciplinary management is to achieve functional restoration of the CRPS body region through long-term, quota-based physical and occupational therapy. The physician's role is to provide pain and symptom relief via medication or procedures and to lead the treatment team. The psychologist's role is to identify comorbid psychiatric conditions, such as depression, posttraumatic stress disorder, and anxiety disorder. Psychological treatment approaches include cognitive-behavioral techniques and supportive psychotherapy, with the goal of teaching the patient pain-coping skills. The role of the physiotherapist, probably the key interventionist and therapeutic provider, is to organize and manage the daily rehabilitative treatment of the patient. All medical providers must be experienced in the care of CRPS patients and work closely as a cohesive team, with frequent team meetings to address patient progress. Multidisciplinary management of CRPS can be painstakingly slow (for patient and providers), taking several months to a year or even longer. The key is slow, gradual, persistent documented functional improvement.

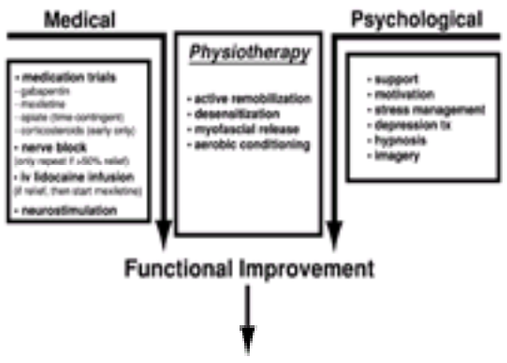

Figure 20-4. Multidisciplinary treatment.

Validation of Symptoms

CRPS patients often believe their symptoms are invalidated by the health care system. Because the symptoms of CRPS are unusual, are not readily explainable or measurable by our current knowledge of pathophysiologic events, cannot be confirmed by any laboratory testing, and do not improve with customary therapies, many physicians who are not familiar with CRPS (and even some who are familiar with CRPS) communicate to patients, either directly or indirectly, that the pain and symptoms are all in their heads or that the problems are not organic but psychogenic. Such conclusions are countertherapeutic and most certainly worsen a patient's physical and psychological state. Health care providers must first and foremost validate the CRPS patient's symptoms: Yes, your symptoms are real; yes, other patients with your condition complain of similar symptoms; and yes, we hope we can lessen the intensity of your symptoms and improve your functioning and quality of life. CRPS patients often state that this validation of their symptomatology is one of the most important therapeutic interventions provided.

Education

When given a diagnosis of a chronic disorder, most patients want information regarding the disorder's etiology, underlying pathophysiology, therapeutic options, known treatment outcomes, and prognosis. For patients with CRPS, answers to all of these appropriate questions are not available. In this day and age of cyberspace, many patients search the Internet for answers and are often provided with misinformation and reasons for pessimism. Thus, patients are often left with a

sense of hopelessness.

That CRPS patients often become fearful and anxious of the unknown and develop a sense of pessimism is understandable. Therefore, these issues must be directly addressed during the initial consultation visits with each specialist. Enough time should be spent with each CRPS patient to address these fears with education. A physician should answer patient questions about pathophysiology and treatments honestly, yet with optimism. A clinical psychologist should also address these concerns therapeutically. A patient psychotherapy and education group, led by a knowledgeable CRPS health care provider, can be helpful, especially if the group includes former CRPS patients who have made functional improvements.

Setting Treatment Goals

The following realistic goals must be set for each CRPS patient:

- The physician attempts to provide pain and symptom relief through safe procedures or medications, although clinically meaningful pain relief is not guaranteed.
- Even if pain relief is found through such therapies, it will not be a cure.
- The patient should be open to nonpharmacologic treatments, such as those offered by the clinical psychologist.
- The most important element of CRPS treatment is the patient's own persistence and efforts at long-term active physical therapy, which may initially exacerbate the symptoms, but are necessary for improvement.

Physiotherapy

The role of physiotherapy in the treatment of CRPS is varied. Although some interventions in this branch of treatment may result in the attenuation of pain or allodynia, the primary responsibility of the physical therapist is the restoration of function through activity (119,120,121,122 and 123). To this end, the fundamental approach is to help the patient work toward achieving a normal quality of movement of the affected limb and allowing it to once again become an integral participant in daily activity.

The therapist works with the patient to promote bilateral symmetry of movement. This may help restore motion, strength, and dexterity to the affected limb while also helping to prevent the contralateral limb or proximal joints from taking on an increased biomechanical burden. Often the *spread* of CRPS may be traced to the mechanical result of increased forces at aberrant joint angles, caused by movement substitution, in an effort to favor the painful part.

Diminished use of the limb and the prolonged maintenance of maladaptive guarding postures have been observed to result in significant soft tissue contractures from adaptive shortening, an accompanying loss of range of motion at the joints, and disuse atrophy of the limb's musculature (124). The patient may also present a history of decreasing overall physical activity level through the reduction, or elimination, of participation in work or recreational activities in an effort to guard against increases in pain. The result can be an overall physical deconditioning and the possibility of increased focal and global discomfort from deactivation pain as muscles shorten and decrease their oxidative capacity, joints stiffen, soft tissue becomes fibrotic, and peripheral breakdowns begin in articular cartilage.

Treatment Goals

Therapeutic activities are guided by functional goals, established in conjunction with the patient. When asked what their goals are in therapy, patients often respond with “I want the pain to go away,” or “I want my arm (hand, leg, foot) to be normal again.” Pursue the issue by asking what things the patient could do if the patient's arm were normal that he or she cannot do now; doing so may yield specific functional activities that can help set the course for therapy. Toward building capacity to facilitate functional outcomes, the following general therapeutic goals are included:

- Eliminate guarding postures and substitute movements.
- Restore normal active range of motion, strength, and motor control.
- Establish equal weight bearing for lower extremities.
- Increase standing duration tolerance with equal weight bearing.
- Increase ambulation distance using a normal, symmetric gait pattern.
- Increase stair climbing ability with symmetric step pattern.
- Increase aerobic capacity and general conditioning.
- Increase total day activity time.
- Increase touch tolerance.
- Decrease pain responses to nonnoxious stimuli.
- Build physical capacity to meet specific requirements for returning to work, when appropriate.

Physiotherapy Assessment

A comprehensive assessment provides insight into the nature of the patient's physical and functional condition and serves to establish multiple quantitative baselines that can be used to objectively evaluate patient progress and responses to therapy. In addition to a relevant medical history, the assessment should include activities and conditions that aggravate or relieve symptoms and modes of treatment and responses to prior physiotherapy.

Essential is obtaining information from the patient regarding his or her current or former occupation (with a general sense of its physical and postural demands), activities of daily living currently restricted or eliminated secondary to pain or its physical complications, and estimated number of daily waking hours the patient currently spends in bed or reclining.

Physical findings should include measurements of active range of motion and muscular strength for both the affected and contralateral limb, documentation of motor abnormalities (e.g., dystonia, apraxia, movement latency, increased tone, intention tremors, involuntary movements, and motor neglect), postural evaluation with specific attention to protective guarding patterns, gait characteristics (i.e., abnormalities, asymmetry, maximum distance walked, need for assistive devices, and ambulation speed over a short standardized distance), duration of aerobic activity tolerance at an age-specific target heart rate, and stair climbing ability. Proximal sites (e.g., the shoulder girdle and periscapular region for upper extremity cases or hip, gluteal and low back regions with affected lower extremities) should be palpated for the presence of myofascial trigger points. For lower extremity cases, uncued standing weight bearing on each leg should be documented. With affected upper extremities, hand grip and key pinch strength should be assessed bilaterally, along with an appropriate standardized measure of functional hand and upper extremity dexterity.

Physiotherapy Treatment

To address the multifaceted goals leading to functional restoration, diverse physiotherapy interventions may be used (125). No appropriately controlled clinical studies exist that adequately address the efficacy of individual physiotherapy methods for the treatment of CRPS. Some authors insist range of motion work and strengthening should only be done under pain-free conditions (126,127 and 128) (i.e., physiotherapy sessions should only follow sympathetic, central, or peripheral nerve blockade). Yet this recommendation is faulty on several accounts. First, many, if not most, CRPS patients do not obtain even temporary relief with nerve blocks. Second, even if such meaningful relief is attained, such practice, although benevolent, is far from being practical. To be effective, the frequency of physiotherapy treatment would require an unreasonably high number of blocks to be performed. Therefore, the therapist is practically faced with the task of working to restore function within a painful limb, without increasing the patient's long-term discomfort. Some clinicians now recommend the use of transcutaneous electric nerve stimulation units during therapy to attenuate pain during the treatment session (128). Again, no controlled studies have appeared that support transcutaneous electric nerve stimulation use to be either effective in temporarily blocking CRPS pain, or producing faster or more complete functional recovery. Additionally, responses to heat and cold as palliative modalities are highly varied and unpredictable, even for an individual patient over time.

Desensitization techniques are used to reduce allodynia (125). Desensitization is a progressive technique to gradually habituate the patient to the presence of nonnoxious stimuli, which previously elicited a pain response. A sequence of materials are selected that progress from soft, light textures to extremely course, irritating surfaces. The patient lightly rubs affected areas with the most nonirritating material for several minutes, rests, then rubs again for several minutes. After a number of sessions, the patient gradually becomes accustomed to the presence of this texture on his or her skin and the painful response diminishes. He or she then moves to the next material in the sequence of increasingly coarse textures and repeats the procedure. Gradually, the affected limb habituates to increasingly irritating

textures, until the patient can easily tolerate the touch of clothing, bed sheets, towels, and so forth during normal activities of daily living. To complete desensitization training, materials triggering diverse sensory modalities should be employed, such as pressure and cold.

To restore range of motion, strength, and motor control, as well as build functional tolerance to activities such as standing, sitting, or walking, appropriate dosing of exercise is critical. For this purpose, a quota-based progression system may be used, as first outlined by Fordyce (129). For each individual activity or specific exercise, a baseline is first established. In setting baselines, the patient is instructed to perform and continue the activity (usually quantified as the number or repetitions of a compete movement cycle, or elapsed time), until he or she just begins to feel the first signs of any of the three following sensations: increased pain, muscle weakness, or fatigue. During the next treatment session (or home exercise session), the patient is instructed to perform just 80% of the number of baseline repetitions (or tolerated elapsed time). During each subsequent session, the number of repetitions is increased by one (or 5% to 10% for activities based on elapsed time). With progressive resistive exercises for strength building, when the number of repetitions reaches 15, resistance is increased, repetitions are dropped to eight, and the progression begins again. This formula allows the individual to begin exercising at a level that is well within his or her reasonable level of exercise tolerance and then progress at a gentle, reasonable rate. Each day, each exercise has a specified quota for number of repetitions. Patients are instructed to perform exactly that number or repetitions, not more or less, regardless of temporal pain. The implementation of quota-based exercise dosing helps the individual to progress in functional physical ability, while decreasing the oscillation cycles of activity tolerance inherent in pain-contingent dosing of activity.

Attempts to restore range of motion begin by instructing the patient in passive arthrokinematic joint mobilization and techniques of active assisted range of motion for joints displaying functionally limited movement. As functional levels of passive and active assisted motion are reached, the patient advances to active range of motion exercise using the muscles directly controlling the joints in question. Active assisted range of motion and active range of motion exercises should have a baseline established for reasonable tolerance and progress on a quota-based system. As the patient begins to display increases in active range of motion, appropriate progressive resistive exercises may be introduced to build muscle strength. Each resistive exercise should have an individual baseline established and progress via the quota formula. Progression should be linear, with daily exercise intensity specified by the quota progression, not pain contingent.

Building tolerance for sustained aerobic activity, as well as functional tasks, such as sitting, standing, walking, writing, or using a keyboard, may also be approached using a quota-based system. Baselines are established using an appropriate measure, such as time, distance, number of written lines, and so forth. A quota progression is then created, beginning at 80% of the baseline value and linearly increasing daily in increments of between 5% and 10% of the original baseline. All functional activities should be performed with appropriate mechanics and without movement substitution or asymmetric distribution of effort. Standing quotas should be met with equal weight distribution and walking with symmetric movement and release of guarding postures. That the functional task be accomplished during a therapy session is less important than that it be done with correct patterns of movement, thereby encouraging reeducation of appropriate neuromotor behavior.

In cases of lower extremity CRPS (and sometimes caused by an expanded guarding pattern in upper extremity CRPS), proper walking mechanics and symmetry may be restored via gait-shaping protocols. Initial and continuous emphasis is placed on equal weight bearing. As equal weight bearing and symmetric gait are established, variable surface training may be used to build ambulatory adaptability to irregular walking surfaces and also enhance proprioception. Weaning from assistive devices, such as canes or crutches, may be facilitated with a quota-based gradual reduction in their use.

Some weight-bearing activity for upper extremity CRPS may also have utility in helping resolve symptoms. Using *stress loading* protocols, balanced weight-bearing tasks may be practiced with the upper extremity (130,131).

Managing edema may also be an issue essential to restoration of appropriate movement. For lower extremities, frequent ankle pump exercises should be performed, whereas for the upper extremities gentle hand grip and release may be used. Self-administered unidirectional massage, along the lines of lymphedema protocols, may aid in swelling resolution and also provide further practice with touch desensitization. When available, hydrotherapy, via warm water pool work, is highly recommended. The pressure gradient created by standing in water facilitates edema management and relieving weight from weight-bearing joints affords an excellent opportunity for building strength and range of motion.

Many CRPS patients manifest proximal myofascial components, which may be limiting movement and exacerbating pain through referred patterns. Typical techniques of myofascial release, involving *spray and stretch* or deep tissue work (132), may not be tolerated with hyperalgesic limbs and may provoke symptoms for a considerable period of time. Complete therapeutic intervention should, however, assess and address potential myofascial trigger points. Myofascial release work may be accomplished when appropriate windows of opportunity present themselves, such as coordinating the timing of therapy sessions with medication schedules. Patients may also be taught self-applied techniques of manual myofascial release for incorporation into their home programs.

Additional physiotherapy modalities have been suggested, but have yet to demonstrate controlled clinical efficacy, or in several cases have yet to establish sound pathophysiologic foundation for their use. These include the use of transcutaneous electric nerve stimulation and high-voltage pulsed current for managing edema, neuromuscular electric stimulation to build strength, and thermal biofeedback to restore normal patterns of peripheral blood flow.

No established standards exist for the frequency and duration of physiotherapy sessions. Much depends on the individual patient's needs. The key decision factor involves how frequently a patient should be seen in the clinic to ensure compliance with quota-based activity. The importance of a home program cannot be overemphasized. To successfully treat CRPS, the patient must be committed to integrating treatment concepts into the daily routine outside the clinic. This includes appropriately pacing physical activity, as well as adhering to instructions to extinguish guarding, and using the affected limb in normal activities of daily living at gently advancing levels of intensity and involvement. The patient should be continually encouraged to generalize movement gains made in the clinic to the routine performance of daily activities at home. Transferring physical and functional gains to activities of daily living is essential.

Progress and Outcome Measures

An extremely useful facet of physiotherapy treatment is that it lends itself easily to direct objective progress measures across multiple parameters. This is of benefit to the therapist in assessing response to treatment modalities and to the patient in perceiving clear progress toward measurable goals, and provides a rich source of quantitative variables for future research. Patient outcomes may easily be quantified and documented on any number of dimensions, including the following: symmetry of lower extremity weight bearing; aerobic activity tolerance, assessed as minutes of continuous activity maintained at a target heart rate; manual or isokinetic testing of muscular strength; grip and pinch strength, measured in kilograms; active range of motion, measured in degrees, or linear distances from anatomic landmarks; ambulation distance with appropriate symmetric gait pattern; ambulation speed over a standardized distance; number of stairs that can be ascended and descended without a rest stop; tolerance for lifting weight to and from varied heights and carrying over a given distance; and the ability to independently perform relevant functional, work-related, or both kinds of activities with the affected limb, which had been discontinued because of limitations of pain, strength, endurance, motion, or motor control.

Outcome Factors

No studies have been reported that use large enough samples to adequately assess factors that may predict a successful response to therapy. However, based solely on clinical experience, there appear to be a few exogenous and endogenous factors that have been associated with a reasonably rapid return to function. Exogenous factors include the speed with which therapy is commenced after the precipitating event or onset of symptoms (120,133) and adequate access to relatively frequent therapy sessions. Using records from 36 pediatric patients, one study reported that physiotherapy sessions conducted as frequently as twice daily were most likely to lead to resumption of activity (134). Large-scale studies on the requisite dosing of physiotherapy are not available.

Endogenous factors typically associated with relative success involve a willingness on the part of the patient to adhere to strict pacing of activity and an intrinsic desire to increase function and return to work or daily activities, as opposed to simply reducing pain. With properly applied and paced physiotherapy, many CRPS patients who possess a real desire to return to normal activity can experience a significant restoration of physical abilities, an improved quality of life, and a meaningful reduction of their symptoms.

Psychological Treatments

Psychological intervention is a crucial part of the multidisciplinary treatment for patients with CRPS. Psychological therapies can help to remove barriers to rehabilitation, such as fear of reinjury and worsening pain, depression, anxiety, disincentives for wellness, and third-party systems issues (e.g., worker compensation, legal, and insurance systems). A thorough psychological evaluation by a psychologist or psychiatrist well versed in chronic pain can be crucial in ferreting out these issues, as well as in diagnosing depression and anxiety disorders. Although many reports in the literature emphasize the importance of psychological factors in CRPS

and RSD, little research has been conducted on the effectiveness of psychological therapies for this condition. Currently, most of what is known and used is based on the general chronic pain treatment literature (53,135,136).

Identify Psychological Comorbidities

As mentioned previously, rates of depression and anxiety are much higher in individuals with all types of chronic pain as compared with non pain community samples. Emerging reports suggest that rates of posttraumatic stress disorder may also be higher in chronic pain populations. Additionally, anger issues can be a significant factor for these patients; although anger related to third- party systems may be understandable given the patient's situation, it may nevertheless tax the patient's ability to manage pain and effectively deal with these issues. If left unchecked, negative emotional states, most likely a consequence of chronic pain and its effects on the patient's quality of life, are likely to exacerbate the pain and other symptoms of CRPS, worsen disability, and hinder efforts at rehabilitation. Appropriate therapies, including psychotherapy and pharmacotherapy, are critical in the overall treatment of CRPS.

Cognitive-Behavioral Psychotherapy

Most of the psychological strategies suggested for the treatment of patients with CRPS are those cognitive-behavioral therapies used in the treatment of general chronic pain conditions (53,136). Standard cognitive-behavioral psychotherapy for depressive and anxiety disorders can be helpful for individuals with CRPS. Therapeutic techniques, such as thought monitoring (e.g., decreasing catastrophizing thoughts and beliefs), cognitive restructuring, goal setting, stress management, and increasing participation in pleasurable activities, can be the most useful interventions for such patients (53,135,136).

Group Psychotherapy

Group psychotherapy for individuals with CRPS is an extremely helpful therapeutic modality to address the comorbid psychological issues and to decrease the social isolation that many of these patients experience. CRPS patients often feel isolated, depressed, and enigmatic, believing that they are unusual and suffer from bizarre symptoms. Introducing patients to other individuals who have had similar experiences with CRPS with regard to symptoms, relationships with health care providers, and systems issues, is a positive experience for many CRPS patients. It is particularly useful to have patients in the group who are in various stages of treatment to provide hope and a model of recovery for the patients who are just starting treatment. These groups should include both a didactic component regarding issues related to CRPS (e.g., sleep and mood management, self-management strategies, family issues, and how to deal with the health care system) as well as supportive psychotherapy approaches. The group should not be allowed to focus entirely on negative issues, but rather focus on more adaptive ways to cope and function with CRPS.

Symptom-Specific Psychological Treatments

Specific psychological techniques may be of particular benefit for individuals with CRPS. The role of biofeedback (137) and hypnosis (138,139) as adjuncts to more traditional cognitive-behavioral psychotherapy has been highlighted in the literature. However, most of these studies are limited by small sample size, and many are single case reports.

Biofeedback. One study found that thermal biofeedback on the affected RSD limb promoted a decrease in RSD-associated symptoms in 20 *treatment refractory* patients (137). At 1-year follow-up, 14 of 20 of these patients were reported to be working. Another study reported that biofeedback was helpful when used as part of a multidisciplinary treatment approach to RSD symptoms (130). Biofeedback can be useful for this population in terms of facilitating learning of relaxation skills and possibly decreasing pain, other CRPS symptoms, and distress via an increased sense of self-control and perhaps by reducing the patient's autonomic stress response.

Hypnosis. Hypnosis with CRPS patients has also been proposed as an effective therapy in reducing some of the symptoms associated with RSD. A case report observed that three RSD patients achieved warming in their affected limb and some relief of other RSD symptoms (138). One study reported that integrating hypnosis into a multidisciplinary approach, which also included psychotherapy and myofascial therapy, was useful for approximately two-thirds of RSD patients who were considered *highly hypnotizable* (139).

Additional Psychological Treatment Issues

As noted elsewhere, validation of the CRPS patient's clinical and life situation seems to be particularly important for this patient population. Because of the bizarre nature of many of the symptoms associated with CRPS, many of the patients believe that the validity of their symptoms has been questioned by other doctors and third-party systems, and therefore they get caught in a bind of trying to convince representatives of such systems, and often significant others, that their symptoms are real. This only serves to compound patient disability and pain behaviors. A lot of mileage can be gained in working with these patients by validating their experiences in the beginning and throughout treatment. For a significant majority of these patients, a trusting relationship with a physician is crucial to treatment success. Equally important is compassionately dispelling unwarranted catastrophic thinking, such as belief in an eventual need for amputation or that “RSD is spreading throughout my entire body.” Psychotherapy can be a useful adjunct to working on these issues while the patient goes through reactivation physical therapy and medical management of the CRPS symptoms.

Medical Therapies

Sympathetic Blockade

> Current neurophysiologic evidence does not support the direct inference of pathogenic mechanism, site, or transmission pathway from observations during neural blockade. Complex physiologic events may confound the simple interpretation of diagnostic blocks…. On the basis of the published material reviewed, we conclude that there are many limitations that weaken the theoretic basis for neural blockade as a diagnostic or prognostic tool. In addition, these procedures in general lack thorough documentation of clinical usefulness (22).

Classic teaching strongly recommends treating RSD and causalgia with sympathetic blocks (14,104). Sympathetic blocks continue to be the first-line and mainstay of treatment by many treating physicians. One study reported that an average of six blocks (range, 0 to 38) was performed without significant benefit on CRPS patients before being evaluated in a chronic pain clinic (33). It is imperative to realize that the data used to support the notion of sympathetic blocks for the treatment of RSD are not based on controlled clinical trials and, in addition, the supportive reasoning behind this notion is circular because prior diagnostic criteria required a positive response to such a nerve block. Thus, it is likely that only RSD and causalgia patients with SMP were treated with sympathetic blocks (and thus the reported high success rate), whereas those who did not report pain relief with sympathetic blocks were not considered to have RSD or causalgia and hence were excluded from study results. Therefore, most of the prior RSD and causalgia reports need to be interpreted with great caution, because the subjects were a selected subgroup of CRPS patients and these studies were not placebo controlled.

Another major issue with sympathetic blocks is their true mechanism of pain and symptom relief. This significant issue has not been questioned. It has been assumed that pain relief after sympathetic blockade results from decreasing an abnormally hyperactive sympathetic tone in the involved body region (14,104). Yet, the acquisition of more recent data brings this assumption into question. For instance, with regional ganglion sympathetic block, there are systemic absorption of local anesthetic and spillage of local anesthetic onto adjacent nerve fibers, which likely result in distinct nervous system activity apart from the local effect on the sympathetic ganglia (22,24,25). Also, several studies have demonstrated no correlation between degree of sympathetic dysfunction and degree of pain relief obtained from sympathetic blockade (20,27,28). Lastly, the time of onset and duration of pain relief do not correlate with the timing of sympathetic block (22,29).

Several techniques exist for sympathetic blockade, including selective sympathetic ganglion blockade, stellate ganglion block for the upper extremity and lumbar sympathetic block for the lower extremity, intravenous regional guanethidine/bretylium block, and intravenous phentolamine infusion. All of these techniques, except phentolamine infusion, have technical factors that may affect the efficacy of the block, including the physician's experience and technique and the patient's anatomy (22). All of these techniques, including phentolamine infusion, have nonspecific effects that could explain their apparent success.

Is There a Need to Perform a Series of Nerve Blocks?

Another clinical practice, based more on folklore than scientific evidence, is that of automatically performing a series of sympathetic nerve blocks to all patients with

CRPS. No controlled published studies have verified the efficacy of this practice. Although it is still recommended that a CRPS patient have one sympathetic nerve block to assess whether SMP is present (realizing the pitfalls of interpretation thereof), if the patient does not report significant pain relief after one well-performed sympathetic block, then further sympathetic blocks are not recommended.

Selective Sympathetic Ganglion Nerve Block

Several problems exist regarding the efficacy studies for selective sympathetic ganglion nerve block and stellate ganglion and lumbar sympathetic block for the treatment of CRPS. First, the actual success rate of blocking the sympathetic activity with these blocks is not known (22). Second, no placebo-controlled trials have been published. Third, the mechanism of pain relief when achieved may be local anesthetic activity on peripheral somatic nerve fibers and not sympathetic fibers via local anesthetic systemic concentration or local spillage (22,24,25). In fact, patients who have reported transient pain relief with sympathetic block may also report similar degrees of pain relief with intravenous lidocaine infusion and then obtain chronic relief with oral mexiletine.

Intravenous Regional Sympathetic Block

Studies have assessed the efficacy of intravenous regional sympathetic blockade using several different agents. Guanethidine is commonly used and is thought to act by depleting norepinephrine, although the drug has also been shown to have serotonergic and anticholinergic activity (140). Based on seven controlled trials (141,142,143,144,145,146 and 147), a critical review of the literature concluded that intravenous regional sympathetic blocks with guanethidine “are ineffective analgesics compared to placebo or no treatment” (117). One of these studies also demonstrated that a series of guanethidine blocks produced similar ineffective results as a single block (147).

Bretylium is also frequently used as the agent in intravenous regional sympathetic block. Bretylium, like guanethidine, is thought to be of potential benefit in SMP because of its activity of depleting norepinephrine. Only one non–placebo-controlled study of intravenous regional sympathetic block with bretylium has been published, comparing bretylium with lidocaine in 12 subjects, which reported bretylium resulted in a significantly longer duration of pain relief than did lidocaine (148).

Other controlled trials of agents administered as intravenous regional sympathetic block include droperidol, ketanserin, reserpine, and atropine. Droperidol, an a-adrenergic antagonist, resulted in no pain relief in six subjects who had responded to a prior stellate ganglion nerve block (149). Ketanserin, a serotonin type 2 antagonist, was studied in nine patients with the report of significant pain relief for several weeks as compared with saline (150). Two controlled studies assessed reserpine, another norepinephrine-depleting drug, in subjects who had a positive prior response to stellate ganglion block, and reported no significant pain relief (142,143). No pain relief was also reported for the anticholinergic atropine in patients who had previously responded to intravenous regional sympathetic guanethidine block (151).

Besides lacking firm positive data from controlled clinical trials, another significant issue with intravenous regional sympathetic blocks has been raised. Pain relief associated with this procedure may result solely from the ischemic tourniquet block and not be caused by the injected medication. Significant A-b and A-d fiber conduction block with clinically evident sensory changes have been documented with only the tourniquet block (152).

Intravenous Phentolamine Infusion

Phentolamine's primary mechanism of activity is believed to be via a $_1$-adrenergic antagonism, although the drug also has serotonergic, histaminergic, and cholinergic activities (29) and local anesthetic properties (153). Controlled clinical trial results are mixed, and methodology of these trials is poor. The one trial with positive results always administered the placebo immediately before the phentolamine (154). One of the trials with negative results also always administered the placebo at the same time and, additionally, was a single-blind study (155). One study reported that phentolamine infusion was less sensitive but more specific than stellate ganglion block for the diagnosis of SMP (28). An uncontrolled report observed that some RSD patients experience days to weeks of pain relief after one phentolamine infusion, and that patients may report a delay of peak pain relief for several days after phentolamine infusion (29).

Phentolamine infusion has advantages over other sympathetic blocks in that it is minimally invasive, is not technician dependent, and has systemic activity that allows for treatment of multiple body regions with SMP. It is unclear whether phentolamine has a dose-response relationship and thereby some patients may need higher doses for an effect (156).

Epidural Clonidine

One double-blind controlled trial reported statistically significant pain relief with epidural clonidine injections for RSD patients who had SMP (157). However, this study also reported significant adverse events both with the single injection and with the open- label continuous epidural infusion.

Predictors of Sympathetically Maintained Pain

One retrospective study reported that RSD patients with early disease (less than 6 months) associated with increased skin temperature and edema were more likely to report pain relief after sympathetic block (74). This and another study also reported that patients with allodynia were more likely to respond to sympathetic blocks, but this was true for RSD and non-RSD limb patients (20,74).

Placebo Blocks

Much discussion has taken place with regard to the need for placebo blocks. When performing and interpreting clinical trials in which a group of subjects' responses to a treatment are being evaluated, placebo treatment is always necessary, especially in a syndrome, such as CRPS, in which the natural history is unknown and no gold standard treatment exists. Thus, in clinical trials research, the response of an overall group of subjects to an inert placebo block must be compared with the response when the active medication is injected.

The use of placebo blocks in clinical practice, however, needs to be seriously questioned (see Chapter 81). It is currently accepted clinical practice to perform placebo blocks on individual CRPS patients to assess for the patient's individual placebo response. Although commonly practiced, this procedure is fraught with multiple problems that make interpretation of the patient's responses impossible, including the following problems:

- There is no such thing as a *placebo responder*. Every person can (and will) respond to a placebo given certain conditions (158).
- An individual's response to a placebo is plastic, not static, and this response changes from day to day, and even minute to minute (159).
- Treatment responses to all treatments and for all medical conditions always have two components, one directly related to the physiologic activity of the treatment and the other evolving from nonspecific treatment effects (159). Thus, a patient who has a true physiologic response to an active block may also have a similar response to a placebo block and report pain relief to both blocks.
- A patient's response to placebo is affected by many variables outside of the treating physician and patient's control, including patient expectation, physician expectation, patient anxiety, environmental setting, patient experience with similar treatments, and physician experience with similar treatments.
- Single-blind procedures are uninterpretable. One prospective study revealed that physician expectation was more important than patient expectation with respect to subsequent response to therapeutic pain procedures, thus questioning the validity of single- blind procedures, in which only the patient is blinded to the medication administered (99).
- An inert substance, such as saline, used as the placebo may not truly be inactive. Injection of saline has physiologic effects and therefore can result in altered sensations. In addition, the simple procedure of needle insertion for the block may actually result in a physiologic response if the needle penetrates a myofascial trigger point. The simple maneuver of the ischemic tourniquet block used for intravenous regional sympathetic blocks results in peripheral nerve alterations and changes in sensory perception (153).

Thus, placebo blocks performed in an individual patient to assist in treatment planning cannot be interpreted with certainty and therefore are not recommended. Non-specific effects including placebo are discussed in Chapter 81.

Are Patients with Complex Regional Pain Syndromes Placebo Responders?

It has been written and promulgated that CRPS patients tend to be placebo responders (97). The data used to validate this postulation are based on single-blind procedures (156), which are uninterpretable (99). In addition, most authorities' clinical experience is that most CRPS patients do not respond to any medical interventions (17,99,109,116) and if indeed CRPS patients tended to be placebo responders one would expect the opposite, positive reports of pain relief after most medical therapies.

Medication

As with sympathetic blockade, no medication has definitive controlled clinical trial evidence and long-term clinical experience as a gold standard for CRPS treatment (Table 20-1). The modus operandi for prescribing medication is still trial and error, with subsequent drug trials. As with the treatment of other neuropathic pains, the key with currently used medication is the need for dose titration until good pain relief or intolerable side effects are reported by the patient. Also an important strategy is titrating one drug at a time, although some patients eventually may require polypharmacy. Many CRPS patients have no success with all currently available drug therapies because of poor pain relief and intolerable side effects.

Antiarrhythmics
Anticonvulsants
Antidepressants
Calcitonin
Calcium channel blockers
Corticosteroids
Opiates
Regional sympathetic blockade
Ganglion block
Intravenous regional
Spinal/epidural
Systemic sympathetic blockade
Oral
Intravenous
Topical local anesthetic
Transcutaneous electric nerve stimulation
Peripheral nerve stimulator
Spinal cord stimulator
Spinal opiates (and other drugs)
Sympathectomy

TABLE 20-1. Medical treatments for complex regional pain syndrome

Corticosteroids

Pulse doses of corticosteroids (60 to 80 mg per day) for 2 weeks have been reported in a small uncontrolled case series to be beneficial in RSD patients (112). Two small single-blind trials of 10 and 17 early RSD subjects, within 2 to 3 months of injury, also reported clinical improvement after 4 or 12 weeks of oral corticosteroid treatment (159,160). None of these studies, however, reported long-term follow-up data. Clinical experience with corticosteroids in CRPS patients who have had symptoms for over 6 months is poor. Also, many patients report a return of their pain and symptoms after the corticosteroids are tapered. Chronic corticosteroid treatment is not recommended.

Gabapentin

Uncontrolled case series have described successful treatment of CRPS pain and other associated symptoms with titrating doses of gabapentin (161). No controlled clinical trial has been published to date. Clinical experience has been good with gabapentin, with approximately 30% of CRPS patients reporting noticeable pain and symptom relief and tolerable side effects (a good percentage for CRPS). The dose can be titrated to a maximum of 6,000 mg per day if needed. Because of gabapentin's excellent safety and side- effect profile, it should be prescribed early with aggressive titration.

Oral Sympatholytic Agents

Like the sympathetic blocks, oral sympatholytic agents theoretically should provide pain and symptom relief to CRPS patients with a component of SMP. No randomized prospective controlled study has assessed the efficacy of these agents, although case reports and case series have reported benefit from prazosin (162), phenoxybenzamine (163), and terazosin (164). Clinical experience has shown that these drugs are often poorly tolerated, resulting in orthostatic hypotension and depression, therefore limiting their clinic utility.

Clonidine

A small, uncontrolled study of transdermal clonidine reported that several RSD patients with a component of SMP obtained relief of allodynia only in the skin region directly under the transdermal patch (165). No controlled clinical trial or long-term prospective outcome study has been published assessing the efficacy of systemic clonidine. Clinical experience has been poor with systemic clonidine, although a rare patient may report significant relief without intolerable side effects (166,167).

A new formulation of topical clonidine gel with minimal systemic activity has been studied in an open-label pilot study. This uncontrolled study observed decreased allodynia and hyperalgesia in some CRPS patients (168).

Tricyclic Antidepressants

No study, controlled or uncontrolled, has assessed the efficacy of tricyclic antidepressant medication in CRPS. Clinical experience is poor, unlike its use for the treatment of other neuropathic pains. Most CRPS patients do not report substantial pain relief and many experience intolerable side effects. As with many other chronic pain states, tricyclics may be of benefit as a sleeping aid to many CRPS patients.

Calcium Channel Blockers

A small, uncontrolled case series reported improvement using the calcium channel blocker nifedipine (169). No randomized controlled trial has been performed using these agents. Clinical experience is poor for these agents, although rarely a CRPS patient reports significant relief.

Beta Blockers

A placebo-controlled trial did not show efficacy for propranolol (170), although relief was reported in case reports (171). Clinical experience is poor.

Calcitonin

Calcitonin has been shown to be of no benefit in two controlled studies, one with subcutaneous administration (172) and another via intranasal route (173) in early RSD, within 8 weeks of injury. One controlled study of intranasal calcitonin, however, demonstrated positive benefit in early RSD after 8 weeks of treatment (174). The clinical experience using intranasal calcitonin for the treatment of CRPS is limited, and no study has assessed efficacy in CRPS patients with a duration of symptoms longer than 2 months.

Local Anesthetic Antiarrhythmics

As mentioned, a potential mechanism of selective sympathetic ganglion block is systemic activity of local anesthetic (24,25). Intravenous lidocaine infusion has been shown in uncontrolled trials to produce transient reductions of pain in some patients with RSD and causalgia (175,176). Although the use of oral mexiletine has not been studied, clinical experience has shown it to be of potential benefit for some CRPS patients.

A new formulation of topical lidocaine patch was reported to produce clinically significant pain relief under the application site in several patients with RSD in an uncontrolled case series (177).

Opiates

As with the treatment of all neuropathic pains, the use of opiate medication in CRPS is controversial, with advocates (116) and detractors (100). Neither side has any solid controlled clinical trials supporting their claims. It is currently recommended that a trial of opiates should use time-contingent dosing, titrating the dose until the patient reports significant pain relief or intolerable side effects. Clinical experience is that most CRPS patients experience the latter and thus do not do well with opiates. However, some CRPS patients experience clinically meaningful pain reductions without significant side effects and thus report increased daily functioning on time-contingent opiates.

Implantable Devices

Over the 1990s, there has been a tremendous increase in the use of implantable devices, such as spinal cord stimulation and intrathecal opioid pumps, for the treatment of chronic pain, including CRPS. Here, too, controlled clinical data are lacking.

Neuroaugmentative Procedures

Spinal cord stimulation (178,179) and peripheral nerve stimulation (180) have been reported to produce pain and symptom relief in uncontrolled case series. A case series of 18 patients treated with spinal cord stimulation reported 4 patients failed the initial 1-week trial, 5 experienced moderate relief, 6 good relief, and 7 patients had technical problems with the hardware (181). A retrospective case series of 12 patients with RSD reported excellent pain relief in 8 and good results in 4, with an average follow-up of 41 months (178). Clinical experience is divided between those who strongly advocate spinal cord stimulation use in CRPS and others, whose poor experiences with these devices suggest limited utility.

Intrathecal Opioid Therapy

Once again, controlled clinical trial data are nonexistent. Most published reports describe patients with a variety of nonmalignant pain diagnoses, of which RSD may be a small group with moderate improvement (182,183). One small uncontrolled report discussed the outcome of three RSD patients, observing 50% to 70% pain relief in two of the patients at 1-year follow-up (184). At this time, intrathecal opioid therapy should be reserved for those who have had no success with other medical and nonmedical therapies.

Neurosurgical Therapies

Neuroablative Procedures

The response rate for surgical sympathectomy varies from 12% to 97%, depending on the series and duration of the follow-up period (185). Besides the inherent risks to surgery and neurolytic blocks, a return of the pain has been documented after sympathectomy in some patients within 6 to 12 months (186). One prospective study assessed the recurrence rate in 66 World War II veterans who underwent surgical sympathectomies for causalgia and reported that all 66 had resolution of the burning pain, 30 had good results maintained for 2 to 8 years, and 6 had good results for less than 2 years (187). A fairly common complication of lumbar sympathectomy is *postsympathectomy syndrome* in up to 44%, characterized by pain in the anterior thigh and thought to be caused by irritation or inflammation in the L-2 and L-3 nerve roots (188).

Because of the lack of good controlled data and of its invasiveness, ablation of sympathetic ganglia, chemical or surgical, should be considered only in patients who report transient pain and symptom relief with a series of different nonablative sympathetic procedures. Specifically, it is recommended a CRPS patient must report clinically meaningful relief of at least several days' duration after at least five sympathetic blocks, each with similar degrees of relief. Moreover, before considering sympathectomy, a CRPS patient should have experienced no success with nonsurgical approaches. Even in this small subset of CRPS patients who meet these criteria, long-term significant relief after appropriately performed surgical sympathectomy is by no means guaranteed.

CONCLUSIONS

Recommended Current Treatment

The key to treating CRPS is to validate the patient's symptoms and initiate a multidisciplinary treatment plan with the goal of functional restoration over months of therapy. The treating physician should be aggressive with medical therapies, systematically initiating different pharmacotherapeutic regimens if the patient continues to report significant pain and other CRPS symptoms. Psychological therapies, including stress management, supportive psychotherapy, and treatment of psychological comorbidities, should be initiated early and be an integral component of the multidisciplinary approach. Probably the most important component of the multidisciplinary treatment is active physiotherapy, which should include a slowly progressive active therapy program. It is imperative that the CRPS patient is cared for by a cohesive team that meets regularly to discuss the patient's progress and shares treatment philosophies and approaches.

Lastly, besides performing nerve blocks and prescribing medication (both activities that rarely significantly alleviate the CRPS patient's pain and suffering), all health care providers must provide the CRPS patient with all of the following: (a) a model for understanding their symptoms, (b) validation of their symptoms and suffering, (c) rewards for even the smallest functional improvement, and (d) a sense of optimism.

Recommendations for Future Clinical Research

As the field moves forward with the primary aim of improving the treatment of patients with CRPS, several recommendations for future treatment outcome studies can be made:

- Future clinical trials should be placebo controlled.
- If possible, a crossover design should be used because of the significant individual variability and the likelihood of subpopulations of CRPS patients with distinct pain mechanisms.
- Outcome measures should include the treatment's effect on the following: (a) various pain descriptors, such as with the Neuropathic Pain Scale (101), (b) various CRPS symptoms and signs, and (c) patient function.
- Post-hoc analyses should be performed to assess whether certain subpopulations of CRPS patients respond to the treatment, perhaps based on the presence of certain pain descriptors, symptoms, or signs, even if an overall treatment effect on CRPS was absent.
- Neuroimaging studies, such as positron emission tomographic and functional magnetic resonance imaging, should be performed, assessing baseline and treatment alterations in brain functioning of CRPS patients.
- Prospective studies should be done of acutely injured patients after surgery and soft tissue and nerve injuries to assess potential risk factors for the development of CRPS, including medical, psychological, and environmental variables.

CHAPTER 21

Pain after Amputation: Phantom Limb and Stump Pain

John D. Loeser

This chapter discusses the pathogenesis and management of two of the most vexatious forms of chronic pain: postamputation stump pain and phantom limb pain. Although clinical similarities exist between these pain syndromes and the pains that develop after spinal cord injury, brachial plexus avulsion, injuries to nerves in the extremities, and severe polyneuropathies, those conditions are discussed elsewhere in the book. It is also likely that the mechanisms that generate these pain syndromes are shared by all neuropathic pains.

Postamputation pain syndromes have also been described after the loss of other body parts, including the nose, tongue, breast, fingers, teeth, testes, penis, bladder, and anus (1,2,3,4 and 5). The incidence of these types of pain is unknown; however, there are few data for meaningful discussion. Although amputation of a breast is far more common than the loss of a limb, only a few reports discuss phantom breast sensations or pain. Mastectomy has been reported to lead to a phantom sensation in 22% to 64% of the women who have had this operation, and some women also report phantom pains (6). Most of these women do not report their symptoms to their physicians; the role of psychological and social factors is unclear. The lessons learned from the study of the loss of an extremity can be applied to some degree to these less well-described forms of phantom pain. A pain syndrome likely occurs in proportion to the amount of tissue loss and the number of axons that are destroyed.

Little has changed in the management of stump and phantom limb pain since 1953, when Bonica (7) summarized the situation in the first edition of this book:

> [T]his type of pain taxes the psychologic as well as the physical endurance of the patient and the therapeutic skill of the physician to the utmost. . . . Many of these patients go from one physician to another and from clinic to clinic seeking relief that, all too frequently, does not come. They undergo a succession of medical and surgical measures, each one tried with a great deal of hope and anticipation that it will be *the one* that will effect a cure, only to fail as miserably as the previous ones.

Phantom limb and stump pain was certainly recognized by Ambroise Paré (8) in the middle of the sixteenth century. Like so many of the physicians who have written on this type of pain, he obtained his experience as a military surgeon. In the 1870s, S. Weir Mitchell (1) emphasized the magnitude of suffering with this type of pain in his medical studies and literary essays based on his observations in the American Civil War. Apparently he was the first to use the term *phantom limb pain*. Every major war for the past 140 years has produced another set of articles on this topic. Yet, a survey by Sherman and Sherman (9) could not identify differences between civilian and military amputees. Since 1980, studies of the anatomic and physiologic changes associated with amputation neuromata and spinal cord changes after nerve injury have led to dramatic advances in our understanding of some of the potential mechanisms of these types of pain (see Chapter 3 and Chapter 4). The reader who wishes to obtain more clinical information is referred to major works by Cronholm (10), Solonen (11), Sunderland (12), Livingston (13), Sherman and Sherman (14), and Jensen et al. (15).

DEFINITIONS

Phantom Limb Sensation

Virtually all amputees describe phantom limb sensations (1,12,15,16,17 and 18). These are a variety of positive sensory phenomena, including the perception that the limb is still present, although usually foreshortened and often distorted in position. The phantom sensation is almost always more vivid in the distal extremity. With time, the phantom part may telescope into the stump. Paresthesias may be reported in the phantom. Many patients report the ability to cause the phantom to move by conscious thought. The phantom usually fades during the first year after amputation (12). The vast majority of patients who have phantom sensations do not have phantom limb pain (12).

Phantom Limb Pain

Phantom limb pain is a chronic pain perceived in the absent body part. It can be a minor problem or can totally consume the patient's life. The incidence of phantom limb pain is variably reported from 0% to virtually 100% (10,11 and 12,15,18). Such a wide range must imply differences in physician and patient labeling of pain.

Stump Pain

Stump pain is a chronic pain perceived in the region of the amputation; the pain is perceived to be located in existing body parts. The incidence of stump pain is between 10% and 25% (12,15,18). It may be diffuse or focal and is often associated by patients and physicians with palpable neuromata in the amputation site. However, all amputees have neuromata and not all have phantom or stump pain. A patient can have stump pain alone, or it can be associated with phantom limb sensations or phantom limb pain. It is critical that stump pain be recognized as distinct from phantom limb pain; treatment strategies for the two conditions are quite different. Whether they have any etiologic similarities is unknown.

PHANTOM LIMB PHENOMENA

Phantom limb sensation, which probably occurs in all amputees, is a vivid, highly articulated image of the lost part, and it contrasts with the poorly defined phantom sensations of the anesthetic body parts in paraplegics and quadriplegics. The vividness of phantom limb sensation in amputees suggests that the spinal segmental apparatus plays a role in the genesis of the phantom that characterizes the loss of a limb; when the spinal cord has been transected, a much vaguer image is created by the remaining more rostral neural structures (19).

Pathophysiology and Mechanisms

Phantom limb sensations can be created by caudal, spinal, or regional anesthesia (20,21,22 and 23). Occasionally, these phantom sensations are considered painful by the patient. Such immediate phantoms after local anesthetics must be caused by the abrupt cessation of peripheral nerve electrical activity. This hypothesis is confirmed by the observation that as soon as any sensation returns, the phantom disappears. Wall (24) suggested that C-fiber silence leads to phantom limb sensations, but the evidence for this is not conclusive. The study by Nyström and Hagbarth suggested that C fibers were active in patients with phantom limb pain (25).

Because many peripheral sensory nerves synapse in the dorsal horns of the appropriate spinal cord segments, it has been presumed that these second-order neurons play a key role in the genesis of phantom sensations. It must be remembered, however, that axons that form the dorsal columns only send collaterals to the segmental apparatus; their first synapse is in the medulla, raising the possibility that abnormal activity in the dorsal column nuclei could also play a role in phantom sensations (see Chapter 4). Kjerulf and Loeser (26) showed that forelimb deafferentation in the cat led to abnormal spontaneous and evoked activity in the lateral cuneate nucleus.

Although rapid changes in sensory fields of dorsal horn neurons have been described after dorsal rhizotomy or peripheral neurotomy, even these are not instantaneous (27,28). Clearly the segmental spinal mechanisms cannot be sufficient for the production of phantom sensations, because alterations in their output must reach higher centers to cause the patient to become aware of a phantom. Lesions occurring higher in the nervous system are well known to influence the presence or absence of phantom sensations (12,29,30 and 31).

Patients with phantom limb phenomena can develop radicular pains secondary to a herniated nucleus pulposus. When this occurs, the patient complains of low back pain that radiates into the stump and phantom, just as if the normal limb were present. Removing the disk alleviates the radicular pain but does not change the phantom itself (7,32). Cohen (33) has made another interesting observation on the referral of the pain of angina pectoris to an amputated left arm. The several patients who have manifested this phenomenon described pain typical of angina, clearly distinct from other phantom sensations or phantom limb pain.

Phantom limb sensations do not depend on the abnormal electrical activity generated in the neuroma. As described above, phantom sensations can follow local anesthesia in which there is not peripheral electrical activity. Mechanically stimulating the neuroma does not alter phantom sensations. Instead, it produces an electricity-like pain that radiates into the peripheral nerve distribution of the transected nerve (34). Blocking the nerves leading into the stump or their neuromata usually does not change phantom sensations either (25).

Clearly, the above observations include a paradox: Phantom sensations can be due to the loss of afferent input, but when some afferent input is reestablished by the development of electrical activity in the neuroma (which takes a few weeks in humans), the phantom sensations do not disappear. This strongly suggests the development of long-term central changes after deafferentation. Yet it is common for the phantom sensations to recede and eventually disappear over a year or more (10,12,35,36).

The vividness and, indeed, the presence of a phantom can be influenced by conscious and unconscious mechanisms. We do not know if the fading of the phantom is the result of changes at the spinal segmental level or in higher centers. Lesions in the spinal cord or brain that would be expected to render a body part anesthetic will abolish phantom sensations but do not often eliminate phantom limb pain. This is another clue that the same central processing systems that deal with normal sensory phenomena are involved in the perception of a phantom body part.

Congenitally absent limbs or those lost early in childhood seem to be less likely to lead to phantom phenomena, implying that the phantom depends on an intact body map in the cerebral hemispheres (37). On the other hand, Poeck (38) and Weinstein et al. (39) have described patients with limb aplasia and loss of limbs in infancy who did have typical phantom sensations. They also found a few other examples in the literature. Smith and Thompson have reported that phantom limb pain in children after amputation for extremity cancer was more common than after amputation for trauma and that chemotherapy increased the likelihood of developing phantom limb pain (40). More studies are needed to accurately determine what the likelihood of phantom phenomena and phantom limb pain is in aplastics or children who sustain early life limb loss.

Symptoms and Signs

If asked, almost all patients who lose a limb or major portion thereof report phantom sensations (10,35,36,41). The likelihood of developing phantom sensations after amputation seems to increase from infancy to approximately 8 years of age, at which point phantom sensations are virtually certain (37). Simmel (42), however, noted that lepers who gradually lost their distal extremities did not develop phantom sensations; when surgical amputation was performed for infection or major trauma, phantom sensations were reported. Price's (43) study suggested that lepers did have phantom phenomena; however, they were not associated with paresthesias and dysesthesias but were instead a sensation that the normal missing part was present. A similar phenomenon has been described in some patients with phantom limbs, but most patients describe active distortions of sensation and not just a feeling that a normal limb is present.

Although there have been a few contradictory reports, it does not appear that the development of a phantom sensation is related to the level of the amputation (whether the amputation involves the upper or lower extremity) or to the rapidity of loss of the extremity or the age of the patient past childhood. Phantom sensations are usually present immediately after amputation but may take a few weeks to develop.

Phantom limb experiences can be divided into three categories: kinesthetic (distortion of positional sensation), kinetic (sensation of movement), and exteroceptive (surface sensations such as pins and needles, buzzing, heat) (44). The patient describes a limb that has a position in space as well as definite length and volume. The limb may be movable, fixed, normal in posture, or distorted. The kinesthetic sensations often change over time; the phantom becomes less normal. Most phantom limbs have the sensation of movement. Exteroceptive sensations are common, but they are often diffuse. All sensory modalities have been reported, and they frequently fluctuate in nature and intensity. Some report that their phantom feels like a normal limb; others describe sensations of paresthesias, dysesthesias, and distorted positions (18).

Phantom sensations usually abate over time, but they can suddenly recur. Older amputees appear to have a more fixed phantom sensation; younger patients can voluntarily influence their sensations to a greater degree (45). Characteristically, the phantom limb “telescopes”; the proximal part of the limb disappears first. A patient may report that his or her hand is attached directly to the stump and that he or she has no sensation of the intervening arm or forearm. Because the perception of superficial tissue damage is one of the exteroceptive sensations, it is not clear that phantom limb pain is qualitatively different from other sensations such as heat, cold, pins and needles, or numbness. What differs may be the behavioral response of the patient to this sensory illusion. In conclusion, phantom experiences clearly depend on changes in the peripheral and central nervous system as well as affective, cognitive, and environmental factors.

Treatment

Phantom sensations, by definition not painful, can be frightening to the unprepared patient. Although there is no reasonable, effective treatment in the medical sense, there certainly is a need for patient counseling and education, which should begin before amputation whenever possible. Meeting an amputee who has successfully rehabilitated him- or herself can be helpful. Explaining to the patient that phantom sensations are normal and not a sign of mental illness is also important. As is true for any type of pain problem, the health care provider can be of great value to the patient by offering education, reassurance, and compassion.

STUMP PAIN

Many authors have not discriminated carefully between stump pain and phantom pain; this failure makes the literature confusing. Stump pain is ubiquitous immediately after amputation; this is simply postoperative pain and can be expected to disappear in a few weeks, as is true for pain after any major operation. Some amputees have stump pain that long outlasts healing time; the reported incidence varies from 13% to 71% (10,46). Some have averred that stump pain is more likely to occur if there has been pain before amputation, but this relationship is not supported by reports of all observers.

There appear to be two categories of stump pain: that due to local pathology and that due to the injury to peripheral nerves and the central nervous system responses to nerve injury. Careful examination of the stump; judicious use of imaging studies, bone scans, thermography, and plethysmography; and proper fitting of the prosthesis can help identify local pathology. As noted by Zborowski (47) and subsequent observers, environmental and cultural factors can also play a role in the

genesis of stump pain.

Etiology and Pathophysiology

There are several recognized causes of pain in an amputation stump: surgical trauma, ischemia, inflammation, skin infection or trauma, bone spurs, local scarring, ill-fitting prosthesis, neuromata, and central changes due to deafferentation (12). The pain of surgical amputation should not last more than a few weeks and almost always disappears as the wound heals. This pain is due to the activation of nociceptive nerve fibers of the A-d and C-fiber spectra.

The stump may have inadequate blood supply due to vascular disease proximal to the stump or to poor vascularization of the muscles and skin of the stump itself. Infection, either superficial or deep, can also lead to stump pain. Osteomyelitis is a frequent form of infection. Poor skin hygiene with pressure areas or ulceration can result from inadequate personal hygiene, marginal blood supply, or a poorly fitting prosthesis. A poorly trimmed bone can lead to pressure on innervated structures; new bone growth can also be a source of pain. All of these provoke nociceptive types of pain (peripheral mechanisms), and they do not necessarily involve any pathology intrinsic to the nervous system.

Stump pain often appears to be due to the presence of neuromata. All amputations result in neuromata not only of the major nerves but also of the smaller nerves in skin and deep structures. Because only a fraction of amputees develop stump pain, the presence of neuromata *per se* cannot be the cause of pain. When a neuroma is repeatedly traumatized by weight bearing or a prosthesis, however, it clearly can be one of the causes of stump pain. In a stump with extensive scarring, neuromata may be mechanically traumatized with any movement. The extreme sensitivity of the axon sprouts in a neuroma to mechanical or chemical stimuli is probably the basis for this type of pain (48). Changes in the dorsal root ganglia and the dorsal horn secondary to nerve injury and neuroma formation can also be contributors to stump pain (see Chapter 3).

There is also the possibility that autonomic nervous system abnormalities play a role in stump pain, even in the absence of local pathology. Some patients experience causalgic symptoms in their stumps, including burning, aching pain and vasomotor, pilomotor, and sudomotor abnormalities. Animal studies have shown ephaptic connections and sprouting axons ascending the proximal nerve stump that involve sympathetic postganglionic axons (49). Sympathetic fibers also grow onto the dorsal root ganglion cells after peripheral nerve injury (50).

Finally, there is a large group of patients who complain of stump pain in whom none of the above factors seems to be playing a role. Almost always, such patients have both phantom limb pain and stump pain. In such patients it is possible that spinal cord or more rostral neural structures are the sites for the genesis of the pain.

In summary, stump pains are varyingly present after healing of the amputation site. They are of diverse etiology and vary widely in their sensory and temporal characteristics (12). Any or all of the mechanisms that underlie neuropathic pain states may be operative in the patient with stump pain (see Chapter 3 and Phantom Limb Pain, below).

Symptoms and Signs

Stump pains may be continuous or intermittent, focal or diffuse. They may be triggered by stimulation of the stump or by emotional stress. The pain can be described as cramping, burning, shooting, hot, cold, aching, or any combination of these. Many patients have movements of the stump in association with their pain. Myoclonic jerks and chronic contractions of agonists and antagonists are seen. Some patients have clear-cut attacks of pain with pain-free intervals. Patients with severe stump pain often also have phantom limb pain and vice versa.

Treatment

As mentioned earlier in this chapter, stump pain can be associated with pathology in the stump itself. Although this does not appear to be the common cause of this complaint, it happens frequently enough to mandate that a painful stump be carefully examined. The presence of a skin lesion, bone spur, osteomyelitis, deep abscess, or circulatory insufficiency requires appropriate medical or surgical therapy. Revision of the stump has had its proponents, but in the absence of demonstrable pathology most experts would doubt the wisdom of this procedure (12,51,52).

Stump pain can be due to a poorly fitted prosthesis. Therefore, careful evaluation of the stump and the prosthesis by an expert prosthetist is always warranted. If the pain is believed to be due to a neuroma, management becomes more complex. Obviously, prevention of a painful neuroma is highly desirable; many have reported surgical strategies that they believe reduce the rate of painful neuromata (53,54). Whether encapsulation of the cut nerve, fascicle ligation, or self-implantation of the nerve reduces the incidence of painful neuromata and stump pain is unknown. In his review of the U.S. Army experience in World War II, White (55) listed several procedures that should never be undertaken to relieve stump pain: repeated resections of neuromata, neurectomies at higher levels, reamputation for pain relief, periarterial sympathectomy, intrathecal alcohol, and dorsal rhizotomy. He believed that the following procedures were useful: single resection of a painful neuroma, sympathectomy, and anterolateral cordotomy. He emphasized that the first two procedures should only be carried out when relief of the stump pain occurs with appropriate prognostic nerve blocks. My observations suggest that only patients with allodynia or dysesthetic stump pain respond to sympathectomy— that is, only when the pain resembles complex regional pain syndrome type I does it respond to sympathectomy. The likelihood that a cordotomy will provide pain relief for more than 2 years appears to be small (see Chapter 106).

Finding other reports that separately consider stump pain and its management is difficult. Clearly, many of the remedies discussed under Phantom Limb Pain have also been used for stump pain; there are not sufficient data to discuss these independently. Some aspects of the management of stump pain are therefore contained in the following section, Phantom Limb Pain.

PHANTOM LIMB PAIN

Epidemiology

The incidence of phantom limb is not known precisely; reports vary from 2% to 97% of patients who have undergone limb amputation (11,12,14,44,50,56,57,58,59 and 60). It is clear that the patient and the observer may vary in what they consider to be a significant amount of pain and where they localize it. All that can be said about incidence is that phantom limb pain is a well-recognized problem in a fraction of the amputees. Surveys with more reliable methodology suggest a prevalence of phantom limb pain of approximately 70% that is stable over many years (Table 21-1).

Time since amputation	Prevalence of phantom limb pain	Primary author
8 days	72%	Jensen (1983)
16 wk	59%	Pohjolainen (1991)
6 mo	67%	Jensen (1983)
1 yr	53%	Pohjolainen (1991)
2 yr	59%	Jensen (1985)
5 yr	73%	Steinbach (1982)

TABLE 21-1. Prevalence of phantom limb pain

Etiology

The role of preamputation pain in the genesis of phantom limb pain is unclear. Some have suggested that pain before amputation increases the likelihood of severe phantom limb pain (1,10,44,61,62,63 and 64). Others have not found this association (14,35,65). Whether “preemptive analgesia” reduces the likelihood of phantom limb pain is uncertain, in my opinion (66,67). Many patients report that their phantom sensations and phantom limb pain are similar to the position of the limb and the sites of pain immediately before amputation, yet a study of patients whose amputations were performed for extremity cancer (65) indicated that most patients' phantom limb pains were unrelated to preamputation pain.

The relationships of the level of amputation and the reason for amputation to the presence of phantom pain are unclear. Use of a prosthesis and lower age at amputation appear to be correlated with a lower incidence of phantom limb pain (56). The extensive survey by Sherman and Sherman (14) failed to note any correlation between preinjury factors and incidence of phantom limb pain. In summary, there is conflicting evidence on the relationships between preamputation factors and phantom limb pain. Moreover, little evidence exists to support the allegation that postamputation factors play a major role in the genesis or perpetuation of phantom limb pain.

It is unclear whether phantom limb pain is part of a continuum that begins with the phantom limb sensations or is a distinct phenomenon with its own neural substrate. Some patients report that their phantom limb pain began at the time of amputation, and others state that the pain developed weeks, months, or even years later.

Pathophysiology and Mechanisms

The hypotheses for the pathophysiology of phantom limb pain can be divided into four categories: (a) peripheral (i.e., due to loss of peripheral nerve activity or development of abnormal activity in the neuroma or dorsal root ganglion cells), (b) spinal segmental (i.e., deafferentation effects), (c) central (i.e., due to changes in thalamus and cerebral cortex), and (d) psychological (implying that mental processes led to the patient's symptoms) (17,68,69).

In the patient who develops phantom limb pain immediately after amputation, the sudden absence of nerve signals from the periphery may trigger changes in the spinal cord or even more rostral structures that lead to the report of pain (24). Another possibility is that a massive discharge of axons at the time of injury or amputation leads to central changes that generate the report of pain (excitatory amino acid toxicity) (see Chapter 3). This explanation has led to the concept of *preemptive analgesia*: dense local anesthetic blockade of the plexus leading to the limb before amputation. Conflicting evidence as to the efficacy of this approach has been published (66,67). Whether preemptive analgesia is effective is impossible to determine on the basis of the published articles; additional clinical trials are required to resolve this debate.

Peripheral Factors

Because the development of phantom limb pain can be delayed and the nature of the abnormal sensations can vary, multiple etiologies must be considered. Animal studies have indicated potential peripheral factors in the genesis of pain that include the following: (a) ephaptic connections, (b) spontaneous activity in the neuroma or in dorsal root ganglion cells whose axons are involved in the neuroma, (c) abnormal sensitivity to mechanical and chemical stimuli in the neuroma, (d) alterations in conduction velocities in damaged nerves, and (e) reflex changes in sympathetic activity (24,49,69,70).

The microneurographic studies of two patients with phantom limb pain by Nyström and Hagbarth (25) clearly showed that spontaneous C-fiber axonal activity could be recorded in transected nerves. Local anesthetic applied to the stump neuroma stopped both the evoked electrical activity and the stump pain reported by the patient when the neuroma was mechanically stimulated, but neither the phantom limb pain nor the spontaneous electrical activity in the nerve was altered by the neuroma blockade. These results imply that the phantom limb pain and some of the activity in the peripheral nerve are generated proximally to the neuroma, either in the dorsal root ganglion, dorsal horn, or more rostral structures.

Dorsal Horn Changes

Changes in the segmental dorsal horn afferentation have also been postulated to be a factor in phantom limb pain. On the basis of clinical observations, Howe (71) proposed that nerve transection leads to the loss of high-threshold input to dorsal horn neurons; new connections are made by low-threshold afferents. This hypothesis would account for the patient's reporting that nonnoxious stimulation of other regions of the body could trigger phantom limb pain. Many years earlier, Haber (72) noted that the skin of an amputation stump was much more sensitive to a wide range of stimuli than the homologous region on the opposite extremity. These observations certainly strengthen the arguments for changes in the dorsal horn connections as key factors in phantom limb and, perhaps, stump pain.

Many observations attest to the role of the stump and its neuromata in the genesis of phantom limb pain (12,24). It has been argued (without much evidence) that special treatments of the transected nerves in the amputation stump reduce the likelihood of phantom limb pain (73). Sensory and autonomic abnormalities are often described in the stumps of patients with phantom limb pain. Local and regional anesthetics and resection of the neuromata usually result in the temporary cessation of phantom limb pain (7,74). Mechanical stimulation or deformation of the stump often alters the pain (1). The fact that *N*-methyl-d-aspartate receptor blockade can relieve phantom pain suggests central sensitization by the peripheral nerve injury (75).

Central Factors

Other observations emphasize the importance of central nervous system factors in the genesis of phantom limb pain. Phantom pain can be present without stump pain or any evidence of disease in the stump or painful neuromata. Often neither section of the dorsal roots nor cordotomy relieves phantom limb pain. The pain often develops immediately after the amputation, before the development of neuromata that could lead to peripheral nerve abnormal activity. Stimulation of a stump neuroma does not activate phantom limb pain (34,35). Surgical repair of a stump usually does not alter phantom limb pain. The phantom sensations and pain can be influenced by affective factors and sensory changes in other parts of the body.

Spinal anesthesia can unmask phantom limb pain at a time when the patient does not have any complaints of phantom limb pain before the administration of spinal or epidural local anesthetic (7,76). The phantom pain persists only as long as the complete loss of proprioception and movement. Such observations imply that the spinal segmental input to rostral structures plays an important role in the sensations that the patient reports. Clear-cut evidence of cortical reorganization suggests that phantom limb pain can be the result of sensory cortex neuronal field changes (77,78).

On the basis of these and other clinical and experimental observations, it appears that both peripheral and central factors play a role in phantom limb pain. We do not know why some individuals become chronic pain patients after amputation and others do not. Certainly, a phenomenon that occurs in a fraction of the amputees cannot be blamed solely on the anatomic injury. Perhaps there are genetic predisposing factors that will be difficult to elucidate in humans. In the dorsal horn and in thalamus and cerebral cortex, there is good evidence that reorganization of sensory fields occurs after amputation; how these changes are related to the genesis of pain remains unclear.

Psychological and Emotional Factors

The psychological aspects of phantom limb pain have been the object of much speculation. Some have argued that this is a psychosomatic disease (79,80 and 81). Bailey and Moersch (61) reviewed 55 cases from the Mayo Clinic and concluded that no physiologic explanation for this type of pain could be discerned. They proposed that phantom limb pain was a “psychic” disease. Certainly, the absence of understanding of physiology does not establish the diagnosis of psychopathology.

Others have noted that stress and emotional factors can aggravate the pain (82). Almagor et al. (83) showed that double amputees were more likely to have phantom limb pain in their dominant extremity, but that the patient's response to his limb loss did not seem to influence the incidence of phantom limb pain. Parkes and Napier (82) described characteristic psychosocial factors: rigid, self-reliant to a fault, unemployed. These individuals were more likely to have significant pain complaints. The psychiatric literature is cluttered with theoretical explanations that cannot be verified by any rational means (79,84): “[T]he phantom, like the dream, is a product of unconscious wishes or drives.” Patients who complain of phantom limb pain are more depressed, have more complaints of other types of pain, and have more interpersonal problems than amputees who do not have phantom pain (85,86 and 87). Genetic factors could also play a role.

The emotional status of an amputee is clearly a function of the setting in which the amputation has occurred and the patient's personality and social environment. The study by Shukla et al. (88) indicated that two-thirds of an unselected group of civilian amputees had significant psychiatric symptoms in the first few months after

amputation. There are very few data on the correlation between early psychiatric symptoms and the persistence of phantom limb pain. Gallinek (89) argued that the hallucinations of psychotics were distinct from the phantom phenomena seen in amputees, although there is no reason to suggest that the mechanisms underlying these two phenomena have any commonality.

Obviously the brain is the organ of behavior, and emotional factors are due to electrochemical events in higher centers. We are so far from understanding these complex cognitive and emotional behaviors that their explanation is couched in a nonphysiologic language. This situation often leads the reader to believe that psychological processes are somehow not the result of electrical and chemical activities in the brain. The evidence for downstream modulation of afferent processing is strong; this is not unique to the problems of the genesis of phantom limb pain.

Cognitive Factors

One explanation for phantom sensations and phantom limb pain is based on cognitive processes. Ewalt et al. (90) wrote that “phantom pain occurs in those individuals who are having phantom sensations but who, by reasons of psychopathology, interpret the phantom sensations as being unpleasant and painful.” It is well known that the human develops a complex set of maps for both internal and external space. The body image appears to depend on the sensory and motor experiences from each region. When afferent information is suddenly distorted, a mismatch between the central map and afferent signals occurs. How the patient labels this phenomenon may determine whether the patient describes phantom sensations or phantom limb pain. It may not be a difference in the peripheral nerve activity or in the dorsal horn response to deafferentation that determines whether the patient has pain. The critical factor may be the labeling of the abnormal sensory experience. This, in turn, can be based on experience, personality type, genetic factors, age, and innumerable other unknown factors.

Amputation in Animals

It is worthwhile to consider the effects of nerve transection in other mammals. In some species, the animal attacks the denervated part; Wall and his associates (91) have labeled this *autotomy* and believe that it is a model for anesthesia dolorosa. No good evidence exists, however, that the animal is in pain. Different species are more or less likely to manifest the phenomenon. Even within one species, the genetic strain is a major determinant of autotomy (92). The histology and physiology do not appear to differ in animals with and without autotomy. By analogy, no evidence exists to support the concept that events at the neuroma or in the spinal cord differ in patients with and without phantom limb or phantom sensations. It seems more likely that preexisting differences in cognitive and affective information processing play a critical role in the genesis and maintenance of these pain syndromes.

Age

A final factor that seems critical is the age of the patient at the time of amputation. Phantom limb pain is rare in young children and becomes more common as the patient ages (10,37,49). This correlation suggests that plasticity of the nervous system is one of the factors that work against the development of a pain syndrome.

At this time, it is not possible to generate a unitary hypothesis for the pathogenesis of phantom limb pain. Clearly, necessary peripheral events exist, and there must be alterations in the spinal cord and brain function. Whether affective and cognitive factors are in response to the peripheral events or are themselves capable of modifying segmental information processing is unclear.

Symptoms and Signs

In most patients, phantom limb pain begins shortly after amputation; there are a few reports of onset months or even years later (1,61,73). Some of the patients who have phantom limb pain experience spontaneous remission in their symptoms, most often in the first year after the onset of their pain (7,11). Most of the pain is usually reported to be in the distal part of the extremity, usually in the foot or hand, particularly in the instep, heel, toes, fingertips, knuckles, palms, or wrists. Some patients report that the phantom extremity is distorted in a way that would be painful for an intact limb.

Characteristics of the Pain

All types of painful sensations have been reported. The pains can be continuous or intermittent and may occur randomly in severe attacks.

The intensity of the pain varies dramatically between patients. For some, it is only an annoyance; for others, it is almost unbearable and totally disrupts all productive activities and interferes with rest, sleep, and social relationships. Most patients freely admit that attention, emotional states, experiences, and other factors influence the amount of pain they experience. Severe pain is usually associated with paresthesias.

The quality of the pain also varies greatly: It has been described as burning, cramping, aching, gnawing, crushing, pulling, stabbing, or shooting. Approximately one-fourth of patients experience predominantly a burning, aching, throbbing pain, not unlike that of causalgia, which they describe is as if the hand or foot were held too close to a fire. This group may respond to sympathetic blockade. Approximately one-third of patients complain primarily of pain associated with an extremely abnormal position of the phantom limb. The hand or foot may be felt to be in a painful twisted, cramped, rigid, or flexed posture, from which the patient is unable to release it. In many of these patients, the fingers and thumb are tightly flexed, with the nails cutting into the palm. Occasionally, the digits or the hand, or both, or foot are felt to be twisted out of shape. When such sensations are present, patients find it difficult or impossible to change the posture of the malpositioned part. Some patients feel as if the nails of the fingers or toes are being pulled off or lifted from their nail beds. Others experience the feeling of the presence of a tight, wirelike band around the phantom limb that gradually gets tighter or that the phantom limb is being squeezed in a vice.

Careful questioning frequently reveals that the patient also experiences bizarre sensations that he or she is often reticent to discuss, lest someone label him or her insane. There is no information on the relationship between the type of sensation reported and the reason for amputation or any other potentially significant factors.

Numerous factors may aggravate the pain, including fatigue, sleeplessness, persistent worry, and even apprehension from knowing that the stump is going to be examined. The pain may also be aggravated by cooling or warming the stump, or even allowing it to hang. Sometimes such actions as yawning, micturition, or defecation temporarily exacerbate the pain. In contrast to the preservation of more or less free movement in painless phantoms, the presence of pain renders voluntary movement difficult, if not impossible. In some patients, wearing a prosthesis causes the phantom limb to elongate temporarily, and this sensation is associated with aggravation of the phantom pain.

The duration of phantom limb pains is unpredictable. In a few patients, they are transitory and recede in months. In others, the pain disappears after a year or so. The majority of patients seem to have pain that persists for a decade or more. Many patients report a constant background pain but also have superimposed major exacerbations of pain that may have a totally different character. Palpation of the stump or pathology in the stump, such as infection, may increase phantom limb pain in some patients. Patients may experience referral of pain into a phantom limb from stimulation elsewhere in the body or, for example, into a phantom arm from angina pectoris. Manipulation of a neuroma may change phantom limb sensations, including pain.

Treatment

The treatments of phantom limb and stump pain are myriad (Table 21-2), but good data for the efficacy of any method are lacking. Therefore, all I can do is to review the published treatments and summary articles and add some comments based on personal experience (12,30,51). One of the reasons for the apparent poor results of any published treatment is the failure to recognize that individuals may, on rare occasion, have a good result, yet the general population has a poor chance of success. Hence, it may be that one in 10 chronic stump or phantom limb pain patients is relieved by a particular medicine or surgical procedure. From that patient's viewpoint, the treatment was successful. Physicians and financial sponsors may be loath to advocate a treatment with so low a success rate; the informed patient should have the right to choose such a procedure. Obviously, such a predicament requires that the physician begin with the least hazardous treatment strategies. Because many papers do not discriminate between stump and phantom limb pain, analysis of possible outcomes is quite difficult. The review by Sherman (51) provides the best modern overview of this topic. Other large series attest to the low success rates of any single form of treatment (11). Sherman also alleges that the type of phantom limb pain mirrors changes in the stump skin and muscle and that therapies tailored to the pain description and physical examination have superior outcomes (93).

TABLE 21-2. Reported treatments for postamputation pain

Pharmacologic Therapies

Nonnarcotic Analgesics. Nonnarcotic analgesics are, of course, the most commonly used medications for any type of chronic pain. There is no evidence for their specificity in phantom limb pain; to the extent that they help a patient without side effects, they can be freely used (94).

Narcotic Analgesics. No studies have been published on the role of narcotics in phantom limb pain, but most of the physicians who deal with phantom limb pain and other deafferentation pain syndromes agree that it is a rare patient who can control this type of pain with narcotics. The usual picture is of increasing dosage and dependence on the drug, with poorer and poorer pain control, and increasing depression and disability. Nevertheless, there may be a small number of amputees whose phantom limb pain is best ameliorated by narcotics and who can maintain themselves without escalation of the dose. If a patient manifests more than just a verbal response to narcotics and actually increases his or her functional activities, it may be worth a cautious trial with oral narcotics. When activity levels decrease and drug intake increases, it is time to withdraw the patient from narcotics. This is the usual outcome when this class of drugs is used for deafferentation pain. The newer partial agonists do not seem to be any more effective than pure opioid agonists.

When oral or transcutaneous opioids fail, a trial of intrathecal or epidural opioids may be useful. If good short-term response is seen, an implanted catheter and pump may be effective (see Chapter 103). However, this is an expensive technology with frequent complications, and the criteria for selection of patients are not yet well established (95). There is no question, however, that some patients can get excellent pain relief with this method of opioid delivery. A large fraction of the patients requires additional intrathecal drugs to get adequate pain relief, such as clonidine or bupivacaine. These medications do not have Federal Food and Drug approval for intrathecal use at this time.

Other Medications. A few reports exist on the efficacy of anticonvulsants in the management of phantom limb pain (96,97). Carbamazepine is the most commonly used drug; others have included phenytoin, valproate, mephenytoin (Mesantoin), gabapentin, and lamotrigine. None of the reports has involved controlled studies.

Antidepressants have been used, but no good data are available attesting to their efficacy in phantom limb pain (98). They seem to be useful in many types of neuropathic pain and are the first class of drugs to try in a patient with phantom limb or stump pain. Personal anecdotes and unsubstantiated series attest to the efficacy of phenothiazines (99,100).

Propranolol, a beta-blocker, has been used in doses of 40 mg per day, with dramatic responses in a small number of patients (101,102). In contrast, Scadding et al. (103) reported poor results with this drug.

Mexiletine, an absorbable local anesthetic, has been reported as useful in patients with phantom limb pain, either alone or in conjunction with propranolol (104).

Calcitonin was found to be effective in a double-blind controlled study by Jaeger and Maier (105); there are few other reports on the use of this drug.

Sedatives and hypnotics have no role in the treatment of phantom limb pain, because they are not only ineffective in relieving it, but they also tend to be habit-forming and increase depression. Moreover, long-term use does not improve sleep disturbances that may be ascribed to the pain.

Other medications that have been the subject of sporadic reports include vitamins and a wide variety of herbs, nostrums, and chemicals that can be ingested or applied to the painful stump. There is no reason to believe that they are in any way effective.

Local and Regional Anesthesia

In the first edition of this book, Bonica (7) reviewed the extensive literature published up to 1953 and his personal experience in the use of regional analgesia for the management of patients with postamputation stump pain, phantom limb pain, or both. Although there have been few recent reports on the use of this method in the treatment for phantom limb and stump pain (51), Bonica believed it had a definite role in the management of these patients. The most important use is for diagnostic and prognostic purposes, although it may also be useful in a small percentage of patients as a therapeutic method (see Chapter 102).

Diagnostic and Prognostic Blocks. Nerve blocks may be valuable as a diagnostic tool to identify candidates for specific surgical procedures. For example, patients with a burning, throbbing pain in the phantom limb or in the stump frequently respond to block of the regional sympathetic nerve supply to the involved limb with a local anesthetic. Such patients may get a good long-term result from sympathectomy when a series of blocks provide complete but only temporary relief. In this regard, it is essential to ascertain that sympathetic interruption to the limb is complete. Bonica cited a number of patients who had undergone surgical sympathectomy with only partial or no relief of burning pain in the phantom limb, but who derived complete relief of pain with a local anesthetic sympathetic block (7). The obvious reason for the discrepancy is that the solution diffuses to include anomalous pathways, whereas the surgery removes the sympathetic chain and may omit such anomalous sympathetic nerves, which continue to provide sympathetic function to the limb. In addition, surgeons may not resect enough ganglia to completely denervate the extremity (see Chapter 105).

Paravertebral somatic nerve block can also be used as a diagnostic tool in the occasional patient who develops symptoms of radiculopathy in the phantom limb consequent to herniation of the intervertebral disk or other pathologic changes. Properly executed, such a procedure helps to ascertain the level of the nerve root or full nerve implicated in the pathophysiologic process. Another technique that has been advocated as part of the comprehensive evaluation of patients with postamputation pain is differential spinal (subarachnoid) block. The evidence that this procedure is of any value is sparse. The indications for these techniques and the advantages and limitations of these procedures are discussed in Chapter 102.

Therapeutic Blocks. Indications for therapeutic nerve blocks are few because, as for most other methods, long-term benefits appear to be infrequent. However, some patients derive long-term relief from repeated nerve blocks. Bonica cited the extensive experience of Leriche, Livingston, and a number of other investigators, as well as his own personal experience in the use of a series of sympathetic blockades in patients who experienced burning, aching pain in the phantom limb or the stump or both (7). It deserves reemphasis that, to achieve effective sympathetic denervation of the upper limb, it is necessary for the local anesthetic to diffuse extensively and block the middle cervical to the third or fourth thoracic ganglion inclusive. For the lower limb, it is essential to block the lowest two thoracic ganglia, as well as the lumbar sympathetic chain. In patients who derive complete but only temporary relief from blocks with local anesthetics and whose physical condition is too poor to tolerate a major neurosurgical operation, Bonica suggested chemical sympathectomy with phenol or alcohol. This procedure requires extensive experience and extreme care to avoid serious complications.

Infiltration of local anesthetics is sometimes effective in relieving the pain and associated phenomena for varying periods of time. Occasionally, trigger points are found in patients with stump pain and in patients with phantom limb pain who develop musculoskeletal disorders consequent to amputation (see Chapter 29). Gross (106) claimed that local anesthetics injected into trigger areas of the contralateral limb at the site of reported phantom limb pain provided long-term relief after several treatments, but no confirmative reports have been published. Bonica stated that intravenous infusion of procaine was effective in some patients (7). It is possible that

the systemic absorption of local anesthetics reduced ectopic firing in damaged nerves without altering nerve conduction.

Physical Methods

Acupuncture. A few anecdotal reports of successful treatment of phantom limb and stump pain with acupuncture can be found in the literature (107). I am dubious of the long-term efficacy of this method for phantom limb or stump pain.

Percussion or Vibration of the Stump. In 1947, Russell and Spalding (108) claimed that repeated percussion of the stump with a small hammer alleviated phantom limb and stump pain in most amputees. Since then, sporadic reports have included mention of either failure or success of this method (109). It is not commonly used today, perhaps because it seems to be low technology in a high-technology era of medicine. Several authors have claimed that vibration of the stump is effective in treating stump and phantom limb pain (110,111).

Other Physical Methods. Application of external heat or cold, internal heating by ultrasound, massage, manipulation of the stump, and adjustment of the prosthesis all have been claimed to be effective in some patients (109). Data are sparse; these treatments have few complications.

Psychological Strategies

Explanation and Reassurance. Little question exists that phantom sensations, phantom limb pain, and stump pain are not only uncomfortable but also may be inexplicable for the patient. One of the physician's primary roles is to educate the patient about the meaning and significance of his or her symptoms. When possible, this education should begin before amputation. The patient should be told that phantom sensations are ubiquitous and are not a sign of mental illness or complication of amputation. The expected course of acute postsurgical stump pain and the initial steps for the fitting of a prosthesis should be discussed in detail. If chronic stump pain or phantom limb pain occurs, the patient must be given the support and encouragement of a concerned physician who will work with the patient to ameliorate the symptoms. It repeatedly amazes me how many patients with phantom limb pain are referred to our pain center with many years of suffering, never having had a reasonable explanation of the causes of their pain syndrome.

Hypnosis. Hypnosis has been reported to be successful in a small number of patients (51). For this approach to be cost-effective, the patient must be able to learn self-hypnosis. I have encountered a few patients who found this strategy helpful.

Psychotherapy. Patients who have lost a limb are not immune to preexisting or subsequent psychiatric illness. Various forms of psychotherapy can be helpful for such cases. Kolb (79) expressed the viewpoint that phantom limb pain was itself a psychiatric illness and could be treated by psychotherapy. Others have reported successes and failures (51). An association between depression and chronic pain of any type exists; to the extent that a patient with phantom limb pain is depressed, psychotherapy may be valuable. Little question exists that some patients benefit from psychotherapy, but it does not appear to be a form of treatment with high specificity for phantom limb or stump pain.

Cognitive-behavioral Therapy. Cognitive-behavioral therapy has been shown to be effective for chronic pain when the patient's complaints are under environmental control, are related to disuse or deconditioning, and are not due to tissue damage or injury to the nervous system (see Chapter 88 and Chapter 89). A patient with stump or phantom limb pain is not usually a candidate for this type of treatment, but the occasional patient may have complaints and pain behaviors that can be ameliorated by such a treatment strategy.

Biofeedback. Some have reported on the efficacy of electromyographic or electroencephalographic biofeedback of phantom limb pain (51,112). Biofeedback does not appear to be widely used for this type of pain, and data are sparse.

Relaxation Training. Sherman et al. (113) reported on the efficacy of relaxation training in the management of phantom limb pain. Twelve of 14 patients benefited, with follow-up periods of 6 months to 3 years. This method has widespread usage for other types of chronic pain and may be valuable for stump pain and phantom limb pain as well.

Vocational Counseling. Patients who have lost a limb require extensive rehabilitative services to return to as normal as possible a lifestyle. Vocational assessment, counseling, and training are essential for every amputee and reduce the extent of disability. Amputees who complain of stump or phantom pain must have vocational counseling as part of their overall management. It is generally true that people who have something better to do do not hurt as much.

Surgical Therapies

Few published reviews exist of surgical therapies for phantom limb and stump pain. Perhaps the best is by Siegfried and Cetinalp in 1981 (114). White and Sweet (30) have discussed their experiences, and Sherman (51) has published his survey, which indicates that few patients admit to success from any surgical procedure. Falconer (115) provided a good review. There are no good prospective or controlled studies; the follow-up periods are often short or unspecified. This does not distinguish the surgical reports from those involving other methods, but the additional risks and costs of surgery seem to mandate that better data be obtained to justify extensive use of surgical procedures.

Revision of Stump. Stump revision is a useless procedure for phantom limb pain, but it may be indicated in selected patients with stump pain. The indications for this operation are few, and the most likely origin of the need for this procedure is an improper amputation in the first place (116). Only when the patient's complaint of pain can be reasonably ascribed to a pathologic process in the stump is revision warranted. When a stump revision is done solely to treat pain without any sign of disease in the stump, it is almost certain to fail. Baumgartner and Riniker (117) reported excellent pain relief in 87% of 172 stump revisions in 100 patients. Eighty percent of these patients had a diagnosable lesion in their stumps, and this type of patient had the best outcome. The duration of follow-up was not given.

Another long-standing debate exists as to the efficacy of special treatment of the nerves at the time of amputation or stump revision in the prevention of stump or phantom limb pain (44,51,53,54,118). There is agreement that the nerve should be transected at the time of amputation so that the neuroma will lie in healthy muscle in a non–weight-bearing area. Beyond this, there is no consensus. Each surgeon claims that his or her strategy reduces the pain problems seen with everyone else's amputations.

Neuroma resection is warranted only when the patient's symptoms are due to mechanical pressure on the neuroma. This operation never alleviates phantom limb pain but may, in the specific case mentioned above, provide symptomatic relief of stump pain. A neuroma always forms at the proximal end of the transected nerve; it is typical for pain relief to last the 3 weeks that it takes for new growth cones to develop at the transection site (12,51). Reports of pain relief exist in the literature, and I have seen patients who have reported pain relief after neuroma resection, but this is a rare outcome. The history of failure to get pain relief with one or more prior neuroma resections should be an absolute contraindication to another attempt with this procedure.

Dorsal rhizotomy is not often effective for the relief of phantom limb or stump pain (30,44,51). Chapter 106 reviews this operation and discusses the potential reasons for its high failure rate. Whether the addition of ganglionectomy and the use of the operating microscope to guarantee complete root section would improve success rates is unknown. There are no contemporary reports on this operation for phantom limb or stump pain.

Dorsal Root Entry Zone Lesions. This operation has been performed for two decades, and the reported series are small (see Chapter 106). In approximately 24 patients, the success rate is approximately 50% (114,119). How to select patients to improve the chances of success is unclear. On the basis of preliminary data, this operation has some chance of alleviating stump or phantom pain and is probably a wiser choice than any other ablative procedure.

Dorsal Column Tractotomy. Dorsal column tractotomy was described by Pool (120) in 1946; a subsequent report by Browder and Gallagher (121) in 1948 brought the total number of cases to nine. Good results were described with very short follow-up periods. It is not known whether this procedure, which interrupts the dorsal columns, would be more effective than anterolateral cordotomy for patients who describe phantom limb pain in which distortion of the body part is a major component. This operation has not been reported in the past 50 years. Whether it ever received an adequate trial is unknown.

Anterolateral Cordotomy. Anterolateral cordotomy has gotten mixed reviews for both phantom limb and stump pain. It does not appear to be very effective for the burning, dysesthetic types of pain. Reports by White and Sweet (30), Falconer (115), Falconer and Lindsay (122), Rousseaux and Lepoire (123), and others suggest

that approximately half of the patients get good results, at least in the first year or so. Cordotomy is discussed in detail in Chapter 106.

Sympathectomy. For patients who complain of a burning or dysesthetic stump pain or phantom limb pain, sympathectomy may be effective (see Chapter 105). It is essential that a favorable response to sympathetic blockade be demonstrated before a surgical procedure is contemplated. Only when repeated blocks yield temporary but not permanent relief is surgery warranted. The report by Echlin (124) demonstrated that, after transection of the lumbar sympathetic chain, stimulation of the distal segment did not produce pain, but stimulation of the proximal segment reproduced the patient's phantom pain. The sympathectomy relieved the phantom pain for the duration of the 3-month follow-up. Others have reported varying degrees of success, but there are many late failures (31,51,125,126). The literature and our experience at the University of Washington Pain Center suggest that sympathectomy is likely to be effective only when the patient's symptoms are similar to those of causalgia. Long-term success is much less likely than immediate good results (31,44).

Thalamotomy. Stereotaxic lesions in various portions of the nonspecific thalamus and subthalamus and mesencephalon have been used in the treatment of phantom limb pain (114). Short-term results suggest a 20% success rate, but long-term follow-up of patients who have had these lesions indicates an even lower success rate (51). They probably are not a wise choice in the management of stump or phantom limb pain (see Chapter 108).

Cortical Resection. First reported by de Gutierrez-Mahoney in 1944 (127), cortical resection has been extensively discussed and occasionally performed. The extent of postcentral gyrus resection is often not detailed, and the results are therefore difficult to compare. There is some evidence to suggest that the better results are obtained with excisions that include the secondary sensory area as well as the primary area. In a survey of all the reported cases before 1969, White and Sweet (30) found that 4 of 23 patients had good pain relief after resection of the postcentral gyrus. I cannot find any more recent reports; this operation is rarely performed and probably does not have a good long-term success rate. Modern studies have shown that amputation leads to changes in cortical sensory projections that are quite extensive; this might explain many surgical failures (78).

Neurostimulation Techniques

Transcutaneous Electrical Stimulation. Transcutaneous electrical stimulation has been used in large numbers of patients with phantom limb and stump pains. Most reports suggest that approximately 50% of patients report significant pain relief, but few writers report long-term data. When long-term data are reported, the success rates usually fall below 25% (51,128,129 and 130). Some authors have described stimulation of the contralateral limb as an effective means of controlling phantom limb pain. Chapter 98 contains a detailed discussion of transcutaneous stimulation. It is a treatment strategy without complication and probably should be tried in most patients, even though Sherman (51) reported a low overall success rate in his survey.

Peripheral Nerve Stimulation. Direct application of implanted electrodes to peripheral nerves has been possible since the early 1970s. A few patients with phantom limb or stump pain have been treated, but there are few published data (129).

Spinal Cord Stimulation. Spinal cord stimulation is the most commonly used form of implanted electrical stimulation, and the technology has gone through several evolutionary stages (see Chapter 100). The surveys by Siegfried and Cetinalp (114), Krainick and Thoden (130), and Lang (131) indicated that the results for phantom limb pain mirror the overall results from spinal cord stimulation: Approximately half of the patients have good initial relief of pain, but only half of these obtain long-term benefit.

Electrical Stimulation of the Brain. There are two deep target sites in electrical stimulation of the brain—the periaqueductal gray (the enkephalinergic system) and the lateral thalamus-internal capsule—although some neurosurgeons have used other medial thalamic structures (see Chapter 101). The results suggest that phantom limb and stump pain are more likely to respond to stimulation of the thalamic sites than to stimulation of the periaqueductal gray (114,132,133). Mundinger and Neumüller (134) reported a 93% success rate in 14 patients treated with the combination of deep brain stimulation and transcutaneous stimulation. There are probably 100 reported cases of deep brain stimulation for phantom limb pain; approximately 25 patients are said to have had good long-term relief of pain. Reports by Tsubokawa et al. (135) have indicated that stimulation of the motor cortex could be effective for relief of central pain states. Not enough cases have been reported to assess the efficacy of this treatment strategy and its usefulness in phantom limb pain.

CONCLUSIONS

No surgical procedure has a high likelihood of success in relieving phantom limb or stump pain. We need better methods of characterizing the pains seen after amputation to see whether there are criteria for the selection of specific operations that will increase the likelihood of favorable results. If we can isolate the mechanisms that lead to phantom and stump pain, it is possible that patients can be selected for particular pharmacologic or surgical treatments with higher likelihood of success. It is probably wisest to use nonablative procedures initially, for the patient will not risk the loss of neurologic function in the attempt to obtain pain relief. All of the neurosurgeons who have seen significant numbers of patients with phantom limb and stump pain have concluded that any operation is more likely to fail than to succeed in a particular patient (136).

CHAPTER 22

Herpes Zoster and Postherpetic Neuralgia

C. Peter N. Watson and John D. Loeser

This chapter reviews the features of herpes zoster (HZ), the most common neurologic illness, and the disease's most frequent and feared complication, postherpetic neuralgia (PHN). It is increasingly important to recognize and treat HZ early to prevent viral replication, to relieve acute pain, and to prevent the complications of the disease. PHN is important because its treatment is difficult and also because it is a valuable clinical condition for research into neuropathic pain. It is important not only to emphasize the optimal therapies of PHN but also its intractability; prevention of PHN may be possible. New information about these disorders includes a new definition (zoster-associated pain), epidemiologic data, the prospect of the prevention of PHN with appropriate measures, and controlled drug trials for PHN that support the use of antidepressants, the anticonvulsant gabapentin, as well as the use of opioids in refractory cases.

HERPES ZOSTER

Basic Considerations

Historic Aspects

The Greek word *herpes* means something that creeps and was commonly employed in early Greek medicine to designate chronic cutaneous diseases. The word *zoster* means a belt a warrior used to secure his armor. The common term for HZ, *shingles*, has an ancient derivation from the Latin verb *cingere*, which means *to gird*. The reader is referred elsewhere for details of interesting ancient treatments of HZ (1).

In 1831, Bright (2) suggested the neurologic basis of HZ because the characteristic rash distribution suggested segmental nerve involvement. Von Barensprung (3,4) identified the dorsal root ganglion as corresponding to the levels of rash. In 1892, von Bokay (5) established that HZ and varicella were different manifestations of the same etiologic process. The largest pathologic study in the literature to date is that of Head and Campbell in 1900 (6), in which the authors found that changes were limited to one ganglion. They noted that some ganglia were more predisposed to be affected than others and that these were the thoracic and the ophthalmic divisions of the trigeminal. Head and Campbell also found that some patients appeared to have the clinical manifestations of zoster without the rash. Weber (7) coined the term *zoster sine herpete* for this phenomenon.

The zoster virus was identified with light microscopy by Paschen (8). In 1926, Netter and Urbain (9) successfully showed the similarity of the antigens in vesicle fluids from HZ and varicella. They suggested that HZ was a recurrent manifestation of the primary infection of varicella. The current concept that HZ is a reactivation because of declining immunity of latent varicella virus in sensory ganglia was proposed by Hope-Simpson (10). Cell-mediated immunity is thought to be of importance in conveying protection against reactivation resulting in zoster (11,12 and 13).

Incidence

The overall incidence of HZ has been estimated at 131 per 100,000 person-years (14). No gender difference has been found (10,15). The incidence, however, is directly related to age (Table 22-1), so that a tenfold greater incidence is seen in individuals 75 years and older compared with those younger than 14 years (10,15,16). There is no seasonal occurrence (10,15). The dermatomes affected tend to be truncal as occurs with varicella, particularly the thoracic dermatomes and the ophthalmic division of the trigeminal nerve (10) (Table 22-2). One study has shown that blacks have a significantly lower risk of developing HZ than whites; the reasons for this have been discussed at length (16). In patients with lymphoproliferative disorders, the likelihood of zoster increases with the severity of the disease and with the aggressiveness of radiotherapy and chemotherapy. A small percentage of patients (5%) have a recurrence of HZ (15), and this may have a tendency to occur in the same dermatome (10). A decline of cell-mediated immunity appears to be associated with HZ rather than a decline in humoral immunity (11,12 and 13).

Pathology

It is thought that the virus that causes varicella gains access to the sensory nerves in the skin and passes to the dorsal ganglion cells in which it lies dormant. The latent virus becomes reactivated often when immune mechanisms are impaired. At the time of reactivation, an intense necrotizing reaction is seen in the dorsal root ganglia, peripheral nerves, and dorsal horn of the spinal cord. At this time the virus is thought to be transported in a retrograde fashion via the sensory axons to the skin to produce the rash.

HZ is a vesicular skin eruption characterized by inflammation of the corium, intranuclear inclusion bodies, edema of the epidermal cells, and giant cell formation (17). The initial lesions may become secondarily infected, and necrosis and hemorrhage can occur. The lesions heal by crusting and may leave regions of hypopigmentation and scarring.

The dorsal root ganglion, dorsal horn of the spinal cord and adjacent leptomeninges are the sites of inflammation, hemorrhage, and necrosis (17). The peripheral nerve of the infected ganglion is also the site of demyelination, fibrosis, and cellular infiltration (18). Ophthalmic HZ was studied by Denny-Brown and colleagues (19) in 1944 and virus particles were seen in the peripheral nerves, ganglion, and posterior roots but not within the axons themselves.

Varicella-zoster virus has been isolated from the dorsal ganglion at autopsy of patients with malignant lymphoma or with Hodgkin's disease associated with acute HZ (17). Microscopic examination of the involved ganglion showed coagulative necrosis and hemorrhage, with intranuclear inclusion bodies in both satellite and ganglion cells. Herpes virus virions have been seen with electron microscopic analysis (20).

Clinical Considerations

Symptoms and Signs

HZ usually commences with pain, paresthesiae, and dysesthesia in the afflicted dermatome(s), followed in a few days by a vesicular eruption. The intensity of the pain in the prevesicular and vesicular phases is variable, but in most patients is severe. Older patients are more likely to have severe pain in the acute stage than younger patients (15,21,22). The vesicles usually scab within 1 week and heal in approximately 1 month. On rare occasions a segmental, painful disease can occur without cutaneous vesicles (*zoster sine herpete*). An acute increase in antibody titers suggests that zoster is the etiologic agent. *Zoster sine herpete* is, of course, a difficult diagnosis to establish. Lewis (23) has described various sensory, visceral, and motor signs attributed to *zoster sine herpete*.

Patients may have occasional vesicles scattered over their bodies that are remote from the involved dermatome, but this does not imply an impending generalized infection. Generalized zoster is seen almost exclusively in immunosuppressed persons. Sacral segment involvement can be associated with urinary retention, and motor deficits have also been described in other regions (24). The facial nerve is the most common site of motor involvement. The development of zoster infection of the central nervous system (encephalomyelitis) is uncommon and usually has a favorable prognosis. Although it has been suggested that the occurrence of HZ might indicate an occult malignancy or immunodeficiency, no evidence exists to support this concept, and extensive diagnostic evaluation is unwarranted in the patient who develops segmental HZ (15).

A systemic response to HZ including fever, stiff neck, headache, and nausea, and regional or diffuse adenopathy is seen in approximately 5% of patients. It is not correlated with the likelihood of any complication, including PHN.

HZ in the first division of the trigeminal nerve may jeopardize vision. Conjunctivitis, keratitis, or iridocyclitis may ensue, especially when the nasociliary nerve is involved. Pain can be caused not only by the vesicles but also by the ophthalmic complications. Loss of vision can result from improper ophthalmologic management.

The distribution of HZ has been well described: Although more than 50% of patients are afflicted in the thoracic region, the ophthalmic division of the trigeminal nerve is also one of the more common sites, particularly in the elderly (15,24) (Table 22-2). The segmental distribution of zoster mirrors that of the exanthem of varicella and the virus itself may have a predilection for certain regions.

Recurrent attacks of HZ are uncommon (only 1% to 5% of those who have one episode have another) and may be associated with immunosuppression or underlying malignant disease.

Differential Diagnosis

A similar vesicular rash can be caused by herpes simplex; a patient with focal vesicles may be thought to have simplex when zoster is actually the causative agent. Viral cultures can resolve this ambiguity (25). Other viral infections without exanthems can produce similar symptoms. It may be impossible to differentiate *zoster sine herpete* from radicular pain of any other origin. Factitious scratching of the skin can create an eruption similar to that of acute HZ, but it is rare that such a patient confines the dermabrasion to one or two dermatomes.

Therapy

Symptomatic Treatment. The acute pain of HZ may be treated both topically and systemically. Compresses of Burrow's solution, or calamine lotion or a petroleum jelly impregnated bandage, with or without topical antibiotics, are commonly used. Nonsteroidal antiinflammatories and acetaminophen with codeine or stronger narcotics may be indicated because of the intensity of the acute pain. Long-acting opioids, such as sustained-relief morphine, oxycodone, and hydromorphone or the fentanyl skin patch, may play a role in difficult cases. Good analgesia for HZ pain may prevent alterations in the central nervous system that could be responsible for PHN.

Antiviral Agents. The hope has been that antiviral agents given within the first 72 hours will prevent viral replication and hence reduce the severity of the acute eruption and prevent PHN. Early studies of some agents that have not gained common usage involved idoxuridine (26), adenosine and cytosine arabinoside, (27,28), amantadine (29,30), and adenosine monophosphate (31).

Initial studies with acyclovir (ACV) were difficult to interpret, probably because they did not focus on or adequately evaluate pain. The use of the term *zoster-associated pain* has been developed to overcome this difficulty. A combined analysis of four ACV trials showed a reduction in PHN by 42% (32). Famciclovir (a nucleoside analogue) has greater oral bioavailability and a longer half-life than ACV. A placebo-controlled trial has shown that the median time to pain disappearance was shorter with this drug (33). A trial comparing famciclovir with ACV showed the time to pain disappearance was similar between the two agents (34).

Valacyclovir is a prodrug for ACV and has a higher bioavailability orally. Valacyclovir administered for 7 or 14 days was more effective than ACV in relieving zoster-associated pain (35). In this study there was no difference between 7 and 14 days' treatment duration. A smaller proportion of patients had pain at 6 months' follow-up with valacyclovir (19% versus 26%, $p = .02$).

Corticosteroids. Trial results with corticosteroids have been confusing: Some are favorable and others not. Large controlled trials have shown early resolution of the acute illness but no effect on PHN (36,37). There appears not to be a risk of dissemination of the virus with these agents.

Regional Anesthesia. A variety of uncontrolled studies have purported to show a faster resolution of the acute illness with regional, sympathetic, somatic, or all three kinds of neural blockade. Symptomatic relief of the pain of HZ can be obtained with somatic block and sometimes with sympathetic block as well. Claims have also been made for a reduction of PHN. No controlled trial has settled this issue to date (38).

Other Methods. No good scientific evidence exists that any of a variety of other approaches attenuates HZ or prevents PHN. Bowsher has suggested that the early initiation of low-dose antidepressants, such as amitriptyline, may prevent PHN (39).

Conclusions

The population with HZ at highest risk for severe acute disease and complications is the group over the age of 60. In elderly patients, it is important to treat the

eruption and pain aggressively. Within the first 72 hours an antiviral agent such as valacyclovir or famciclovir should be commenced. Adequate analgesia with opioids, if necessary, is important to relieve acute pain. The early institution of low-dose amitriptyline may help with pain relief and prevent PHN. In patients with refractory pain, it is reasonable to consider regional anesthesia.

POSTHERPETIC NEURALGIA

PHN is the most frequent and feared complication of HZ and is a common cause of chronic pain in the elderly population. The eruption of HZ, the most common neurologic illness (40), is a harbinger of long-standing neuropathic pain in at least 50% of those older than 60 years (41). Lifestyles are dramatically disturbed; many older patients become reclusive, restricted in activities of daily living, and chronically depressed because of this misery. This section of the chapter reviews what is known about the natural history, demography, clinical features, pathology, pathogenesis, and management of PHN. Although the natural history is of slow improvement for many patients, some experience symptoms for years. With judicious choice of agent and careful monitoring, it is possible to provide reasonable pain control to approximately 60% of patients. Approximately 40% remain unsatisfactorily relieved or are intractable; this is why prevention with vaccination or early aggressive treatment of the acute zoster pain may be of critical importance.

Basic Considerations

Definition

PHN has been defined as pain along the course of a nerve after the characteristic acute segmental rash of HZ. It is important to be more precise than this to interpret the results of clinical trials and to define a fairly chronic, stable pain state for the design of uncontrolled trials but also to reduce the numbers required in controlled studies. A commonly used definition of PHN is pain persisting after the rash has healed (usually 1 month). Because of the tendency for pain to further diminish with time after 1 month, some investigators studying therapeutic approaches have chosen longer periods of 2, 3, or even 6 months after the disease onset.

Incidence, Natural History, and Demographics

The incidence of PHN (defined as pain persisting for more than 1 month) has been variously estimated from 9% to 14% (10,15,21). Other work indicates that of an original 100 patients with HZ at 3 months and as few as five and at 1 year, only three patients have persistent severe pain (41). These data emphasize that to minimize the sample in any study of the treatment of this disorder, patients should be included with severe pain at 1 or even 3 or 6 months. Despite this overall low incidence and marked early tendency for PHN to improve with time, the incidence and the severity (as measured by duration) are directly related to age (Table 22-3). Approximately 50% at age 60 years and nearly 75% at age 70 years with HZ develop PHN 1 month or more after the rash (41). This, combined with the knowledge that HZ itself is common and also directly increases with age, means that PHN is already a major geriatric problem in the developed countries and its incidence will increase. Additional factors contributing to the morbidity of this disease are the limited efficacy and untoward effects of pharmacotherapy.

Age (yr)	Patients with pain (%)	Patients with pain longer than 1 yr (%)
10–19	4.0	4.0
20–29	2.0	2.0
30–39	15.0	10.0
40–49	33.0	7.0
50–59	49.0	18.0
60–69	65.0	37.0
70–79	74.0	48.0

TABLE 22-3. Incidence of postherpetic neuralgia

Most studies have found no gender predilection for PHN when normal demographic change with age is considered (22,42). The dermatomal distribution of PHN has been found to reflect that of HZ in that a predilection occurs for thoracic dermatomes, especially T-5, and for the ophthalmic division of the fifth cranial nerve (43).

Pathology

In 1900, Henry Head and A. W. Campbell reported autopsy findings in 21 cases of HZ (6). Some cases were obviously chronic and had scarring in the sensory ganglia (Fig. 22-1) and nerves; however, in only one of their chronic examples (case 7) was the subject documented as having persistent pain. More recently, this scarring in the peripheral nervous system has been found in several cases of well-established PHN (18,44,45). Evidence exists that the nerve fiber population shifts with a preponderance of small unmyelinated and myelinated fibers and loss of large myelinated fibers (45,46). Atrophy of the dorsal horn of the spinal cord has been documented in several cases (45,46) (Fig. 22-2).

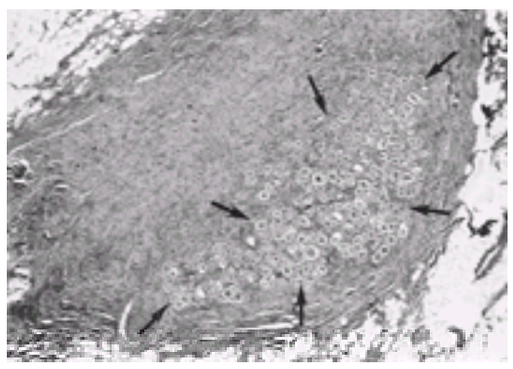

Figure 22-1. Postherpetic neuralgia with scarring in the sensory ganglion and some surviving ganglion cells (*arrows*).

Figure 22-2. Postherpetic neuralgia with atrophy of the dorsal horn of the spinal cord (*arrows*).

The pathogenesis of PHN remains unknown. Noordenbos (46) thought that the pain and hyperesthesia in PHN were caused by preferential destruction of larger myelinated fibers in the peripheral nerve, leaving an excess of the small myelinated and unmyelinated fibers. This would result in a loss of inhibitory (large fiber) input to the spinal cord with unopposed, nociceptive (small fiber), afferent bombardment. Evidence that ongoing small fiber input might be important in painful nerve injuries has been reported (47). This work demonstrates that preferential sprouting of small diameter afferents in experimental neuromas occurs after nerve transection in the rodent. These axons showed spontaneous activity, increased sensitivity to mechanical stimuli, and sensitivity toa-adrenergic agonists and to sympathetic efferent activity. The discovery of pathologic change in the dorsal horn and relief by dorsal root entry zone lesions in some patients with PHN supports the concept of a derangement in that area of hypersensitive neurons. It has been suggested that pain relief in PHN by antidepressants may act by increasing inhibition of pain perception in serotonergic and noradrenergic pathways descending from the brainstem onto the dorsal horn. Occasional patients with PHN have inflammatory infiltrates persisting for many months (45), suggesting that some persistent occult inflammation may play a role in the symptoms and that antiinflammatory or antiviral agents could be useful in some individuals with PHN.

Clinical Considerations

When the acute rash has healed, the affected skin often exhibits a reddish, purple, or brownish hue. As this subsides, pale scarring often remains. Occasionally, severe pain with no residual scar may occur or the scars in cases of long duration are barely perceptible. The scarred areas are usually at least hypoesthetic and often anesthetic, and yet the skin often exhibits marked superficial pain on tactile stimulation (allodynia), increased pain to noxious stimulation (hyperalgesia), or an increased sensitivity to touch (hyperesthesia) (Fig. 22-3). Two types of pain may be found: one a steady burning or aching, the other a paroxysmal, lancinating pain. Both may occur spontaneously and are usually aggravated by any contact with the involved skin, such as friction from even the lightest clothing. Firm pressure on the skin may curiously be soothing but lighter brushing unbearable. Some patients describe unbearable itch, formication, or dysesthesia. As well as clothing contact, these symptoms may be exacerbated by physical activity, temperature change, and emotional upset.

Figure 22-3. Postherpetic neuralgia showing scarring and sensory loss (*solid lines*) and allodynia (*dotted lines*).

The examination of the affected, scarred skin often reveal a loss of sensation to pinprick, temperature, and touch over a wider area than the scars and an even wider area of sensitive or painful skin. This sensitive skin may paradoxically include the anesthetic areas in which it is elicited by skin stroking or skin traction between thumb and forefinger, an effect that is thought to be caused by summation on hypersensitive, deafferented central neurons with expanded receptive fields.

Prevention

As many as 40% of patients with PHN have either incomplete or no relief from our best treatments. Because of this, the future may lie with prevention through vaccination and early aggressive treatment of HZ with antivirals and analgesics to reduce the extent of the nerve damage and sensitization that may correlate with PHN.

Live attenuated varicella vaccine elicits protective immunity against varicella zoster virus in children and adults (48,49,50 and 51), although mild breakthrough cases of varicella may occur. It is possible that waning varicella zoster virus–specific cell-mediated immunity in the elderly can be stimulated by varicella vaccine to prevent the occurrence and severity of HZ and hence PHN.

Early treatment of HZ with the antiviral agent ACV may prevent or attenuate the occurrence of PHN. Initially, studies of ACV were not impressive, but more recent trials that have paid more attention to persistent pain suggest a protective effect of this drug when used in high doses orally (800 mg 5 times a day) (32). Newer antivirals, such as valacyclovir, may prove more effective than ACV in preventing PHN (35).

A number of uncontrolled studies of small numbers of patients with HZ treated with corticosteroids have claimed a reduction in PHN. Two controlled trials have purported to prove such an effect (52,53). These trials have been criticized, and more recent controlled trials have shown no effect (36,37,54,55).

Uncontrolled trials of sympathetic blocks for HZ have claimed relief of the acute pain of HZ and a reduction in the subsequent development of PHN (56,57,58 and 59), although one study showed no effect (60). With the marked natural tendency for improvement of pain with time, it is easy to confuse this with a treatment effect in uncontrolled studies (38).

One placebo-controlled trial supports the preventive effect of amantadine hydrochloride in PHN when used in a dose of 100 mg twice a day at the onset of HZ (29,30). Other unreplicated trials claim a prophylactic effect with levodopa (61) and adenosine monophosphate (31). Good control of the acute pain of HZ with opioids, if necessary, could also be important in reducing PHN.

Treatment of Established Postherpetic Neuralgia

Antidepressants. A large number of studies support the utility of antidepressants in a variety of chronic pain problems (62,63 and 64). An important part of this literature concerns favorable, well-designed trials of the use of these agents in neuropathic pain, particularly PHN. PHN is a good model of neuropathic pain for drug trials because, if patients are chosen carefully, the pain is fairly stable over time and sufficient numbers of cases for trials can be readily obtained. Antidepressant therapy, as opposed to many other putative therapies of this difficult problem, is built on a sound, scientific basis.

Woodforde et al. (65) were the first to recognize that amitriptyline could afford relief in truly chronic postherpetic pain problems. They thought that all 14 of their patients were depressed and used an initial dose of 10 mg four times daily gradually, increasing to 25 mg four times a day; good pain relief was noted in 11 patients from 1 to 11 months. Taub (66) reported successfully treating five subjects with PHN of greater than 3 months' duration with amitriptyline combined with a phenothiazine (fluphenazine, perphenazine, or thioridazine). In a later publication, Taub and Collins (67) used amitriptyline, 75 mg, with fluphenazine, 1 mg three times a day, in 17 patients with pain of greater than 1 year's duration. The patients had good relief in both studies with some mild residual pain after 3 to 6 years of follow-up. The authors commented on their belief in the lack of efficacy of amitriptyline alone. There has been no placebo-controlled trial of a phenothiazine in PHN, and it is proven that the beneficial effects seen with the combination of an antidepressant and phenothiazine are caused by the antidepressant, the efficacy of which has been proven by a number of controlled trials. There are well-known side effects from phenothiazines that can be severe enough to make us cautious about using the drugs unless there are clear-cut benefits. A double-blind, placebo-controlled, crossover trial of amitriptyline found good results in 16 of 24 patients (67%) (68). Most patients were not depressed and pain relief occurred without a change in depression ratings in most patients, indicating that the drug appeared to result in pain relief independently of its antidepressant effect. This pain relief occurred at lower doses than usually used to treat depression (median, 75 mg). Follow-up was a median 12 months with good results maintained in 12 of 22 (55%). A subsequent trial (69) has corroborated these results. Amitriptyline has significant limitations in the long term because of side effects and the fact that relief is rarely complete and occurs in only approximately two-thirds of patients. One of the effects of this drug is to potentiate serotonin and noradrenaline in the central nervous system. Subsequent research has explored whether selective serotonergic or noradrenergic agents

might be more effective and have fewer untoward effects.

Experience with serotonergic agents (clomipramine, trasodone, nefasodone, fluoxetine, and zimelidine) in PHN has been disappointing (43,70,71). The evidence supporting the use of noradrenergic agents is more compelling (72,73 and 74).

Desipramine, a selective norepinephrine reuptake inhibitor, has been shown to be more effective than placebo in PHN. Pain relief with this drug, as well, was found not to be mediated by mood elevation (72). A randomized, double-blind trial comparing maprotiline (noradrenergic) with amitriptyline (73) found that although both were effective, amitriptyline was more so. Nine patients responded equally well to both drugs, seven responded only to maprotiline, and eight other responders required amitriptyline for good relief. All three aspects of the pain of PHN responded to treatment in this study (i.e., steady pain, brief jabbing pain, and pain on tactile skin contact). Side effects were troublesome with both agents, therefore limiting effectiveness. Most patients were not depressed and pain relief occurred in most without a change in depression-rating scales. A comparison of nortriptyline (more noradrenergic) with amitriptyline showed approximately equal efficacy for both drugs with fewer side effects with nortriptyline (74).

Neuroleptics. Farber and Burks (75) used high doses of chlorprothixene in patients with postherpetic pain with a duration of 2 days to 8 weeks. In an uncontrolled study of 30 subjects of unstated age, they found total relief of pain within 72 hours in all but one. Nathan (76) attempted to duplicate this work in established PHN (median duration, 1 year) by the same method and also in a lower dose, double-blind, placebo-controlled study. He concluded that dosages less than 100 mg per 24 hours were ineffective. The high- dose regimen helped approximately one-third of patients, but only in the short term, and was accomplished by a high incidence of side effects. They used an initial dose of 10 mg four times a day, achieving at least good relief in 11 patients for 1 to 11 months. Taub (66) reported treating five subjects with PHN of more than 3 months' duration with amitriptyline and a phenothiazine (perphenazine, fluphenazine, or thioridazine). In a later publication (67), Taub and Collins used amitriptyline hydrochloride, 75 mg every night, with fluphenazine, 1 mg three times a day, in 17 patients with pain of duration more than 1 year. The subjects in both studies had good relief with some mild residual pain at 6 months' to 3 years' follow-up. Taub commented on his impression of the lack of efficacy of amitriptyline alone.

Anticonvulsants. Studies using the anticonvulsants carbamazepine, phenytoin, and valproic acid for PHN have been either unimpressive (77) or difficult to interpret because of the concomitant use of antidepressants (78,79 and 80). Although carbamazepine is a popular agent for the paroxysmal, lancinating pain that commonly occurs, no conclusive evidence exists to justify its use in this fashion. A recent randomized controlled trial suggests a modest effect of gabapentin (81).

Opioids. For many years, there has been a bias against using opioids for nonmalignant pain. Increasing support exists for the view that these drugs can be helpful and justifiable in chronic pain caused by nerve injury (82,83,84,85,86,87,88,89 and 90). One study suggested that opioids did not relieve neuropathic pain, but this study did not include patients with PHN and its conclusions have been challenged.

Survey data in PHN have indicated that opioids are useful for some patients (43). Twenty-five of 90 patients with otherwise intractable pain achieved good to excellent results, and 50 others had 25% to 50% relief in one report (43). A placebo-controlled trial of 50 patients treated with sustained-release oxycodone has shown that 58% of patients had at least moderate improvement with this drug versus 18% with placebo (91).

Topical Agents. A variety of topical agents have been studied in PHN (capsaicin, aspirin, and local anesthetics) (see Chapter 87). Capsaicin, the active ingredient in red peppers and other plants, acts by depleting the neurotransmitter substance P in small primary afferent fibers. Capsaicin has a modest effect (92) and may best be used as an adjunct to other treatments. The burning sensation induced by capsaicin is often unpleasant or unbearable and usually limits therapy. Open-label, uncontrolled studies suggest that aspirin in a variety of vehicles such as chloroform, ether, and Vaseline ointments may help PHN (93,94 and 95). Similarly, a variety of topical local anesthetic agents, such as lidocaine and EMLA (eutectic mixture of local anesthetics) applied under occlusive dressings, may be useful, but again this effect appears modest (96,97 and 98).

Miscellaneous Therapies. Russell and colleagues (99) advocated repeated nerve blocks, interspinal ligament injection of hypertonic saline solution, or skin infiltration with procaine hydrochloride for relief of hyperesthesia and spontaneous pain in PHN. They also discussed the use of a hand vibrator over the injured skin. Of 100 patients, they provided details for only five. No duration of antecedent pain was stated. Taverner (100) reported 16 cases treated with ethyl chloride spray to the scarred area. Symptoms for 12 of these were relieved for 3 to 21 months, with their pain duration being 10 months to 13 years. The spray was applied daily to twice a week. The author commented on the failure of vibration in his experience, cautioning about the risk of skin injury. Todd and colleagues (101) reported on 86 patients with PHN of at least 3 months and found that 58 (67%) obtained relief with a combination of ethyl chloride spray followed by the application of a hand vibrator; follow-up was 6 months to 6 years. Colding (56,57) concluded that sympathetic blocks for established PHN were of no value. Forrest (102) treated 37 patients with postherpetic pain of more than 6 months' duration with three epidural injections of methylprednisolone acetate at weekly intervals. At 1 year, 90% of the patients were free of pain, with “some patients” followed up for more than 3 years. Forrest postulated that the corticosteroid, local anesthetic used, or preservative might have been the effective component. Another study (103) of five patients with established PHN, treated with epidural bupivacaine hydrochloride and methylprednisolone, concluded that no patient had more than 50% relief at 1 and 5 months.

Nathan and Wall (104) used prolonged transcutaneous electrical nerve stimulation (TENS) and found good results in 11 of 30 patients with established PHN. The voltage, pulse width, frequency, site of application, and duration were all controlled by the patient. The subjective sensation of the input was usually nonpainful and tingling. Pain relief often outlasted stimulation by hours. Follow-up duration was not clearly stated for many patients. Gerson and colleagues (79) found the intermittent use of TENS unsuccessful in 17 patients with chronic PHN. Haas (105) concluded that TENS was helpful in 9 of 11 patients, with follow-up over 1 to 18 months. Lewith and colleagues (106) concluded that acupuncture was of little value in PHN when compared with placebo (mock TENS) in 62 patients. Claims have been made for a variety of other therapies, but these studies suffer from small numbers of patients, lack of controls, inadequate data about the patient population, or lack of adequate follow-up.

Surgical Therapy. No proven surgical cure for PHN has been found (see Chapter 105 and Chapter 106). Browder and deVeer (107) reviewed the poor results of cordotomy, rhizotomy, and sympathectomy, but argued for excision of the painful area. Sugar and Bucy (108) reviewed the surgical attacks on this disease in 1951 and concluded that almost every operation was said to work occasionally, but none consistently. White and Sweet (109) came to similar conclusions. Their lists included retrogasserian rhizotomy, avulsion of the supraorbital nerve or gasserian ganglion, greater superficial petrosal neurectomy, trigeminal tractotomy, stereotaxic thalamotomy or mesencephalotomy, sympathectomy, and sensory corticectomy. Resection or undermining of the skin in the involved areas also rarely seemed to provide long-term pain relief, despite initial reports of good results (107,110). Suzuki and colleagues (111) alleged that applying dry ice to the hyperesthetic skin was effective. Cryocautery has some side effects, and is likely to bring only short-term relief (111). Hitchcock and Schvarcz (112) reported that stereotaxic trigeminal tractotomy was successful in three patients with PHN, all with less than one year's follow-up. No reports of this procedure by other neurosurgeons have been published.

Dorsal root entry zone lesions may prove to be effective for PHN, but too few cases have been reported to permit meaningful analysis of data. Friedman and colleagues (113,114) described good results in 10 of 17 patients who underwent this procedure. Certainly, no other ablative procedure has been reported to have this great a chance of providing long-term relief. Whether the results of dorsal rhizotomy would be improved by adding ganglionectomy is unknown.

Stimulation of the nucleus ventroposteromedialis was reported to provide pain relief for some patients with PHN (115). Approximately one in three patients can be expected to obtain good long-term results. Stereotaxically implanted electrodes can also be directed at other nuclear structures, but the ventroposteromedialis appears to be the best target area (116,117).

Conclusions

None of the putative preventive approaches to PHN can be regarded as conclusively established to be effective in preventing this disorder. Pending final proof, it is reasonable to treat patients early and aggressively to relieve the pain of HZ and to hope to prevent PHN if the therapy is safe and well tolerated. It is important to recognize that the population at highest risk for PHN is the age group 60 years and older who may have a risk of 50% or more of developing this complication. Valacyclovir and famciclovir appear safe and modestly reduce the occurrence of PHN. Although no controlled trial has ever been performed of nerve blocks to treat HZ pain or prevent PHN, they are reasonable and safe in experienced hands and may be repeated if effective as symptoms dictate. The use of nonsteroidal antiinflammatory drugs, acetaminophen, and narcotics, are justified to relieve severe pain with the acute illness on an as needed or round the clock basis. The initiation of low-dose amitriptyline may be considered at this stage.

For established PHN (neuropathic pain persisting more than 1 month after HZ) the most consistently effective agents appear to be antidepressants; controlled trials

support this approach. These data indicate that pain may be reduced from moderate or severe to mild in approximately two-thirds of patients. It is reasonable to commence with amitriptyline or nortriptyline in a dose of 10 mg at bedtime in those older than 65 years and with 25 mg in those 65 years or younger. The dose is increased by similar increments at bedtime every 7 to 10 days until relief is obtained or intolerable side effects supervene. If these fail, one can try desipramine or maprotiline in similar doses. Gabapentin may be regarded as a first-line therapy in divided doses of up to 3,500 mg per day. Occasional patients who have no success with these may benefit from a serotonergic drug such as trazodone, clomipramine, or fluoxetine, but no controlled trial has been done and these do not appear useful for the majority of patients. It is also possible that the addition of a neuroleptic such as fluphenazine, 1 mg up to three times a day, may give added benefit in some. A trial and error approach in refractory patients may also include the anticonvulsants carbamazepine, phenytoin, clonazepam, and valproate. For resistant cases, opioids may be safely prescribed on an as needed or round the clock basis. Methadone or long-acting oral forms of oxycodone, morphine, and hydromorphone and the fentanyl skin patch may be of advantage, and trials of different opioids may reveal one that is preferred. The use of topical agents is attractive, as it is simple and free of systemic effects. These include capsaicin, acetylsalicylic acid, and local anesthetic agents. Although for most patients these do not appear useful as sole therapy, they may be a valuable adjunct in some individuals. TENS may be worth trying. Electrode placement, frequency, intensity, and duration of stimulation are a matter of trial and error. Some patients may benefit from nerve blocks that, if efficacious, may be repeated at appropriate intervals. At least 40% of patients remain totally refractory or unsatisfactorily relieved. Our approach with those is to see them regularly, try different narcotics for the limited relief they give, and try any new or older approach that seems reasonable and safe, hoping that improvement will occur with time. Approximately 50% of patients, even those with long-duration pain, improve over the years; approximately one-half of these are receiving no treatment. It is hoped that new and more successful treatments for PHN will be developed in the immediate future. These could include strategies to prevent the onset of HZ in addition to the attempt to prevent the onset of PHN after the onset of HZ.

CHAPTER 23

Central Pain States

Ronald R. Tasker

Central pain is defined (1) as "pain associated with lesions of the central nervous system" and is among the most spectacular, distressing, and intractable of chronic pain syndromes. It seems amazing that transection of the spinal cord can result in agonizing pain in the body below the level of the lesion or that a stroke can result in such distressing pain on the opposite side of the body. Central pain belongs to the group of neuropathic pain syndromes and shares many features with the pain syndromes induced by lesions of peripheral nerves, plexuses, and roots, strongly suggesting a shared pathophysiology. Table 23-1 lists the more obvious of these shared characteristics, a topic that has been reviewed by many authors (2,3,4,5,6,7,8 and 9). Nevertheless, our understanding of neuropathic pain including central pain syndromes remains meager.

Caused by damage to somatosensory pathways.
Degree of damage variable from slight with no sensory loss to massive with anesthesia.
Pain idiosyncratic (genetic predisposition in animals).
Pain in distribution of sensory damage.
Onset may be delayed.
Brain central pain may be reversible.
Three common components: steady and neuralgic, spontaneous, and evoked.
May be temporarily relieved by proximal, distal, or both somatosensory local anesthetic blockade.
May be temporarily relieved by sympathetic block if evoked element present.
Steady pain better relieved by intravenous sodium thiopental than opiate infusion.
Steady pain not relieved by proximal neural transection but may respond to chronic stimulation producing paresthesia in pain area.
Evoked and neuralgic pain may be relieved by neural transection.

TABLE 23-1. Features of neuropathic and central pain

This chapter is divided into two sections, one dealing with central pain caused by lesions of the spinal cord and the other with that caused by lesions of the brain. Each section deals both with basic and clinical considerations. However, because no satisfactory laboratory models of pain caused by spinal cord or brain injury exist, the human patient is the best research subject, and insight into the pathophysiology of central pain must be derived from studying the clinical features of each patient. A more general discussion of the different types of pain seen after injury to the spine and spinal cord may be found in Chapter 34.

SPINAL CORD CENTRAL PAIN

Clinical Features

The diagnosis of central pain caused by spinal cord injury is rarely in doubt; the causative events usually are obvious. The patient presents for treatment of pain after therapy for the causative condition, usually trauma, has been completed. Rarely is central pain the presenting feature of a spinal cord lesion. In those rare exceptions, the combination of a pain syndrome and the accompanying neurologic signs usually confirms the diagnosis, assisted by magnetic resonance imaging or other imaging and electrical studies (see Chapter 13 and Chapter 14).

Incidence and Etiology

The incidence of spinal cord central pain has been estimated to be between 6.4% and 94.0% of patients who experience spinal cord injury, as shown in Table 23-2. Sved and colleagues (21) performed a prospective longitudinal study of 100 patients with spinal cord injury and showed that the incidence of central pain was not influenced by early surgical treatment of the spinal cord injury.

Incidence (%)	Reference
6.4	10
7.5–10.0	11
10–30	9
18–63	12
25	13
26.8	14
27	15
33–94 (one-third severe)	16
47–96	16
69.5 (49% severe)	17
77	18
80–94	19
94	20

TABLE 23-2. Published estimates of percent incidence of cord central pain after spinal cord injury

Trauma is the most common cause of spinal cord central pain, as shown in Table 23-3, which lists the etiology of pain in my personal series of 127 patients (22). In this series, 76.4% were men, and 57.4% were younger than 40 years at the time of the injury. Forty-two percent of my patients had lesions in the cervical area, 21% in

the T1-9, and 37% in the T-10–L-2 areas; 32% of lesions were clinically complete, 64% incomplete, and 4% of patients had no clinically detectable sensory loss. There appeared to be no correlation between patterns of pain and etiology, level of injury, and completeness of spinal cord transection, although Richards and colleagues (23) found pain more common after gunshot wounds than other lesions.

	% of Patients
Trauma	65
Iatrogenic	12
Inflammatory	9
Neoplasm	6
Skeletal pathology	2
Vascular pathology	2
Congenital lesions	4

TABLE 23-3. Etiology of 127 cases of cord central pain

Eide and colleagues (24) examined 16 patients with spinal cord injury and dysesthetic pain, comparing the somatosensory function in normal, painful, and nonpainful denervated skin. No difference existed between the degree of deficit in dorsal column and spinothalamic tract functions, but allodynia and wind-up were more common in painful than nonpainful denervated areas.

Delayed Onset

Table 23-4 charts the time of onset of spinal cord central pain after the causative event in 72 of my patients (25). When onset was delayed beyond 1 year, 56% of these patients were found to suffer from a syrinx; 37% of those with onset before 1 year did so. Thus, long-delayed onset of pain should alert the physician to the possibility of syringomyelia. This condition was reviewed in detail by Milhorat and colleagues (26).

Quality of Pain

Patients describe a considerable variety of pain types after spinal cord injury, in addition to the three common components: spontaneous steady, spontaneous neuralgic, and evoked pain including allodynia and hyperpathia. As Boureau and colleagues (27) have shown, the words used by patients are related to the underlying pathophysiology. Table 23-5 lists the descriptions used in 127 of our cases to describe their spinal cord central pain. Ninety-six percent reported steady, burning, dysesthetic, or all three types of pain. Table 23-6 lists the terms used by other authors to describe spinal cord central

Pain quality	% of Cases[a]
Burning	75
Numb, tingling	26

[b]Two percent in isolation.
[c]Four percent in isolation.
[d]Below a complete level of sensory interruption.

TABLE 23-5. Nature of pain in 127 cases of cord central pain

Author(s)	Terms
White and Sweet (51)	Radicular (neuralgic), psychic, diffuse, sympathetic, visceral
Pagni (6)	Visceral, radicular (especially cauda lesions), remote (causalgic, dysesthetic below level)
Pollock et al. (28), Waisbrod et al. (29)	Segmental, diffuse (burning or visceral), lesional (projected or triggered)
Rose et al. (17)	Radicular, 12.4%; constant, 43%
Beric et al. (30)	Central dysesthetic, 13%
Davis and Martin (31)	Shocklike, electric at or below level one-third
Richards et al. (18)	Musculoskeletal (innervated area), radicular (at level and distally), visceral, central (dysesthetic), psychogenic, lesional (at zone of injury), reflex sympathetic dystrophy, limb pain (especially upper limb from compression nonneuropathic)
Hashold (32)	Radicular, segmental, segmental with syrinx, phantom, visceral
Milhorat et al. (26), 71 cases of syrinx	Segmental dysesthetic, 51%; radicular, 36%; headache, 25%; suboccipital cervical, 67%; in back, 17%; in face, 9%
Sidall et al. (33)	Neuropathic (1) at level (a) radicular (b) central (2) below level

TABLE 23-6. Terms used to describe cord central pain

In our patients, little difference existed between the distribution of the steady component between complete and incomplete cases, other than the fact that the prevalence of a band of steady pain at the upper margin of sensory loss was more characteristic of an incomplete lesion, as was the presence of diffuse pain below the level of injury. Visceral, rectal, and perineal pain was more common in complete lesions. Some patients suffered from pain that resembled that of musculoskeletal

disease, such as the pain of spinal instability or muscle tension. Such pain could indeed be associated with such problems in spinal cord–injured patients when it occurred in an innervated area above the level of injury. However, such pain also occurred below the level of injury, particularly in complete lesions, and was presumably not related to musculoskeletal problems. Facial pain was pathognomonic of a syrinx in the cervical area interfering with the descending tract of the trigeminal nerve.

Table 23-7 lists the patterns of sensory loss in 72 of our patients. It is noteworthy that three had no clinically detectable sensory loss, and 16 had dissociated loss of spinothalamic tract function; the rest had varying degrees of loss both of dorsal column and spinothalamic function. Spinal cord injury pain typically begins well after the traumatic event. Although the pain rarely, if ever, subsides on its own, it may change slowly but significantly over time. Patients with spinal cord injuries, like amputees, may experience phantoms below a complete level. These are said to be less prevalent in patients who were comatose at the time of their spinal cord injury than those who were not (34,35). Phantom onset is delayed by days to months, and the phantoms are said to be less vivid than those of amputees, not telescoping with time (35,36 and 37).

Sensory loss	% of Patients
None	3

TABLE 23-7. Patterns of sensory loss in 72 patients with cord central pain

The most common type of central pain after a spinal cord injury is spontaneous steady, burning, or dysesthetic pain, affecting 96% of our patients (Table 23-8). Its severity fluctuated, some patients distraction. It was described as burning in 75% and dysesthetic in 28%; the dysesthetic element was variably described as tingling in 20%, numb in 6%, crawling in 2%, and pricking in 1%. The pain was aching in 13%, had a sense of compression or distraction in 18% (crush, 3%; tight, 2%; squeeze, 2%; pull, 2%; pinch, 2%), whereas it was rhythmic in 9% (throb, 5%; cramp, 3%; pound, 1%; pump, 1%), cold in 4%, and had the feeling of a cut in 2%.

	Distribution (%)	
Pattern	33 Clinically complete	39 Incomplete
Band at upper margin of sensory change	24	3
Diffuse below level	18	36
Patchy below level	36	49
Visceral below level	24	13
Rectal-perineal	15	8
Facial	3	2

TABLE 23-8. Location of steady pain in 72 patients with spinal cord lesions

Forty-seven percent of our patients experienced allodynia, hyperpathia, or both, but only in areas of preserved sensation. This was usually associated with spontaneous pain, although in 4% of our patients evoked pain occurred in isolation. It affected 39% of patients with complete lesions where it usually occurred as a band at the upper level of the sensory loss, and 51% of patients with incomplete lesions. In these it was found diffusely in 67%, patchily in 75%, and as a band at the upper level of the sensory deficit in 18%. Taking complete and incomplete lesions together, in 21% it occurred in a band at the upper level of the sensory loss, in 29% diffusely, and in 50% patchily below the patient's level. It could also occur in radicular distribution from damage to a root near the level of spine injury. Some patients had allodynia alone, and others allodynia accompanied by hyperpathia; the allodynia might be elicited by single or multiple somatosensory modalities such as touch, hair bending, cold, hot, or muscle and joint movements; deep pressure was much less likely to evoke it than other modalities.

Neuralgic intermittent pain can shoot down the legs, especially in patients with lesions of the cauda equina and conus. This type of pain affected 31% of our patients. It usually accompanied steady pain, but in 2% of patients it was the only type of pain present. When it occurred in the presence of other types of pain, it was usually the most severe. In our patients it was described as shooting in 12.0%, shocklike in 8.0%, stabbing and jabbing in 3.1% each, sharp in 2.4%, and knotting and stinging in 1.0% each. It afflicted 27% of patients with complete and 33% with incomplete lesions, and ran up or down the trunk or legs, particularly in incomplete lesions or else around the body at the patient's level, particularly in complete lesions. It was present in 82% of patients with complete T-10–L-2 lesions, and 64% of incomplete lesions at this level. Pain resembling abdominal or pelvic disease usually occurred below a level of complete sensory loss and often led to extensive investigation of the viscera and even to abdominal surgery.

Thus, pain syndromes can accompany the full spectrum of motor and sensory loss, complete or incomplete and at any level. Pain may even occur in someone with normal spinal cord function on clinical examination but who gives a history of past injury or illness that could have damaged the spinal cord even though it has been followed by complete recovery.

Animal Models

The author is aware of few laboratory studies directed at spinal cord central pain. Levitt and Levitt (38) have studied rodent pathways, whose involvement is necessary for spinal cord central pain to develop. They concluded that the anterolateral quadrant of the spinal cord must be sectioned or else hemisection of the spinal cord performed, preserving some sensation in ipsilateral nociceptive pathways for pain behaviors to occur. Pain never followed posterior quadrant section, whereas simultaneous section of ipsilateral, lateral, or anterolateral quadrants in addition to anterolateral quadrant section or hemisection on the other side of the spinal cord did not result in pain. How this observation matches the clinical facts of spinal cord central pain after complete spinal cord section is unclear. One must keep in mind that their marker for the presence of spinal cord central pain was autotomy, which may not have the same implication as the steady, burning, dysesthetic pain seen in humans. Consonant with human studies, pain onset was delayed and morphine administration, subsequent rostral spinal cord transection, or subsequent rostral selective spinal cord lesions, such as the ones that caused the autotomy in the first place, all failed torelieve it.

Functional Imaging

Functional imaging studies are likely to contribute much to our future understanding of the problem of central pain. Pagni and Canavero (39) and Cesaro and colleagues (40) have demonstrated diminished perfusion of the human contralateral thalamus in single photon emission computed tomography (SPECT) and positron emission tomography scans associated with spinal cord injury, stroke-induced, peripheral neuropathic, or cancer pain. These changes could be normalized by relief of the pain by resection of a syrinx in one case of spinal cord central pain or by cordotomy in cancer pain. These observations support the concept of a final common path for pain, regardless of the individual pathophysiology.

Melzack and Loeser (41) concluded that spinal cord central pain was the result of a “pattern generating mechanism” for pain based on the observations that the pain

was not relieved by cordectomy and persisted if the sympathetic chain was cut or blocked as well. This meant that the pain originated centrally to the lesion and was probably related to loss of sensory input.

Treatment

No clear guidelines exist for the early management of spinal cord lesions that would prevent the onset of central pain. In the patient with established pain, one must address general issues such as nutrition, skin care, elimination, pulmonary function, seating, and appropriate ongoing active physiotherapy to maintain surviving muscle mass and strength. Socioeconomic issues must be attended to to restore as far as possible independence, self-respect, and confidence. Spasticity and spasms often require separate care through appropriate seating, bracing, antispastic medications, and, in some cases, intrathecal baclofen infusion. Attention to psychosocial issues is essential to maximize the patient's functional capabilities. Pain is the major reason for failure of rehabilitation after spinal cord injury (42).

General Principles of Treating Central Pain

Figure 23-1 presents an algorithm for the management of spinal cord central pain. Central pain is a particularly refractory pain syndrome. Only one-third to one-half of patients who experience spinal cord central pain have severe pain. Chronic pain syndromes can almost never be eradicated and can only significantly be reduced in less than one-half the patients treated. Even after initially successful treatment, chronic pain tends to recur with time, regardless of the syndrome or treatment modality (43). Therefore, a treatment modality must be selected by the patient on the basis of the patient's reaction to realistic outcome statistics, risks of therapy, and cost.

Figure 23-1. Algorithm for the treatment of cord central pain. (DBS, deep brain stimulation; DCS, dorsal column stimulation; DREZ, dorsal root entry zone.)

Medical Treatment

The initial treatment should be conservative. Although there have been many investigations of the possible pharmacologic bases of spinal cord central pain and of strategies for its relief, a dearth of specific therapeutic guidance exists (44). Drewes and colleagues (45) found valproate of no value in a double-blind crossover study. Chiou-Tan and colleagues (46) found mexiletine of no value. On the other hand, Eide and colleagues (47) in a randomized double-blind crossover study found that the *N*-methyl- d-aspartate receptor blocker ketamine and the μ opioid receptor agonist alfentanil reduced both spontaneous and evoked pain. Ketamine, although it diminished allodynia, did not affect wind-up pain. Taira and colleagues (48) suggest that intrathecal baclofen not only reduced spasticity in spinal cord–injured patients but also brought about a 64% reduction in the central pain of spinal cord as well as of brain origin. The pain diminished within 1 to 2 hours of infusion, and relief lasted 10 to 24 hours. Middleton and colleagues (49) suggest, based on a single case, that the combination of intrathecal baclofen with clonidine is more effective than the use of baclofen alone. Fenollosa and colleagues (50), in a questionnaire study of 380 patients (38% of whom responded) who suffered from spinal cord injury, revealed that 65.5% experienced pain, of which the steady, burning, dysesthetic component was the most common. Their pharmacotherapy strategy was reported as successful in 33 cases (35% by my calculation) and included the use of amitriptyline, clonazepam, nonsteroidal antiinflammatory drugs, and 5-hydroxy-tryptophane. They also found intrathecal morphine infusion useful. Watson (51) recommended the use of carbamazepine in central pain states related to multiple sclerosis. Both this drug and amitriptyline were effective in a three-phase placebo-controlled study of stroke pain (52), but trazodone, a serotonin-potentiating antidepressant, failed to show benefit in spinal cord central pain (53). Desipramine (54), a norepinephrine-potentiating antidepressant, may relieve neurogenic pain. Watson could find no controlled studies of opioids and anticonvulsants in central pain. Further information on drugs for central pain states can be found in Chapter 84, Chapter 85 and Chapter 86.

Most authors recommend the use of nonsteroidal antiinflammatory drugs and simple analgesics to manage the nociceptive musculoskeletal pain and the use of amitriptyline, carbamazepine, diphenylhydantoin, chlorpromazine, and diazepam for the neuropathic pain. In this author's opinion, narcotics are an unwise choice because of the relative insensitivity of the central pain to these drugs and the development of side effects. Anecdotal reports indicate that some patients may have a good response; a trial of opiates may be warranted when other drugs have failed. Depression and other concomitant psychological problems must also be managed. However, few attempts have been made to evaluate the use of different psychological treatment strategies in the management of spinal cord injury pain. However, if central pain is severe, medical therapy is often disappointing (5,6,44), forcing consideration of more invasive strategies.

Surgical Treatment

In the choice of surgery for spinal cord central pain, the general principles mentioned previously must be kept in mind: the limited success and the incidence of complications balanced against the severity of the pain and its effect on life. The simplest and safest measures should be used first. The pain must be analyzed and broken down into its component parts, each with its separate pathophysiology. Then, a procedure must be chosen that addresses the pathophysiology of the primary pain. Before embarking on pain-relieving surgery, the need for any primary spinal procedure must be ruled out and appropriate imaging studies obtained. The latter helps with planning such operations as the dorsal root entry zone (DREZ) procedure and dorsal column stimulation (DCS) and also identifies a secondary syrinx that, if progressive, must be dealt with first. The use of a multidisciplinary approach is essential. Success after pain surgery is not manifest by the score on an analog pain scale alone, but also by the patient's overall satisfaction with the procedure, the beneficial effect on lifestyle, the requests for medication, and subsequent health care consumption (55). Inappropriate narcotic intake should be managed before commencing surgical treatment.

Local anesthetic diagnostic blocks are of little benefit (5,6). They usually yield temporary pain relief in neuropathic pain syndromes whether done proximal or distal (56) to the causative lesion. Repeated local anesthetic blockade in our hands has not reduplicated the therapeutic benefits described by Livingston (7). Permanent section of the same neural structure affected by the block does not lead to long-term pain relief (2,3 and 4,7). Nerve blocks may be useful in monoradicular syndromes by allowing confirmation of the fact that division of a particular root can stop the allodynia or hyperpathia. They also allow an assessment of the degree of sensory loss, particularly position sense, to be expected should that root be divided in an attempt to relieve the pain, which is particularly important in a quadriplegic with allodynia from a root lesion in the arm. Sympathectomy has little utility except in the rare case of complex regional pain syndrome type I that is superimposed on spinal cord injury (see Chapter 20).

Operations for Syrinx. If the preliminary investigation discloses the presence of a syrinx, the first step is to treat it, usually with an appropriate shunting procedure. Syringomyelia should be suspected in long delayed onset of spinal cord central pain and in patients who show delayed changes in their neurologic status. Contrary to general impressions, we and others, including Milhorat and colleagues (26), have found that drainage of a syrinx usually does not significantly improve spinal cord central pain. Milhorat and colleagues reported 37 patients with syrinx associated with spinal cord central pain. After decompression of the syrinx, only 19% of patients were totally, and 41% partially, relieved of their pain after a 6-week interval. Any improvement was maintained for a year in only 24% of patients, all of whom retained unpleasant symptoms. It may be useful in the management of neuralgic pain presumably caused by impingement of the upper level of the syrinx on the spinal cord, but most patients still must be treated for their spinal cord central pain after decompression of the syrinx in the same way as those not experiencing this complication. In summary, the syrinx must be treated to prevent additional neurologic deficits; pain, when present, is not usually alleviated by treatment of the syrinx.

Miscellaneous Procedures. Procedures such as the intrathecal injection of hypertonic saline, cold saline, phenol, or alcohol are seldom reported in the current literature, although selective phenol or alcohol rhizotomy could be useful as an alternative to percutaneous radiofrequency rhizotomy. They have the disadvantage, compared with radiofrequency lesioning, of not easily permitting physiologic corroboration of the target site, of being less discriminate, and of not uniformly

penetrating the target structure.

Significance of the Outcomes of Destructive versus Neuroaugmentative Surgery

This issue is addressed here, before consideration of the individual procedures, because it reflects on the pathophysiology of the pain. Table 23-9 documents our experience with surgical treatment of spinal cord central pain (22). Chronic stimulation that produces paresthesiae in the area of pain has limited efficacy for the relief of spontaneous, steady pain but is not useful for the treatment of intermittent spontaneous neuralgic pain or of allodynia and hyperpathia; the reverse seems to be true for destructive lesions such as cordotomy, cordectomy, and the DREZ operation, the differences being statistically significant.

		Relief by pain type (% of patients)					
		Steady		Neuralgic		Evoked*	
Surgery	No. of patients	Good	Fair	Good	Fair	Good	Fair
Cordotomy	39	6	21	54	32	50	25
Cordectomy	12	8	38	66	49	66	29
Dorsal root entry zone lesion	4	0	1	1100	0	50	50
Dorsal column stimulation	22 incomplete lesions	27	14	0	0	0	25
	19 complete lesions	0	28	0	0	0	0
Paresthesia-producing deep brain stimulation	12	25	17	0	0	0	0

*Allodynia and hyperpathia.

TABLE 23-9. Response of cord central pain to surgery

How can we interpret this? Patients with spinal injury may experience injury to either spinal cord, spinal roots, or both (see Chapter 34). Pain resulting from injury to roots is in fact an example of peripheral neuropathic rather than of central pain, regardless of the quality of the pain. For example, patients with cervical cord lesions may experience disabling allodynia in the distribution of a spared cervical root emerging near the level of injury. However, allodynia and hyperpathia may also occur in patterns compatible only with spinal cord damage. It is now recognized that allodynia associated with peripheral (including spinal root) lesions is the result of altered processing in the dorsal horn of incoming nonnoxious stimuli. This leads to signals being transferred into the spinothalamic tract rather than the dorsal columns and results in the experience of pain (57,58). It would be expected that such allodynia would be relieved by medical or surgical strategies that blocked transmission in the spinothalamic tract either by modulation or transection, which is confirmed when one examines the surgical experience. It is more difficult to understand the mechanism of allodynia or hyperpathia caused by spinal cord lesions, because the causative lesion in these cases is proximal to the dorsal horn. Nevertheless, in such cases the evoked pain is relieved by transection of the spinothalamic tract, the DREZ procedure, and cordectomy (see Chapter 105 and Chapter 106).

The next element of spinal cord injury pain to be considered is the spontaneous, intermittent neuralgic pain that has been recognized by many authors to be associated with conus and cauda lesions (59). Such pain may be the result of root damage. Our experience and that of others is that, like allodynia and hyperpathia, it is relieved by interrupting the spinothalamic tract, by the DREZ operation, or by transection of the spinal cord (22). Like Sindou and colleagues (60), we regard the DREZ procedure as interrupting part of the spinothalamic pathway. In the literature concerning Nashold's DREZ operation (32,61,62 and 63), it is recognized that this procedure, like cordectomy in Jefferson's experience (14), and cordotomy in our own (22) and that of Botterell and colleagues (20), is ineffective for the relief of the spontaneous, steady pain but that it relieves *end-zone* pain, by which Nashold and his group mean pain beginning at the level of the lesion and extending caudally for a variable number of dermatomes as well as radicular pain (32,64). A possible explanation for this type of pain is that injury to a root in the cauda equina or to the spinal cord may establish a focus of ectopic impulse generation that is transmitted proximally in the spinothalamic tract (65,66).

Visceral and musculoskeletal spinal cord pain is so infrequent that conclusions cannot be made about its possible pathogenesis.

There remains the most common element of spinal cord central pain, the spontaneous, steady, often causalgic or dysesthetic element similar to that seen in all types of neuropathic pain. In spinal cord central pain, this is more characteristic of lesions above the level of the conus, although it can also occur in radicular distribution. This is the type of pain that is most difficult to relieve. It is not stopped by spinal cord transection above the level of the injury (14,22,59), but responds best to chronic stimulation that produces paresthesiae in the area of the patient's pain. It is wise to keep an open mind concerning the pathophysiology of such pain, as no theory adequately accounts for it or for its relief by chronic stimulation. Again, as outlined in Table 23-1, its features are that it is not always present after spinal cord injury, it may take time to develop, it may appear after a long interval when the patient develops a syrinx; the change in the pattern of such pain may reflect the fact that the damage caused by a syrinx is now being added to the pain that was already there from the spinal cord injury. This subject has been reviewed by Yezierski and Nashold (16,32).

Various explanations have been offered to explain neuropathic pain as listed in Table 23-10. In reviewing such a list, it is necessary to reconcile the suggested hypothesis with the clinical facts. Ephapses and ectopic impulse generation could explain the generation of neuralgic pain. Pathologic sympathetic drive could be at work in sympathetically maintained pain caused by peripheral root injuries, but it is difficult to see how it could have anything to do with central pain; the same is true for hypothalamic dysfunction. Denervation neuronal hypersensitivity, with its suggested marker of bursting cells, is discussed under Brain Central Pain, later in this chapter. To result in pain, somatotopographic reorganization, which also is discussed under Brain Central Pain, must be capable of occurring through synaptic reorganization rather than sprouting, because in some patients the pain onset is immediate. Whether sprouting is involved later on cannot be easily determined. Other suggestions involve various patterns of activation or disinhibition of pain pathways, and most of these suggestions would be compatible with the clinical facts. Because they are more difficult to review in the case of pain caused by spinal cord injury than by brain lesions, they also are discussed with the latter.

Ephapses at injury site
Ectopic impulse generation at injury sites
Pathologic sympathetic drive
Hypothalamic origin
Denervation neuronal hypersensitivity of either somatosensory-specific or reticulothalamic-nonspecific pathway, usually correlated with presence of bursting cells
Somatotopographic reorganization in response to injury with opening of alternate pathways through synaptic reorganization or sprouting
Irritation of sensory pathways
Disinhibition of pattern-generating systems
Selective neospinothalamic destruction with disinhibition of spinoreticulothalamic system
Interference with inhibitory mechanisms acting on the nociceptive afferents
(a) At thalamus allowing disproportionate nociceptive projection or with loss of inhibition by reticular nucleus on medial thalamus
(b) By loss of retrograde thalamocortical influence
(c) By loss of medial lemniscal dumping of nociceptive fibers

TABLE 23-10. Suggested mechanisms for central pain

Percutaneous Radiofrequency Dorsal Rhizotomy. In monoradicular pain syndromes, particularly with allodynia, physiologically monitored radiofrequency percutaneous dorsal rhizotomy may be useful in selected patients after due consideration for the sensory deficit incurred by the loss of that root.

Dorsal Column Stimulation. Peripheral nerve stimulation is rarely feasible in spinal cord central pain, but one of the first surgical procedures that should be considered is DCS, because of its simplicity and low risk (see Chapter 100) (67,68,69,70,71 and 72). It is indicated as a first procedure in any case of spinal cord central pain in whom it is deemed that sufficient dorsal columns survive above the lesion to allow their stimulation to produce paresthesiae in the patient's area of pain; it has no role in the treatment of pain in an anesthetic or near anesthetic part and proves useless in most patients with incomplete lesions because of inability to produce appropriate paresthesiae. It is because of the inability to produce adequate paresthesiae that DCS has such a low success rate in treating spinal cord central pain. Another problem is that spinal cord injury itself or the primary surgical treatment of the pain- causing lesion may have so disturbed the local anatomy that DCS is

rendered impossible or unusually risky. The author prefers the simpler percutaneous technique of DCS to the use of paddle-type electrodes installed at laminotomy.

Usually, a trial of stimulation is performed first, proceeding to implantation of a permanent device only if more than 50% of pain reduction occurs during the trial. Twenty-two of our patients with incomplete spinal cord lesions were treated with DCS, 27% enjoying good (more than 50%) and 14% fair (25% to 50%) relief of steady pain (22). In 11 patients with complete lesions, 20% reported fair relief and then only of pain at the level of their sensory loss. It was most effective in patients with steady pain with incomplete lesions of the conus and cauda equina. Published outcome data are given in Table 23-11 confirming general unsatisfactory experience with this modality in spinal cord central pain. Complications consist of up to a 5% superficial infection rate and 10% technical problems, such as lead migration, equipment failure, and pain at implant sites. Pagni (6) and Nashold (73) concluded that the modality was disappointing for the relief of central pain. Despite the poor outcome, the simplicity and safety of DCS dictate its trial whenever possible.

No. of patients	% Relieved	Reference
19	16	66
9	22 (pass trial of dorsal column stimulation)	67
10	50 (pass trial of dorsal column stimulation)	69
3	33	68
33	18	22
25	18.2 (after 3 yr)	70
101	31 (short term)	71
	18 (longer term)	

TABLE 23-11. Published outcome of dorsal column stimulation for cord central pain

Deep Brain Stimulation. In the author's opinion, when DCS fails in the treatment of the steady component of spinal cord central pain, deep brain stimulation (DBS) to produce paresthesiae in the painful part of the body is the next surgical choice. This can be accomplished by implanting electrodes either in the medial lemniscus if a large part of the body is affected with pain, or more usually, in the tactile relay (Hassler's ventrocaudal) nucleus of the thalamus or the lemniscal radiations for more localized pain. Spinal cord central pain is often bilateral, and this necessitates bilateral implants. The best indication is steady pain in patients in whom DCS failed to produce paresthesiae in the area of pain; in our experience, if DCS produces adequate paresthesiae and fails to relieve the pain, paresthesia-producing DBS also fails (74). Paresthesiae-producing DBS is preferable to periventricular gray (PVG) or periaqueductal gray DBS for the steady neuropathic pain, the latter being preferable for nociceptive pain. This dichotomy in the use of the two types of DBS is supported by the conclusions of Bendok and Levy (75) (Table 23-12). Table 23-13 lists outcome data for DBS in the treatment of neuropathic pain. Complications occur in less than 8% of patients, and death in 0.6% (75).

Treatment of the Neuralgic Component of Spinal Cord Central Pain

In the patient with (usually) a conus/cauda lesion with significant neuralgic pain shooting up or down the legs below this level, relief is unlikely with DCS, although it is probably best to offer a trial of this modality first because of its simplicity. If DCS fails, and it usually does, the next simplest step is a destructive procedure to interrupt the pain pathways such as cordotomy, cordectomy, or DREZ lesion.

Cordectomy. The simplest destructive procedure is to retransect the spinal cord, usually referred to as *cordectomy*, just above the level of the patient's injury, at the expense of elevating the sensory level one or a few segments and of denervating the lower abdominal muscles. The history of cordectomy has been reviewed by Nashold (32), and has usually consisted of small series of patients with unspecified pain types and somewhat inconsistent results. The exception is the work of Jefferson (14), who reported 19 patients treated by cordectomy. He found the procedure successful with lesions below T-10, especially if the pain was referred to anterior thighs and knees and if it was episodic in nature. Twenty-five percent of four patients with lesions at or above T-10 derived slight relief, whereas 47% of 15 patients with lower lesions were completely relieved, 47% more than 70%. The remaining patients reported 50% relief. In 12 of the author's patients undergoing cordectomy for spinal cord central pain, 60% enjoyed good relief and 40% fair relief of neuralgic pain; 80% good relief and 20% fair relief of allodynia, hyperpathia, or both; but only 30% enjoyed fair relief of steady pain. In these days of optimism for eventual restoration of damaged spinal cord function, cordectomy has become a psychologically unacceptable procedure despite its advantages for the patient with a complete lesion.

Cordotomy. Cordotomy, preferably by the percutaneous technique, achieves the same result as cordectomy, interruption of the spinothalamic tract. Various authors have noticed the selective differential benefit of cordotomy on the neuralgic compared with the steady element of the patient's pain (10,11,20,31,83), and our own experience is similar (22). Out of 39 of our own patients undergoing cordotomy, mostly by the percutaneous technique, 54% enjoyed good relief and 32% fair relief of the neuralgic pain, 50% good relief and 25% fair relief of the evoked pain, and 6% good relief and 21% fair relief of the steady elements of spinal cord central pain.

However, percutaneous cordotomy carries a small risk of producing ipsilateral limb paresis and of aggravating bladder dysfunction, crucial matters for the spinal

cord–injured patient with an incomplete lesion. Open thoracic cordotomy can obviate any risk of respiratory or upper extremity dysfunction in patients with thoracic or lumbosacral spinal cord injuries.

It has already been stressed that chronic pain tends to recur after its initial relief by medical or surgical strategies. This is clearly documented by Rosomoff and colleagues (83) in the case of cordotomy. Although we do not know how many of his patients suffered from spinal cord central pain, because of the reported length of follow-up the pain was unlikely to be caused by cancer and the same outcome would be expected in spinal cord central pain as we have found (84). He found that, initially, cordotomy relieved 90% of patients operated on, but that after 3 months relief had fallen to 84%, after 1 year to 61%, after 1 to 5 years to 43%, and after 5 to 10 years to 37%.

Dorsal Root Entry Zone Procedure. Although the pathophysiology corrected by the DREZ operation has not been clarified (63), the work of Sindou (60) with a related procedure has convinced this author that it relieves pain by interrupting the pain pathway from the somatotopographically related area of the body. This procedure has proved equally successful as cordectomy and cordotomy in the relief of the neuralgic and evoked elements of spinal cord central pain. Like cordectomy, it results in an elevation of the patient's sensory level and requires a laminectomy and considerable skill to do. It probably does not share the disapproval of the cordectomy procedure regarding future spinal cord regeneration, and it avoids the risk of paresis from cordotomy. It does have the propensity when performed at the conus, as is usually necessary, to interfere with any surviving bladder function. Table 23-9 lists our own and Table 23-14 lists published outcome data with the DREZ procedure for spinal cord central pain.

39	64	90

TABLE 23-14. Published outcome data for dorsal root entry zone operation for cord central pain

Although I have stated previously that the DREZ procedure is beneficial for the neuralgic element of spinal cord central pain, this is my interpretation of the work of others. Nashold and Bullitt (62) and Friedman and Bullitt (64) found the procedure most useful for the relief of end-zone pain (i.e., pain starting at the level of injury and extending distally), and not so effective for the diffuse, often sacrally distributed pain. Friedman and colleagues (87) found the procedure useful for pain that extended into the dermatomes immediately caudal to the level of injury, which they referred to as *root, radicular*, or *end-zone pain*. Pain extending into areas remote from the injury site described as *phantom, body*, or *diffuse burning pain* was not very responsive.

Stereotactic Surgery. In this author's experience, with his own patients, and reviewing the literature, destructive stereotactic procedures such as medial thalamotomy or mesencephalic pain tract section yield such poor relief of central pain that they are rarely indicated. Meglio (44), who reviewed the overall management strategies for central and deafferentation pain, agrees with this conclusion. I found 22% to 36% of 150 patients with central pain improved after various thalamotomy procedures (92). Nashold's literature review (93) suggested a 50% benefit after mesencephalic tractotomy. My review suggested 27% (94), whereas Cassinari and Pagni (5) suggested 50%, Pagni (95) 50%, and Davis and Stokes (96) 50%. Pagni, reviewing his own cases, found 30% relief (95), and Gybels and Sweet (97) found 44% relief of various neuropathic pains after mesencephalic tractotomy.

Other Procedures. I agree with Nashold (74) that destructive procedures performed on the cerebral cortex are only of historic interest in the treatment of central pain (see Chapter 108). Procedures directed toward the limbic system, hypothalamus, and hypophysis have all been advocated, but data are too sparse to draw conclusions. We do not consider the treatment of spasticity and spasms as within the realm of this chapter, although they may contribute to the problem of the pain. Although it has become popular to use chronic spinal infusion of opiates for the relief of various types of pain, like Meglio (44) we cannot find convincing evidence for the usefulness of spinal opiates in central pain.

BRAIN CENTRAL PAIN

Central pain caused by brain lesions is more enigmatic and more intractable than that arising from the spinal cord. Another example of neuropathic pain, it shares with the latter the peculiar clinical features described under Spinal Cord Central Pain. It can arise from lesions of any etiology between the foramen magnum and the cerebral cortex, whether minimal or massive or associated with minor or major neurologic deficit. Like other types of neuropathic pain, it is idiosyncratic, often has a delayed onset, may occur in the absence of clinically detectable sensory loss, and commonly has three features: spontaneous steady, neuralgic pain, and evoked pain (allodynia and hyperpathia). Whereas in spinal cord central pain, steady pain, and neuralgic pain are most common, in brain central pain, steady pain, and evoked pain predominate. The papers by Riddoch (98) and Dejerine and Roussy (99) are pioneering masterpieces in its clinical description.

Incidence and Etiology

Most cases of brain central pain are caused by strokes. Table 23-15 lists the etiology in 73 of the author's cases. Brain central pain is rare, said to occur in only 1% to 2% of all strokes (9). Andersen and colleagues (100) studied 207 consecutive stroke patients and found that 8% went on to develop central pain, severe in 5%; 7% of the patients had allodynia.

TABLE 23-15. Etiology in 73 cases of brain central pain

The paper by Dejerine and Roussy (99) planted the notion that stroke-induced pain depended on thalamic lesions, but modern imaging has confirmed what a few pioneering studies, such as that of Biemond (101), had long suggested: Pain can arise from lesions in brainstem, thalamus, subcortical white matter, and cerebral cortex (102,103). When thalamic lesions cause pain, they tend to lie in ventroposterior thalamus (104), although anatomic studies have failed to agree on a specific site [somatosensory relay and posterolateral thalamus (105), lateral posterior and lateral dorsal thalamus (106) being suggested]. On the other hand, brain central pain is rare after craniocerebral injury (107), craniotomy, or cerebral cortical lesions. Electrical stimulation of the brain (25) and epileptic seizures (108) rarely evoke pain. When they do occur, algogenic cortical lesions are usually located in the parietal area, thought by some to include the spinothalamic projection to the second

somatosensory cortex (109), particularly in the white matter deep to the caudal ansa and the opercular region.

It has been noted that when the thalamus is involved in stroke-induced pain, right-sided lesions are more prevalent than left (110,111), because a literature search revealed 63% of 114 cases of stroke-induced pain involving the thalamus were right-sided. In the author's 11 patients with central pain after six isolated thalamic lesions and five that involved thalamic and suprathalamic structures, 82% were on the right side (112). Tantalizing information that has never led to useful therapy includes the anecdotal accounts of relief of brain central pain after a second stroke, such as the report by Soria and Fine (113) in which a second stroke involved the corona radiata interrupting thalamoparietal connections.

Brain central pain can be reversible in other ways. Potagas and colleagues (114) describe a patient with intermittent pain in the right upper limb caused by an otherwise asymptomatic low-grade glioma of the white matter of the parietal operculum whose pain stopped after excision of the tumor. In a personal patient who had a right parietal hemispheral meningioma with contralateral brain central pain, the pain disappeared after removal of the tumor.

Hamby (115) reported relieving posttraumatic brain central pain associated with allodynia by exploring and excising the patient's atrophic, gliotic parietal cortex, stimulation of which had been painful; pain relief persisted for 10 years. Erickson and colleagues (116) reported two patients with *thalamic pain syndrome* relieved by resection of the postcentral gyrus, but that experience does not appear to have been duplicated by others (4).

Functional Imaging in Brain Central Pain

Functional imaging is a promising tool for the investigation of the mechanism of brain central pain. Cesaro and colleagues (117) found that stimulating the affected half of the body so as to produce hyperpathia in two patients with stroke-induced pain associated with hyperpathia produced thalamic hyperactivity in the SPECT scans, but this was not seen after stimulation of the unaffected side. Stroke pain patients without hyperpathia did not show this hypersensitivity to stimulation. They hypothesized that many thalamic inhibitory neurons lie in the nucleus reticularis thalami and project to the medial nuclei. Loss of their function after a stroke involving thalamus could therefore result in disinhibition of the medial thalamic nuclei and possibly pain; no other connections are known between the medial and lateral thalamic nuclei. Canavero and colleagues (118), in a SPECT scan study of five patients with different neuropathic pain syndromes, found reduced perfusion in the parietal lobe further reduced by inducing allodynia and postulated that cortical inhibition was in some way involved in the production of central pain. The injection of propofol reduced brain central pain for 5 minutes, during which time the thalamic hypoperfusion improved.

Hirato and colleagues (119) studied 5 controls and 11 patients with stroke pain using positron emission tomographic scans. Patients with thalamic lesions tended to have *superficial* pain, those without it *deep* pain. In the thalamic group, background neural activity was reduced in the ventral intermediate region and increased in centrolateral nucleus, whereas regional cerebral oxygen consumption was well maintained on the side of the stroke except in the thalamus, including the cerebral cortex surrounding the central sulcus; regional oxygen extraction ratio was increased around central sulcus. In nonthalamic stroke pain patients, neural activity was generally maintained except in centrolateral nucleus, in which it was low, whereas in these pain patients and after strokes that failed to produce pain, regional cerebral oxygen consumption and regional oxygen extraction ratio were reduced in all contralateral brain structures, as was the regional oxygen extraction ratio. They concluded that the function of nonspecific afferents was maintained in thalamic stroke patients and was possibly contributing to the pain. They postulated that the increased bursting activity in thalamus was related to the increased activity in the motor and premotor cortex, which in turn had a facilitating effect on spinal cord dorsal hornd the thalamic intralaminar nuclei. They also postulated that lost activity in the sensory cortex might result in disinhibition and that this disinhibition, as well as the effect on intralaminar nuclei, might be related to the central pain.

Another study (120) described 13 stroke patients. Irregular burst discharges were often encountered in the posterolateral thalamus, their prevalence correlating inversely with the number of sensory responses there. These findings were associated with increased regional cerebral glucose metabolism and the relative value of glucose to oxygen metabolism in the cortical precentral area ipsilateral to the lesion. These factors were reduced in thalamus and cortical postcentral area in all cases. They postulated that sensory cortex damage could disinhibit the motor area, somehow resulting in pain.

Canavero and colleagues (121) reported one patient with poststroke pain from a suprathalamic lesion who demonstrated parietal hypoperfusion on SPECT scan and two with thalamic lesions with either frontal parietal or thalamic hypoperfusion. They considered this evidence of inhibition and went on (122) to suggest that central pain resulted from a chemical imbalance between glutamatergic and GABAergic mechanisms in transmission between sensory thalamus and cortex. They proposed that these imbalances might be corrected by opposing glutamatergic or potentiating GABAergic transmission, for example, by administering ketamine or propofol, respectively.

Clinical Features of Brain Central Pain

Although published data vary, the clinical features of 73 personal cases of brain central pain are summarized here (112): 54.8% of our 73 patients were men, and pain was right-sided in 43.9%, left-sided in 53.4%, and bilateral in 7%. Age of affected patients at the time of onset is shown in Table 23-16. Accompanying neurologic signs are listed in Table 23-17 and lesion sites in Table 23-18, nearly 70% having hemiparesis, which was severe in 21.9%. After a variable delay, pain with three chief features (64.4%) or dysesthetic (31.6%), intermittent (16.4%), and allodynia and hyperpathia (64.9%).

Age (yr)	%

TABLE 23-18. Location of brain lesions causing central pain

Steady pain was usually described as burning (64.4%), although other adjectives were applied (Table 23-19). Distribution of intermittent pain was similar to that of pain overall, as shown in Table 23-20, and so was its association with sensory loss. Allodynia and hyperpathia are characterized in Table 23-21 and Table 23-22. The only feature noted is its relative infrequency in the absence of clinically detectable sensory loss.

TABLE 23-23. Type of pain in 40 cases of brain central pain and correlation with lesion site

Onset is often delayed; Table 23-24 tabulates the time of onset in 73 personal cases (112) and two published series (100,123). Pain was almost always referred to a part of the body in which sensation was affected except where there was no clinically detectable sensory loss at the time the patient was seen with the pain, although there might have been loss earlier in the patient's history. Distribution of pain varied and bore no relation to any clinical features. Size, side, or location of the lesion; degree of sensory loss; age; and sex all had no effect on the quality or severity of the pain (100,112).

TABLE 23-24. Delayed onset in brain central pain

It is just as important to cite structures whose damage does not cause pain as those that do. First, the lesion must affect the somatosensory system. Lesions of the nonspecific spinoreticulothalamic tract, limbic system, dorsomedian, centrum medianum, intralaminar and reticular nuclei, and kinesthetic somatosensory pathway (ventrolateral, posterolateral, anterior nuclei of thalamus and globus pallidus and Forel's fields) virtually never cause pain, as attested to by the absence of central pain in the thousands of patients undergoing medial thalamotomy, cingulumotomy, hypothalamotomy, and various lesions for the treatment of movement disorders (4,5,73,124). However, central pain follows 4% to 18% of lesions made in the lemniscal relay nucleus of the thalamus in attempts to (125).

Table 23-25 shows the distribution of sensory loss in our 73 patients. It was confined to the face in 6.9%, in which it was usually dissociated. Pain was usually associated with sensory loss in all modalities, less often dissociated sensory loss, and rarely occurred in the absence of spinothalamic loss. Boivie and Leijon (123), using psychophysical techniques in 63 cases, concluded that all stroke pain patients have sensory abnormalities, with impaired pain and temperature appreciation being the key common factor; they report, however, one additional case outside their study group of 63 patients in whom no clinically detectable sensory loss was present. They found allodynia in 57% of their Swedish patients, 23% of their British ones.

Hemibody, all modalities	46.5
Dissociated sensory	20.5
All modalities but chiefly pain and temperature	8.2
Hyperpathia, allodynia, or both	6.8
Touch, position, vibration alone	5.5
None	5.5

TABLE 23-25. Pattern of sensory loss in 73 cases of brain central pain

Vestergaard and colleagues (126) studied sensory deficit in 11 stroke pain patients, all of whom had increased threshold for pain appreciation in the affected areas, 10 increased threshold for cold, and a less striking increase in the threshold for heat and cold pain. Four of the 11 also had an increased threshold to touch and three to argon laser pain. There was a tendency for neuralgic pain to accompany brainstem lesions as in the case reported by Nashold and colleagues (125), in whom paroxysms of pain seemed to be accompanied by bursting slow wave electrical activity recorded in the midbrain, which was relieved by lesions made there. Leijon (127) correlated steady pain with infratentorial brainstem and extrathalamic supratentorial lesions and lancinating pain with thalamic lesions. This is not in agreement with our observations.

Andersen and colleagues (100) studied 207 consecutive stroke patients, of whom 16 developed central pain, finding that the patients who went on to develop pain had larger lesions and more pronounced abnormalities of sensitivity to cold and warm than did those who did not. These abnormalities consisted of increased sensitivity to cold, decreased sensitivity to warmth, and allodynia or dysesthesia to touch or cold but not to warmth. Stroke pain in the absence of sensory loss has been reported by others (5,6,107), in addition to ourselves (112) and Boivie and Leijon (123). We have seen brain central pain in patients with selective damage to the lemniscal pathway, and one case has been reported in the literature (128). As with spinal cord central pain, not all patients with appropriate sensory abnormalities go on to develop pain, suggesting that neuropathic pain may be related to factors other than neuronal loss.

Bowsher (129) studied 156 stroke and spinal cord central pain patients, finding pain onset usually delayed (between 1 week and 6 years in more than 69% of patients). Right and left sides were equally affected, and two-thirds had allodynia, including movement allodynia. Pain occurred within the area of sensory deficit, the critical component of which was interference with thermal and pinprick appreciation. These losses were particularly prominent in areas of maximum pain. Deficits in mechanoreceptive functions were not so related. He concluded that the best hypothesis to explain the pathophysiology of central pain was upregulation or downregulation of receptors for transmitters, particularly noradrenergic ones that developed over time.

Hoogenraad and colleagues (130) described a case of visually induced pain in the numb side of the body after a right parietal cortical infarction associated with left hemianesthesia. Jensen and Lenz (131) commented on the hyperalgesia and allodynia described in the original paper by Dejerine and Roussy (99) concerning stroke-induced pain. These evoked elements are said to occur in three-fourths of stroke patients by Andersen and colleagues (100). Jensen and Lenz suggest that allodynia and hyperpathia never occur in stroke pain patients without accompanying spontaneous pain. However, we have observed evoked pain in the absence of

spontaneous pain in spinal cord (see Table 23-5) and brain central pain (see Table 23-25), and Pagni (4) reports it in stroke central pain. Jensen and Lenz comment that the essential damage necessary to produce brain central pain is to the spinothalamic tract, but comment on the fact that some patients who have such damage do not have pain.

Relationship to Dyskinesia

The original description of the Dejerine-Roussy syndrome (99) included dystonia on the same side of the body as the pain. Dystonia affected 8.2% of our 73 cases (112), always associated with thalamic lesions. It must be remembered that stroke- induced dystonia occurs regularly in the absence of central pain. Of our 73 patients, 6.8% had tremor accompanying their central pain, especially in the case of brainstem lesions, in keeping with observations on experimentally induced tremor produced by brainstem lesions in experimental animals. Again, tremor can occur after brainstem strokes in the absence of pain.

Pathophysiology of Brain Central Pain

The features of brain central pain are similar to those of spinal cord central pain and to peripheral neuropathic pain, suggesting the possibility of a common pathophysiology. The issue has been partly discussed under Spinal Cord Central Pain, and common theories are listed in Table 23-10. This matter may be easier to pursue in brain than in spinal cord central pain, because imaging identifies the responsible lesions that are then accessible to physiologic exploration during the course of stereotactic surgery aimed at alleviating the pain. Whatever the accepted theory, it must be consistent with clinical facts. It must take into account the features listed in Table 23-1, such as immediate or delayed onset and reversibility after removal of the causative lesion, and it must take into account the causative lesions, the neural deficit produced, and the response to treatment strategies. Although by no means exhaustive, Table 23-10 lists popular theories offered to explain central pain, some of which can be examined physiologically during stereotactic surgery. Ephapses and ectopic impulse generation seem reasonable explanations for, particularly, the intermittent neuralgialike pain in conus and cauda and possibly stroke lesions. There do not appear to be convincing data to incriminate sympathetic or hypothalamic involvement. Denervation neuronal hypersensitivity could take the form of bursting cells (a popular notion) or some less obvious alteration of neuronal function. Most of the remaining suggestions are variations on the theme that loss of an ascending pathway damaged by the stroke results not only in loss of the function of that pathway but also in disinhibition of other structures. Regev and colleagues (132) reported a patient with a pontine hematoma without somatosensory deficit but with transient spontaneous pain and allodynia to touch, pinprick, and temperature, attributed to damage to the central tegmental tract, with resulting disinhibition of the thalamus by the reticular formation resulting in the pain. Cassinari and Pagni (5) found central pain rare after medullary spinothalamic tractotomy and attributed this observation to concomitant damage to the reticulospinothalamic tract with resultant lack of disinhibition.

Boivie and Leijon and their colleagues (123,127,133) concluded from their clinical studies that lesions of the spinothalamic cortical pathways or their trigeminal equivalents were necessary for brain central pain to develop, in contradistinction to the older hypothesis that medial lemniscal pathway damage was essential. Bowsher (134) proposed that selective destruction of the spinothalamic tract sparing the spinoreticulothalamic tract fibers that subserve pain was responsible for central pain through disinhibition of the nonsomatotopographic pathway. Craig (135) has collected evidence to support the hypothesis that stroke- induced pain results from selective loss of thermal sensitivity pathways with disinhibition of cold-evoked pain.

Jensen and Lenz (131) suggest that the pain is caused by central sensitization of the third- or higher-order deafferented neurons. They theorize that the deafferented cells in reticular nucleus can generate bursting activity that can cause hyperpolarization and bursting activity of thalamic relay cells projecting to cortex. Corticothalamic axons pass through the reticular nucleus, giving the neurons collaterals on the way. Thus, a cortical lesion could result in reticular nucleus neuronal hyperactivity and pain. They suggest loss of spinothalamic tract function leads to hyperpolarization of thalamic cells and bursting. Because some of such cells are involved in pain processing, they could cause pain. They rationalize the functional imaging studies showing both increased and decreased thalamic activity in chronic pain and hypothesize that pain control might be achieved by manipulating the interplay of glutamatergic, GABAergic, noradrenergic, serotonergic, histaminergic, and cholinergic input to thalamus. They suggest that serotonergic, noradrenergic, and cholinergic input may be responsible for the bursting and that noradrenergic and serotonergic input might modulate thalamic bursting by action on the thalamic reticular and relay nuclei.

Microelectrode Exploration of the Thalamus in Brain Central Pain

Observations made using stereotactic surgery reflect on these theories. In 29 patients operated on to institute DBS, 22 of them with microelectrodes, in whom lesions ranged from brainstem through thalamus to cortex, we correlated receptive fields (RFs) and projected fields (PFs) with clinical features.

Issue of Bursting Cells

A considerable literature suggests that bursting cells may be markers of neuronal denervation hypersensitivity (2,3,4,136,137,138,140,141,142,143,144,145,146 and 147), and it is currently popular to suggest that these bursting cells, which can occur at any level upstream from the site of injury, could trigger pain. We have extensive experience recording bursting cells in lateral thalamus during microelectrode exploration preliminary to making destructive lesions or implanting chronic stimulators for the relief of chronic pain or movement disorders. Bursting cells occur normally in sleep (148) and in the normal waking state in various medial thalamic nuclei including dorsomedian. In the lateral thalamus we have found them only in patients who have deafferenting lesions, such as amputation, other peripheral deafferentation, spinal cord injury, stroke, previous thalamotomy for tremor, and multiple sclerosis, regardless of whether the deafferentation is associated with pain (149,150). Hirayama and colleagues (151) have suggested that regularly bursting cells that have RFs and are located in the tactile relay might be correlated with pain. Lenz and colleagues (152,153) found a series of abnormalities in the tactile relay nucleus of patients with spinal cord central pain: absent RFs below the level, increased numbers of neurons without RFs, replacement of some missing RFs by RFs from parts of the body that border the level of the lesion, resulting in mismatches between RFs and PFs (sites in the contralateral body where the patient experiences paresthesiae during microstimulation), as well as bursting cells with characteristics of calcium spikes in the deafferented thalamic area. It is possible that bursting cells are responsible for central pain. However, careful study (150) of bursting cells in deafferented patients, with and without pain, failed to provide any correlation between pain and bursting cells in the lateral thalamus.

During surgical exploration of the medial thalamus, Rinaldi and colleagues (154) found bursting cells in dorsomedian, centrolateral, centrum medianum, and parafascicular nuclei in 8 of 10 patients with various types of neuropathic pain, including one case of stroke and one of central pain. These bursting cells occurred from the junction between lateral dorsomedian nucleus, centrolateral nucleus, and centrum medianum to the inferior limit of centrum medianum. Jeanmonod and colleagues (155) made similar observations in 39 of 45 patients with pain, 7 of whom had spinal cord lesions, 2 brainstem, 2 thalamic, and 3 parietal lesions. In their patients, bursting cells were clustered around the centrolateral nucleus, and many of them had the characteristics of calcium spikes. Both groups of authors implicate the bursting cells as generators of neuropathic pain, with Jeanmonod's group reporting considerable success in relieving neuropathic (including stroke) pain by medial thalamic lesions aimed at destroying the bursting cells. I suggest caution in interpreting these findings; we have routinely found bursting cells in this region of thalamus in patients who did not have pain.

Somatotopographic Reorganization

It has been suggested that somatotopographic reorganization may lead to central pain. Kiss and colleagues (156) demonstrated that in humans somatotopographic reorganization can occur within minutes in the ventrocaudal nucleus of the thalamus, presumably by synaptic rearrangement, although, in other settings, it could be the result of sprouting. In our thalamic explorations we found various patterns of RFs and PFs with no correlation with the pain syndrome produced: preserved RFs and PFs with good somatotopographic matching, preserved RFs and PFs with somatotopic mismatch, absent RFs with preserved PFs, preserved RFs with absent PFs, and absent PFs and RFs.

Figure 23-2 is a computed tomographic scan of a patient with a small right-sided thalamic infarct that resulted in fluctuating left-sided burning dysesthetic pain with allodynia. When he was explored stereotactically with microelectrodes to identify sites for electrode implantation for DBS, no neurons were recorded and no responses to stimulation up to 160 μA were found in the 14-mm sagittal plane (Fig. 23-3) except for two sites in which deep tactile facial responses were recovered. This plane, which would normally be expected to house responses referable to hand and face, appeared otherwise dead. The responses that would have been expected there were found laterally misplaced in the 17-mm sagittal plane (Fig. 23-4). At some sites RFs and PFs matched; at others mismatch occurred. In keeping with the fact that the patient had allodynia (see following discussion) pain was elicited seven times, and burning was elicited twice where normally paresthesiae would have been expected.

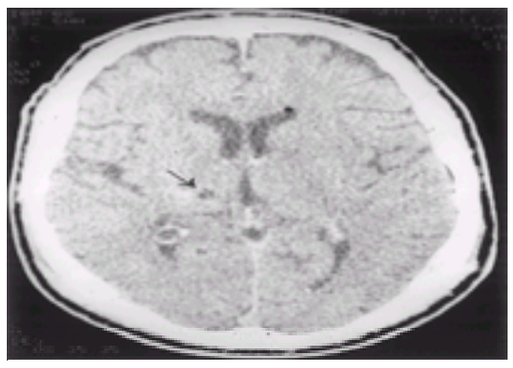

Figure 23-2. Computed tomographic scan of a man who suffered a thrombotic stroke (*arrow*) at the age of 60 years with left hemiplegia. Central pain began 5 to 6 years later. He was studied for 7 years. Pain varied over time, consisting of burning and dysesthesia associated with allodynia relieved by rest and aggravated by activity, affecting chiefly the left upper extremity, face, and head, rarely the trunk or leg. It was associated with dystonia in the left upper limb. There was slight reduction of feeling of pinprick and warmth on the left half of the body; absence of position sense distal to left wrist and ankle; at first, slight reduction of appreciation of touch in left upper and lower extremities, and later no clinically detectable abnormality of appreciation of touch, vibration, or cold. Allodynia was induced by vibration, repeated light touch, and movement in the left upper extremity on some occasions, and by light touch throughout the left side, especially in the cheek at others. There was extinction with simultaneous stimulation bilaterally on the left face and slight reduction of two-point discrimination on the left. A trial of dorsal column stimulation and two trials of paresthesiae-producing deep brain stimulation failed, the latter actually being described as painful. Pentothal, 150 mg intravenously, abolished his pain temporarily.

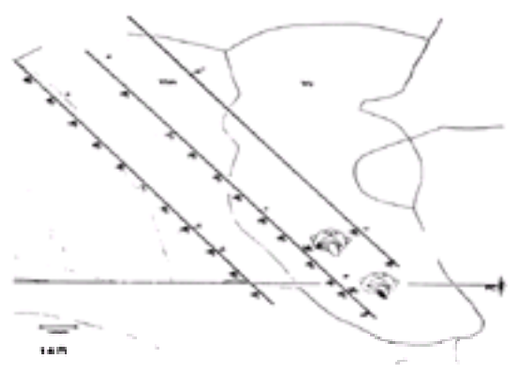

Figure 23-3. Figurine map of the thalamus of the patient seen in Figure 23-2 explored in the 14-mm sagittal plane with microelectrodes. Three trajectories were made with continual recording (receptive fields shown in body diagrams to the right) and microstimulation every 1.0 mm (projected fields shown in body diagrams to the left). *Triangle*, no response to stimulation at the current used. Numbers indicate stimulation strength in microamperes. (M, bursting cells; PC, posterior commissure; SA, slowly adapting; TD, deep tactile; U, unidentified cell; Vc, ventrocaudal nucleus of thalamus; Vim, ventral intermediate.)

Figure 23-4. As in Figure 23-3, but the 17-mm sagittal plane is shown. (B, burning; Do, pain; MR, motor response; P, paresthetic response; SA, slowly adapting; SM, sensory response with motor connotations; TD, deep tactile; TS, superficial tactile stimulus; U, unidentified cell; Vc, ventrocaudal nucleus of thalamus; Vim, ventral intermediate.)

In general, RF/PF match or mismatch as well as sensory changes caused by the stroke did not correlate with the clinical features of the pain. In fact, some patients appeared to have experienced total destruction of the sensory thalamus and its projections [no RFs or PFs on extensive recording (157,158)], but they still showed the same patterns of sensory loss and pain as a patient with a small stroke and preserved RFs and PFs.

Evidence for Ipsilateral Mediation of Stroke Pain

Pain was identical in our patients with absent RFs from proximal tract interruption to that seen in the presence of intact PFs and RFs; the former retained intact PFs, showing that transsynaptic degeneration does not occur in the thalamus and that thalamic neurons and thalamocortical connections can be left intact and apparently isolated after a stroke yet still capable of generating conscious effects and presumably capable of activation by alternate somatosensory input, possibly to generate pain.

Figure 23-5 is a computed tomographic scan of a patient who had a massive right-sided thrombotic stroke causing left homonymous hemianopsia, spastic hemiplegia, and multimodality hemisensory loss with allodynia and hyperpathia. Stereotactic exploration with microelectrodes to treat him with DBS was carried out. However, 14 trajectories explored with microelectrodes and microstimulation and three with macrostimulation from the third ventricle to the 15-mm left sagittal plane failed to reveal any neuronal activity or response to stimulation (Fig. 23-6). Exploration in the 6-mm sagittal plane on the side ipsilateral to the hemiplegia, however, done to implant an electrode in functioning PVG, gave normal responses for that area (Fig. 23-7); stimulation there produced a feeling of warmth in face and chest and reduced his allodynia.

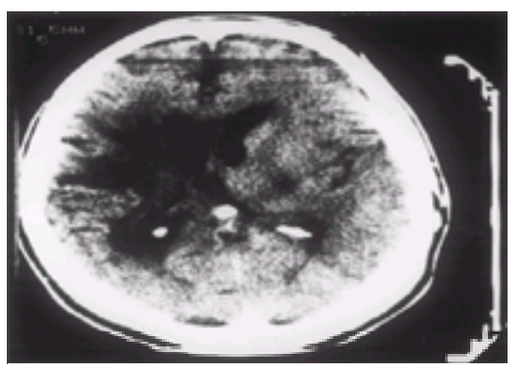

Figure 23-5. Computed tomographic scan of a man who at age 56 years had a thrombotic stroke causing spastic left hemiplegia, left homonymous hemianopsia, and almost immediate onset of central pain. He was followed over 4 years with a somewhat variable pain and sensory picture until he died of bronchogenic carcinoma. Constant sharp pain was felt in the left shoulder, left hip, and left hand, with spontaneous exacerbations every 2 minutes increased by activity. There was burning pain in the left medial thigh, knee, and foot and cramps in the left calf. Appreciation of light touch, pinprick, position, and vibration sense was reduced on the left side, although he was an inconsistent witness and the degree of position and vibration senses varied; there was mild allodynia to light touch, mild hyperpathia, inconsistently localized, to pinprick and severe cold allodynia. He was treated with left deep brain stimulation in periventricular gray inserted December 19, 1990, which reduced his allodynia dramatically at first, less so over the 4 years of follow-up. This induced a warm feeling in the face and chest.

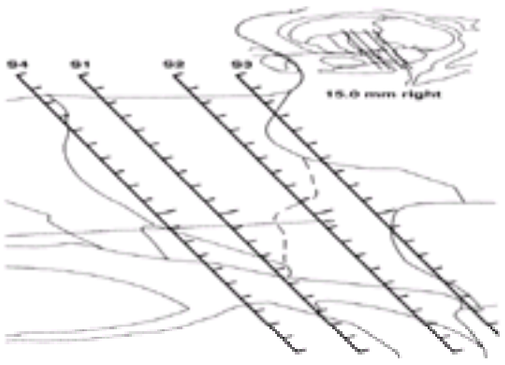

Figure 23-6. Four microelectrode trajectories in the 15-mm sagittal plane of the thalamus of the patient seen in Figure 23-5, showing absence of receptive fields and projected fields.

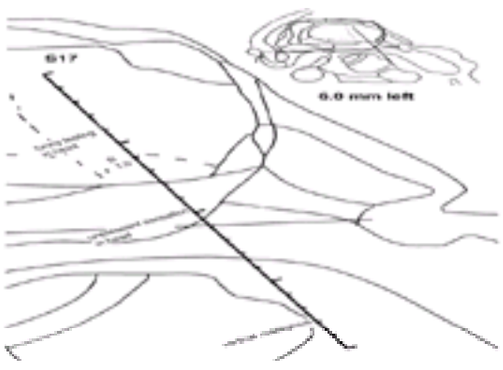

Figure 23-7. Macroelectrode trajectory through the medial (6.0-mm sagittal plane) thalamus of patient in Figure 23-5 that is on the side opposite to the stroke. Responses characteristic of this area occurred. (B, burning; 1.0, stimulation current in milliamperes.)

These observations implicate ipsilateral pathways in the generation of the steady pain and allodynia and hyperpathia that plague such patients. Whatever the ipsilateral paths responsible for the pain, they must be somatotopographically organized to preserve the somatotopographic features of the pain and capable of inducing steady pain and allodynia, incriminating the ipsilateral spinothalamic tract; the method of their activation is unclear. Miller Fisher (159) found two patients with stroke hemiplegia who were beginning to regain motor function when they suffered new strokes on the opposite side of the brain. At that time, the originally paralyzed but recovering side again became paralyzed, implicating ipsilateral mechanisms in the motor recovery.

Implication of the hemisphere opposite to the stroke is demonstrated in one of our patients who had suffered a massive thrombotic stroke (Fig. 23-8) that produced a spastic right hemiplegia, aphasia, right hemibody sensory loss, and right-sided head and neck pain. Microelectrode exploration revealed intact RFs but few PFs. DBS produced paresthesiae in the painful area but failed to lessen the pain. Consequently, a Resume electrode (Medtronic Corporation, Minneapolis, MN) was implanted extradurally over the motor cortex on the side of the head opposite to the stroke and ipsilateral to the hemiplegia (Fig. 23-9). Bipolar stimulation of this electrode produced paresthesiae on the right (paralyzed) head, neck, and arm; and, at higher intensities, the right half of the body. Stimulation reduced the patient's pain, but to a diminishing degree, over 6 years of follow-up. The electrode was repositioned in the subdural space when stimulation no longer produced responses, recapturing for a few months the same effect as before. Suprathreshold stimulation tetanized the right cheek and neck and caused speech arrest for the few words this severely dysphasic patient could utter.

Figure 23-8. Computed tomographic scan of a man who suffered a massive left (dominant hemisphere) thrombotic stroke at age 61 and who has been studied for 6 years. He experienced immediate spastic right hemiplegia and aphasia but regained the ability to walk. He developed steady, aching, pulling pain on the right side of his head, face, and neck, with episodes of shooting pain associated with reduction of appreciation of pinprick, touch, vibration, and cold on the right side of the body, with questionable mild allodynia to cold and touch in the face. There was absence of position sense distal to right wrist and reduction in the right lower extremity. His left thalamus was explored with four microelectrode trajectories, revealing intact receptive fields and absent projected fields. Nevertheless, a site was found in which deep brain stimulation provided paresthesiae in the right side of the head and face. This, however, had no effect on his pain.

Figure 23-9. Anteroposterior view of plain radiograph of the head of the same patient as in Figure 23-8, showing a Resume electrode (Medtronic Corporation, Minneapolis, MN) implanted over the motor cortex ipsilateral to the hemiplegia and a disconnected unipolar electrode implanted in the tactile relay nucleus of thalamus on the side of the stroke contralateral to the hemiplegia. Stimulation between the two highest poles (2 and 3) produced ipsilateral paresthesiae and reduced his pain on the side ipsilateral to the electrode.

Observations Implicating Particular Brain Structures in the Generation of Pain

Implication of a brain structure in the generation of a patient's pain can be made from various observations: production of pain by stimulating the structure, elimination of pain by destroying or otherwise manipulating it, or physiologic observations within the structure that link the region to the pain.

Induction of Pain by Stimulation of Medial Thalamus and Mesencephalic Tract

Burning and pain are rarely evoked by brain stimulation. However, in stereotactic procedures guided by macrostimulation (160), we induced burning at 162 of approximately 10,000 brain sites, nearly always on the contralateral side of the body. Forty-three percent of these sites occurred in the 89% of patients with movement disorders, usually sporadically, in isolation from other pain sites, and 57% occurred in the 13% of patients operated on for chronic pain. In the latter group, the pain sites were usually clustered. Burning was induced contralaterally without somatotopographic organization. Eighty percent of the sites at which stimulation induced burning occurred in the 41% of pain patients who experienced neuropathic pain; only 20% occurred in the 59% with cancer pain. Finally, these burning responses were clustered in medial mesencephalic tegmentum and medial thalamus, in which stimulation usually evokes no conscious response at all except by volume conduction to adjacent structures. Of the seven patients with neuropathic pain who showed these abnormal burning responses on stimulation, four had brainstem cerebrovascular accidents and one each multiple sclerosis, anesthesia dolorosa, and peripheral neuritis.

In the same study, macrostimulation at 67 points induced nonsomatotopically organized painful rather than burning responses on the opposite side of the body, 39% of them occurring in the 89% of patients with movement disorders, 61% in 8 of the 22 who had intractable pain. Eighty percent of the pain points occurred in patients with deafferentation pain (five brainstem cerebrovascular accidents, one surgical anesthesia dolorosa, one multiple sclerosis, one peripheral neuritis, and one spinal cord vascular accident). When pain was induced in patients with deafferentation pain, the induced pain was always similar to the patient's discomfort; in patients with cancer pain, this was never the case. The induction of pain occurred in the same sites as did the induction of burning. We have not had the opportunity to study these medial sites in similar patients with microelectrodes. The observations implicate the medial structures in the generation of neuropathic pain, but also raise questions as to how structures in which no conscious response is normally elicited by stimulation become sensitive in neuropathic pain states and how their stimulation impinges on consciousness.

Induction of Pain by Stimulation of the Tactile Relay Nucleus of Thalamus

In most patients, macrostimulation or microstimulation of the tactile relay nucleus of thalamus [Hassler's ventrocaudal nucleus (Vc)] even at four times threshold, induces paresthesiae in projected fields that match the RFs of the tactile cells at the same sites. This occurs despite the fact that spinothalamic input is thought to project to all of Vc in a somatotopographic manner as supported by the ability to record cool sensitive neurons (161) in the same area. Surgical lesions in Vc, once practiced in attempts to relieve chronic pain, produce loss of all somatosensory modalities (159,160) and commonly induce central pain (5).

The findings are different, however, in the posterior-inferior rim of Vc, in Hassler's parvocellular Vc. Here, a variety of warm, cold, burning, or painful responses occur with stimulation in the normal state (162,163,164,165 and 166), and nociceptors can be recorded there (167,168).

In patients with stroke-induced pain, microstimulation of the main body of Vc may induce not paresthesiae but pain (169,170,171 and 172). This phenomenon appears to be associated with the presence of allodynia, hyperpathia, or both as in the patients shown in Figure 23-2 and Figure 23-5. It is not usually present in other neuropathic pain syndromes, regardless of whether allodynia or hyperpathia is present (172). When this phenomenon is present, one cannot use paresthesiae-producing DBS to treat the patient's pain. It also has pathophysiologic implications for stroke-induced pain by implicating Vc in the generation of allodynia, hyperpathia, or both, suggesting that normally nonnoxious stimulation of Vc becomes garbled, presumably at the cortex, so that neurons that are normally not nociceptors now signal pain. Moreover, the evoked pain in stroke-induced pain syndromes appears to be relieved by PVG stimulation (173). Whatever the process, it is different from that involved in stroke pain without allodynia or hyperpathia, which is sometimes relieved by paresthesiae-producing DBS (74).

Observations on Surgical Attempts to Relieve Pain

Further insight may be gained by studying the outcomes of different surgical procedures used to treat brain central pain. Table 23-26 summarizes our experience. As in spinal cord central pain, steady pain appears to respond best to paresthesiae-producing DBS, and evoked and neuralgic pain to destructive lesions in the mesencephalic pain tract and medial thalamus. It has been mentioned that PVG stimulation (173) also relieves allodynia and hyperpathia, as in the case of the patient shown in Figure 23-5. Thus, even in the brain, steady pain does not seem to depend on pain pathways, but stimulation of PVG or section of spinoreticulothalamic tracts is useful for the treatment of evoked or intermittent pain. The seven patients relieved of these features by pain tract sections all suffered from brainstem strokes with prominent elements of neuralgialike pain or of allodynia and hyperpathia.

	Steady	Neuralgic	Evoked
Stimulation	53	0	25
Destructive	30	(100)	60

TABLE 23-26. Surgical treatment of 73 cases of brain central pain: percent relieved

Conclusions

In an attempt to synthesize information into a hypothesis explaining stroke central pain, the first question is whether the mechanism is the same in all cases. Possibly

it is not, but because the clinical features are so uniform and the clinical picture appears largely unrelated to the site and degree of neural damage, it would be useful to establish a mechanism applicable in all cases.

Although brain central pain may have a delayed onset, suggesting that, whatever the causative process, it may take time to develop, it can also appear immediately, suggesting that sprouting is not necessary. Brain central pain is idiosyncratic, suggesting that something beside the damaged neurons is required to produce the report of pain. Brain central pain can be reversible, again suggesting that it is not dependent on fixed anatomic changes, but pharmacologic and surgical therapies have yet to clearly identify the essential underlying chemical and anatomic substrates.

Much has been written about the causative lesions, particularly emphasizing selective damage to one structure over another, setting up either irritation or disinhibition in projection pathways responsible for pain. However, brain central pain can result from lesions so minimal that they induce no clinically detectable sensory loss or by lesions so massive that they appear to eliminate all somatosensory function on one side of the brain. Indeed, surgical hemispherectomy can induce brain central pain (5,6). Any hypothesis must account for these observations.

One implication of these observations is that spontaneous pain and evoked pain appear to arise equally readily from brain mechanisms ipsilateral to the causative lesion in the case of milder strokes or contralateral in the most severe strokes. Yet, the pain syndromes are the same in each case. There are no significant interhemispheral connections for somatosensory structures above the brainstem after severe hemispherectomylike strokes, which should eliminate the connections of the corpus callosum or thalamus. Current thinking stresses the importance of damage to the fast conducting spinothalamic system in the origin of brain central pain, but it is difficult to be sure of the importance of this factor. Lesions in the tactile relay nucleus and its projection to cortex, however, cause central pain, but these structures also contain spinothalamic input. Patients with brain central pain may show no detectable sensory loss, selective loss of spinothalamic function, or global loss of all somatosensory modalities. Although some authors deny its presence, selective loss of lemniscal function has also rarely been associated with brain central pain in our experience and in that of others (6). Could the much more common relationship of selective spinothalamic over selective lemniscal lesions in cases of spinal cord and brain central pain simply reflect anatomic curiosities? For example, is the spinothalamic tract more readily exposed to selective iatrogenic or naturally occurring damage than the medial lemniscus? One striking cause of neuropathic pain, tabes dorsalis, is alleged to be the result of damage to the dorsal columns. Thus, although the evidence is impressive, it does not seem inevitable to this author that damage to some component of the spinothalamic is the essential cause of brain central pain.

The primary dilemma, however, is to explain how a small, localized lesion on one side of the brain can result in the same clinical picture as a lesion so massive that spinothalamic tract, medial lemniscus, and lateral and medial thalamus are all eliminated. It is perhaps easier to think in terms of pain caused by stroke hemispherectomy than that caused by a lesser lesion, because one can eliminate mechanisms that depend on the thalamocortex on the side of the stroke and try to imagine what derangement of the normal hemisphere on the opposite side to the stroke can cause the pain. This author dismisses the possibility that bursting cells or somatotopographic reorganization is responsible.

The infrequency of neuralgic pain after strokes makes it difficult to come to conclusions concerning it. Its slightly greater incidence with infratentorial strokes, the observations of Nashold and colleagues (125), and its tendency to be relieved by destructive proximal lesions in the spinoreticulothalamic tract would be in keeping with its generation by ectopic impulse generation at an injury site and propagation in the pain pathways in a similar manner to that described in spinal cord central pain.

Allodynia and hyperpathia appear to be associated with garbled central (cortical?) processing of usually nonnoxious stimuli so as to induce pain in a manner similar to that that occurs at the dorsal horn after peripheral lesions that induce neuropathic pain (57,58). It appears to respond to PVG DBS (173) and to proximal section of pain pathways. It still occurs in patients whose stroke has completely eliminated RFs and PFs on the side of the stroke, so that the undamaged ipsilateral hemisphere must be implicated in its generation. The other clue we have is that it changes the response to stimulation of the tactile relay nucleus of thalamus (Vc) from a paresthetic one to a painful one in the case of strokes with surviving thalamic function on the side of the stroke. If the process is the same in lesser and massive strokes, one must conclude that loss of somatosensory input can sensitize the contralateral damaged or the ipsilateral intact hemisphere so that incoming nonnoxious stimuli are interpreted as painful (i.e., are processed in the pain pathway rather than the nonnoxious pathway between thalamus and cortex). This processing appears to be suppressed by PVG stimulation.

The most common feature of brain central pain (and of all neuropathic pain syndromes) is the steady pain. Only three of our observations reflect on the pathogenesis of steady pain. First, it seems to be associated with a process that activates the medial thalamic and brainstem sensory pathways normally silent to stimulation and whose lesioning normally produces no sensory loss (160) so that macrostimulation in these structures induces a somatotopographically organized conscious experience of contralateral pain. Second, the pain is not relieved by PVG DBS or lesioning pain structures, but only by DBS that produces paresthesiae in the area of the patient's pain. Third, the pain can occur in the absence of identifiable RFs and PFs in the thalamus on the side of the stroke, thereby implicating the normal ipsilateral hemisphere. It would be interesting to explore the ipsilateral hemisphere in such cases; we have, however, demonstrated that stimulation of the sensorimotor cortex on the side opposite to the stroke in one patient with a massive stroke caused ipsilateral paresthesiae, ipsilateral motor twitches, diminished the ipsilateral pain, and caused arrest of the limited speech he had after his dominant hemisphere stroke. The findings would be in keeping with pain resulting from disinhibition of the ipsilateral or contralateral component of the medial nonspecific pain pathway with the somatotopic localization dependent on deficits in the specific somesthetic paths damaged by the stroke. Presumably, chronic paresthesiae-producing stimulation can reverse this process.

Treatment of Brain Central Pain

Figure 23-10 presents an algorithm for treating brain central pain. General principles and medical treatment are similar to those described under Spinal Cord Central Pain, whereas surgical approaches are limited both in choice and success by virtue of the fact that only procedures performed on the brain itself are likely to benefit brain central pain; peripheral procedures, including cordotomy and DCS, are futile (174).

Figure 23-10. Algorithm for the treatment of brain central pain. (DBS, deep brain stimulation.)

Nonsurgical Strategies

Dehen and colleagues (175) concluded that stroke pain was independent of endogenous opioid pathways. Crisologo and colleagues (176) reported lidocaine-induced spinal block relieved poststroke pain accompanied by allodynia in two-thirds of patients; one of the successes and the failure had thalamic lesions. Galer and colleagues (177) found intravenous lidocaine infusion useful, although more so in patients with peripheral than central neuropathic pain. Edmondson and colleagues (178) also found intravenous lidocaine infusion useful, and sometimes mexiletine, an oral cogener of lidocaine, gave good results. Loh and colleagues (179) reported that stellate block or guanethidine infusion relieved or reduced the steady pain and allodynia in eight patients with brain central pain as well as benefiting the accompanying dystonia. Canavero and colleagues (180) found propofol useful in central but not neuropathic pain. Bowsher (181) suggested first a trial of adrenergically active antidepressants, then mexiletine. Strumpf and Zenz (182) suggested opioids. Budd (183) found naloxone useful. Taira and colleagues (48) found that intrathecal baclofen reduced poststroke pain as well as that after spinal cord injury. In our earlier studies of neuropathic pain, we found intravenous

infusions of 50 to 225 mg of sodium pentothal reduced brain central pain in 73% of our patients, whereas 15 to 18 mg of morphine was not effective in any (2,3 and 4).

Surgical Treatment

Our own experience with surgery for brain central pain is summarized in Table 23-26.

Cordotomy. Pagni (6) recounted that Frazier and colleagues alleviated a case of paroxysmal neuralgic pain caused by a stroke, as Nashold and colleagues (125) had done with mesencephalic tractotomy. He quoted Turnbull's success in another case, but stated that there have been no further successful reported cases, although there have been many published unsuccessful cases.

Trigeminal Dorsal Root Entry Zone. Sampson and Nashold (184) have reported one patient with brain central pain caused by a pontine infarct and another with an arteriovenous malformation of the tectum of the mesencephalon who suffered from facial pain that was relieved by a DREZ procedure on the trigeminal nucleus caudalis. The first patient had allodynia and some steady pain; the second had steady pain. In both cases, the DREZ procedure induced mild ipsilateral upper limb dysmetria.

Medial Thalamotomy. In the section on Spinal Cord Central Pain, I pointed out the poor results of medial thalamotomy in neuropathic, including brain central, pain compared with results in cancer pain. It is difficult to obtain specific outcome statistics for brain central pain, because most series quote data from mixed groups of pain patients. Table 23-27 lists outcome data from four surgical series of brain central pain, showing strikingly different outcome figures.

Procedure	No. of patients	% Successful	Reference
Medial thalamotomy	9	89 (recur in 2 yr)	185
	17	Recur in 6 mo	186
	–	25	173
	69	67	154
Mesencephalic tractotomy	28	64	187
	26	62	188
	11	27	93
	–	54	25

TABLE 23-27. Published outcome data for destructive surgery for brain central pain

Mesencephalic Tractotomy. Table 23-27 includes outcome data for mesencephalic tractotomy in brain central pain. Two series (187,188) are surprisingly encouraging. It is hoped that other studies will support these more promising outcomes.

Miscellaneous Procedures. Levin and colleagues (189) reported relief of three cases of stroke pain with intrahypophyseal alcohol injection, but there does not appear to be other published experience with this procedure.

Electrical Stimulation

Trigeminal Stimulation. Seven of the patients on whom we have used trigeminal stimulation (190) for the relief of chronic neuropathic facial pain suffered from brain central pain, three with lateral medullary syndrome, one with a middle cerebral artery area infarct, one with a massive thalamic and suprathalamic infarct, one with an infarct after internal carotid artery ligation, and one with neuropathic pain after a medullary trigeminal tractotomy. Five of these seven patients reported relief during trial stimulation and went on to enjoy more than 50% ongoing pain relief after implantation of a permanent device, a rather surprisingly good result. The chief complication of this procedure was superficial infection at hardware sites.

Dorsal Column Stimulation. Pagni (6) found DCS of no benefit in brain central pain. Of 12 of the author's cases, 6 reported pain relief during trial stimulation and received a permanent stimulator, but only 17% of the original group enjoyed ongoing relief. In four patients, all experiencing allodynia, hyperpathia, or both, DCS was unsuccessful because it was perceived as painful. This observation recalls the experience described previously in which microstimulation of the tactile relay of thalamus is often painful in patients experiencing stroke-induced pain with allodynia, hyperpathia, or both.

Deep Brain Stimulation. The dichotomy between paresthesia-producing and PVG/periaqueductal gray DBS in nociceptive versus neuropathic pain has already been mentioned. Thus, we would suggest that paresthesiae-producing DBS, and not PVG/periaqueductal gray DBS, should be used in attempts to treat most cases of brain central pain. Table 23-28 lists some published outcome data. Anecdotal evidence suggests (203,204 and 205) that stimulating in the internal capsule is preferable to that at other sites, but until larger numbers of patients have been reported it is difficult to draw conclusions (see Chapter 101).

No. of patients	% Relieved	Site stimulated	Reference

TABLE 23-28. Published outcome data for deep brain stimulation for brain central pain

Six of the author's patients (74) treated with paresthesiae-producing DBS, all of whom suffered from allodynia, hyperpathia, or both, found stimulating in the ventrocaudal nucleus painful, preventing use of that treatment modality, whereas patients with neuropathic pain not caused by cerebral lesions who had allodynia or hyperpathia seldom found such stimulation painful. In three patients with stroke-induced allodynia, hyperpathia, or both, PVG stimulation relieved the allodynia and hyperpathia (173). When we reviewed our 18 patients with brain central pain explored stereotactically (not necessarily implanted with electrodes) in whom microstimulation in ventrocaudal nucleus was painful, we found that all suffered from allodynia, hyperpathia, or both, whereas only 5 of 20 patients in whom such stimulation was not painful experienced this feature of pain. The sense of burning was induced equally frequently in the two groups. It is therefore not surprising that 10 of 16 patients with brain central pain who did not have allodynia or hyperpathia reported pain relief with paresthesiae-producing stimulation, but only 2 of 12 who had allodynia, hyperpathia, or both did so.

Motor Cortex Stimulation. Tsubokawa and colleagues (206) described motor cortex stimulation for the treatment of brain central pain, placing paddle-type electrodes designed for DCS extradurally parallel to the central sulcus 3 to 4 cm from the midline for upper limb, and 1 cm from midline for lower limb pain. Ninety percent of 10 cases of brain central pain so treated did well after 1 year of follow-up. In another report (207), 11 patients were described with brain central pain, 73% of whom enjoyed initial, 45% long-term pain relief at 2 years' follow-up. Hosobuchi (208) reported that 50% of six patients were effectively controlled by motor cortex

stimulation. It is to be hoped that more published experience will accumulate to support this simple technique for treating such a refractory problem.

In using motor cortex stimulation, Tsubokawa and colleagues applied stimulation below the threshold for motor events, at which level it usually caused tingling or mild vibration in the area of pain. Pain typically diminished after 5 to 10 minutes of stimulation, and pain relief outlasted a 10-minute period of stimulation by 2 to 6 hours. Thus, patients would typically use five to seven bouts of stimulation daily. They believed that to relieve neural injury pain, it was necessary to stimulate rostral to the causative lesion (explaining the failure of DCS in brain central pain), hypothetically activating the fourth-order sensory neurons whose nonnociceptive impulses induced by cortex stimulation inhibited nociceptive neurons.

Yamamoto and colleagues (209) tried to correlate certain pharmacologic tests with the success of motor cortex stimulation. They concluded in 25 cases of brain central pain with thalamic lesions and 14 with suprathalamic lesions that those patients whose pain was diminished by thiamytal and ketamine administration but not by morphine responded best to motor cortex stimulation.

Septal Stimulation. Schvarcz (210) reported relief of neuropathic pain in 12 of 19 patients by chronic septal stimulation, both spontaneous and evoked elements being diminished. No other case reports of this stimulation site have been reported.

CHAPTER 24

The Psychophysiology of Pain

C. Richard Chapman

Psychophysiology is a field of study that seeks to relate subjective awareness and behavior to physiologic events (1,2 and 3). As a field of scientific inquiry, it concerns itself with central mechanisms of cognition and behavior, including learning, the emotions, and the relationship of brain activity to consciousness. As a clinical area, psychophysiology has classically addressed somatoform disorders, stress (most recently posttraumatic stress disorders) and affective disorders in general. Psychophysiology is an important resource for the pain field for two primary reasons. On the one hand, it provides valuable resources for addressing the difficult question of how noxious signaling becomes conscious. On the other hand, and more important, it offers a framework for understanding pain as an emotion.

Most physicians think of pain as an unpleasant sensation that originates in traumatized tissues, but pain is more than sensory information about the condition of the body. It has powerful emotional qualities. Any reasonable and unbiased observer studying mammals, particularly humans, would have to conclude that pain's affective features, rather than its sensory properties, govern behavioral responses to injury. People who experience pain do not quietly report the fact; they express negative emotions.

Is the affective dimension of pain as important as its sensory aspect? A contemporary nonmedical writer described pain's characteristics as including extreme aversiveness, an ability to annihilate complex thoughts and other feelings, an ability to destroy language, and a strong resistance to objectification (4). Her perspective resonates with the lessons of everyday life. Although pain has sensory features and lends itself to sensory description, it is above all else a powerful negative feeling. One cannot evaluate and address the suffering of a person in pain without an appreciation of its emotional nature.

The International Association for the Study of Pain acknowledged the central role of emotion in its keystone definition: “Pain [is] an unpleasant sensory and *emotional* experience associated with actual or potential tissue damage, or described in terms of such damage” (5) (italics added). This definition clearly emphasizes the role of affect as an intrinsic component of pain. Emotion is not a consequence of pain sensation that occurs after a noxious sensory message arrives at somatosensory cortex. Rather, it is a fundamental part of the pain experience.

The purposes of this chapter are to describe the psychophysiology of pain and to explore its importance for the care of patients. This involves characterizing the emotional aspect of pain, emphasizing current understanding of the psychophysiologic mechanisms that produce it, and outlining emerging issues associated with the growth of knowledge in this area. In this chapter I show that: (a) pain (awareness of tissue trauma) has emotional properties including negative emotional arousal; (b) the brain creates bodily states and arousal (emotions) in response to threat to biologic integrity; and (c) the affective dimension of pain involves hypervigilance, bodily arousal, and the awareness of altered bodily states.

HISTORIC PERSPECTIVE: MIND-BODY ISSUES

Through most of the twentieth century, our understanding of the relationship between mental processes and the body stemmed directly from Cartesian notions of mind-body dualism. For Descartes, a seventeenth-century philosopher and mathematician, human beings are dualistic: The mind and body are separate entities. Descartes described the life processes of the body as though they were clockwork mechanisms. The actions of the mind were, in his thinking, the workings of the soul.

Descartes believed that the awareness of pain, like awareness of other bodily sensations, must take place in a special location in which the mind observes the body. Dennett (6) termed this hypothetical seat of the mind the *Cartesian theater*. In this theater, the mind observes and interprets the array of multimodality signals that the body produces. The body is a passive environment; the mind is the nonphysical activity of the soul.

Today, most people avow that such a theater of the mind cannot exist. Scientifically, the activity of the brain and the mind is inseparable. And yet, Cartesian dualism is endemic in Western thought and culture. Classical approaches to psychophysiology stemmed from Cartesian thinking, as did psychophysics. Early work on psychosomatic disorders focused on mind-body relationships. Today, much of the popular movement favoring alternative medicine emphasizes the mind-body connection, keeping one's self healthy through right thinking, and the power of the mind to control the immune system. It is hard to avoid Cartesian thinking when the very fabric of our language carries it along as we reason and speak.

Cartesian assumptions are subtle but powerful barriers for someone seeking to understand the affective dimension of pain. Relegating emotions to the realm of the mind and their physiologic consequences to the body is classic Descartes. It prevents us from appreciating the intricate interdependence of subjective feelings and physiology, and it detracts from our ability to comprehend how the efferent properties of autonomic nervous function can contribute causally to the realization of an emotional state. This chapter emphasizes the interdependence of mental processes and physiology. What we call the mind is *consciousness*, and consciousness is an emergent property of the activity of the brain. In a feedback-dependent manner, the brain regulates the physiologic arousal of the body, and emotion is a part of this process.

EMOTIONS: DEFINITION AND MECHANISMS

What Are Emotions?

The first step in understanding pain as an emotion is appreciating the origins and purposes of emotion. Many physicians regard emotions as epiphenomenal feeling states associated with mental activity, subjective in character, and largely irrelevant to the state of a patient's physical health. In fact, emotions are primarily physiologic and only secondarily subjective. Because they can strongly affect cardiovascular function, visceral motility, and genitourinary function, patient emotions can have an important role in health overall and especially in pain management. Simple negative emotional arousal can exacerbate certain pain states, such as sympathetically maintained pain, angina, and tension-type headache. It contributes significantly to musculoskeletal, pelvic, and other pain problems in some patients.

Emotions are complex states of physiologic arousal and awareness that impute positive or negative hedonic qualities to a stimulus (event) in the internal or external environment. The objective aspect of emotion is autonomically and hormonally mediated physiologic arousal. The subjective aspects of emotion, *feelings*, are phenomena of consciousness. Emotion represents in consciousness the biological importance or meaning of an event to the perceiver.

Emotion as a whole has two defining features: valence and arousal. *Valence* refers to the hedonic quality associated with an emotion: the positive or negative feeling attached to perception. *Arousal* refers to the degree of heightened activity in the central nervous system and autonomic nervous system (ANS) associated with perception.

Although emotions as a whole can be positive or negative in valence, pain research addresses only negative emotion. Viewed as an emotion, pain represents threat to the biological, psychological, or social integrity of the person. In this respect, the emotional aspect of pain is a protective response that normally contributes to adaptation and survival. If uncontrolled or poorly managed in patients with severe or prolonged pain, it produces suffering.

Emotion in a Sociobiological Perspective

Psychologists have many frameworks for studying emotion. I favor a sociobiological (evolutionary) framework, because this way of thinking construes feeling states, related physiology, and behavior as mechanisms of adaptation and survival. Nature has equipped us with the capability for negative emotion for a purpose; bad feelings are not simply accidents of human consciousness. They are protective mechanisms that normally serve us well, but, like uncontrolled pain, sustained and uncontrolled negative emotions can become pathologic states that can produce maladaptive behavior and physiologic pathology.

By exploring the emotional dimension of pain from the sociobiological perspective, the reader may gain some insight about how to prevent or control the negative affective aspect of pain, which fosters suffering. Implementing this perspective requires that we change conventional language habits that involve describing pain as a transient sensory event. Pain is a compelling and emotionally negative state of the individual that has as its primary defining feature awareness of, and homeostatic adjustment to, tissue trauma.

Adaptive Functions of Emotion

Emotions, including the emotional dimension of pain, characterize mammals exclusively, and they foster mammalian adaptation by making possible complex behaviors and adaptations. They play a strong role in consciousness and serve the function of producing and summarizing information that is important for selection among alternative behaviors. According to MacLean, emotions “impart subjective information that is instrumental in guiding behavior required for self-preservation and preservation of the species. The subjective awareness that is an affect consists of a sense of bodily pervasiveness or by *feelings localized to certain parts of the body*” (7) (italics added). Because negative emotions such as fear evolved to facilitate adaptation and survival, emotion plays an important defensive role. The ability to experience threat when encountering injurious events protects against life-threatening injury.

The strength of emotional arousal associated with an injury indicates and expresses the magnitude of perceived threat to the biological integrity of the person. Within the contents of consciousness, threat is a strong negative feeling state and not a pure informational appraisal. In humans, threatening events such as injury that are not immediately present can exist as emotionally colored somatosensory images.

Phenomenal awareness consists largely of the production of images. Visual images are familiar to everyone: We can readily imagine seeing things. We can also produce auditory images by imaging a familiar tune, a bird song, or the sound of a friend's voice. Similarly, we can generate somatosensory images. We can, for example, imagine the feeling of a full bladder, the sensation of a particular shoe on a foot, or a familiar muscle tension or ache. Cognition operates largely on images.

Patients can react emotionally to the mental image of a painful event before it happens (e.g., venipuncture), or for that matter they can respond emotionally to the sight of another person's tissue trauma. The emotional intensity of such a feeling marks the adaptive significance of the event that produced the experience for the perceiver. In general, the threat of a minor injury normally provokes less feeling than one that incurs a risk of death. The emotional magnitude of a pain is the internal representation of the threat associated with the event that produced the pain.

Emotions and Behavior

Negative emotions compel action, such as fight or flight, along with expression through vocalization, posture, variations in facial musculature patterns, and alterations of activity. This action represents communication and often elicits social support, thus contributing to survival. Darwin (8), observing animals, noted that emotions enable communication through vocalization, startle, posture, facial expression, and specific behaviors. He held that emotions must be inborn rather than learned tendencies. Darwin pursued this issue by comparing the facial and other emotional expressions of children born blind with those of other children, reasoning that blind children would express emotion differently if emotion is primarily a learned behavior. As others have since confirmed (9), Darwin learned that the basic blueprints for human emotional expression are innate.

Contemporary investigators who study emotions and human or animal social behavior emphasize that communication is a fundamental adaptive function of emotional expression (10,11). Social mammals, including humans, depend on one another or their social group as resources for adaptation and survival. The emotional expression of pain in the presence of supportive persons is socially powerful; it draws on a fundamental sociobiological imperative, communicating threat and summoning assistance.

Central Neuroanatomy of Emotion: Limbic Structures

The limbic brain represents an anatomic common denominator across mammalian species (7), and emotion is a common feature of mammals. Consequently, investigators can learn much about human emotion by studying mammalian laboratory animals.

Early investigators focused on the role of olfaction in limbic function, and this led them to link the limbic brain to emotion. Emotion may have evolutionary roots in olfactory perception. MacLean introduced the somewhat controversial term *limbic system* and characterized its functions (12). He has identified three main subdivisions of the limbic brain—amygdala, septum, and thalamocingulate (7)—that represent sources of afferents to parts of limbic cortex (Fig. 24-1). He also postulated that the limbic brain responds to two basic types of input: interoceptive and exteroceptive. These refer to sensory information from internal and external environments, respectively. Because nociception by definition involves signals of tissue trauma, it excites the limbic brain via interoceptive signaling (13).

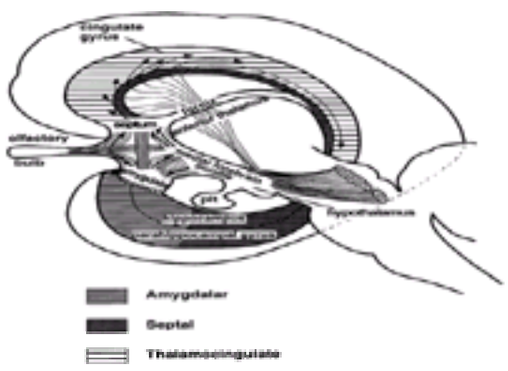

Figure 24-1. Three subdivisions of the limbic brain. MacLean (7) proposed a three-part grouping of limbic structures and functions: amygdalar, septal, and thalamocingulate subdivisions. These groupings appear as shadings. The figure, derived from MacLean's illustration, portrays the hippocampus as an upright arch joining the septum at one end and the amygdala at the other. (Adapted from MacLean PD. The triune brain in evolution: role in paleocerebral functions. New York: Plenum Publishing, 1990.)

Pain research has yet to address definitively the links between nociception and limbic processing. However, anecdotal medical evidence and careful psychometric studies implicate limbic structures in the distress of pain. Cingulumotomy interrupted pathways projected from hypothalamus to cingulate cortex and relieved the suffering of intractable pain without destroying sensory awareness, cognitive functioning, or social interactions (14). Such neurosurgical records help to clarify positron emission tomographic (PET) observations of human subjects undergoing painful cutaneous heat stimulation: Noxious stimulation activates contralateral cingulate cortex and several other limbic areas.

Peripheral Neuroanatomy of Emotion: Autonomic Nervous System

The ANS plays an important role in regulating the constancy of the internal environment, and it does so in a feedback-regulated manner under the direction of the hypothalamus, solitary nucleus (nucleus tractus solitarius), amygdala, and other central nervous system structures (15,16). In general, it regulates activities that are not normally under voluntary control. The hypothalamus is the principal integrator of autonomic activity. Stimulation of the hypothalamus elicits highly integrated patterns of response that involve the limbic system and other structures (17).

Many researchers hold that the ANS comprises three divisions: the sympathetic, parasympathetic, and enteric (18,19). Others subsume the enteric under the other two divisions. Broadly, the sympathetic nervous system makes possible the arousal needed for fight and flight reactions, whereas the parasympathetic system governs basal heart rate, metabolism, and respiration. The enteric nervous system innervates the viscera via a complex network of interconnected plexuses.

The sympathetic and parasympathetic systems are largely mutual physiologic antagonists: If one system inhibits a function, the other typically augments it. However, important exceptions that demonstrate complementary or integratory relationships exist. The mechanism most heavily involved in the affective response to tissue trauma is the sympathetic nervous system.

During emergency or injury to the body, the hypothalamus uses the sympathetic nervous system to increase cardiac output, respiration rate, and blood glucose. It also regulates body temperature, causes piloerection, alters muscle tone, provides compensatory responses to hemorrhage, and dilates pupils. These responses are part of a coordinated, well-orchestrated response pattern called the *defense response* (20,21 and 22). It resembles the better-known orienting response in some respects, but it can only occur after a strong stimulus that is noxious or frankly painful. It sets the stage for escape or confrontation, thus serving to protect the organism from danger. In an awake cat, both electrical stimulation of the hypothalamus and infusion of norepinephrine into the hypothalamus elicit a rage reaction with hissing, snarling, and attack posture with claw exposure, and a pattern of sympathetic nervous system arousal accompanies this reaction (23,24 and 25). Circulating epinephrine produced by the adrenal medulla during activation of the HPA axis accentuates the defense response, fear responses, and aversive emotional arousal in general.

Because the defense response and related changes are involuntary in nature, we generally experience them as something that the environment does to us. We generally describe such physiologic changes not as the bodily responses that they are, but rather as feelings. We might describe a threatening and physiologically arousing event by saying that “It scared me” or “It made me really mad.”

Phenomenologically, feelings seem to happen to us; we do not *do* them in the sense that we think thoughts or choose actions. Emotions are who we are in a given circumstance rather than choices we make, and we commonly interpret events and circumstances in terms of the arousal that they elicit. ANS arousal, therefore, plays a major role in the complex psychological experience of injury and is a part of that experience.

Early views of the ANS followed the lead of Cannon (20) and held that emergency responses and all forms of intense aversive arousal are undifferentiated, diffuse patterns of sympathetic activation. Although this is broadly true, research has shown that definable patterns characterize emotional arousal, and that these are related to the emotion involved, the motor activity required, and perhaps the context (15,16). An investigator attempting to understand how humans experience emotions must remember that the brain not only recognizes patterns of arousal; it also creates them.

One of the primary mechanisms in the creation of emotion is feedback-dependent sympathetic efferent activation. The ANS has afferent and efferent functions. The afferent mechanisms signal changes in the viscera and other organs, whereas efferent activity conveys commands to those organs. Consequently, the ANS can maintain feedback loops related to viscera, muscle, blood flow, and other responses. The visceral feedback system exemplifies this process. In addition, feedback can occur via the endocrine system, which under the control of the ANS releases neurohormones into the systemic circulation. Because feedback involves both autonomic afferents and endocrine responses, and because some feedback occurs at the level of unconscious homeostatic balance and other feedback involves awareness, the issue of how visceral change contributes to the creation of an emotional state is complex. The mechanisms are almost certainly pattern dependent, dynamic, and at least partly specific to the emotion involved. Moreover, they occur in parallel with sensory information processing.

The feedback concept is central to the field of psychophysiology. Awareness of physiologic changes elicited by a stimulus is a primary mechanism of emotion. The psychiatric patient presenting with panic attack, phobia, or anxiety is reporting a subjective state based on patterns of physiologic signals and not an existential crisis that exists somewhere in the domain of the mind, somehow apart from the body. Similarly, the medical patient expressing emotional distress during a painful procedure, or during uncontrolled postoperative pain, is experiencing the sensory features of that pain against the background of a cacophony of sympathetic arousal signals.

Figure 24-2 illustrates some of the general mechanisms of feedback associated with autonomic arousal. It helps to illustrate an essential point: A sensory stimulus does not have purely sensory effects. It undergoes parallel processing at the affective level. When that signal involves threat to biological integrity, it elicits strong patterns of sympathetic and neuroendocrine response. These, in turn, contribute to the awareness of the perceiver. Sensory processing provides information about the environment, but this information exists in awareness against a background of emotional arousal, either positive or negative, and that arousal may vary from mild to extreme.

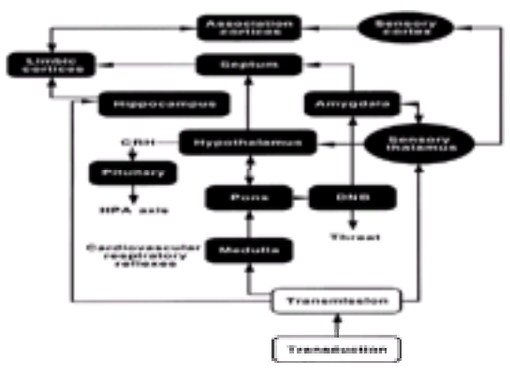

Figure 24-2. Feedback-dependent mechanisms associated with autonomic arousal. A noxious sensory stimulus has both sensory and affective effects. (CRH, corticotropin-releasing hormone; DNB, dorsal noradrenergic bundle; HPA, hypothalamo-pituitary-adrenocortical.)

Nociception and Central Limbic Processing

Central sensory and affective pain processes share common sensory mechanisms in the periphery. As described in Chapter 3, A-d and C fibers serve as tissue trauma transducers (nociceptors) for both processes, the chemical products of inflammation sensitize these nociceptors, and peripheral neuropathic mechanisms such as ectopic firing excite both processes. In some cases, neuropathic mechanisms may substitute for transduction as we classically define it, producing afferent signal volleys that appear, to the central nervous system, like signals originating in nociceptors. Differentiation of sensory and affective processing begins at the dorsal horn of the spinal cord. Sensory transmission follows spinothalamic pathways, and transmission destined for affective processing takes place in spinoreticular pathways. For more detail on the sensory processing of nociception, see Chapter 3, Chapter 4 and Chapter 5 and Willis and Westlund (26).

Nociceptive centripetal transmission engages multiple pathways: spinoreticular, spinomesencephalic, spinolimbic, spinocervical, and spinothalamic tracts (26,27). The spinoreticular tract contains somatosensory and viscerosensory afferent pathways that arrive at different levels of the brainstem. Spinoreticular axons possess receptive fields that resemble those of spinothalamic tract neurons projecting to medial thalamus, and, like their spinothalamic counterparts, they transmit tissue injury information (28,29). Most spinoreticular neurons carry nociceptive signals, and many of them respond preferentially to noxious activity (30,31). The spinomesencephalic tract comprises several projections that terminate in multiple midbrain nuclei, including the periaqueductal gray, red nucleus, nucleus cuneiformis, and Edinger-Westphal nucleus (26). Spinolimbic tracts include the spinohypothalamic tract, which reaches both lateral and medial hypothalamus (32,33) and the spinoamygdalar tract that extends to the central nucleus of the amygdala (34). The spinocervical tract, like the spinothalamic tract, conveys signals to the thalamus. All of these tracts transmit tissue trauma signals rostrally.

Central processing of nociceptive signals to produce affect undoubtedly involves multiple neurotransmitter systems. Four extrathalamic afferent pathways project to neocortex: the dorsal noradrenergic bundle (DNB) originating in the locus ceruleus (LC); the serotonergic fibers that arise in the dorsal and median raphe nuclei; the dopaminergic pathways of the ventral tegmental tract that arise from substantia nigra; and the acetylcholinergic neurons that arise principally from the nucleus basalis of the substantia innominata (35). Of these, the noradrenergic and serotonergic pathways link most closely to negative emotional states (36,37 and 38). The set of structures receiving projections from this complex and extensive network corresponds to the classic definition of the limbic brain (7,37,39,40).

Although other processes governed predominantly by other neurotransmitters almost certainly play important roles in the complex experience of emotion during pain, I emphasize the role of central noradrenergic processing here. This limited perspective offers the advantage of simplicity, and the literature on the role of central noradrenergic pathways in anxiety, panic, stress, and posttraumatic stress disorder provides a strong basis (38,41). This processing involves two central noradrenergic pathways: the dorsal and ventral noradrenergic bundles (VNBs) (Fig. 24-3).

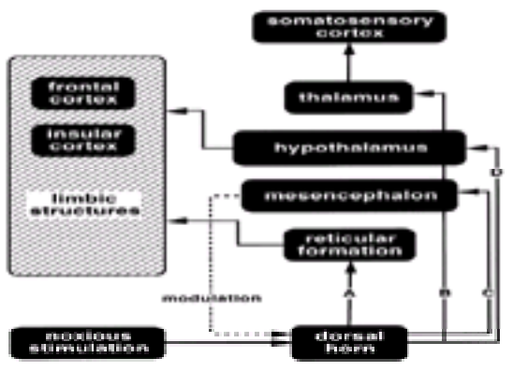

Figure 24-3. Multiple pathways of corticopetal nociceptive transmission. (A, spinoreticular; B, spinothalamic; C, spinomesencephalic; D, spinohypothalamic tracts.)

Locus Ceruleus and the Dorsal Noradrenergic Bundle

Substantial evidence supports the hypothesis that noradrenergic brain pathways are major mechanisms of anxiety and stress (38). The majority of noradrenergic neurons originates in the LC. This pontine nucleus resides bilaterally near the wall of the fourth ventricle. The locus has three major projections: ascending, descending, and cerebellar. The ascending projection, the DNB, is the most extensive and important pathway for our purposes (42). Figure 24-4 illustrates the DNB. Projecting from the LC throughout limbic brain and to all of neocortex, the DNB accounts for approximately 70% of all brain norepinephrine (43). The LC gives rise to most central noradrenergic fibers in spinal cord, hypothalamus, thalamus, hippocampus (44), and in addition it projects to limbic cortex and neocortex. Consequently the LC exerts a powerful influence on higher level brain activity.

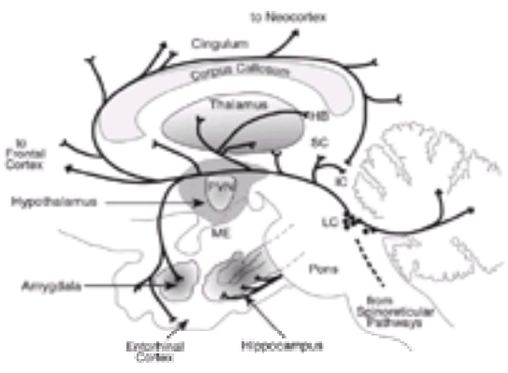

Figure 24-4. The dorsal noradrenergic bundle (parasagittal view). Tissue injury signals from spinoreticular pathways excite the primarily noradrenergic locus ceruleus (LC), activating the dorsal noradrenergic bundle, which extends throughout the limbic brain and to neocortex. (HB, habenula; IC, inferior colliculus; ME, median eminence; PVN, paraventricular nucleus; SC, superior colliculus.)

The *noradrenergic stress response hypothesis* holds that any stimulus that threatens the biological, psychological, or psychosocial integrity of the individual increases the firing rate of the LC, resulting in increased release and turnover of norepinephrine in the brain areas involved in noradrenergic innervation. Studies show that the LC reacts to signaling from sensory stimuli that potentially threaten the biological integrity of the individual or signal damage to that integrity (43). Spinal cord lamina I cells terminate in the LC (29). The major sources of LC afferent input are the paragigantocellularis and prepositus hypoglossi nuclei in the medulla, but destruction of these nuclei does not block LC response to somatosensory stimuli (45). Other sources of afferent input to the locus include the lateral hypothalamus, amygdala, and solitary nucleus. Whether nociception stimulates the LC directly or indirectly is still uncertain.

It is quite clear that nociception inevitably and reliably increases activity in neurons of the LC, and LC excitation appears to be a consistent response to nociception (43,46,47 and 48). Notably, this does not require cognitively mediated attentional control because it occurs in anesthetized animals. Foote and colleagues (49) reported that slow, tonic spontaneous activity at the locus in rats changed under anesthesia in response to noxious stimulation. Experimentally induced phasic LC activation produces alarm and apparent fear in primates (50,51), and lesions of the LC eliminate normal heart rate increases to threatening stimuli (52). In a resting animal, LC neurons discharge in a slow, phasic manner (53).

Although the LC reacts consistently, it does not respond exclusively to nociception. LC firing rates increase after nonpainful but threatening events, such as strong cardiovascular stimulation (47,54), and certain visceral events, such as distension of the bladder, stomach, colon, or rectum (43,55). Highly novel and sudden stimuli that could represent potential threat, such as loud clicks or light flashes, can also excite the LC in experimental animals (53). Thus, the LC responds to biologically threatening or potentially threatening events, of which tissue injury is a significant subset. Amaral and Sinnamon (56) described the LC as a central analogue of the sympathetic ganglia. Viewed in this way, it is an extension of the autonomic protective mechanism described previously.

Invasive studies confirm the link between LC activity and threat. Direct activation of the DNB and associated limbic structures in laboratory animals produces sympathetic nervous system response and elicits emotional behaviors such as defensive threat, fright, enhanced startle, freezing, and vocalization (57). This indicates that enhanced activity in these pathways corresponds to negative emotional arousal and behaviors appropriate to perceived threat. LC firing rates increase two- to threefold during the defense response elicited in a cat that has perceived a dog (25). Moreover, infusion of norepinephrine into the hypothalamus of an awake cat elicits a defensive rage reaction that includes activation of the LC noradrenergic system. In general, the mammalian defense response involves increased regional turnover and release of norepinephrine in the brain regions that the LC innervates. The LC response to threat, therefore, may be a component of the partly *prewired*

patterns associated with the defense response.

Increased alertness is a key element in early stages of the defense response. Normally, activity in the LC increases alertness. Tonically enhanced LC and DNB discharge corresponds to hypervigilance and emotionality (38,49,58). The DNB is the mechanism for vigilance and defensive orientation to affectively relevant and novel stimuli. It also regulates attentional processes and facilitates motor responses (35,37,43,59). In this sense, the LC influences the stream of consciousness on an ongoing basis and readies the individual to respond quickly and effectively to threat when it occurs.

LC and DNB support biological survival by making possible global vigilance for threatening and harmful stimuli. Siegel and Rogawski (60) hypothesized a link between the LC noradrenergic system and vigilance, focusing on rapid eye movement (REM) sleep. They noted that LC noradrenergic neurons maintain continuous activity in both normal waking state and non-REM sleep, but during REM sleep these neurons virtually cease discharge activity. Moreover, an increase in REM sleep ensues after either lesion of the DNB or following administration of clonidine, an a $_2$-adrenoceptor agonist. Because LC inactivation during REM sleep permits rebuilding of noradrenergic stores, REM sleep may be a necessary preparation for sustained periods of high alertness during subsequent waking. Siegel and Rogawski (60) contended that ". . . a principal function of NE in the central nervous system is to facilitate the excitability of target neurons to specific high priority signals." Conversely, reduced LC activity periods (REM sleep) allow time for a suppression of sympathetic tone.

Adaptation and sensitization can alter the LC response to threat. Abercrombie and Jacobs (61,62) demonstrated a noradrenergically mediated increase in heart rate in cats exposed to white noise. Elevated heart rate decreased with repeated exposure as did LC activation and circulating levels of norepinephrine. Libet and Gleason (63) found that stimulation via permanently implanted LC electrodes did not elicit indefinite anxiety. This indicates that the brain either adapts to locus excitation or engages a compensatory response to excessive LC activation under some circumstances. In addition, central noradrenergic responsiveness changes as a function of learning. In the cat, pairing a stimulus with a noxious air puff results in increased LC firing with subsequent presentations of the stimulus, but previous pairing of that stimulus with a food reward produces no alteration in LC firing rates with repeated presentation (53). These studies show that, despite its apparently prewired behavioral subroutines, the noradrenergic brain shows substantial neuroplasticity. The emotional response of animals and people to a painful stimulus can adapt, and it can change as a function of experience.

From a different perspective, Bremner and colleagues (38) postulated that chronic stress can affect regional norepinephrine turnover and thus contribute to the response sensitization evident in panic disorder and posttraumatic stress disorder. Chronic exposure to a stressor (including persevering nociception) could create a situation in which noradrenergic synthesis cannot keep up with demand, thus depleting brain norepinephrine levels. Animals exposed to inescapable shock demonstrate greater LC responsiveness to an excitatory stimulus than animals who have experienced escapable shock (64). In addition, such animals display *learned helplessness* behaviors: They cease trying to adapt to, or cope with, the source of shock (65). From an evolutionary perspective, this is a failure of the defense response as adaptation; it represents surrender to suffering. Extrapolating this and related observations to patients, Bremner and colleagues (38) suggested that persons who have once encountered overwhelming stress and suffered exhaustion of central noradrenergic resources may respond excessively to similar stressors that they encounter at a later time.

Ventral Noradrenergic Bundle and the Hypothalamo-Pituitary-Adrenocortical Axis

The VNB originates in the LC and enters the medial forebrain bundle. Neurons in the medullary reticular formation project to the hypothalamus via the VNB (66). Sawchenko and Swanson (67) identified two VNB-linked noradrenergic and adrenergic pathways to paraventricular hypothalamus in the rat: the A1 region of the ventral medulla (lateral reticular nucleus), and the A2 region of the dorsal vagal complex (the nucleus tractus solitarius, or solitary nucleus) that receives visceral afferents. These medullary neuronal complexes supply 90% of catecholaminergic innervation to the paraventricular hypothalamus via the VNB (68). Regions A5 and A7 contribute in a comparatively minor way to the VNB.

The noradrenergic axons in the VNB respond to noxious stimulation (43), as does the hypothalamus itself (69). Moreover, nociception-transmitting neurons at all segmental levels of the spinal cord project to medial and lateral hypothalamus and several telencephalic regions (26,32,33). These projections link tissue injury and the hypothalamic response, as do hormonal messengers in some circumstances.

The hypothalamic paraventricular nucleus (PVN) coordinates the hypothalamo-pituitary-adrenocortical (HPA) axis (Fig. 24-5). Neurons of the PVN receive afferent information from several reticular areas, including ventrolateral medulla, dorsal raphe nucleus, nucleus raphe magnus, LC, dorsomedial nucleus, and nucleus tractus solitarius (67,70,71). Still other afferents project to the PVN from the hippocampus, septum, and amygdala (72). Nearly all hypothalamic and preoptic nuclei send projections to the PVN. This suggests that limbic connections mediate endocrine responses during stress. Feldman and colleagues note that limbic stimulation always increases adrenocortical activity in rats (72).

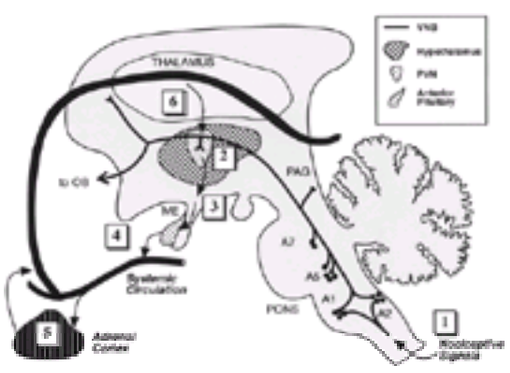

Figure 24-5. Response of the hypothalamo-pituitary-adrenocortical axis to noxious stimulation. Feedback-modulated response is depicted in six steps. In the first step signals of tissue injury excite the ventral noradrenergic bundle (VNB), including several medullary and pontine nuclei (designated A1, A2, A5, and A7). When these signals reach the hypothalamus, they stimulate the paraventricular nucleus (PVN) (step 2). The PVN produces corticotrophin-releasing hormone (CRH). CRH-producing neurons extend from the PVN to the median eminence (ME), from which they release CRH into the portal circulation (step 3). At this point, the tissue-injury signals become neurohumoral rather than neuronal. The anterior pituitary responds to CRH by releasing adrenocorticotropic hormone into the systemic circulation (step 4). The adrenocortex responds to adrenocorticotropic hormone by releasing corticosteroids into the systemic circulation (step 5). In addition to their extensive metabolic effects, the corticosteroids bind to receptors at the PVN (step 6), thus closing the feedback loop. This mechanism provides the physiologic arousal associated with the affective component of pain. (ME, median eminence; OB, olfactory bulb; PAG, periaqueductal gray.)

In responding to potentially or frankly injurious stimuli, the PVN initiates a complex series of events regulated by feedback mechanisms. These processes ready the organism for extraordinary behaviors that will maximize its chances to cope with the threat at hand (73). Although laboratory studies often involve highly controlled and specific noxious stimulation, real-life tissue trauma usually involves a spectrum of afferent activity, and the pattern of activity may be a greater determinant of the stress response than the specific receptor system involved (74). Traumatic injury, for example, might involve complex signaling from the site of injury, including inflammatory mediators, baroreceptor signals from blood volume changes, and hypercapnea. Tissue trauma normally initiates much more than nociception.

Diminished nociceptive transmission during stress or injury helps people and animals to cope with threat without the distraction of pain. The medullary mechanisms involved in this are complex and include the response of the solitary nucleus to baroreceptor stimulation (75). Laboratory studies with rodents indicate that animals placed in restraint or subjected to cold water develop analgesia (76,77 and 78). Lesioning the PVN attenuates such stress-induced analgesia (79).

Some investigators (80,81) emphasize that neuroendocrine arousal mechanisms are not limited to emergency situations, even though most research emphasizes that such situations elicit them. In complex social contexts, submission, dominance, and other transactions can elicit neuroendocrine and autonomic responses, modified perhaps by learning and memory. This suggests that neuroendocrine processes accompany all sorts of emotion-eliciting situations.

The hypothalamic PVN supports stress-related autonomic arousal through neural as well as hormonal pathways. It sends direct projections to the sympathetic intermediolateral cell column in the thoracolumbar spinal cord and the parasympathetic vagal complex, both sources of preganglionic autonomic outflow (82). In

addition, it signals release of epinephrine and norepinephrine from the adrenal medulla. Adrenocorticotropic hormone release, although not instantaneous, is quite rapid: It occurs within approximately 15 seconds (83). These considerations implicate the HPA axis in the neuroendocrinologic and autonomic manifestations of emotion associated with tissue trauma.

In addition to controlling neuroendocrine and ANS reactivity, the HPA axis coordinates emotional arousal with behavior (84). As noted previously, stimulation of the hypothalamus can elicit well-organized action patterns, including defensive threat behaviors and autonomic arousal (85). The existence of demonstrable behavioral subroutines in animals suggests that the hypothalamus plays a key role in matching behavioral reactions and bodily adjustments to challenging circumstances or biologically relevant stimuli. Moreover, stress hormones at high levels, especially glucocorticoids, may affect central emotional arousal, lowering startle thresholds and influencing cognition (83). Saphier (86) observed that cortisol altered the firing rate of neurons in limbic forebrain. Clearly, stress regulation is a complex, feedback-dependent, and coordinated process. The hypothalamus appears to take executive responsibility for coordinating behavioral readiness with physiologic capability, awareness, and cognitive function.

Central Serotonin Pathways

The serotonergic system is the most extensive monoaminergic system in the brain. It originates in the raphe nuclei of the medulla, pons, and mesencephalon (87,88). Descending projections from the raphe nuclei modulate nociceptive traffic at laminae I and II in the spinal cord and also motor neurons. The raphe nuclei of the midbrain and upper pons project via the medial forebrain bundle to multiple limbic sites, such as hypothalamus; septum and hippocampus; cingulate cortex; and cerebral cortex, including frontal cortex.

The potential role of serotonergic mechanisms in affective disorders, particularly depression and panic disorder, continues to receive a great deal of attention (88,89). Currently, the major antidepressant medications are selective serotonin (5-hydroxytryptamine) reuptake inhibitors, often called *selective serotonin reuptake inhibitors* (90). Increased receptor selectivity in the newer drugs helps to maximize benefit and minimize side effects of these medications.

It is now clear that the older assumptions of simple bioamine deficiency are insufficient to account for the role of serotonin in affective disorders. Although a definitive understanding is still at issue, it has become clear that the serotonergic system influences the actions of the HPA axis, particularly by augmenting cortisol-induced feedback inhibition (91,92 and 93). Moreover, it interacts with noradrenergic pathways in complex ways, including attenuation of firing in LC neurons (94). The interdependence of the monoamine systems and the HPA axis makes it clear that we cannot hope to account for complex patterns of brain or behavioral responses by considering these elements individually. They appear to be components of a larger system that we have yet to conceptualize.

Primary and Secondary Features of the Affective Dimension of Pain

The physiology of emotion suggests that the affective dimension of pain involves a two-stage mechanism. The primary mechanism generates an immediate experience akin to hypervigilance or fear. In nature, this rapid response to injury serves to disrupt ongoing attentional and behavioral patterns. At the same time, efferent messages from the hypothalamus, amygdala, and other limbic structures excite the ANS, which in turn alters bodily states. Cardiac function, muscle tension, altered visceral function, respiration rate, and trembling all occur, and awareness of these reactions creates a strong negative subjective experience. This body state awareness is the second mechanism of the affective dimension of pain.

Damasio (95) submits that visceral and other event-related, autonomically mediated body state changes constitute *somatic markers* (i.e., they serve as messengers, delivering affective evaluations of perceptual experiences that either confirm or deny the potential threat inherent in an event). A *somatic marker* is essentially a somatic image. Perceptually, the brain operates on images that are symbolic representations of external and internal objects or events. Just as it is more efficient for a listener to work with words in language as opposed to phonemes, cognition is more efficient when it uses images rather than simple sensations. The somatic marker images associated with tissue trauma are often complex patterns of physiologic arousal. They serve as symbolic representations of threat to the biological (and sometimes the psychological or social) integrity of the person. Like other images, they can enter into complex patterns of association. Because the secondary stage of the affective response involves images and symbols, it represents cognition as well as emotion.

NEUROPLASTICITY AND PSYCHOLOGICAL PROCESSES

Emotion in Learning and Memory

Sociobiologically, species that can learn readily from experience have adaptive advantages over those that cannot. That which promotes learning fosters adaptation. The affective component of pain contributes to both operant (instrumental) learning and classical conditioning (learning by association). One learns to associate threat with certain environments, social encounters, or other experiences and thereby gains the capacity for avoidance or coping. Patients sometimes learn to associate threat with health care providers, as all dentists know, and they can also learn, maladaptively, to attach threat to various somatic messages of muscle tension or visceral distension that do not, as biological facts, signal actual or impending tissue trauma. The role of learning in the experience of pain and the progression of acute pain to chronic pain is therefore substantial.

Classical Conditioning

Classical conditioning is a form of learning that involves the formation of an association between a normally neutral event and the negative emotion associated with the onset of pain (see Chapter 25). Memory of past events, like learning, depends heavily on emotion, and memories of past experience tend to shape expectations for the present and future.

Imagine conducting a study in which we pair the sound of a bell with a stimulus that evokes a response of interest, such as strong sympathetically mediated arousal. We sound a bell a half-second before we deliver a strong but harmless electrical shock to the fingers of a volunteer. The sudden intense shock elicits many physiologic changes, including an increase in heart rate, rapid shallow breathing, increased skin conductance, pupil dilation, and a sense of fear. After several pairings of the two stimuli, the sound of the bell, presented alone, elicits a similar pattern of physiologic arousal.

In the language of classical conditioning, the arousal reaction to the bell alone is the conditioned response. The sound itself is a conditioned stimulus. The intense electrical shock is the unconditioned stimulus, and the physiologic arousal that the unconditioned stimulus elicits is the unconditioned response. The essence of classical conditioning is that a stimulus that heretofore was neutral (the conditioned stimulus) can, after conditioning, elicit a strong response, such as arousal and fear (conditioned response). This is one of the mechanisms by which the environment can alter the emotional responsivity of the brain.

Nonnoxious stimuli can elicit the emotional patterns normally associated with tissue trauma through classical conditioning. The negative emotion that normally accompanies tissue trauma can become associated with normally neutral, nonnoxious stimuli through classical conditioning. In fear conditioning, the repeated pairing of a neutral stimulus with a noxious one can condition the perceiver so that the neutral stimulus, occurring alone, acts as a trigger to elicit fear. The term for a learned negative emotional response (awareness of threat, increased heart rate, shallow respiration, and so forth) to an objectively nonthreatening stimulus is *conditioned emotional response*. Many people develop fear or frank phobia in dentists' offices through classical conditioning.

Biologically, the conditioned emotional response supports survival because it helps an organism to avoid recurring and potentially dangerous situations. Through conditioning, ordinarily neutral stimuli become warning cues for danger (96). It also helps the individual martial a flight or fight response to a challenge after preexposure to it. Osborne and colleagues (97) found that 3-methoxy-4-hydroxyphenylglycol, an indicator of norepinephrine turnover in the brain, can provide a marker of fear conditioning. Exposure to a painful event increases 3-methoxy-4-hydroxyphenylglycol in a manner that tracks the conditioning process.

Conditioned emotional responses are essentially sensory-affective associations. The amygdala is a key structure in the linking of sensory experience to emotional arousal and in the conditioning of negative emotional associations (36,98,99). Aggleton and Mishkin (100) described the amygdala as a gateway to the emotions for stimuli (simple or complex) in all sensory modalities, both conditioned and unconditioned.

Sensory processing (in the case of pain, spinothalamocortical processing) can elicit complex, negative emotional processes through Pavlovian conditioning (the standard model for classical conditioning). This is not a *postsensory* cortical association but rather a by-product of thalamic processing. LeDoux and colleagues (81,98), working with auditory stimuli, determined that projections from acoustic thalamus to the amygdala allow the classical conditioning of emotional responses to normally neutral auditory stimuli in experimental animals. To condition animal subjects, they paired tones with foot shock, evaluating autonomic responses and

emotional behaviors. Their lesion work implicates separate efferent projections from the amygdala in conditioning of autonomic and behavioral responses. Moreover, emotional memories established by conditioning of subcortical systems strongly resist extinction (101). Once we learn to pair a sensory experience with a negative emotion, it is extremely difficult to unlearn the association. These and other observations indicate that the negative emotion associated with a long-standing painful condition is a complex process, probably sustained by several mechanisms.

Fear conditioning, the formation of a conditioned fear response, almost certainly occurs in patients who undergo repeated painful diagnostic or treatment procedures. Fear conditioning can exacerbate the affective dimension of pain in cases in which circumstances pair minor pain and intense affective arousal. Moreover, fear conditioning can link the environment surrounding a painful event and affective processing of that event so that the environment alone could elicit some elements of the affective dimension of pain.

Operant Learning

Operant learning (also called *operant conditioning*) has received substantial attention in the chronic pain literature (102,103; also see Chapter 25). This type of learning requires that patients emit specific behaviors (e.g., grimacing, bracing, and groaning with postures indicating back pain) and that rewarding events (nurturing, social attention, rest) follow the behaviors. Through operant mechanisms, some patients build complex habit patterns of complaining, expressing pain, seeking nurturing, and evading the quotidian responsibilities of everyday life. In short, they learn pain as a social behavior and develop elegant skills for pain expression. Such patients differ markedly in presentation from the deeply distressed and usually stoic cancer patient with pain.

The typical emotion researcher is quick to contend that positive reinforcers are events accompanied by positive emotions. It is not the fact of the reward that counts in shaping behavior patterns, but rather the emotional experience of reward. Because people and animals alike will work for simple tokens and symbols that have no intrinsic value apart from their conditioned association to positive emotion, this seems a compelling argument.

In any setting in which patients are active and others introduce reinforcing (emotionally rewarding) events, operant learning can occur. A reinforcer is an event that alters the likelihood of a behavior's recurring when it follows an instance of that behavior (103). Events that create pleasant feelings function as rewards (positive reinforcers); events that produce negative feelings are punishments (i.e., they suppress behaviors or delay them until a later time). The positive or negative nature of reinforcers and their personal significance occur in conscious awareness as feelings (104). Put another way, the events that shape behavior are those that are emotionally prominent. Emotion-free events have no reinforcing properties and therefore cannot contribute to adaptive (or maladaptive) learning.

Emotion associated with pain probably influences memory. Memory researchers surmise that both limbic and nonlimbic mechanisms contribute to memory processes (105). Emotional significance controls at least some and perhaps much memory formation. Evidence exists that the brain preferentially stores information that has strong emotional loadings (106,107). Heath (108) proposed that learning and memory are “rooted in feeling and emotion” and identified hippocampus, cortical medial amygdala, and cingulate gyrus as key areas involved in negative emotions.

In sum, the emotional component of pain appears to support adaptation and survival by facilitating learning, memory, and related cognitive processes. It provides a bridge by which pain can influence the psychological status of the individual and his or her behavioral tendencies. Inadvertent classical conditioning can cause anticipatory anxiety or exacerbate the emotional distress of a painful event. Operant conditioning can shape patient behavior in the direction of increased pain complaint and disability.

EMOTION AND COGNITION

Negative emotions are much more than reactions to undesirable events; in nature, they help an organism determine which things benefit and which things threaten survival, and they compel behavior consistent with such evaluations. Moreover, emotional expression communicates this judgment to others and thus sets up group approach or avoidance behaviors. As noted previously, MacLean (7) described emotion as a process that imparts subjective information. In these respects, our feelings approximate crude intelligence. How we feel about something is often as important, or more important, than what we know about it. If emotion is a protointelligence, then evolutionarily newer structures—namely, the later stages of cortical development—should have demonstrable links with limbic structures and functions.

Such interconnections exist. Parts of frontal lobe (the dorsal trend) appear to have developed from rudimentary hippocampal formation, whereas other parts (the paleocortical trend) originated in olfactory cortex. Although these two areas interconnect anatomically, the former analyzes sensory information, whereas the latter contributes emotional tone to that sensory information (109). Pribram (110), noting that limbic function involves frontal and temporal cortex, offered a bottom-up concept for how cognition relates to feelings (i.e., emotion determines cognition). However, the multimodal neocortical association areas project corticofugally to limbic structures (111), and this suggests that cognitions may drive emotions.

The debate on whether emotion or cognition is primary may never resolve. For immediate purposes, it seems best to conclude that knowing and feeling are closely interrelated. Still, these processes are not identical. We can know something about our feelings, and we can have emotional responses to what we know. The brain is a complex, dynamic organ, constantly constructing its internal model of reality from sensory input and memory storage. Feeling and thinking are major processes in this construction.

PAIN, STRESS, AND SICKNESS

The defensive response of the central nervous system to injury or disease is complex. We have already seen that it is not limited to simple sensory signaling of tissue trauma, awareness of such signaling, and conscious response. Much of the information processing is unconscious, and physiologic responses are initially unconscious, producing affective changes and subsequent awareness of emotional arousal. The HPA axis plays a strong role in emotional arousal and the defense response, and it helps to govern the immune system (112). The immune system does much more than identifying and destroying foreign substances: It may function as a sense organ that is diffusely distributed throughout the body (113,114).

Some investigators (74,114) contend that the brain and immune system form a bidirectional communication network. First, products of the immune system communicate injury-related events and tissue pathology to the brain. The key products are cytokines, such as interleukin-1 and interleukin-6, released by macrophages and other immune cells. They appear to do this not by functioning as blood-borne messengers, but by activating the vagus nerve. Paraganglia surrounding vagal terminals have dense binding sites for interleukin-1, and they synapse on vagal fibers that terminate in the solitary nucleus. Thus, cytokines appear to excite (albeit indirectly) vagal afferents that terminate in one of the major control centers for the ANS.

Second, the brain controls the immune system via the actions of the sympathetic nervous system and the hypothalamic secretion of releasing factors into the bloodstream that activate the anterior pituitary via the HPA axis (112). The pituitary body releases peptides related to proopiomelanocortin, such as adrenocorticotropic hormone and b-endorphin, and these in turn trigger the release of glucocorticoids. Because the cells and organs of the immune system express receptors for these hormones, they can respond to humoral messenger molecules of central origin. This system is important for pain research because, according to Maier and Watkins (114), activation of these pathways by a stressor such as tissue trauma produces a constellation of adaptive behaviors and physiologic changes that correspond to the *sickness response*.

The sickness response is a negative experience, but it evolved to promote recuperation and survival. It includes fever, increased slow-wave sleep, increased leukocytosis, reduced exploration, diminished sexual interest, reduced activity, depressed mood, and somewhat diminished cognitive abilities. Collectively, these responses conserve energy and foster its redirection to increased body temperature, which suppresses the reproduction of microbial organisms. Sickness tends to occur with both microbial infection and tissue injury because an open wound normally invites infection. Viewed broadly, sickness is an unpleasant motivational state that promotes recuperation.

These considerations suggest that feeling sick is a part of the brain's defense against microbial invasion. Tissue trauma can provoke it, and thus it tends to accompany the experience of pain. Obviously, chronic sickness in the absence of definable injury of pathology serves no biological purpose. The role of the sickness response in chronic pain states merits study.

MODEL FOR THE AFFECTIVE DIMENSION OF PAIN

Figure 24-6 summarizes the concepts covered previously. This is a bottom-up depiction of the fate of nociceptive signals produced by injury or disease. Spinothalamic (sensory thalamus) and spinolimbic processing occurs in response to noxious signaling. In the person with pain, spinothalamic and thalamocortical sensory processing produces sensory information related to the tissue trauma and performs feature extraction on it: intensity, location, duration, and general nature of the injury. Spinolimbic processing, which involves spinohypothalamic pathways and central noradrenergic innervation, provides emotional arousal. Figure 24-5 provides a more detailed description of the interdependence of sensory and limbic processes.

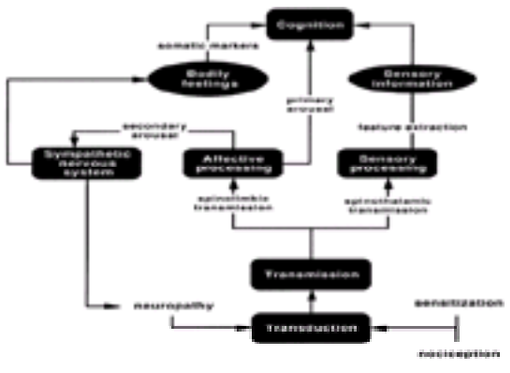

Figure 24-6. A bottom-up model of how nociception produced by tissue pathology or injury enters into cognition. The experience of pain is the product of both spinothalamic and spinolimbic processing.

Spinolimbic processing involves two stages, as Figure 24-6 shows. The first stage, primary arousal, produces a generalized heightened alertness and sense of threat. The perceiver is not directly aware of this state in the way that one is aware of sensory information; rather, it is the emotional coloring against which the perceiver appreciates the sensory information processed via the parallel spinothalamic tract. It is a sense of disquiet and apprehension akin to fear. The key point is that the perceiver is hypervigilant without being concomitantly aware of the hypervigilance.

As this happens, the hypothalamus and ANS initiate a secondary arousal response that involves efferent sympathetic stimulation of visceral organs, skeletal muscle, skin, and the vasculature. Figure 24-7, a top-down model, depicts many central structures contributing to sympathetic arousal and the defense response.

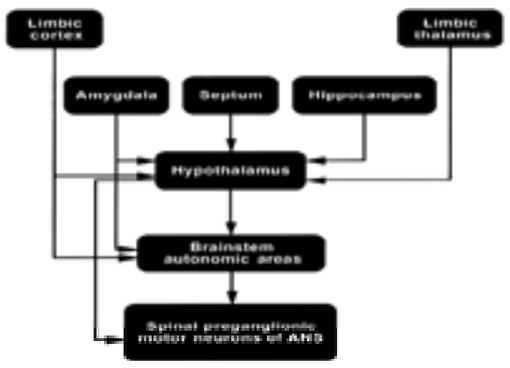

Figure 24-7. A top-down model for how the limbic brain influences autonomic function. Many central structures contribute to the defense response and to sympathetic arousal. (ANS, autonomic nervous system.)

This defense response largely readies the body for flight or fight. Its sudden onset creates a wave of emotion that follows on the heels of the primary negative arousal response. The perceiver is ordinarily quite aware of this arousal because of its dramatic bodily effects. In some cases, such as panic attack, the arousal itself becomes the focus of attention; in others, it simply colors the immediate sensory experience. The essential concept here is that secondary arousal creates and sustains an emotional state.

Both pathways feed forward into cognition. Figure 24-8 illustrates some of the processes that act on sensory and affective input. Primary arousal captures and directs attention. Secondary arousal affects memory, the formation of schemata (perceptual hypotheses), and the retrieval of learned schemata for memory. If the painful stimulus persists, it elicits a sustained stress response that creates a negative mood state.

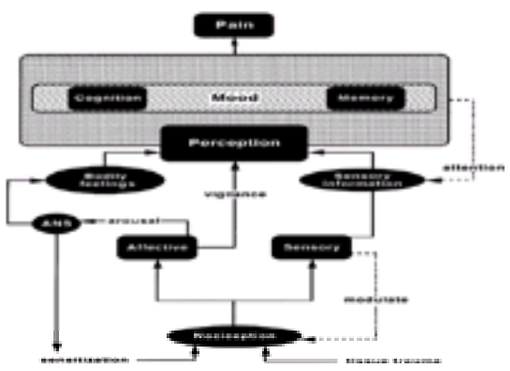

Figure 24-8. Higher-order processes that influence the transmission and processing of sensory and affective input. Negative mood states can bias attention and memory retrieval. (ANS, autonomic nervous system.)

Mood states are extended emotional predispositions that can strongly bias cognition, as Figure 24-8 indicates. A negative mood, such as reactive depression, biases memory by ensuring that only negative, emotionally unpleasant recollections come forward. Similarly, it directs attention toward threatening, aversive, or otherwise unpleasant things, and it fosters the creation of schemata that are inherently negative. In this way, an unchallenged negative mood state can sustain itself indefinitely.

Sensory information feeds forward into thinking (ratiocination), goal-directed efforts (motivation), and awareness of the external and somatic environment. Emotional arousal and mood can distort thinking and foster metacognition: errors in perception and reasoning (115). Metacognition is a major source of erroneous self-report of pain intensity and the effect of pain on lifestyle. Through affective mechanisms, excessive, persistent, or both, pain can extract a substantial toll on the mental and physical health of the individual.

Supporting Findings from Brain Imaging Studies

The model offered in this chapter predicts that noxious stimulation, whether of experimental or pathologic origin, generates massive, parallel distributed processing in the central nervous system. This processing must involve limbic structures as well as sensory pathways.

Studies involving positron emission tomography (PET) of regional cerebral blood flow (rCBF) in volunteers experiencing pain, and similar studies in pain patients, offer strong support for the hypothesis that noxious stimulation activates limbic structures. Changes in rCBF index neuronal activity in specific brain regions.

The partial review that follows targets studies designed to capture the complex central processing associated with pain. Collectively, they have puzzled and challenged pain researchers with classical sensory neurophysiology perspectives. Although not perfectly consistent, they demonstrate beyond any doubt that massive parallel distributed processing occurs in the brain after tissue damage. Processing includes, but is not limited to, sensory pathways. The most striking feature of this massive, parallel distributed processing is that a great deal of it occurs in limbic brain. This provides supporting evidence for the contention that pain has an affective dimension.

Just what does increased rCBF in a brain area mean? Glib interpretation is tempting, but fraught with pitfalls. It seems naïve to presume that the brain works on a rope and bell basis: Pull the rope in the periphery and ring a bell in a specific brain center. It is quite clear that the brain as a whole, and especially the limbic brain, operates as a system with complex feed-forward and feedback mechanisms. Notions of *centers* for one or another function have largely disappeared from the landscape of contemporary brain research. Consequently, attempts to chase nociception-specific messages to nociception-specific centers are probably doomed to fail. Also, little justification exists for assuming that brain activation means that sensory information processing is taking place. Affective processing may involve such processes as arousal and anticipation.

Because of these uncertainties, clear interpretation of massive parallel rCBF indicators of brain activation still eludes us. Moreover, in the end, we have no idea how any of the areas feeds forward into the contents of consciousness. Despite these limitations, the following studies indicate a striking consistency, and they strongly implicate limbic structures in the construction of the pain experience.

Pioneering studies examined healthy subjects and patients. Jones and colleagues (116) applied heat via a Peltier thermode to the hands of six normal volunteers. They contrasted the rCBF findings across three stimulus intensities, ranging from noxious to innocuous. Pain-related changes in rCBF appeared in contralateral thalamus, lenticular nucleus, and cingulate cortex. The same team studied rCBF in five cancer patients with pain before and after percutaneous, ventrolateral cervical cordotomy. They compared patients before pain with healthy subjects and then compared patients with themselves before and after neurosurgical intervention. The comparison of patients with healthy subjects revealed significantly less blood flow in three of four of the individual quadrants of the hemithalamus contralateral to the side of pain in the cancer patients. Cordotomy abolished the differences. Cordotomized patients demonstrated decreased CBF in the dorsal anterior quadrant of the thalamus contralateral to the side of pain, but no changes were evident in either primary somatosensory cortex or prefrontal cortex.

The lenticular nucleus, or lentiform nucleus, resides lateral to the thalamus and within the internal capsule. It comprises two parts, the larger putamen and (medial to it) the smaller globus pallidus, which is separated from the thalamus by the posterior limb of the internal capsule.

Talbot and associates (117) stimulated the forearms of six normal volunteers with noxious heat from a contact thermode. Pain- related rCBF changes appeared in contralateral cingulate gyrus and in primary and secondary somatosensory cortex. Coghill and colleagues (118) followed this with a PET study comparing rCBF changes in normal volunteers during painful heat stimulation and vibrotactile stimulation. With painful stimulation, subjects demonstrated rCBF changes in contralateral thalamus, primary and secondary somatosensory cortices, anterior cingulate cortex, insula, and frontal cortex. With vibrotactile stimulation, changes appeared contralaterally in primary somatosensory cortex and bilaterally in secondary somatosensory cortex and insula. Both types of stimuli activated primary and secondary somatosensory cortical areas, but painful stimuli had a significantly greater effect on insula and produced in general a more widely dispersed effect.

Casey and colleagues (119) delivered noxious and innocuous heat pulses to the forearms of volunteers during PET analysis of rCBF. Significant rCBF increases occurred contralaterally with painful stimulation in thalamus, cingulate cortex, primary and secondary somatosensory cortex, and insula. Ipsilaterally, secondary somatosensory cortex, thalamus, medial dorsal midbrain, and cerebellar vermis also showed increases in rCBF.

In a later study, Casey and colleagues (120) sought to detect rCBF increases in 27 normal humans as they discriminated differences in the intensity of noxious and innocuous thermal stimulation applied to the nondominant (left) arm. They divided subjects into three groups of nine each: repetitive contact heat stimuli (40°C and 50°C of thermode stimuli), cold pressor, and warmth discrimination (36°C and 43°C of thermode stimuli). Significant increases in rCBF to the 43°C stimuli occurred in the contralateral ventral posterior thalamus, lenticular nucleus, medial prefrontal cortex (Brodmann's areas 10 and 32), as well as cerebellar vermis. The painful stimuli elicited more extensive brain activity. Significant rCBF increases to 50°C stimuli appeared contralaterally in the thalamus, anterior cingulate cortex, premotor cortex, and secondary somatosensory (S2) and posterior insular cortices. Significant activity also appeared within the region of the contralateral anterior insula and lenticular nucleus. The ipsilateral premotor cortex and thalamus and the medial dorsal midbrain and cerebellar vermis also showed significant rCBF increases. In the heat pain and cold pain conditions, five areas responded consistently: cerebellar vermis, ipsilateral thalamus, contralateral premotor cortex, contralateral anterior cingulate cortex, and contralateral insula and lenticular nucleus. Cold pain created a greater rCBF increase than did heat pain. These observations are consistent with the interpretation that rCBF increases reflect activity both of the sensory and affective processing of nociceptive signaling.

Vogt and coworkers (121) studied the rCBF responses of seven healthy subjects to noxious and nonnoxious heat stimulation. They used statistical parametric mapping for the group to identify regions of altered relative rCBF. In addition, they fitted the PET data on a subject-by-subject basis to magnetic resonance images of the brain. The mapping analysis of the group showed one site with elevated rCBF in the midcingulate cortex and one in the perigenual cortex predominantly contralateral to the side of stimulation. Bilateral sites of reduced rCBF were in the cingulofrontal transitional cortex and in the posterior cingulate cortex as well. Coregistered PET and magnetic resonance images for individuals showed that only one case had a single, large region of elevated rCBF, whereas the others had a number of smaller regions. This study helps clarify the noteworthy range of individual differences in rCBF responses during pain.

Hsieh and colleagues (122) investigated rCBF in eight patients with neuropathic pain (lateralized mononeuropathy). They compared two conditions: normal ongoing pain experience and a condition in which the experimenters had temporarily blocked the pain via lidocaine block. The ongoing neuropathic pain produced activation of bilateral anterior insula, posterior parietal, lateral inferior prefrontal, and posterior cingulate cortices as well as the posterior sector of the right anterior cingulate cortex. The contralateral posterior thalamus demonstrated reduced rCBF. However, they found no significant change in rCBF in the somatosensory areas SI and SII. The investigators concluded that these findings point to the affective-motivational dimension of chronic ongoing neuropathic pain.

In a later study, Hsieh and colleagues (123) explored the effects of minor dermal injury elicited by intracutaneous injection of a minute amount of ethanol on rCBF in four subjects. A saline injection served as control. The painful condition (ethanol) prominently activated the hypothalamus, periaqueductal gray, prefrontal cortex, insula, anterior cingulate cortex, posterior parietal cortex, primary motor and somatosensory areas, supplementary motor area, and cerebellum.

Silverman and associates (124) looked at pain threshold rCBF in six patients with irritable bowel syndrome, contrasting them to six normal subjects tested under identical conditions of noxious rectal distension. For the healthy subjects, a significant relationship existed between activity of the anterior cingulate cortex and actual or simulated delivery of the painful stimuli, but no response occurred for nonpainful stimuli. In patients, no response occurred in anterior cingulate, and instead they demonstrated a significant activation of left prefrontal cortex during activation and anticipation.

Jones and colleagues (125) examined rheumatoid arthritis patients with chronic inflammatory pain in a test of the hypothesis that such pain alters endogenous opioid binding at receptors in the brain. A high concentration of such receptors exists in periaqueductal gray, medial thalamus, lentiform nucleus, anterior cingulate cortex, and insular cortex. If chronic pain is associated with increased production of endogenous opioids and increased binding at receptors, then an exogenously introduced opioid substance should find fewer binding sites in these areas. The investigators used PET scanning to tracer quantities of ^{11}C diprenorphine after its intravenous injection in four patients, in pain and after pain relief. They observed significant changes in superior and inferior frontal cortex, straight gyrus, anterior and posterior cingulate, and superior and midtemporal cortex.

Derbyshire and coworkers (126) studied rCBF in six patients with atypical facial pain, applying noxious and innocuous heat stimuli to the back of their hands and contrasting their regional blood flow patterns to those of normal controls. Patients and controls showed marked rCBF differences between painful and nonpainful conditions in thalamus, anterior cingulate cortex, lentiform nucleus, insula, and prefrontal cortex. The patient group showed increased blood flow in anterior cingulate cortex but decreased blood flow in prefrontal cortex.

Does chronic and acute pain produce different patterns in rCBF? Mountz and colleagues studied women diagnosed with fibromyalgia syndrome, a disorder characterized by widespread chronic pain and fatigue (127). They examined resting state rCBF in 10 patients and compared their data with those of seven healthy women. Resting regional bilateral blood flow was significantly lower in the fibromyalgia patients than in normal subjects at the thalamus, at the head of the caudate nucleus, and in cortex. The observation of lower rather than higher rCBF levels in the fibromyalgia patients led the authors to speculate that chronic pain may eventually reduce blood flow in certain brain areas. They postulated that a release of C-fiber neuropeptides in response to chronic noxious stimulation, together with diminished rCBF, altered central nervous system sensitivity to normally mildly noxious stimulation in fibromyalgia patients. These findings open new hypotheses about central differences in acute and chronic pain and the role of potential compensatory processes.

Collectively, these brain imaging studies demonstrate massive parallel distributed processing, largely in limbic structures, and thereby support the hypothesis that there is an affective component of pain. Thalamus, anterior cingulate cortex, insula, and frontal cortex emerge with high consistency across studies of normal volunteers and patients with pain. This response pattern corresponds to MacLean's thalamocingulate division of the limbic brain (7). Moreover, the results of the various PET studies are broadly consistent with the hypothesis that noradrenergic activation plays a major role in the affective component of pain.

Can one derive any strong interpretations about pain as a modality? This line of research seems to demonstrate that pain is not limited to a sensory modality. The patterns of central arousal demonstrated thus far are not specific to pain as a sensory modality; whether any of them is specific to threatening stimuli in general remains to be seen. Central activation, not surprisingly, appears to correspond to higher-order psychological processes. As more studies appear in various areas, it becomes increasingly clear that PET studies demonstrate that such processes are a part of the complex experience of pain.

FUTURE DIRECTIONS

Psychophysiology is a rapidly expanding field. To date, its influence on pain research has been minimal, because many pain investigators have favored the classical view of pain as a sensory modality. Now that brain imaging observations are challenging classical models, pain research has to expand its horizons. Psychophysiology has much to contribute in theory as well as in methodology. Integrating the rich knowledge base in psychophysiology with contemporary models of pain at present is difficult, but such integration is inevitable. Pain is a psychophysiologic phenomenon.

As brain imaging research on pain unfolds, it becomes increasingly clear that the brain deals in complex ways with signals of tissue trauma. Highly organized patterns of protective response exist, and they involve the ANS, the HPA axis, and the immune system, as well as subjective awareness. Negative emotion is a major feature of pain and a direct consequence of complex central processing. In light of these findings, it is no longer enough to trace the sensory messages of tissue trauma to somatosensory cortex. The challenge for the twenty-first century is to discover and describe the complex central processes involved in pain. Expanded models of central processing will help substantially in bridging basic science knowledge and theory with clinical care.

CHAPTER 25

Learned Pain: Pain as Behavior

Wilbert E. Fordyce

Pain is a concept, not a *thing*. People do not *have* pain; they experience the unpleasant effects of nociceptive stimulation or they suffer in ways that they associate with pain. Recognition of this point is basic to understanding pain and suffering. If pain consisted solely of a hard-wired stimulus-response capability, there would be no role for learning or for other cognitive processes. Conversely, if a hard-wired stimulus-response capability were the defining characteristic of pain, neuroanatomic and pathophysiologic parameters would suffice in dealing with clinical pain, which, obviously, they do not (1,2 3) (see Chapter 6, Chapter 7, Chapter 8, Chapter 9 and Chapter 10).

In an intact organism, a nociceptive stimulus virtually always elicits some form of pain behavior, as well as a subjective unpleasant sensation. However, it also commingles with whatever other stimuli are currently active, extant physiologic and mood states, and perceived or anticipated consequences to whatever actions might be taken. Responses emerge from this process. It is those responses that tell us that the person is experiencing what he or she identifies as pain. It is the commingling of the processing of nociceptive stimuli with other cognitive and sensory phenomena that ensures an opportunity for learning. *Learning* is the persistence or inhibition of a response, across time. As a consequence of learning, the response occurs or is inhibited in different contextual circumstances.

Melzack and Wall's gate control theory was first presented in 1965: a pioneering recognition that pain is a complex affair implicating central processing capabilities. It pointed toward the current and changing state of the individual as being capable of exerting major influence on responses to nociception. Clearly, the observed, inferred, or alleged nociceptive stimulus could not encompass the concept of pain alone. It follows that, when confronted with a pain problem, the clinician should not focus solely on the peripheral stimulus and make inferences as to its cause.

Subsequent to the emergence of the gate control theory, behavior modification technology in the form of operant conditioning techniques was applied to selected problems of chronic pain (4,5). This had the effect of extending the range of parameters affecting pain problems to include the residuals of prior experience and, perhaps more important, environmental contingencies. Behavioral-based interventions have proven to have considerable potential for improvement in function, reduction in pain-related health care use, and subjective reports of pain and suffering in appropriately selected cases.

The gate control theory and behavioral interventions pointed to the need for a paradigm shift. Instead of viewing chronic pain as solely a biomedical-based problem, it became apparent that it is a problem having psychological and environmental-relational aspects potentially every bit as important as neuroanatomic ones. To understand a person's pain, one needs to factor in responses or behavior and the factors that influence it.

Persisting noxious stimuli can produce lasting changes in neurophysiologic mechanisms that influence ensuing responses. Those matters are considered in Chapter 3, Chapter 4 and Chapter 5 and Chapter 10. It is not always clear whether nervous system changes are induced by peripheral mechanisms at the injury site or whether they are brought about by environmental factors.

Behavior is a product of prior learning or experience as well as current stimulation. That is why we must consider learning and behavior when we consider pain. Although this concept is now virtually universally understood and accepted by health care professionals, it is far less common that this understanding is translated into how pain is diagnosed or treated. We often do not recognize the extent to which our thinking is guided by often implicit and infrequently articulated conceptual models. These models help us to organize our thoughts and to understand more readily the phenomena with which we are dealing. The lure of a seemingly simpler and more straightforward model of pain, as embodied in a stimulus-response or biomedical-rooted view, is strong both in health care professionals and in the patient consumers of their services. It is all too often the case that the relatively straightforward biomedical perspective is either assumed to be the major force in seeking to understand a pain problem, or, at the least, must be eliminated before equally viable alternatives receive the consideration they deserve. This chapter focuses on one of these alternative major influences on clinical pain: learning. It examines behavior because that is the primary manifestation of learning or experience.

Viewing pain in behavioral terms arose serendipitously. A more detailed account of the origins of this view was related in an earlier edition of this text (2). It is repeated here, although in abbreviated fashion, because it is a particularly graphic illustration of the potential effect of environmental influence in the form of social feedback on pain behavior.

The circumstances were that a pain-ridden patient in an inpatient setting was confronted in the course of events by a treatment team decision to respond to his verbal expressions of pain by looking away instead of maintaining eye contact. This crude and simple-minded action led surprisingly to a marked change in the patient's behavior. Initially, he was bed-bound with complaints of pain; then he began arising and undertaking physical reactivation procedures. The patient made it clear that he knew how the team was reacting to his expressions of suffering, but it made little difference in his ensuing pain behaviors and in his progress toward reactivation. This demonstration that pain behaviors are sensitive to consequences tells us two things: (a) that pain behaviors are an integral part of pain problems and (b) that those pain behaviors are subject to influence by consequences.

BASIC CONSIDERATIONS

Distinctions between a biomedical and a biopsychosocial model of pain are important, for they may lead us to quite different actions when dealing with patients who complain of pain. The biomedical model points to seeking a diagnostic explanation for the observed or inferred nociceptive stimulus. At least a passing attention is paid to personality and motivational considerations, but the initial focus clearly is to seek to understand what is considered to be the initiating event: the nociceptive stimulus.

A biopsychosocial model leads to a different focus. It is no less important to sort out the role, if any, of noxious stimulation from disease or injury. The complaints of pain (i.e., the pain behaviors) may be occurring for a variety of reasons, perhaps a complex mix of neuroanatomic and psychosocial. The two models are not mutually exclusive; their explanatory powers are often intertwined. It is rarely the case that a patient's chronic pain problem should be addressed solely from the perspective of either model (2,6).

This chapter presents conceptual and empiric bases for adding a behavioral science perspective to the medical science perspective in dealing with clinical pain. A

brief description of basic concepts of learning is needed before proceeding.

Classic and Operant Conditioning

Classic conditioning has also been termed *Pavlovian conditioning*. A conditioned stimulus, the bell in the case of Pavlov's dog, is paired with an unconditioned stimulus, the food, which in turn elicits salivation by reflex. After repeated training trials (i.e., experience), that response comes to be elicited successfully by a previously unconditioned but now conditioned stimulus, the bell. Learning has occurred in that classical conditioning paradigm.

Instrumental or operant conditioning works differently. A behavior (e.g., pain behavior) previously in the repertoire, when elicited, acts on the environment; therefore, it is likely to have effects or influence on the environment by eliciting some environmental reaction. If the effect is to evoke a reinforcing consequence, the behavior is likely to be repeated when cues indicating potential reinforcing consequences are again present.

In classic (respondent) conditioning, the behavior is said to occur in response to the antecedent stimulus. In the Pavlovian example, the bell was antecedent to the salivation. The response was automatic and reflexive. In operant conditioning (the term *operant* is used because the response acts on the environment), change or learning occurs because of what follows, or is anticipated to follow, the behavior. Smiling at other people may serve as an illustration. Experience probably has taught us that smiling often leads to approval or emotional support from those exposed to the smile, a reinforcing consequence that is likely to encourage future smiling. Similarly, moaning or rubbing an aching body part may elicit supporting or commiserating responses in observers, thereby potentially encouraging persistence of those pain behaviors.

The ability to *anticipate* consequences is important, as are the effects of the consequences. Anticipation of consequences is a cognitive act. Operant conditioning can never be isolated entirely from cognitions. The term *cognitive-behavioral* is a partial recognition of this, although that term relates to other matters as well. This chapter focuses on operant conditioning. Cognitive factors going beyond operant conditioning are addressed in Chapter 6 and Chapter 89.

Respondent and operant conditioning differ in important ways. The difference most relevant to clinical pain, and the only one to be considered here, is that behavior elicited by antecedent stimuli, as in respondent or Pavlovian conditioning, is unlikely to persist, unless it continues to be systematically exposed to reinforcing consequences. Pavlov's dog did not long persist in salivating to the bell when food no longer followed. Additional conditioning trials with bell and food were necessary to reestablish the conditioned response. An exception to this point is noted below in relation to trauma-induced pain problems.

Pain behaviors under operant control persist or diminish because of persistence of consequences favorable or unfavorable to learning, or the anticipation of such consequences. This means that the behavior may persist even when it receives reinforcing consequences only intermittently. Responses or behavior reinforced on every occasion that it occurs tends to satiate and diminish in strength. Responses reinforced intermittently are persistent. If, however, reinforcement occurs too infrequently, the behavior also is likely to disappear, a process known as *extinction*. A whole technology is concerned with schedule or frequency of reinforcement and receives more consideration in Chapter 88.

The potential for conditioning effects points to a different target for treatment of pain problems. The first objective of treatment for pain problems under control of nociceptive stimuli is usually to diminish or eliminate the nociceptive stimulation. Treat the cause, not the symptom. Pain problems that have come under control of conditioning effects they may have originated, however, should be treated in a different way. The focus of treatment may be to modify consequences to pain behaviors, while also helping the patient to become reactivated. In the practical case, clinical pain problems, particularly if they are chronic, present features relevant to both biomedical and learning-based strategies. To paraphrase, it is often the case that one should seek to treat both the cause and the symptom; to do only one and not the other well may result in needless persistence of the pain problem.

Suffering

Expectations or anticipation of consequences has another type of importance to clinical pain, relating to the ease with which suffering from pain and suffering for other reasons may be confounded. A nociceptive stimulus is perceived. Part of that process is the assignment of a *meaning* (i.e., an interpretation). That interpretation or meaning assigned often reaches beyond the nociceptive stimuli coming from the periphery. Coincidental or contiguous stimuli may be incorporated into the meaning. Expectations as to what might occur, given the context of the situation, play a role, as does anticipation of probable or possible consequences. During the course of a football game, a player expects to receive physically punishing blows that, if received by another person in a different context, would probably produce a highly charged emotional response. For the football player, it may be a relatively inconsequential event because of experience and expectations. Emotional responses often become implicated in meanings assigned to stimulus situations. When the situation is noxious or unpleasant, these emotional responses often elicit feelings that can be thought of as suffering.

Cassell (7) distinguishes suffering from physical distress in this fashion:

> Suffering occurs when an impending destruction of the person is perceived; it continues until the threat of disintegration has passed or until the integrity of the person can be restored in some other manner . . . although suffering often occurs in the presence of acute pain . . . or other bodily symptoms, suffering extends beyond the physical. Most generally suffering can be defined as the state of severe distress associated with events that threaten the wholeness of the person.

Suffering, as defined by Cassell and seen as the emotional component of pain, involves the anticipation of consequences. If the person does not understand the natural course of the pain problem and the timing and character of the outcome, the future is clouded and the suffering will be greater. Suffering, like nociceptive stimulation, produces pain or suffering behaviors. These behaviors may be maintained if the future looks aversive or uncertain.

Suffering behaviors, because they are operant, may also come under the control of conditioning. One of the greatest problems in clinical pain, particularly chronic pain, is the confounding of pain with suffering, both by the patient and the clinician. Pain behavior may reflect nociceptive stimulation at onset of the problem, as in tissue injury, but can continue long after the nociceptive stimulation has ceased and the injury has healed. Suffering behavior can continue as a consequence of learning without substantial ongoing nociceptive input.

One long-term effect of prolonged nociceptive stimulation is that it tends to promote guarding or resting behaviors. Unless the person clearly distinguishes hurt from harm by continuing to move, or to resume moving in a timely fashion, guarding behaviors persist and the effects of disuse (8) replace the effects of nociceptive stimulation associated with the originating injury. Thereafter, movement continues to be painful and the future continues to be clouded with doubts or, much worse, seems to promise continued impairment, both of which produce pain or suffering. Reinforcement derives from the patient's mistaken belief that the pain of movement means that healing is incomplete. Reinforcement may also come from the environment because pain or suffering behaviors meet reinforcing consequences in the patient's milieu.

CLINICAL CONSIDERATIONS

Influence of Learning on Pain Behavior

When a behavior is followed contingently by positive or reinforcing consequences, it tends to persist. The probability of its recurrence or persistence also increases in the presence of cues that signal that reinforcing consequences may be forthcoming (9). Because pain behaviors are behavior, they can be influenced by the same factors that influence any other behavior.

Two patterns of operant conditioning important to clinical pain can be distinguished. One is the case in which a reinforcing consequence is contingently applied after an overt behavior: a *positive reinforcement* paradigm. The consequence is generally something of positive value to the person and is therefore reinforcing. The second is when a consequence is removed as a contingency after an overt behavior: a *negative reinforcement* paradigm. That which is removed is generally an aversive or unpleasant consequence. The negative reinforcement paradigm is also known as *escape* or *avoidance conditioning* in that it tends to establish and maintain behavior designed to escape or avoid the negative consequence (10).

Positive and negative reinforcement is implicated in clinical pain. For example, a muscle is strained in the low back during the course of heavy lifting. Pain behaviors ensue and may meet reinforcing consequences from the environmental milieu in the form of solicitous behavior from a spouse or attention from a highly regarded

physician who may also prescribe rest, itself likely a potent reinforcement. If analgesics are also prescribed, another positive reinforcement may occur in the form of a relatively carefree state induced by the medications. Concomitant to the potentially positive reinforcers just noted, negative reinforcement may also occur. Curtailed activity and avoiding flexing the back may successfully escape anticipated suffering. Medically sanctioned time out from a job already aversive for other reasons may provide additional escape or avoidance conditioning opportunities.

In both examples cited, the learning or conditioning effects occurred as automatic consequences of experience (3,11). They did not occur as a conscious decision by the suffering person to engage in pain behaviors. Thus, these events do not indicate malingering, imagining pain, or some manifestation of mental illness.

In these examples, I have not referred to such mental concepts as inferred underlying motivation, conversion reaction, or personality types. The examples refer to cues, processing of those cues, and anticipation of consequences. They focus on what a person does, not on what a person is alleged to have, as is the case with most psychological approaches.

Operant Conditioning and Reinforcing Consequences

Potential reinforcing consequences to pain behaviors abound. A chronic pain patient may receive special attention, sanctioned rest, or pleasurable effects of a prescribed analgesic. These consequences readily may occur contingent on pain behavior. This is illustrated by prescription of analgesics on an as-needed basis (i.e., the effect of the analgesic depends on the occurrence of pain behaviors). Similarly, a person who moves guardedly thereby conveys to a helpful spouse that movement is painful. The consequences may be solicitous behaviors by the spouse, who offers to complete a half-finished task or provides admonitions to rest. If those consequences are positively reinforcing, the pain behaviors have been rewarded and are more likely to persist. In these illustrations, note that the consequences occurred only if pain behaviors occurred. They were contingent on pain behavior.

Not all consequences of behavior are positively reinforcing to every patient (e.g., not everyone finds attention pleasurable, and some find sedation aversive). For conditioning to occur, the consequences must occur with fair frequency, be positive or reinforcing to the individual, and be contingent on pain behaviors. If they occur irrespective of the occurrence or nonoccurrence of pain behaviors, conditioning is unlikely.

Assessment of the role of operant conditioning in clinical pain requires that one determine which potentially reinforcing consequences are presently contingent on pain behaviors. This is accomplished by detailed interviewing of patient and spouse or significant others around the patient (4,12) (see Chapter 16 and Chapter 18).

Treatment of acute and chronic pain must also take into account whether reinforcing contingencies are being set up systematically by a treatment regimen that persists over time. This is particularly an issue in management by analgesics and rest versus activity when pain is likely to persist for extended periods. In the case of a recent injury in which healing is expected in days or weeks, little need for concern usually exists. Similarly, postoperative pain with an expected course of only a few days probably will not lead to enduring conditioning effects.

Analgesics

Prescription of analgesics, muscle relaxants, and tranquilizers for more than a few days on an as-needed or pain-behavior contingent basis sets up a conditioning paradigm that risks causing pain behaviors to persist long past healing time and perhaps indefinitely (3,5,13). Time-contingent medications are a preferable style of drug delivery for both psychological and pharmacologic reasons.

Rest

Rest often is overprescribed (13). Healing is usually rapid and is often promoted by motion (14). Rest, excessively or carelessly prescribed, may inhibit or interfere with healing while also encouraging deactivation. The problem is compounded if the task of determining whether healing has occurred and activity is now appropriate is assigned to the untrained patient (15), as by saying to the patient, “Let pain be your guide” to determine when to terminate rest and resume activity. Often, the result of this arrangement is that the patient, on moving, experiences some discomfort and interprets it to mean that healing has not occurred and that continued movement may impair healing. The patient then moves less, thereby increasing the adverse effects of disuse and making it more probable that future movement of the involved body part will be painful. Thus begins a vicious circle. Each painful movement interpreted to reaffirm that healing has not occurred encourages greater disuse and more pain. It also pairs movement with events in the environment that, through conditioning, become cues capable of eliciting more discomfort. In sum, the pain problem may persist and worsen despite adequate healing, because the consequences of use and movement were misinterpreted because of ambiguous clinician guidance.

AVOIDANCE LEARNING

Behavior that avoids or postpones an anticipated aversive consequence, known as *avoidance learning*, has been studied in clinical pain (10). The following are the most important points about avoidance learning.

Aversive Consequences to Pain

A person learning that an activity has aversive consequences is likely to avoid that activity. Anticipating that a body position or physical activity will likely result in increased pain usually leads to avoiding or minimizing that activity. A strained back muscle is likely to lead to avoiding flexing forward and lifting heavy objects.

Resistance to Extinction

Once established, avoidance behaviors are highly resistant to extinction, because the behavior to be avoided rarely occurs. Each time it is avoided there appears to be a confirmation of the effectiveness of the avoidance. Conversely, the opportunity to disprove the expectation that a movement leads to pain does not occur. For example, a chronic low back pain patient during the early history of the problem may have experienced great pain on flexing the torso forward. Now the patient may hold him- or herself rigidly erect and studiously avoid flexing forward. The back muscles, of course, soon become tight, ensuring pain on flexing as a consequence of disuse. Although healing may long since have occurred, the patient continues to avoid flexing. Each guarding or avoidance of flexing seems to have confirmed the success of avoidance.

Other Aversive Consequences

An avoidance behavior that successfully minimizes pain may also avoid other aversive consequences and thereby receive additional reinforcement. The avoidance behavior has successfully prevented aversive consequences relating to pain, but also relating to the significant others. To illustrate, a housewife whose back pain is aggravated by vacuuming, who also finds housekeeping generally unpleasant irrespective of pain, receives reinforcement for avoiding pain by not using the vacuum. She is also reinforced by time out from housekeeping. The avoidance behavior may be maintained long after healing by the reinforcement of avoiding the housekeeping chore of vacuuming.

Further Considerations

It is not necessary for nociceptive stimuli to occur for avoidance learning-based pain behaviors to occur. Only an anticipation that an activity will lead to suffering is required. Humans can and do anticipate. A person with leg pain knows from experience that climbing stairs results in increased pain. We return to the back pain patient who avoids flexing forward. The patient need not begin to flex forward, experience pain, and then arrest the motion. Experience causes the patient to anticipate that forward flexing will be be painful, thus the avoidance behavior of holding the torso rigidly upright to occur in circumstances in which the patient might otherwise flex.

TRAUMA-INDUCED CONDITIONING

Stimuli previously unable to produce a given response may, through conditioning, come to have that ability, as in classical conditioning. Classical conditioning in the normal course of events rapidly extinguishes. However, if the originating stimulus event was traumatic, clear evidence exists that there may be persisting and

profound alterations in stress hormone secretion and memory processing that make pain and suffering responses highly resistant to extinction (16,17 and 18). Because of the adverse influence on memory functioning, the person may be unable to relate persisting suffering or pain behaviors to extant stimuli now producing them. Studies reporting persistent pelvic pain in women reporting histories of sexual abuse are an example (16,19). However, the findings as they pertain to chronic pelvic pain, although suggestive, are thus far conclusive (19). As viewed from the perspective of the learning process, studies have failed to search for and delineate specific discriminated stimuli presently capable of evoking previously traumatically conditioned pain behaviors, but related only adventitiously to the site of pain.

IMPLICATIONS FOR THE CLINICIAN

The major implications of learning or conditioning on occurrence and persistence of pain behaviors follow:

- Pain behaviors are not reliable indicators of underlying pathophysiology. Pain behaviors may accompany nociceptive stimuli, but they may also occur and persist in their absence.
- In chronic pain, evaluation of the pain problem requires analysis of possible sources of nociceptive stimuli and of possible learning-conditioning effects. Neither suffices without the other.
- Learning and conditioning may play an important role in treatment as well as diagnosis of chronic pain.

EFFICACY OF BEHAVIORALLY BASED TREATMENT OF CHRONIC PAIN

Numerous studies have appeared in the professional literature regarding the efficacy of behavioral or learning-based treatment for chronic pain (20,21 and 22). Three essential questions should be addressed in outcome studies. First, do the treatment methods produce significant changes in patient performance? Second, do the treatment methods produce results equal to or better than alternative methods? Third, are the methods cost-effective? In the evaluation of treatment outcomes, the array of variables to be considered is broad. These include site and duration of pain, extent of suffering, general health status of patient, activity level, restoration of social role function, pain-related health care use, and employment status. The diversity of these parameters and of studies addressing various aspects of them is too great to warrant detailed analysis and reporting here and is further discussed in Chapter 109. Flor and colleagues (22) have provided comprehensive and exhaustive analyses of the data available. Table 25-1 and Table 25-2 report findings selected to portray the efficacy and effect of treatment programs reflecting the concepts addressed in this chapter (Fig. 25-1).

27 of 100 fewer back surgeries for patients treated at multidisciplinary pain centers (23).

Applying that percentage to patients included in the metaanalysis of multidisciplinary pain centers by Flor et al. (22), we could anticipate 832 fewer back surgeries for patients treated at multidisciplinary pain centers.

The estimated cost of back surgery is $40,000; multiplied by 832 fewer surgeries, this represents a savings of $33,280,000.

From Turk DC. Efficacy of multidisciplinary pain centers in the treatment of chronic pain. In: Cohen M, Campbell J, eds. *Pain treatment centers at a crossroads: a practical and conceptual reappraisal*. Seattle: IASP Press, 1996;7:264–265, with permission.

TABLE 25-1. Reduction in surgical expenditures

Tollison (24) reported that at 1-year follow-up, 18% of patients treated at multidisciplinary pain centers compared with 55% of conventionally treated patients were hospitalized for pain.

Simmons et al. (25) reported a 58% reduction in medical costs following treatment at a multidisciplinary pain center. Average cost of medical care for 1 year before treatment was $15,675; average cost for 1 year after treatment was $6,603.

Extending these figures to the 3,089 patients treated in the studies included in the metaanalysis by Flor et al. (22) leads to the following: 3,089 × $15,675 = $48,420,075 pretreatment versus 3,089 × $6,603 = $20,396,667 posttreatment, for a savings of $28,023,408.

Average cost of multidisciplinary pain center treatment is $5,900 (based on University of Pittsburgh Multidisciplinary Pain Center and corrected for inflation). Cost of treating 3,089 patients included in Flor et al.'s (22) metaanalysis: 3,089 × $5,900 = $18,225,100.

Estimated savings in medical expenditures: $28,023,408 savings minus $18,225,100 cost of multidisciplinary pain center = $9,798,308 savings.

FUTURE CONSIDERATIONS

The implication of assigning importance to learning factors in conceptualizing clinical pain is great. Conceptual models or perspectives, once adopted and practiced, tend to fade into the background of our thinking. What started as hypotheses or ways of thinking come to be perceived as facts. The commonly expressed dictum *Pain is a symptom of some underlying problem* is only a hypothesis, which is sometimes true and sometimes not, or only partially so, but it has taken on the coloration of a fact. One consequence is that the health care system and training for health care professionals, by failing to distinguish hypothesis from fact, tends to perpetuate the error. Students as well as practitioners accept as fact what is only a hypothesis or extrapolation from a particular theory.

Chronic trauma-induced pain persisting after healing can reasonably be expected to have occurred and, in the absence of a demonstrable residual pathoanatomic defect, often continues to be treated from within the perspective of a biomedical model. That is true despite the absence of demonstrated effectiveness sufficient to contain and diminish the problem and in the presence of data pointing to more favorable outcome from methods derived from alternative models. It is a paradox that has for too long remained unresolved.

As health care and workers' compensation costs soar, most particularly in regard to chronic low back pain, ever-growing pressure exists for change in pain

management methods. Change is needed and will occur, whether from within the health care system or in response to social pressure. One major element of that change appears to this author to reflect a growing awareness of the impact of learning and conditioning and of the influence of social contingencies on human functioning, including illness behavior. Changes in professional training and in allocation of treatment resources should follow greater understanding of this issue.

CHAPTER 26

Psychiatric Illness, Depression, and Psychogenic Pain

Mark D. Sullivan and Dennis C. Turk

The high rates of psychiatric illness in patients with chronic nonmalignant pain, although well recognized, are still poorly understood. Diagnostic hierarchies taught to physicians in medical school and residency, impairment rating strategies used by compensation systems, and the natural scientific method used by medicine that looks for objective causes for clinical phenomena force us into a mind-body dualism. If we cannot explain pain in terms of objective tissue pathology, we seek to explain it in terms of patients' psychopathology. Although this dichotomy is popular, if not inescapable, in current clinical settings, scientific evidence for it is lacking.

Epidemiologic evidence supports the use of inclusive rather than exclusive models of psychiatric diagnoses in medical settings. Medical illness in no way excludes the possibility of a clinically important psychiatric illness. Medically ill patients are, in fact, much more likely to have psychiatric illness than patients without medical illness. Psychiatric illness in no way precludes the possibility of a clinically important medical illness. Psychiatric illness is, in fact, associated with health behaviors and psychophysiologic changes known to promote medical illness.

The structure of our clinical settings makes the integrated delivery of mental and physical health care difficult. Nowhere is this more important than in the care of the patient with chronic pain. Psychotherapeutic and psychopharmacologic interventions for chronic pain are rarely effective in isolation from somatic treatments. Distress, disuse, and disability are important facets of a chronic pain problem, and all require clinical attention. Neglect of one of these components can result in treatment failure even in the presence of excellent care for the other components.

Any discussion of psychiatric disorders in patients with chronic pain is haunted by the concept of psychogenic pain. We are drawn to the concept of psychogenic pain because it fills the gaps left when our attempts fail to explain clinical pain exclusively in terms of tissue pathology. Psychogenic pain, however, is an empty concept. Positive criteria for the identification of psychogenic pain, mechanisms for the production of psychogenic pain, and specific therapies for psychogenic pain are lacking. Psychiatric diagnosis of many disorders, such as depression, can be helpful to clinician and patient by pointing to specific effective therapies. But the diagnosis of psychogenic pain too often only serves to stigmatize further the patient who experiences chronic pain.

In the discussion that follows, psychiatric disorders as defined in the *Diagnostic and Statistical Manual*, fourth edition, of the American Psychiatric Association (DSM-IV, 1994) are used as an organizing strategy. It is important to note, however, that the categorical model of mental disorder favored by psychiatrists and used in DSM-IV can imply more discontinuity between those with and those without a mental disorder than is actually the case. For example, it is common for patients with chronic pain to partially meet criteria for a number of mental disorders. Therefore, it is sometimes useful to think of these disorders as dimensions rather than categories. The DSM-IV nevertheless provides a well-recognized and systematic template for the discussion of psychiatric disorders in patients with chronic pain.

DEPRESSION

One must begin by distinguishing between depressed mood and the clinical syndrome of major depression. It is important to note, especially when working with chronic pain patients, that depressed mood or dysphoria is not necessary for the diagnosis of major depression. Anhedonia, the inability to enjoy activities or experience pleasure, is an adequate substitute. It is common for patients with chronic pain to deny dysphoria but to acknowledge that enjoyment of all activities has ceased, even those without obvious relation to their pain problem (e.g., watching television for a patient with low back pain).

The DSM-IV criteria for major depressive episodes are listed in Table 26-1. These include psychological symptoms, such as worthlessness, and somatic symptoms, such as insomnia. It is important to note that somatic symptoms count toward a diagnosis of major depression unless they are caused by “the direct physiologic effects of a general medical condition” or medication. The poor sleep, poor concentration, and lack of enjoyment often experienced by patients with chronic pain are frequently attributed to pain rather than depression. However, because they are not a direct physiologic effect of pain, these symptoms should count toward a diagnosis of depression. In fact, studies of depression in medically ill populations have generally found greater sensitivity and reliability with “inclusive models” of depression diagnosis than with models that try to identify the cause of each symptom (1).

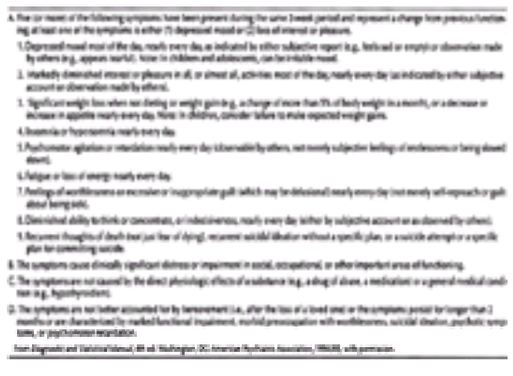

TABLE 26-1. *Diagnostic and Statistical Manual*, Fourth Edition, Criteria for Major Depressive Episode

Patients with chronic pain often dismiss a depression diagnosis, stating that their depression is a direct reaction to their pain problem. Psychiatry has long debated the value of distinguishing a *reactive* form of depression caused by adverse life events from an *endogenous* form of depression caused by biological and genetic factors (2). Life events are important in many depressive episodes, although they play a less important role in recurrent and severe or melancholic or psychotic depressions (3). Only bereavement excludes someone from a depression diagnosis who qualifies on the basis of symptoms. Determining whether a depression is a *reasonable response* to life's stress may be important to patients seeking to decrease the stigma of a depression diagnosis and has been of interest to pain investigators [for a review, see Fishbain and colleagues (4)]. It is not, however, important in deciding that treatment is necessary and appropriate. Indeed, no clinical benefit is gained from debating whether the depression caused the pain or the pain caused the depression, although such information may be useful in psychotherapy. If patients meet the diagnostic criteria outlined previously, it is likely that they can benefit from appropriate treatment. It may be useful when initiating depression treatment to accept that the pain caused the depression because it builds rapport and is consistent with epidemiologic evidence about the current depressive episode.

A variety of biological tests for depression have been investigated (5). These tests have included the dexamethasone-suppression test, thyrotropin-releasing hormone stimulation test, clonidine-induced growth hormone secretion, and rates of imipramine binding to platelet membrane serotonin transporters. Forty percent to 50% of patients with major depression do not show normal suppression of morning plasma cortisol after receiving dexamethasone the night before. However, high false-positive rates for this dexamethasone-suppression test exist in patients who are pregnant; patients with dementia, alcoholism, anorexia nervosa, and other chronic debilitating diseases; and patients who are taking medications that induce microsomal enzymes, including barbiturates and opioids. This has limited the clinical value of this test (6). The serotonin transport mechanism on platelet membranes is similar to that on serotonergic neurons. ^{3}H-imipramine binding to this platelet receptor is reduced in patients with major depression. It appears to be further reduced in patients who have both pain and depression (7). Although patients show significant differences on these tests, when considered as a group, substantial variation between individual patients limits the usefulness of these tests in the clinical setting. In the future, they may be able to provide a better understanding of the biochemical links between pain and depression.

When considering the diagnosis of depression in the patient with chronic pain, important alternatives include bipolar disorder, substance-induced mood disorder, and dysthymic disorder (particularly if accompanied by a severe personality disorder, such as borderline personality disorder). Patients with bipolar disorder have extended periods of abnormally elevated as well as abnormally depressed mood. These periods of elevated mood need to last more than 1 continuous day and include features such as inflated self- esteem, decreased need for sleep, and racing thoughts. A history of manic or hypomanic episodes predicts an atypical response to antidepressant medication and increases the risk of antidepressant-induced mania. Substance-induced mood disorders can also occur in those with pain. Patients with chronic pain may be taking medications such as corticosteroids, dopamine-blocking agents (including antiemetics), or sedatives (including muscle relaxants) that produce a depressive syndrome. Current medication lists should be scrutinized before additional medications are prescribed for any patient.

Dysthymic Disorder

Dysthymic disorder is a chronic form of depression lasting 2 years or longer. Individuals with dysthymia can develop major depression as well. This combined syndrome has often been called *double depression* (8). It is important to note dysthymia, because it is frequently invisible in medical settings, often being dismissed as “just the way that patient is.” Dysthymia has been shown to respond to many antidepressants, including the selective serotonin reuptake inhibitors (SSRIs) (9). Treatment of double depression can be particularly challenging because of treatment resistance and concurrent personality disorders (10). Psychiatric consultation should be considered when dysthymia or double depression is suspected.

Epidemiology

The prevalence of depression is much higher in medical settings and in patients with chronic illnesses than in the general population. It has been shown in studies using structured psychiatric interviews that a linear increase occurs in the prevalence of major depressive disorder when comparing community, primary care, and inpatient medical populations. Although 2% to 4% have major depression in the community, 5% to 9% of ambulatory medical patients and 15% to 20% of medical inpatients meet diagnostic criteria (11). Primary care patients with major depression have been found to have more severe medical illness than those who are not depressed (12). Even among community samples, the risk for depression appears to increase with worse perceived health status, number of chronic medical conditions, and number of medications taken (13).

Prevalence rates of depression among patients in pain clinics have varied widely depending on the method of assessment and the population assessed. Rates as low as 10% and as high as 100% have been reported (14). The reason for the wide variability may be attributable to a number of factors, including the methods used to diagnose depression (e.g., interview, self-report instruments), the criteria used (e.g., DSM-IV, cut-off scores on self-report instruments), the set of disorders included in the diagnosis of depression (e.g., presence of depressive symptoms, major depression), and referral bias (e.g., higher reported prevalence of depression in studies conducted in psychiatry clinics compared with rehabilitation clinics). The majority of studies report depression in more than 50% of chronic pain patients sampled (15).

Studies of primary care populations (in which generalization is less problematic) have revealed a number of factors that appear to increase the likelihood of depression in patients with chronic pain. Dworkin and colleagues (16) reported that patients with two or more pain complaints were much more likely to be depressed than those with a single pain complaint. Number of pain conditions reported was a better predictor of major depression than pain severity or pain persistence (16). Von Korff and colleagues developed a four-level scale for grading chronic pain severity based on pain disability and pain intensity: (a) low disability and low intensity; (b) low disability and high intensity; (c) high disability, moderately limiting; and (d) high disability, severely limiting. Depression, use of opioid analgesics, and doctor visits all increased as chronic pain grade increased (17). Engel and colleagues showed that depression was associated with high total health care costs, but not high back pain costs among health maintenance organization patients with back pain (18). When dysfunctional primary care back pain patients are studied for a year, those whose back pain improves also show improvement of depressive symptoms to normal levels (19).

These epidemiologic studies provide solid evidence for a strong association between chronic pain and depression, but do not address whether chronic pain causes depression or depression causes chronic pain. As indicated previously, this question has more importance in medicolegal contexts than clinical contexts. Because it is a perennial question, however, some attempt to answer it should be made. Prospective studies of patients with chronic musculoskeletal pain have suggested that chronic pain can cause depression (20), that depression can cause chronic pain (21), and that they exist in a mutually reinforcing relationship (22).

One fact often raised to support the idea that pain causes depression is that the current depressive episode often began after the onset of the pain problem. The majority of studies appears to support this contention (23). However, it has been documented that many patients with chronic pain (especially those disabled patients seen in pain clinics) have often had episodes of depression that predated their pain problem by years (24). This has led some investigators to propose that there may exist a common trait of susceptibility to dysphoric physical symptoms (including pain) and to negative psychological symptoms (including anxiety and depression). They conclude that “pain and psychological illness should be viewed as having reciprocal psychological and behavioral effects involving both processes of illness expression and adaptation” (25).

Pain and Depression: Mechanisms of Association

Beyond documenting the association of chronic pain and depression lies the question concerning mechanisms by which they may interact. Biological, psychological, and social mechanisms have been proposed to explain the concurrence of chronic pain and depression.

Biological Theories

Pain Sensitivity. It is well documented that patients with major depression, or even depressive symptoms, have more pain complaints that those without depression. Studies have shown that 30% to 60% of depressed patients complain of pain (26). These findings raise the possibility that depressed patients may have a greater sensitivity to noxious stimuli. In other words, depressed patients may have a reduced pain threshold. Although this theory appeared confirmed in an early study (27), it has been discounted repeatedly in more recent studies. Pain threshold to both thermal and electrical stimuli has been found to be elevated in depressed patients by multiple investigators (28). Sensitivity to nonnoxious thermal stimuli appears unaltered or slightly reduced (29). This diminished sensitivity does not appear to be caused by a general decrease in reaction time in depressed patients. Although depressed patients have been reported to have high plasma and cerebrospinal fluid endorphin levels, this decreased sensitivity to noxious stimuli is not reversed by naloxone (30). Thus, the stoic response of depressed patients to noxious stimuli

remains unexplained by known psychophysiologic mechanisms. It remains an intriguing and well-confirmed anomaly in the research linking pain and depression.

Biogenic Amines. The highly variable relationship between injury severity and pain severity has been known since Henry Beecher's studies of the soldiers at Anzio beach in World War II. Since the 1970s, great strides have been made in identifying the central nervous system mechanisms of endogenous pain modulation. Opioid and nonopioid branches to this system have been identified (see Chapter 4). Stimulation of the rostral ventromedial medulla or the dorsolateral pontine tegmentum produces behavioral analgesia in animals and inhibition of spinal pain transmission. The rostral ventromedial medulla is the principal source of serotonergic neurons that project to the spinal dorsal horn. The dorsolateral pontine tegmentum is the major source of noradrenergic neurons that project to the dorsal horn. Both neurotransmitters inhibit nociceptive dorsal horn neurons when locally applied (31).

Antidepressants Associated with Analgesia Enhance Serotonergic and Noradrenergic Neurotransmission. That antidepressants associated with analgesia enhance serotonergic and noradrenergic neurotransmission has been hypothesized to be responsible for both the antidepressant and analgesic effects of antidepressants (see Chapter 85). The interdependence of the opioid and nonopioid systems has been suggested by studies that show enhanced opioid analgesia in the presence of antidepressant treatment (32) and decreased opioid analgesia after serotonin and norepinephrine depletion (33). Therefore, it appears that biogenic amines play a critical role in endogenous pain modulation. To the extent that depletion or impaired function of amines such as serotonin and norepinephrine occurs in depression, this may contribute to the pain experienced and reported by those with major depression. It is not clear why this is not also manifested as increased sensitivity to external noxious stimuli.

Sleep Disturbance. Depression produces well-documented disturbances to sleep architecture. Polysomnographic recordings have documented reduced slow wave sleep, early onset of the first period of rapid eye movement (REM) sleep, and increased phasic REM sleep in patients with major depression (34). Sleep continuity disturbances and increased phasic REM sleep tend to normalize with depression remission, even with psychotherapeutic treatment. However, reduction of REM latency and decreased slow wave sleep tend to persist despite clinical recovery. Thus, there appear to be *state* and *trait* elements to the sleep disturbance associated with depression.

Some studies have demonstrated that sleep disturbance can cause chronic pain. The best studies have investigated the association of sleep disruption and fibromyalgia. Moldovsky and colleagues produced fibromyalgia-type symptoms in volunteers by depriving them of stage 4 slow wave sleep (35). In another study, however, those deprived of REM sleep did not develop these symptoms (36). Tricyclic antidepressants (alone or in combination with SSRIs) have been shown effective for fibromyalgia, even in the absence of a full depressive syndrome, perhaps because of restoration of sleep continuity.

Psychological Theories

Psychodynamic Theory. In classic psychoanalytic theory (37), depression is postulated to be derived from anger unconsciously turned inward, excessive dependence on others for self-esteem, and feelings of helplessness in achieving one's goals. Some have suggested that the depression in some chronic pain patients is a manifestation of a personality style that draws from early developmental conflicts of guilt, anger, and masochism (38,39). From this perspective, chronic pain may be a symptom of depressive disorder (40).

Psychoanalytic theory stresses the fundamental parallelism between mental and physical pain and the possible displacement from the former to the latter. Intrapsychic links between pain and depression suggest that pain may function as a *hysterical* or conversion symptom that may prevent the breakthrough of more severe depression. These intrapsychic links largely correspond with the dynamics of *pain proneness* that were originally described by Engel (41) and, in a further elaboration, connected with the concept of *masked depression* by Blumer and Heilbronn.

Blumer and Heilbronn (38) proposed a new psychological disorder, the “pain-prone” disorder, building on Engel's (41) notion of the pain-prone patient. In this view, pain should be considered as a variant of depressive disease. The central explanation is unconscious core conflicts. Core issues include “strong needs to be accepted and to depend on others, as well as marked needs to receive affection and to be cared for.”

Pain in the absence of organic pathology is considered by Blumer and Heilbronn (38) to be a *depressive spectrum disorder*. According to this model, pain and depression are viewed as manifestations of a single, common disease process. Specifically, the pain-prone disorder is viewed as a masked “depressive equivalent . . . the prime expression of a muted depressive state.” No empiric research has supported the psychoanalytic formulation as presented by Blumer and Heilbronn (42,43).

Behavioral (Operant Conditioning) Theory. The behavioral model of depression concentrates on the most obvious symptom of depression, the motivational deficit characterized by a reduction in active behavior. A central feature of the behavioral model is response-contingent reinforcement (i.e., the responses from significant others to the individual's behavior). From this perspective, depressive behavior and depression are associated with low rates of positive reinforcement from the environment. Lack of positive reinforcement leads to a decrease in the frequency of the individual engaging in these behaviors and ultimately, they may be extinguished completely. These low rates of reinforcement may occur because (a) positive reinforcers in the environment may become less available, or aversive events in the environment may have become more prevalent; (b) the positive effect of previous reinforcers may have declined, or the negative impact of aversive events may have increased; or (c) the individual may lack the skills either to attain the available positive reinforcers or to cope with aversive aspects of the environment. When individuals experience low rates of positive reinforcement, they reduce the performance of those behaviors, unless they are self-reinforcing. The reduction of behavior decreases further opportunities to receive positive reinforcement.

In the case of chronic pain, the individual may reduce his or her behavior because of physical impairments or because of fear of additional pain or further injury. Thus, by the restriction in behavior and social contacts, chronic pain patients may reduce the opportunity to achieve positive reinforcement and to engage in previously rewarding activities and consequently become depressed.

Cognitive Theory. According to Beck (44), people may be vulnerable to depression because, from an early age, they have possessed negatively biased conceptualizations (schemas) of themselves and their experiences. When they are challenged by stressful life events, these schema become activated, which in turn elicits negative thoughts about themselves, the world, and the future (the *negative cognitive triad*).

In depressed patients, Beck suggests that the cognitive triad serves as a filter for incoming information. This filter creates a negative bias that serves to put a pessimistic light on information and reinforces the depressed state. It also creates low expectations about their ability and thus may lead to lack of effort. Moreover, these people tend to discount their performance, underestimating their accomplishments.

Beck's (44) cognitive theory of depression emphasizes the importance of peoples' appraisal processes. In particular, it is believed that depressed persons show faulty information processing reflected by errors of logic. Through these cognitive errors (collectively referred to as *cognitive distortions*), depressed persons systematically misinterpret or distort the meaning of events so as to consistently construe themselves, their world, and their experiences in a negative way (the negative cognitive triad). According to this perspective, differences in cognitive errors and cognitive distortions, in general, should differentiate depressed and nondepressed patients.

Cognitive-Behavioral Perspective. The cognitive-behavioral perspective is based on five central assumptions: (a) People are active processors of information and not passive reactors. They attempt to make sense of information and determine what constitutes positive reinforcers. (b) Thoughts (e.g., appraisals, expectancies, beliefs) can elicit and influence mood, affect physiologic processes, have social consequences, and serve as impetuses for behavior; conversely, mood, physiology, environmental factors, and behavior can influence the nature and content of thought processes. (c) Behavior is reciprocally determined by both the individual and environmental factors. (d) People can learn more adaptive ways of thinking, feeling, and behaving. (e) Individuals should be active collaborative agents in changing their maladaptive thoughts, feelings, and behaviors (45). From the cognitive-behavioral model, the way in which one thinks about pain and behaves in response to pain affects the extent of depression experienced. Like Beck's cognitive theory, its essential difference from the purely behavioral model is its view of patients as active interpreters of their environment.

Depression in chronic pain patients is postulated to result from patients' interpretations of the meaning and effect of their symptoms and their inability to exert any control over their symptoms. It is only when patients interpret their pain as interfering with important life activities and believe that they (or anyone) can do little to control the symptoms that they become depressed (i.e., they become depressed when they feel helpless and hopeless to exert any control, overwhelmed by the disruption of their lives, and unable to attain significant positive reinforcement from previous activities) (22). Thus, the cognitive-behavioral approach integrates the principles of operant conditioning and behavioral techniques with the emphasis of cognitive theory on the patients' appraisals, beliefs, and attributions (46).

Sociologic Theories

Traditional and industrial societies appear to hold individuals less responsible for somatic symptoms than psychological symptoms. This difference may be especially prominent in modern Western biomedicine, in which symptom complexes are validated or invalidated through their correspondence with objective disease criteria (47). A somatic “idiom of distress” therefore becomes the favored means for communicating distress of any origin that is overwhelming or disabling (48). In many cultures, pain is a more acceptable reason for disability than depression. Therefore, cultural incentives exist for translation of depression into pain. Because depressed patients have many physical symptoms, these can become the focus of clinical communication and concern. Giving patients with chronic pain permission to talk of distress in the clinical setting, using nonsomatic terms, can facilitate treatment as long as they do not feel that somatic elements of their problem are being neglected or discounted.

Depression Treatment

Pharmacologic Agents

Antidepressant medication can effectively treat depression in the presence of chronic pain. When depression accompanies chronic pain, as when it accompanies other chronic medical disorders, there may be some extra hurdles for depression treatment to overcome. These include aversive physical symptoms, severe deactivation, vocational dysfunction, marital conflict, social isolation, and concurrent medications. Comprehensive assessment of these issues and formulation of a treatment plan that takes them into account increase the likelihood of successful depression treatment in the chronic pain patient. When antidepressant treatment is suggested, patients often respond that their depression will resolve when the pain gets better. This may be true. However, depression is often more accessible to treatment than an entrenched and multidetermined pain problem. If depression can be relieved, many other aspects of rehabilitation, such as physical therapy, are often much more easily accomplished. Pain often subsides with improvement in depressive symptoms.

All currently marketed antidepressants are equally effective for the treatment of depression. Whatever differences may exist among antidepressants in efficacy for neuropathic pain do not appear to affect their ability to treat depression. Given the lack of greater efficacy of any one antidepressant compared with another, medications should be selected based on their side effects.

The clinical art of depression treatment for those with chronic pain consists of establishing a solid therapeutic alliance around the problem of depression and finding a medication regimen with a side-effect profile that the patient can tolerate. Because patients with chronic pain can be vigilant and catastrophic thinking about somatic symptoms, care must be taken to educate them about antidepressant side effects. Sometimes it becomes necessary to initiate an antidepressant regimen at the lower doses used for geriatric patients to ease habituation to side effects. The SSRIs (SSRIs available in the United States include fluoxetine, fluvoxamine, sertraline, and paroxetine) have become the most popular antidepressants because of their favorable side-effect profiles. Bupropion and venlafaxine are useful medications for those who do not respond to the SSRIs. Nefazodone is a useful alternative for patients who have problems with agitation or insomnia on the SSRIs. More detailed information is available in one of the standard psychopharmacology manuals (49,50). A number of case reports have described relief of chronic pain in patients with treatment-resistant depression using electroconvulsive therapy (51); however, no carefully controlled studies demonstrate the effectiveness of electroconvulsive therapy for treatment of chronic pain.

Chronic pain is frequently associated with insomnia and anxiety. It is, therefore, common that patients are treated with benzodiazepines or other sedatives (e.g., the muscle relaxers). Some patients begin taking these medications during the acute phase of the pain problem and then continue to take them for many months or years. Assessing chronic pain patients who take benzodiazepines for depression is important. These medications mask some symptoms of depression (e.g., initial insomnia, agitation), but they are not adequate treatments for depression. Indeed, dangerous levels of depression can develop under the cover of benzodiazepines. It has been suggested that benzodiazepines can induce depression with chronic use, but the evidence for this is not strong (52). More important is the masking of depression by benzodiazepines.

Nearly all patients with chronic pain should be tapered off benzodiazepines. Few conditions exist for which chronic benzodiazepines are the treatment of choice (53). The treatment of choice for chronic anxiety disorders, which are almost always accompanied by depressive symptoms, is antidepressant medication (54). Buspirone (a 5-HT_{1a} partial agonist) is marketed as an anxiolytic, but is more similar to the antidepressants in its pharmacology and side-effect profile. It is a reasonable alternative to the benzodiazepines for the treatment of chronic anxiety, particularly for those who experience agitation on the antidepressants.

Psychotherapy

Psychodynamic Psychotherapy. In general, psychodynamic theory emphasizes the long-term predisposition to depression, rather than the losses that occur in the short term. Treatment of depression from the classical psychoanalytic perspective tries to help the patient achieve insights into the repressed conflict and often encourages outward release of hostility turned inward. In the most general terms, the goal of therapy is to uncover latent motivations for the patient's depression. The psychodynamic approach to the depressed individual with chronic pain emphasizes the importance of individual differences in patients based on their developmental history, intrapsychic conflicts, interpersonal difficulties, and the subsequent failure to adapt to chronic illness. Patients' premorbid characteristics are hypothesized to color their adaptation to their current situation and affect their vulnerability to depression.

Psychodynamic therapy emphasizes the need for patients to address unconscious conflicts that may contribute to and maintain the depression and makes use of the therapeutic relationship, assuming that the patient will transfer or project his or her feelings onto the therapist (55). This approach can be contrasted with treatment based on operant conditioning, in which it is assumed that the basic principles of learning apply to all individuals and the environmental contingencies of reinforcement can influence the reports of pain, distress, and suffering (see Chapter 88).

Behavioral Model. As noted, the behavioral model of depression concentrates on the reduction in active behavior that is a central feature of depression. The focus of treatment for depression is on the shaping of behavior through the use of graded task assignments and response-contingent reinforcement. Depressed individuals are encouraged to engage in more activities and to behave in ways that are likely to be regarded more positively by others. In some instances, it is believed that depressed patients are deficient in certain skills necessary to achieve positive reinforcement. Social skills training may also be included when the therapist determines that the patient is deficient in specific skills (e.g., communication skills). Attention may also be given to assisting the patient in planning pleasant events that the patient will find reinforcing.

Cognitive Model. From the cognitive perspective, therapy is based on the rationale that an individual's affect and behavior are largely determined by the ways in which he or she construes the world and the therapeutic techniques were designed to identify, test, and correct distorted conceptualizations and the dysfunctional beliefs (schemas) underlying these cognitions. Beck's (44) therapy for depression is based on the assumption that the affected people engage in faulty information processing and reasoning and subscribe to schema that are self-defeating. In particular, depressed people are subject to the negative cognitive triad, in which they have feelings of pessimistic helplessness about themselves, the world, and their future. The aim of the cognitive therapist is to identify and then help patients to correct these distorted ideas and also to improve their information processing and reasoning. In contrast to psychodynamic therapy, the focus is on the here and now. Thus, attention to the origin of dysfunctional schemas in the cognitive model is limited.

The therapeutic procedures are highly structured and time limited and begin with the recognition of the connections between cognitions and affect, careful recording of these connections, collection of evidence for and against the ideas, followed by substitution of more adaptive and realistic interpretations. The cognitive approach is most frequently combined with behavioral techniques to treat patients with chronic pain, even though some debate exists about the compatibility of these approaches (44,45).

Cognitive-Behavioral Model. No one cognitive-behavioral model exists, but rather sets of models that share a perspective and incorporate some common features, namely: (a) an interest in the nature and modification of patients' thoughts, feelings, and beliefs, as well as behaviors; and (b) some commitment to behavior therapy procedures in promoting change (e.g., graded practice, use of homework, training in relaxation, coping skills training, problem solving, and relapse prevention) (46).

Depressed people may focus attention selectively on and become preoccupied with somatic symptoms and their potentially ominous significance for their health and future. They may view themselves as helpless and their situation as hopeless and beyond their control. To break this vicious circle, the cognitive-behavioral therapist applies a comprehensive approach to treatment that combines physical, psychological, behavioral, and social interventions. Coping skills training, problem-solving strategies, communications skills training, and directing patients to attend to their appraisals, interpretations, and beliefs are commonly used techniques (see Chapter

89).

The cognitive-behavioral therapist attempts to assist patients to try new behaviors and to adopt more adaptive modes of thinking. Alterations in behavior become information that the patients are encouraged to use as the basis for changing their views of their situation and themselves from being helpless, hopeless, and out of their control to being resourceful and capable of exerting at least some control over their plights. Changing the cognitive schema by cognitive and behavioral means is designed to result in different interpretations of information about themselves and their futures. Thus, changing behaviors and thoughts may be reciprocally related and mutually reinforcing. Neither attending exclusively to behavior, as in the behavioral model, nor only attending to patients' thinking, as in the cognitive model, is adequate to alleviate depression (45). The cognitive-behavioral approach has become a central component for treating depression in many multidisciplinary pain rehabilitation and functional restoration programs.

All of the psychological therapies emphasize patients' active role in alleviating depression. In contrast to the psychodynamic model, in which the therapist plays a relatively passive role, in behavioral, cognitive, and cognitive-behavioral therapies, the therapist takes an active, directive role, attempting to guide patients into changing their behavior and reorganizing their thinking and actions. The behavioral, cognitive, and cognitive-behavioral therapies are all centered in the present, compared with psychodynamic therapy, which focuses on the past.

ANXIETY DISORDERS

It is not unusual for patients with symptoms of pain to be anxious and worried. This is especially true when the symptoms are unexplained, as is often the case for chronic pain syndromes. For example, in a large-scale, multicenter study of fibromyalgia patients, between 44% and 51% of patients indicated that they were anxious (56). Anxiety and concern about symptoms, however, are not synonymous with a psychiatric diagnosis of an anxiety disorder. When anxiety is debilitating, it may meet criteria for an anxiety disorder. Anxiety disorders almost always accompany mood disorders, so clinicians should remain alert to the possibility of a mood disorder when patients complain of severe anxiety.

Generalized Anxiety Disorder

When patients with chronic pain do suffer from an anxiety disorder, it is rare that this is their sole psychiatric diagnosis. Most pain patients with chronic anxiety also meet criteria for either major depression or dysthymia. In these cases, treatment should be directed toward the mood disorder. With successful treatment of the mood disorder, the anxiety should be relieved as well. Benzodiazepines should almost always be avoided, as discussed previously.

Panic Disorder

Panic disorder is a common, disabling psychiatric illness associated with high medical service use and multiple medically unexplained symptoms. The diagnosis of panic disorder requires recurrent, unexpected panic attacks (Table 26-2) followed by at least 1 month of worry about having another panic attack, the implications or consequences of the panic attacks, or behavioral changes related to the attacks. These attacks should not be the direct physiologic consequence of a substance or other medical condition. The panic attacks should not be better accounted for by another mental disorder, such as posttraumatic stress disorder (PTSD; see following discussion) or obsessive-compulsive disorder. At least two unexpected attacks are required for the diagnosis, although most patients have many more.

A discrete period of intense fear or discomfort, in which four (or more) of the following symptoms developed abruptly and reached a peak within 10 minutes:

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, lightheaded, or faint
9. Depersonalization (feelings of unreality) or derealization (being detached from oneself)
10. Fear of losing control or going crazy
11. Fear of dying
12. Paresthesias (numbness or tingling sensations)
13. Chills or hot flushes
14. Persistent concern about having additional attacks
15. Worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, "going crazy")
16. A significant change in behavior related to attacks

From *Diagnostic and Statistical Manual*. 4th ed. Washington, DC: American Psychiatric Association, 1994:395, with permission.

TABLE 26-2. *Diagnostic and Statistical Manual*, Fourth Edition, Criteria for Panic Attack

One of the most common problems with panic disorder is the fear of an undiagnosed, life-threatening illness. Patients with panic disorder can receive extensive medical testing and treatment for their somatic symptoms before the diagnosis of panic disorder is made and appropriate treatment initiated.

Epidemiology

Lifetime prevalence of panic disorder throughout the world is estimated to be 1.5% to 3.5%. One-year prevalence rates are from 1% to 2%. Panic disorder is two to three times more common in women than in men. Age of onset is variable, but most patients typically start between late adolescence and the mid-30s. Of all common mental disorders in the primary care setting, panic disorder is most likely to produce moderate to severe occupational dysfunction and physical disability (57). It was also associated with the greatest number of disability days in the past month.

The most common complication of panic disorder is agoraphobia, or fear of public places. Patients with panic disorder learn to fear places where escape might be difficult or help not available in case they have an attack. One-half to two-thirds of patients with panic disorder also suffer from major depression. These patients are the most disabled panic disorder patients. The differential diagnosis of patients presenting with panic symptoms in the medical setting includes thyroid, parathyroid, adrenal, and vestibular dysfunction, seizure disorders, cardiac arrhythmias, and drug intoxication or withdrawal. Patients with panic disorder typically present in the medical setting with cardiologic, gastrointestinal, or neurologic complaints. These include chest pain, abdominal pain, and headaches (58).

Chest pain is one of the most common complaints presented to primary care physicians, but a specific medical etiology is identified in only 10% to 20% of cases. From 43% to 61% of patients who have normal coronary arteries at angiography and 16% to 25% of patients presenting to emergency rooms with chest pain have panic disorder. A number of these patients eventually receive the diagnoses of vasospastic angina, costochondritis, esophageal dysmotility, or mitral valve prolapse. High rates of psychiatric disorders have been found in some of these groups as well (59). Many of these patients remain symptomatic and disabled 1 year later despite reassurance concerning coronary artery disease (60).

Patients with documented coronary disease also have elevated rates of panic disorder. A number of studies have found nearly identical rates of panic disorder in chest pain patients with and without coronary disease. Increased mortality has been noted in those with anxiety and coronary disease. These data point to the importance of remaining alert to both medical and psychiatric diagnoses in those presenting with chest pain. Patients with unexplained chest pain who were given low-dose imipramine (50 mg per day) reported significant reductions in pain regardless of whether they had increased anxiety symptoms or another psychiatric disorder. This has been postulated to be caused by a *visceral analgesic effect* of imipramine (61). It is possible, however, that imipramine was treating subthreshold anxiety and depressive symptoms, because 63% of the sample had a history of these disorders at some point in their lives.

Approximately 11% of primary care patients present the problem of abdominal pain to their physician each year. Less than one- quarter of these complaints are associated with a definite physical diagnosis in the following year. Among the most common reasons for abdominal pain is irritable bowel syndrome. It is estimated that irritable bowel syndrome accounts for 20% to 52% of all referrals to gastroenterologists (see Chapter 66). Various studies have found that 54% to 74% of these patients with irritable bowel syndrome have associated psychiatric disorders. Walker and colleagues determined that patients with irritable bowel syndrome have much higher current (28% versus 3%) and lifetime (41% versus 25%) rates of panic disorder than a comparison group with inflammatory bowel disease (62). This suggests that the psychiatric disorder was not simply a reaction to the abdominal distress.

Among 10,000 persons assessed in a community survey who consulted their physicians for headache, 15% of female and 13% of male subjects had a history of panic

disorder. Further studies have suggested that migraine headache is most strongly associated with panic attacks (63). Often, anxiety symptoms precede the onset of the headaches, whereas depressive symptoms often have their onset after the headaches. Some authors have suggested that a common predisposition exists with headaches (especially migraines and chronic daily headache), anxiety disorders, and major depression.

Treatment

Psychopharmacologic and psychotherapeutic treatments for panic disorder have been proven effective. The American Psychiatric Association has released a *Practice Guideline for the Treatment of Patients with Panic Disorder* (64). Panic-focused cognitive- behavioral therapy and four classes of medications (SSRIs, tricyclic antidepressants, monoamine oxidase inhibitors, and benzodiazepines) have demonstrated effectiveness. These drugs may be used in combination with cognitive-behavioral therapy. Panic-specific cognitive-behavioral therapy includes psychoeducation, continuous panic monitoring, development of anxiety management skills, cognitive restructuring, and *in vivo* exposure. As discussed previously with depression, the SSRIs likely are the easiest antidepressants to use for panic disorder. However, starting doses should be halved to avoid any initial exacerbation of agitation or anxiety. Tricyclic antidepressants and monoamine oxidase inhibitors are now reserved for those patients who do not respond to the SSRIs. Benzodiazepines should only be used for early symptom control in conjunction with one of the other classes of effective medication.

Posttraumatic Stress Disorder

Diagnosis

At the time of initial physical trauma, patients who develop chronic pain may also experience overwhelming psychological trauma. George Crile, a surgeon and experimental physiologist, laid the foundation for our modern concept of psychological trauma. He suggested that fear is the memory of pain. This fear holds an adaptive advantage in directing individuals to anticipate and avoid injury. Freud added anxiety to our modern conceptualization. Anxiety is the capacity to imagine pain and not merely to remember it. In other words, anxiety is memory of pain set loose (65).

After direct personal exposure to an extreme traumatic event, some individuals develop a syndrome that includes reexperiencing the event, avoidance of stimuli associated with the event, and persistent heightened arousal. PTSD was originally described after exposure to military combat, but is now recognized to occur after sexual or physical assault, natural disasters, accidents, life- threatening illnesses, and other events that induce feelings of intense fear, hopelessness, or horror. Persons may develop the disorder after experiencing or just witnessing these events. DSM-IV diagnostic criteria are shown in Table 26-3.

TABLE 26-3. *Diagnostic and Statistical Manual*, Fourth Edition, Diagnostic Criteria for Posttraumatic Stress Disorder

Epidemiology

Up to 80% of Vietnam veterans with PTSD report chronic pain in limbs, back, torso, or head (66). Increased physical symptoms, including muscle aches and back pain, are also more common in Gulf War veterans with PTSD than in those without PTSD (67). The prevalence of PTSD in medical populations has been shown to be quite high. For example, a number of patients presenting at medical clinics with myocardial infarctions (68) and cancer (69,70) often meet the criteria for PTSD. Averaging the prevalence rates of PTSD across a number of studies reveals that after motor vehicle accidents sufficient to require medical attention, 29.5% of patients meet the criteria for PTSD (71). For more than one-half of these patients, the symptoms resolve within 6 months. In one study, 15% of idiopathic facial pain patients seeking treatment were found to have PTSD (72). In another study, 21% of fibromyalgia patients were found to have PTSD (73). Case reports have associated reflex sympathetic dystrophy (complex regional pain syndrome) with PTSD. Other studies suggest that 50% to 100% of patients presenting at pain treatment centers meet the diagnostic criteria for PTSD (73,74). Pain patients with PTSD have been shown to have more pain and affective distress than those without PTSD (75), so it is not surprising that PTSD rates among pain patients increase as treatment settings become more specialized.

Pain and Posttraumatic Stress Disorder: Mechanisms of Association

The relationship between pain and PTSD is multifaceted, as suggested by the early thinking by Crile and Freud discussed previously. Pain and PTSD may result from a traumatic event. Sometimes acute pain can constitute the traumatic event, as described in a case of traumatic eye enucleation (76). PTSD also appears to permit induction of an opioid-mediated stress-induced analgesia. PTSD- related stimuli can result in a naloxone-reversible decreased sensitivity to noxious stimuli in affected individuals (77). Much research remains to be done on the relative contributions of physical trauma and psychological trauma to chronic pain problems.

Treatment

It is best to institute treatment for PTSD as close in time to the trauma as possible. Acute crisis intervention may reduce the development of chronic PTSD and other complications, including, possibly, chronic pain. This treatment should establish support, promote acceptance of what happened, provide education and information about symptoms, and attend to general health needs. Beyond the acute phase, the cognitive-behavioral therapy treatment described for panic disorder earlier has been shown to be effective with PTSD as well. Stress-inoculation training, implosive therapy, and systematic desensitization have also been reported to have some efficacy (71,78). Medications are rarely adequate as the sole treatment for PTSD. Controlled trials of tricyclic antidepressants, SSRIs, and monoamine oxidase inhibitors have demonstrated some benefit by 8 weeks at reducing core intrusive features. These benefits appear to be in addition to the antidepressant and antianxiety effects of these medications (79).

SCHIZOPHRENIA

Schizophrenia is a chronic mental disorder characterized by delusions, hallucinations, disorganized speech and behavior, and negative symptoms (e.g., flattening of affect and lack of volition). At least 6 months of continuous symptoms are required for the diagnosis. Most individuals are affected for many years with exacerbations and partial remissions. Onset typically occurs in late teens to early 30s. Lifetime prevalence is estimated at 0.5% to 1.0% throughout the world.

Patients with schizophrenia appear to complain of pain less frequently than patients with other psychiatric disorders. This can pose problems in the diagnosis of acute medical illnesses that are usually painful, such as peritonitis (80). Numerous studies have demonstrated decreased sensitivity to noxious stimuli in schizophrenic patients, although the precise character of this insensitivity and its mechanism remain to be elucidated (81). Chronic pain problems appear to be rare in schizophrenics. Studies of psychiatric diagnoses in patients with chronic pain have identified few patients with schizophrenia. Two schizophrenic patients were identified in a study of atypical facial pain patients (82). In another study, 78 schizophrenics were documented to have 29 current pain complaints. Sixteen of these were thought to be of likely *psychological origin* (83). How this was determined is not clear. In fact, it is unclear how any pain could be established to be delusional.

Schizophrenics commonly have delusions of persecution, passivity, and somatic damage, but pain is rarely a part of these delusions, even when it is an expected part of the delusional illness (e.g., *dead bowels*). The existence of delusional pain is therefore in doubt. This is important because delusional pain is the prototypical case

of psychogenic pain. If no delusional pain exists, then there may be no purely psychogenic pain.

Dementia

Dementia is characterized by the gradual onset of multiple cognitive deficits, including memory impairment and either aphasia, apraxia, agnosia, or disturbances in executive functioning. The deficits cannot occur exclusively in the course of a delirium. The prevalence of dementia increases exponentially with age, from 1% at age 65 years to 25% by age 85 years. Our understanding of clinical pain in patients with dementia is generally derived from patients with mild to moderate dementia who remain communicative (84). Although it has been hypothesized that demented patients may complain of pain to mask failures caused by dementia, only case reports exist to support this theory. Large studies of institutionalized elderly have generally found an inverse relationship between cognitive impairment and reported level of pain (85). These differences persisted after controlling for functional status and medical illness severity. Dementia appears to be most important in the clinical care of pain because it impairs the ability of patients to communicate pain and therefore the capacity of caregivers to adequately respond to pain.

SUBSTANCE ABUSE

Diagnosis

Diagnosis of substance abuse and substance dependence in patients with chronic pain is controversial because it is difficult to achieve consensus on what constitutes a maladaptive pattern of substance use. DSM-IV distinguishes between substance dependence and substance abuse. The essential feature of substance dependence is continued use of a substance despite a cluster of cognitive, behavioral, and physiologic problems. It is characterized by tolerance, withdrawal, and compulsive drug-taking behavior. DSM-IV diagnostic criteria are presented in Table 26-4.

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

1. tolerance, as defined by either of the following:
   (a) A need for markedly increased amounts of the substance to achieve intoxication or desired effect.
   (b) Markedly diminished effect with continued use of the same amount of the substance.
2. Withdrawal, as manifested by either of the following:
   (a) The characteristic withdrawal syndrome for the substance (refer to criteria A and B of the criteria sets for Withdrawal from the specific substances).
   (b) The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms.
3. The substance is often taken in larger amounts or over a longer period than was intended.
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use.
5. A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain smoking), or recover from its effects.
6. Important social, occupational, or recreational activities are given up or reduced because of substance use.
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption).

Specify if:

With physiologic dependence: evidence of tolerance or withdrawal (i.e., either item 1 or 2 is present)

Without physiologic dependence: no evidence of tolerance or withdrawal (i.e., neither item 1 nor 2 is present)

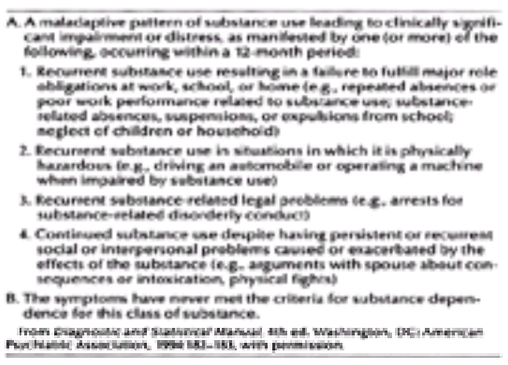
From Diagnostic and Statistical Manual, 4th ed. Washington, DC: American Psychiatric Association, 1994:181, with permission.

TABLE 26-4. *Diagnostic and Statistical Manual*, Fourth Edition, Criteria for Substance Dependence

Traditionally, opioids have been considered appropriate for terminal cancer pain when tolerance, dependence, and dose escalation are limited in their importance by the impending death of the patient. But they have been considered by many who treat chronic pain as problematic for the chronic noncancer pain patient in cases in which long-term function is an essential issue. A large percentage of patients referred to multidisciplinary pain centers report taking opioids at the time of assessment. After treatment, the majority of these patients reports significantly reduced pain concurrent with elimination of opioid medication (86,87). Portenoy and others have argued forcefully that chronic opioid therapy can be appropriate and beneficial in some patients with chronic noncancer pain (88). One of the current unanswered questions is what factors characterize those patients who are likely to benefit from long-term opioids without problems of addiction, tolerance, or increased disability. To date there have been no long- term, double-blind studies that help to select the group for which long-term opioids are beneficial.

In a series of 20 patients with chronic noncancer pain and substance abuse, Dunbar and Katz found that those with alcohol abuse alone, and especially those with a stable family and those active in Alcoholics Anonymous, were least likely to abuse opioids (89). Others have suggested that the label of substance abuse may deny appropriate analgesia to some patients. A study by Breitbart and colleagues of ambulatory patients with acquired immunodeficiency syndrome suggests that a past history of substance abuse may lead to inadequate analgesia for current pain problems (90). These concerns about underuse of opioids must be weighed against the personal and social costs of impaired function caused by substance abuse and dependence in patients with chronic noncancer pain. A number of guidelines have been proposed to assist the physician in prescribing opioids for chronic pain patients (91). In a joint statement, the American Academy of Pain Medicine and the American Pain Society have provided a balanced approach to the issue of prescribing opioids on a long-term basis for chronic, noncancer pain patients (86,87). The issues associated with prescribing opioids are discussed in more detail in Chapter 84.

The essential feature of substance abuse is a maladaptive pattern of substance use characterized by recurrent and significant adverse consequences. These include impaired role function, use in physically hazardous situations, and legal problems. It is distinguished from substance dependence in that it does not require tolerance, dependence, or a compulsive pattern of use. DSM-IV criteria are presented in Table 26-5.



A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:

1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
2. Recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
3. Recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)
4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)

B. The symptoms have never met the criteria for substance dependence for this class of substance.

From Diagnostic and Statistical Manual, 4th ed. Washington, DC: American Psychiatric Association, 1994:183, with permission.

TABLE 26-5. *Diagnostic and Statistical Manual*, Fourth Edition, Criteria for Substance Abuse

Epidemiology

Prevalence rates for substance abuse in chronic pain patients are variable because of differences in definitions used and populations assessed. Studies have used the DSM-III-R criteria that are similar to those listed in Table 26-5. Chabal and colleagues assessed patients attending a pain clinic at a VA Medical Center using five criteria derived from DSM-III-R (92). Nineteen percent of clinic patients were on chronic opiates. Thirty-four percent met one criterion, and 27% met three criteria. They found no differences concerning histories of drug and alcohol abuse between those on opioids who did and who did not meet abuse criteria. Brown and colleagues compared primary care patients making repeated visits for back pain to a random sample of other patients in the clinic (93). Lifetime substance abuse rates were approximately 53% for both groups; current substance abuse rates were 23% for both groups. Substance abuse predated the onset of chronic pain in 77% of patients who met criteria for current substance abuse. Kouyanou and colleagues reported on patients attending pain clinics in South London (94). In this study, 70% of patients were on opioids, but DSM-III-R substance abuse or dependence was diagnosed in only 12%.

The studies cited previously suggest that substance abuse and dependence occur in a minority of chronic pain patients on opioids. They do not answer the more difficult question as to whether opioids are, on balance, beneficial treatment for these patients. Studies involving random assignment of patients with chronic pain to opioid treatment are necessary to answer the question of what patients, with what characteristics are able to obtain benefits (pain reduction and improvement of

function) from long-term opioids without developing deleterious effects.

Treatment

When a patient with chronic pain meets criteria for substance abuse or dependence, treatment for the substance abuse should precede rehabilitative chronic pain treatment. Actively substance-abusing patients do not have the frustration tolerance necessary to succeed at the difficult task of chronic pain rehabilitation. Details concerning substance abuse treatment are beyond the scope of this book. Readers are referred to some of the standard texts in this area (95). However, a few comments about the interface between pain treatment and substance abuse treatment are in order. Laws in the United States strongly distinguish between the prescription of opioids for the treatment of pain and for the treatment of addiction (96). All physicians are allowed to do the former; only specialized methadone centers are allowed to do the latter. Because both groups of patients may be maintained on methadone long term, it can be difficult to distinguish the purposes of the prescription. If a patient with chronic pain has a history of illicit drug use or substance abuse (opioid or otherwise), it is wise to obtain a consultation from an expert in substance abuse before prescribing opioid maintenance therapy.

SOMATOFORM DISORDERS, ILLNESS BEHAVIOR, AND SICK ROLE

Definitions

Sickness is a complicated psychological and social state that has been understood from a variety of perspectives over the years. We consider those of sick role, illness behavior, and somatoform disorder.

The concept of the *sick role* was first introduced by Talcott Parsons in 1951 (97) and was formulated more concretely 12 years later (98). The sick role is granted to an individual provided that he or she regards his or her condition as undesirable, and is not held responsible for it (i.e., under his or her control and able to be reversed voluntarily). If granted, the individual is allowed exemption from his or her usual obligations to a greater or lesser extent and is considered to be deserving of care and attention. Associated with the sick role are the obligations of seeking the advice and assistance of a person regarded as competent to diagnose and treat the condition and of cooperating with that person.

The basic concept of *illness behavior* was introduced by Mechanic and Volkart (99) and later fully formulated by Mechanic (100). Mechanic's concept of illness behavior complements the sick role, because it delineates the contribution of the patient to the role-granting process. Illness behavior was originally defined as the ways in which individuals differentially perceive, evaluate, and respond to their symptoms. This concept proved to be an extremely useful one, because it has facilitated the empiric study of behaviors that are of considerable importance to clinicians and other health care providers, as well as to the individual's family and society.

Although useful as it stands, health care providers find Mechanic's definition restrictive because it refers to *symptoms* as the focus of behavior, and consequently deemphasizes actions directed toward avoidance of the illness. A slightly modified definition describes illness behavior as “the ways in which individuals experience, perceive, evaluate and respond to their own health status.” This definition recognizes the possibility that a person may be concerned about illness in the absence of symptoms.

Illness behavior is a concept more easily applied to individual patients than sick role and has therefore seen more use in clinical settings. However, it is dependent on social definitions of what constitutes legitimate illness. Although medical science determines what qualifies as *disease* based on objective changes in anatomy and physiology, society determines what qualifies as illness. These often follow each other quite closely, but there can be interesting discrepancies. Essential hypertension is a disease usually without symptoms. It has taken a concerted educational effort on the part of the medical profession to convince the public that it is an illness that should be monitored and treated. Chronic fatigue syndrome and fibromyalgia are illnesses increasingly recognized and accepted by the public. Because the medical profession has not been able to identify objective changes in physiology with these illnesses, many physicians question whether they qualify as legitimate diseases. Physicians, insurance companies, and compensation systems can find themselves in disagreement with patients experiencing chronic pain about whether a legitimate disease or illness is causing the pain.

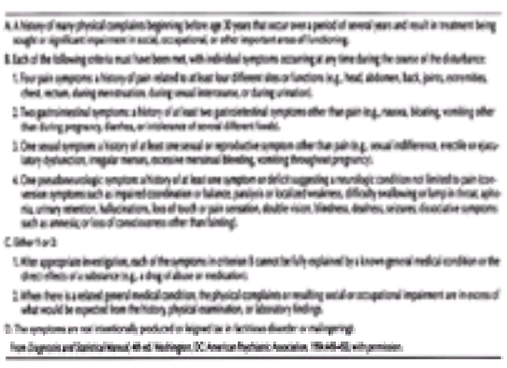
Pilowsky introduced the concept of *abnormal illness behavior* for those situations in which physician and patient disagree about the applicability of the sick role to the patient's condition (101). He contends that patients with truly abnormal illness behavior have extreme difficulty accepting the advice of any physician if it does not agree with their own appraisal of their health status. He cautions that misdiagnoses of abnormal illness behavior can occur when physician and patient do no share a common culture. We might add that it is also important to keep in mind the limitations of current diagnostic tests and disease criteria when diagnosing the patient's disagreement with his or her physician as pathologic.

SOMATIZATION DISORDER

Current psychiatric theory dictates diagnoses of somatoform disorders rather than abnormal illness behavior or misuse of the sick role. The essential feature of the somatoform disorders is the presence of physical symptoms that suggest a general medical condition but are not fully explained by a general medical condition. These symptoms must cause impairment in social and occupational functioning. The somatoform disorders are distinguished from factitious disorders and malingering in that the symptoms are not intentionally or voluntarily produced in the somatoform disorders.

Diagnosis

Somatization disorder is a chronic condition characterized by a pattern of multiple and recurrent somatic complaints resulting in medical treatment and impairment in role functioning, but not explained by a general medical condition. For this particular somatoform diagnosis, the somatic symptoms must be persistent and pervasive. These complaints must begin before 30 years of age and last for a period of years. Diagnostic criteria are displayed in Table 26-6.



A. A history of many physical complaints beginning before age 30 years that occur over a period of several years and result in treatment being sought or significant impairment in social, occupational, or other important areas of functioning.

B. Each of the following criteria must have been met, with individual symptoms occurring at any time during the course of the disturbance:

1. Four pain symptoms: a history of pain related to at least four different sites or functions (e.g., head, abdomen, back, joints, extremities, chest, rectum, during menstruation, during sexual intercourse, or during urination).
2. Two gastrointestinal symptoms: a history of at least two gastrointestinal symptoms other than pain (e.g., nausea, bloating, vomiting other than during pregnancy, diarrhea, or intolerance of several different foods).
3. One sexual symptom: a history of at least one sexual or reproductive symptom other than pain (e.g., sexual indifference, erectile or ejaculatory dysfunction, irregular menses, excessive menstrual bleeding, vomiting throughout pregnancy).
4. One pseudoneurologic symptom: a history of at least one symptom or deficit suggesting a neurologic condition not limited to pain (conversion symptoms such as impaired coordination or balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia, urinary retention, hallucinations, loss of touch or pain sensation, double vision, blindness, deafness, seizures, dissociative symptoms such as amnesia, or loss of consciousness other than fainting).

C. Either 1 or 2:

1. After appropriate investigation, each of the symptoms in criterion B cannot be fully explained by a known general medical condition or the direct effects of a substance (e.g., a drug of abuse or medication).
2. When there is a related general medical condition, the physical complaints or resulting social or occupational impairment are in excess of what would be expected from the history, physical examination, or laboratory findings.

D. The symptoms are not intentionally produced or feigned (as in factitious disorder or malingering).

TABLE 26-6. *Diagnostic and Statistical Manual*, Fourth Edition, Diagnostic Criteria for Somatization Disorder

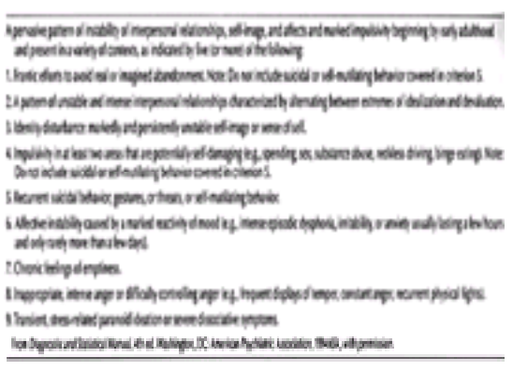
Many of the somatoform diagnoses, including somatization disorder, have their historic roots in the diagnosis of hysteria (102). The Egyptians first ascribed multiple unexplained somatic symptoms to the displacement of other organs by a wandering uterus. In the seventeenth century, Thomas Sydenham dissociated hysteria from the uterus and associated it with psychological disturbances. In 1859, Briquet described the multisymptomatic and protracted course of the illness in 430 Parisian patients. This description was taken up in the 1950s by investigators at Washington University in St. Louis (102). They described *Briquet's syndrome* as a multisymptomatic form of hysteria with 25 symptoms from 10 different symptom groups. By the publication in 1980 of DSM-III, the diagnosis had been streamlined to require 14 of 37 potential symptoms, and the name had been changed to *somatization disorder*. Through these changes, the essential feature of somatization disorder has remained multiple unexplained somatic symptoms producing disability and health care use. Somatization disorder must be distinguished from medical disorders producing multiple and scattered symptoms, such as multiple sclerosis or systemic lupus erythematosus. It must also be distinguished from panic disorder that also

produces multiple somatic symptoms but is a more acute and treatable psychiatric disorder.

Epidemiology

The prevalence of somatization disorder in the community has been reported to be between 0.13% and 0.4%, with the vast majority of cases occurring in women (103). Prevalence estimates in the primary care setting have ranged from 0.2% to 5.0%. Studies of patients referred to pain clinics have produced estimates from 8% to 12%. Although prevalence rates clearly increase when moving from community to primary care to tertiary care settings, somatization disorder patients remain in the clear minority in all settings. Unexplained somatic symptoms are a common problem in medical settings that extend far beyond the bounds of somatization disorder. Various attempts have been made to assess the prevalence of an abridged version of somatization disorder in primary care, requiring four to six unexplained symptoms (4.4% of patients) or three symptoms persistent over a 2-year period (8.2% of patients) (104). Even these abridged forms of somatization disorder are associated with increased rates of disability, health care use, and mood and anxiety disorders. Although the initial emphasis with Briquet's syndrome and somatization disorder was on a discrete, familial, even genetic, disorder, evidence suggests that somatization is a process that exists along a spectrum of severity (105). A large international study confirms that medically unexplained somatic symptoms are common, whereas full somatization disorder is quite rare (106). A great deal of confusion exists between somatization as a process and somatization as a disorder. Somatization as a process, meaning the somatic experience of distress, is ubiquitous (107). It accounts for the majority of symptoms presented to primary care physicians. It is most frequently associated with transient stressors (therefore time limited) or acute psychiatric disorders (which are treatable). Somatization disorder is a rare, chronic, and treatment-resistant condition that characterizes the most severely and chronically distressed individuals. When clinicians use the term *somatizer* to refer to a patient with unexplained symptoms, it is unclear whether they are implying the process or the disorder.

Although somatization disorder frequently occurs within families and has a genetic component, it also appears to have a strong association with childhood physical and sexual abuse (108). A significant percentage of patients who meet criteria for somatization disorder also meet criteria for borderline personality disorder (109). This has led some investigators to question the independence of these diagnoses and others to stress their common origin in severe childhood abuse. Borderline personality disorder is a severe, chronic pattern of chaotic and dysfunctional interpersonal relationships. Diagnostic criteria are presented in Table 26-7.



A pervasive pattern of instability of interpersonal relationships, self-image, and affects and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment. Note: Do not include suicidal or self-mutilating behavior covered in criterion 5.
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.
3. Identity disturbance: markedly and persistently unstable self-image or sense of self.
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating). Note: Do not include suicidal or self-mutilating behavior covered in criterion 5.
5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior.
6. Affective instability caused by a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days).
7. Chronic feelings of emptiness.
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights).
9. Transient, stress-related paranoid ideation or severe dissociative symptoms.

From Diagnostic and Statistical Manual, 4th ed. (Washington, DC: American Psychiatric Association, 1994), with permission.

TABLE 26-7. *Diagnostic and Statistical Manual*, Fourth Edition, Diagnostic Criteria for Borderline Personality Disorder

In a study of 200 patients with back pain attending a pain clinic, 51% of patients had some personality disorder and 15% had borderline personality disorder determined by structured psychiatric interview (110). This is a strikingly high prevalence of these disorders compared with other clinical populations. Some controversy exists about the validity of these diagnoses, especially as to whether they constitute a cause or effect of the chronic pain problem (111).

Treatment

Recognizing patients with somatization disorder is important, because they are among the most difficult patients to treat in the entire health care system. Above all, it is important to prevent iatrogenic damage to these patients through overly focused and invasive attempts to treat pain complaints. These patients are typically resistant to standard cognitive-behavioral treatment strategies used in chronic pain. They have extreme problems with trust and do not form therapeutic relationships easily. Any attempt to reframe somatic distress in emotional terms is likely to be experienced as an invalidation until a therapeutic alliance is well established. An adaptation of cognitive-behavioral therapy called *dialectical-behavioral therapy* has been shown effective for patients with borderline personality disorder, but has not been tested in patients with somatization disorder (112).

Psychotropic medications have highly unpredictable effects in this group (113). Any medications associated with tolerance and dependence, such as opioids and benzodiazepines, should be avoided, because they are often associated with clinical deterioration. Antidepressant medications also have unpredictable effects and should be prescribed only in collaboration with a psychiatrist. For patients with soft psychotic symptoms, such as depersonalization and derealization, low-dose antipsychotic medication may be of some benefit.

PAIN DISORDER

Diagnosis

In many prevalent pain syndromes (e.g., low back pain, headache, fibromyalgia), it is difficult to identify the tissue pathology giving rise to symptoms. When a somatic cause for pain cannot be identified, many clinicians begin to seek psychological causes. The identification of psychogenic pain is a difficult and perhaps impossible task. *Pain disorder* is the current psychiatric diagnosis that most closely corresponds to the diagnosis of psychogenic pain.

Because pain disorder is an important but problematic concept at the interface of pain medicine and psychiatry, it is important to understand some of the history of the concept. In DSM-II (published in 1968), no specific diagnoses existed that pertained to pain. Painful conditions caused by emotional factors were considered part of the psychophysiologic disorders. In 1980, DSM-III introduced a new diagnostic category for pain problems, *psychogenic pain disorder* (114). To qualify, a patient needed to have severe and prolonged pain inconsistent with neuroanatomic distribution of nociceptors or without detectable organic etiology or pathophysiologic mechanism. Related organic pathology was allowed, but the pain had to be “grossly in excess” of what was expected on the basis of physical examination. Accepted evidence that psychological factors were involved in the production of the pain were (a) a temporal relationship between pain onset and an environmental event producing psychological conflict, (b) pain appearing to allow avoidance of some noxious event or responsibility, and (c) pain promoting emotional support or attention the individual would not have otherwise received. It is important to note that this kind of evidence never proves that psychological factors have caused a pain complaint.

Difficulties in establishing that pain was psychogenic led to changes in the diagnosis for DSM-III-R, which was published in 1987 (115). In DSM-III-R, the diagnosis was renamed *somatoform pain disorder*, and three major changes were made in the diagnostic criteria. The requirements for etiologic psychological factors and lack of other contributing mental disorders were eliminated, and a requirement for “preoccupation with pain for at least six months” was added. The diagnostic criteria were thus reduced to the following:

1. Preoccupation with pain for at least 6 months
2. Either a or b:
   a. Appropriate evaluation uncovers no organic pathology or pathophysiologic mechanism to account for the pain.
   b. When there is related organic pathology, the complaint of pain or resulting social or occupational impairment is grossly in excess of what would be expected from the findings (116).

In DSM-III-R, therefore, somatoform pain disorder becomes purely a diagnosis of exclusion. The diagnosis is made when medical disorders are excluded in a patient *preoccupied* with pain.

The DSM-IV subcommittee on pain disorders found that, despite these changes, *somatoform pain disorder* was rarely used in research projects or clinical practice. They identified a number of reasons for this: (a) the meaning of “preoccupation with pain” is unclear, (b) whether pain exceeds that expected is difficult to determine, (c) the diagnosis does not apply to many patients disabled by pain in which a medical condition is contributory, (d) the term *somatoform pain disorder* implies that this pain is somehow different from organic pain, and (e) acute pain of less than 6 months' duration was excluded (117). They therefore proposed the DSM-IV category of pain disorder described in Table 26-8.

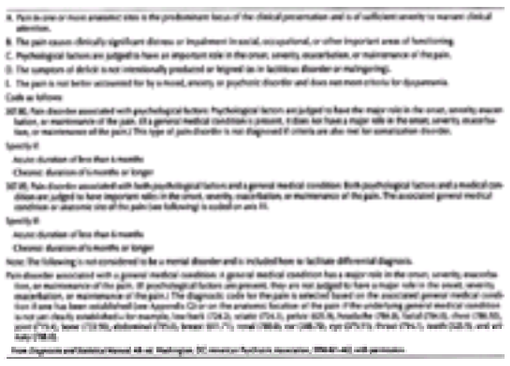


TABLE 26-8. *Diagnostic and Statistical Manual*, Fourth Edition, Diagnostic Criteria for Pain Disorder

The DSM-IV subcommittee has tried to devise a broader diagnostic grouping encompassing both acute and chronic pain problems. They wanted to have all the factors relevant to the onset or maintenance of the pain delineated and also to have a diagnostic category that does not require more training than the majority of DSM-IV users would be expected to have. These two requirements may not be compatible. Furthermore, no guidance is given in determining when psychological factors have a major role in pain or are considered important enough in the presence of a painful medical disorder to be coded as a separate mental disorder. Given the high rates of mood and anxiety disorders among disabled chronic pain patients, many patients most appropriate for the diagnosis would be excluded. Although depression and anxiety diagnoses point toward specific proven therapies, this is not true for pain disorder. The diagnosis thus continues covertly as a diagnosis of exclusion with neither clear inclusion criteria nor implications for therapy.

Epidemiology

Because pain disorder has poor interrater reliability (118) and (as suggested previously) poor validity, there have been few epidemiologic studies of the DSM pain disorders. There have, however, been good studies of pain complaints and unexplained medical symptoms. In a study of adult health maintenance organization members, Von Korff and colleagues found the prevalence of pain over a 6-month period was 41% for back pain, 26% for headache, 17% for abdominal pain, 12% for chest pain, and 12% for facial pain (119). These pain complaints were typically long-standing but nondisabling. However, 9% to 40% reported 1 or more days of disability in the past 6 months. Persons with a pain condition had higher levels of anxiety, depression, and nonpain somatic complaints.

Multiple studies have also demonstrated the association between medically unexplained symptoms (pain and nonpain) and psychiatric disorders. A linear relationship has been demonstrated between the lifetime number of medically unexplained physical symptoms and the lifetime number of depressive and anxiety disorders or the degree of neuroticism or harm avoidance the patient demonstrates on psychological testing (120). Increased psychiatric morbidity has been repeatedly demonstrated for levels of unexplained medical symptoms far below the number required for a DSM diagnosis of somatization disorder (121). This suggests that the somatoform disorders may be less distinct than implied by their separate DSM categories and that they have a strong kinship with the depressive and anxiety disorders. It may be more accurate and productive to think of somatization as a process present in varying degrees throughout the population rather than a set of disorders affecting a small subset of the population (122).

Treatment

Because chronic pain often has multiple causes or contributing factors, it often does not respond to purely somatic or purely psychological modes of treatment. Persistent pain can set a vicious cycle of reinforcing features into motion that then becomes a self-perpetuating problem independent of the initiating illness or injury. Deactivation, depression, disuse, medication misuse, and vocational dysfunction are all common contributing factors to the suffering and disability associated with chronic pain. Although simpler cases of chronic pain may respond to an approach based on the biomedical model, this is not true for the extremely disabled or prolonged cases likely to be referred to psychiatrists or psychologists.

Patients with disabling chronic pain are prone to *doctor shopping*, in which they obtain medications and procedures from a number of physicians unknown to each other. It is not possible to successfully treat a patient with chronic pain who has not formed a solid and honest therapeutic alliance with his or her treating physician. When evidence of doctor shopping becomes apparent, the patient should be confronted immediately and a conversation opened about the doctor–patient relationship. If the patient does not agree to stop unannounced visits to other physicians, he or she should be dismissed from care, as it is impossible to provide appropriate service in this situation.

The needs of patients with disabling chronic pain often outstrip the resources of the most enlightened and eager primary care physician. These patients are most appropriately treated by a multidisciplinary team experienced in the treatment of chronic pain. Members of this team may include a psychiatrist, psychologist, neurologist, neurosurgeon, physical therapist, occupational therapist, nurse, and vocational counselor. Although each case does not require the expertise of each of these disciplines, all of these disciplines have expertise relevant to the management of chronic pain (see Chapter 11).

The treatment of chronic pain is in many ways counterintuitive to the clinician and the patient. Many medications used for acute pain are contraindicated. Relief from pain must often be secondary to reduction in disability and deactivation. Clinical phenomena that seem clearly caused by the pain (e.g., depression must be addressed before pain relief is possible).

Most important, pain is not itself a psychiatric disorder. Chronic pain is frequently complicated by psychiatric disorders, however. The most common of these is depression. Psychiatric treatment of these disorders has an important role to play in the rehabilitation of the chronic pain patient.

CONVERSION DISORDER

The essential feature of conversion disorder is an alteration in voluntary motor or sensory function that suggests a neurologic or general medical disorder. Classic examples include hysterical paralysis, blindness, or mutism. Psychological factors must be associated with the initiation or exacerbation of this deficit. Diagnostic criteria are displayed in Table 26-9.

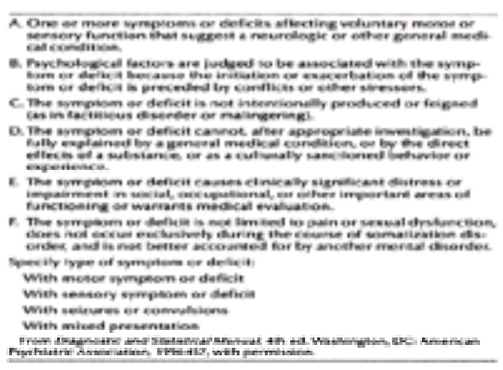

TABLE 26-9. *Diagnostic and Statistical Manual*, Fourth Edition, Diagnostic Criteria for Conversion Disorder

Great caution must be exercised in making the diagnosis of conversion disorder, because the presence of relevant psychological factors does not exclude the possibility of a concurrent organically caused condition.

In “Psychogenic Pain and the Pain-Prone Patient,” George Engel proposed that psychogenic pain arose from guilt and an intolerance of success (41). He indicated that it functioned as a substitute for loss or a replacement for aggression. He furthermore stated that “. . . patients with conversion hysteria constitute the largest percentage of the pain-prone population.” Others have also contended that pain is probably the most common conversion symptom encountered clinically (123). However, only case reports exist to support this contention. Pain is not a classic conversion disorder symptom, and it is controversial whether chronic pain can ever qualify as a conversion disorder by itself. Some, for example, have contended that reflex sympathetic dystrophy (complex regional pain syndrome) can be understood as a conversion reaction; however, this is highly controversial (124). Some elements of conversion disorders appear to be present in reflex sympathetic dystrophy/complex regional pain syndrome patients (e.g., indifference or neglect toward the affected body part), although it is highly unlikely that the condition is entirely psychogenic.

Rather than labeling some chronic pain problems as conversion reactions and others as not, it may be more useful to understand what components of conversion reaction may be present in chronic pain problems. Being ill surely creates problems in living for those affected. Being ill, however, can also solve problems in living. For example, being ill provides an excuse for not being at school or not meeting a deadline at work. These interpersonal advantages of illness were originally recognized by Freud and termed *secondary gain*.

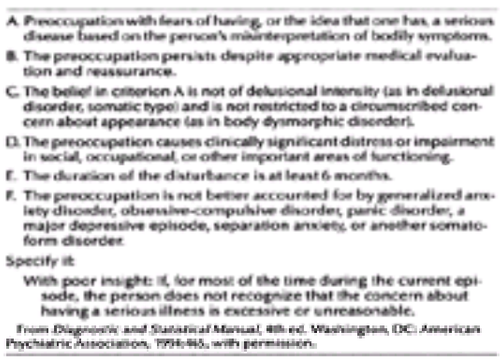
The term *secondary gain* has been distorted and misunderstood in the care of chronic pain, probably because of medicolegal pressures. A number of corrections are in order. First, all illnesses are characterized by some secondary gain, not just illnesses considered to be psychogenic. Being sick always has advantages as well as disadvantages. Second, secondary gain includes all potential interpersonal benefits of illness, not just monetary advantages. Many of the advantages of illness are quite subtle and individualized. Third, secondary gain must be understood in the context of *primary gain*, the intrapersonal advantages of illness. For example, focusing on pain rather than depression may allow patients to avoid self-blame and thereby achieve primary gain. This is a common phenomenon in chronic pain. Indeed, blame avoidance has been hypothesized by some to be one of the main functions of somatization (125). Thus, traditional elements of conversion disorder may be present in many chronic pain problems without many pain problems qualifying as conversion disorders *per se*.

Purely psychogenic or conversion models of chronic pain have some questionable implications for diagnosis and therapy of chronic pain disorders. Interview of the patient with a suspected conversion disorder with the aid of a sodium amobarbital (Amytal) infusion has been a standard tool in psychiatric diagnosis (126). It is more common that motor and sensory deficits than pain resolve under Amytal sedation. Furthermore, some patients have had violent or suicidal reactions to abrupt resolution of their somatic symptoms under Amytal, possibly caused by loss of face-saving primary gain aspects of the illness. Psychodynamic theories of the origin of conversion symptoms imply that psychological treatments alone will be effective.

Psychodynamic treatments for chronic pain, however, have little documented success. The most effective psychological treatments, such as cognitive-behavioral therapy, include a reactivation component that addresses the profound disuse and deconditioning found in many patients with chronic pain.

Hypochondriasis

Many patients with chronic pain resist their physician's reassurance that “nothing is wrong” or that the “tests reveal nothing.” These patients know that they hurt and cannot accept that a bodily cause cannot be identified for their pain. This has been described as *disease conviction* in the chronic pain literature. Disease conviction has been measured with the Illness Behavior Questionnaire, and Hypochondriasis is assessed with the Minnesota Multiphasic Personality Inventory. In DSM-IV there also exists a disorder called *hypochondriasis*. Diagnostic criteria are list in Table 26-10.



A. Preoccupation with fears of having, or the idea that one has, a serious disease based on the person's misinterpretation of bodily symptoms.
B. The preoccupation persists despite appropriate medical evaluation and reassurance.
C. The belief in criterion A is not of delusional intensity (as in delusional disorder, somatic type) and is not restricted to a circumscribed concern about appearance (as in body dysmorphic disorder).
D. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
E. The duration of the disturbance is at least 6 months.
F. The preoccupation is not better accounted for by generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, a major depressive episode, separation anxiety, or another somatoform disorder.

Specify if:

With poor insight: if, for most of the time during the current episode, the person does not recognize that the concern about having a serious illness is excessive or unreasonable.

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:465, with permission.

TABLE 26-10. *Diagnostic and Statistical Manual*, Fourth Edition, Diagnostic Criteria for Hypochondriasis

The prevalence of hypochondriasis in primary care has been reported to be 4% to 9% (127). The prevalence of hypochondriasis in pain clinic populations is difficult to determine, but is likely to be high if patients are not excluded by qualifying for pain disorder, because of the likelihood of disagreement between patient and physician about the cause of the pain problem.

Treatments of hypochondriasis have attempted to shift patient focus from cure of the disease causing the symptoms to strategies of symptom management (128). These strategies are common components of multidisciplinary pain treatment programs as well (see Chapter 11). It is indeed critical to achieve early in treatment some agreement with the patient about the cause of the pain that acknowledges the reality of the pain and yet points away from invasive attempts to cure disease or repair broken parts. The task is not to convince the patient that “nothing serious is wrong,” because his or her pain may be severe and persistent. The task is to convince the patient that the appropriate treatment is different than the treatment he or she thought necessary.

CONCLUSION: A BIOPSYCHOSOCIAL MODEL OF PAIN AND SUFFERING

Psychiatric diagnosis and treatment can add an essential and often neglected component to the conceptualization and treatment of chronic pain problems. However, it is absolutely critical to avoid a dualistic model that postulates that pain is either physical or mental in origin. This model alienates patients who feel blamed for their pain. It also is inconsistent with modern models of pain causation. Since the gate control theory of pain, multiple lines of evidence suggest that pain is a product of efferent as well as afferent activity in the nervous system. Tissue damage and nociception are neither necessary nor sufficient for pain. Indeed, it is now widely recognized that the relationship between pain and nociception is highly complex and must be understood in terms of the situation of the organism as a whole.

We are only beginning to understand the complexities of the relationship between pain and suffering. Pain usually, but not always, produces suffering. Suffering can, through somatization, produce pain. We have traditionally understood this suffering, as we have understood nociception, as arising from a form of pathology intrinsic to the sufferer. Hence, the traditional view that pain is caused by either tissue pathology (nociception) or psychopathology (suffering). An alternative model that allows us to escape this dualism is to think of pain as a *transdermal process* with causes outside as well as inside the body. For humans, social pathology can be as painful as tissue pathology. We can investigate the physiology and the psychology of this *sociogenic* pain without losing sight of its origins in relations *between* people.

Psychological care for patients with chronic pain should occur within the medical treatment setting whenever possible. This is the most effective way to reassure

patients that the somatic elements of their problems are not neglected. It also allows integration of somatic and psychological treatments in the most effective manner.

CHAPTER 27

Arthritis and Periarthritic Disorders

Gregory C. Gardner and Bruce C. Gilliland

This chapter contains a concise discussion of the most painful arthritides encountered in clinical practice. These are osteoarthritis (OA), rheumatoid arthritis, ankylosing spondylitis, Reiter's syndrome, psoriatic arthritis, gout, pseudogout, and infectious arthritis. Tendinitis, bursitis, fibrositis, bone lesions, and soft tissue inflammation are discussed in Chapter 31. More comprehensive discussion of arthritides can be found elsewhere (1,2).

BASIC CONSIDERATIONS

Joint Anatomy

Joints in the extremities are synovial (diarthrodial) joints that permit movement over a wide range (3) (Fig. 27-1). The joint is held together by a capsule of dense fibrous tissue and ligaments and gains further support from overlying muscle and tendons. The inner surface of the joint capsule is covered by synovium, which consists of an intimal layer of specialized cells called *synoviocytes*, and an outer layer of highly vascularized connective tissue. Synoviocytes comprise one to three cell layers and are of two basic types, A and B. Type A synoviocytes are active in phagocytosis, and type B cells synthesize hyaluronate, which is responsible in large part for the high viscosity of normal synovial fluid. Synovial fluid in a normal joint lubricates the surfaces of synovium and cartilage. The synovium is folded along the inside of the joint capsule and does not cover the load-bearing surface of articular cartilage. The connective tissue layer of synovium blends with periosteum, which does not cover the bone within the joint. The synovium has a rich network of capillaries, venules, and lymphatics, and it is innervated by sympathetic nerve fibers. The knee and the sternoclavicular and radiocarpal joints contain disks of fibrocartilage that help to stabilize these joints when they rotate. The intervertebral facet joints are diarthrodial joints and are covered by synovium.

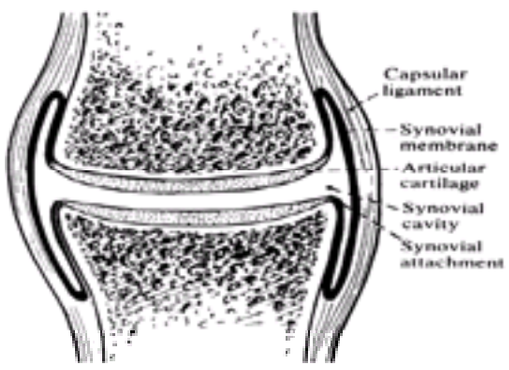

Figure 27-1. Schematic diagram of the anatomic features of a typical synovial joint seen in a section cut across the middle of the joint. The extent of the joint cavity is exaggerated to show the anatomic arrangement of the synovial membrane more clearly. (From Polly HF, Hunder GG. *Rheumatologic interviewing and physical examination of the joints*. Philadelphia: Saunders, 1978, with permission.)

Amphiarthrodial joints are only slightly movable and include the symphysis pubis and the joints between vertebral bodies. The joint surfaces are separated by intervertebral disks. The sacroiliac joint has elements of both a diarthrodial and an amphiarthrodial joint.

Articular cartilage is composed of type 2 collagen and proteoglycans. Type 2 collagen is unique to joints and provides cartilage with form and tensile strength. Proteoglycan molecules are linked noncovalently to a long chain of hyaluronic acid and are interwoven within the network of collagen fibers. Proteoglycan molecules bind most of the water present in cartilage, which represents approximately 70% of the total weight of articular cartilage. The proteoglycan molecules are constrained within the meshwork of collagen fibers and are responsible for the resiliency of cartilage. Chondrocytes secrete collagen, proteoglycans, and enzymes that degrade the cartilaginous matrix. The process of remodeling and degradation is kept in balance unless the microenvironment of these cells is altered. Joints normally contain a small amount of synovial fluid, which is viscous, clear, and does not clot spontaneously. Normal synovial fluid contains fewer than 200 cells per cubic millimeter; most of these cells are mononuclear.

Nerve and Blood Supply

Joints are supplied partly by articular nerves, which are branches of major peripheral nerves, and partly by branches of nerves supplying adjacent muscles, as well as vasomotor sympathetic fibers. Nerve endings are distributed in the interstitial and perivascular tissue located in the subsynovium fibrous capsule, articular fat pads, and in the adventitial sheaths of arteries and arterioles supplying the joints. The periosteum is innervated, but articular cartilage and subchondral bone are not.

Figure 27-2 shows the four types of receptors that supply joints (4). Type I receptors are ovoid corpuscles with a thin connective tissue capsule and each is supplied by a small myelinated nerve fiber (5 to 8 mm in diameter) that arborizes within the capsule. The type I receptor occurs almost exclusively in the fibrous joint capsule, acts as a slowly adapting mechanoreceptor (stretch receptor), and resembles both structurally and functionally the Ruffini endings in the dermis. The type II receptor is approximately twice as large as the type I receptor and is supplied by a somewhat thicker myelinated fiber (8 to 12 mm in diameter) that usually ends as a single terminal within a rather thick laminated capsule. These receptors, which resemble the pacinian corpuscles, occur only in the fibrous joint capsule and have been shown to be rapidly adapting mechanoreceptors (acceleration receptors) that are sensitive to rapid movements. Type III receptors, which are the largest, are supplied by thick myelinated fibers that branch profusely. These receptors, which resemble the Golgi organs, are present in extrinsic and intrinsic ligaments (and not in the joint

capsule) and adapt slowly and at high thresholds. Type IV receptors are represented by plexuses of fine unmyelinated fibers that occur in the fibrous joint capsules, ligaments, and subsynovial capsules and fat pads; they are considered to be the joint nociceptors.

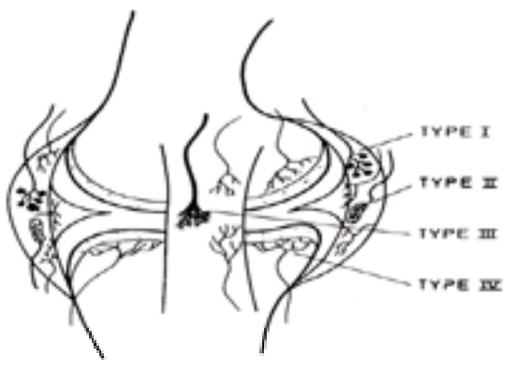

Figure 27-2. Schematic diagram of the knee joint showing the distribution of the various types of receptors in the capsule ligaments of the joint. The menisci are free from nerve fibers except at their attachment to the fibrous capsule. See text for details. (From Brodal A. *Neurological anatomy in relation to clinical medicine*, 3rd ed. New York: Oxford University Press, 1981, with permission.)

An anastomotic plexus of blood vessels called the *periarticular anastomosis*, together with these nerves, surrounds the capsule, and its branches penetrate the capsule. The periarticular anastomosis is fed by branches of arteries passing the joint and is the source of blood to the capillary bed in the synovial membrane and also to the epiphysis (Fig. 27-3).

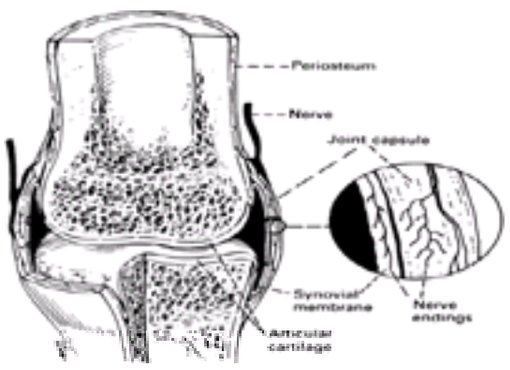

Figure 27-3. Blood and nerve supply to bone and the synovial joint. The upper bone is shown before and the lower bone after obliteration of the growth plate cartilage. The blood vessels that enter the periosteum from the attached muscles have been omitted from the illustration. (Modified from Rosse C, Clawson DK, eds. *The musculoskeletal system in health and disease*. Hagerstown, MD: Harper & Row, 1980.)

MAGNITUDE OF THE PROBLEM

Surveys on the prevalence of a variety of health conditions in the United States, including arthritis, are carried out by the National Center for Health Statistics on an ongoing basis. The data derived from these surveys, known as the *National Health Interview Survey*, estimated in 1976 that 26.2 million people in the United States were affected by arthritis or other musculoskeletal conditions and by 1986 this number had risen to 34.5 million (5). The most recent data from these surveys indicate that currently there are 40 million people in the United States with musculoskeletal conditions and by 2020 it is projected that 60 million will be affected (6). Women are almost twice as likely to report the presence of a musculoskeletal condition as men and are also twice as likely to feel the condition is activity limiting. Twenty percent of people in the lowest income bracket in the United States (less than $10,000 per year) report the presence of a musculoskeletal condition and 6% thought it was limiting. This compares with a 13% prevalence of musculoskeletal conditions in the highest income bracket (more than $50,000 per year), with only 1.6% considering the condition limiting. Moreover, arthritis and rheumatism ranks first as a cause of mobility limitation and second only to heart disease as a cause of activity limitation in the United States. In England, arthritis is the disease most frequently causing severe handicap, and it ranks second only to respiratory infections in number of visits to physicians in that country.

Approximately 23% of people with a musculoskeletal condition have some form of limitation directly related to the underlying musculoskeletal problem (7). Mortality is elevated for most of the major forms of arthritis including OA, in which a slight increase in mortality exists for knee OA, but not hip OA. People with rheumatoid arthritis have 10 to 15 years taken off life expectancy by the disease, with factors such as higher number of joints involved, worse functional status, and less education, all helping to predict mortality (8). Diseases such as scleroderma, systemic lupus erythematosus, and myositis have significant morbidity and mortality both caused by the disease itself and the treatment.

Estimates of the economic impact of arthritic conditions vary widely. Yelin and Callahan estimated that the costs of arthritis in the United States are as high as $149 billion in 1992 dollars with $71 billion attributed to direct costs and the rest attributed to lost wages related to the musculoskeletal condition (9). This figure represents 2.5% of the gross national product of the United States in 1992. A more conservative estimate is offered by Praemer and colleagues, who calculated the direct cost of caring for patients with musculoskeletal conditions at $13 billion and the indirect cost at $55 billion during the same period reported by Yelin and Callahan (10).

CLINICAL APPROACH TO ARTHRITIS

A variety of disorders, both systemic and local, cause joint pain. A thorough history should be taken and a careful physical examination should be performed on each patient, along with appropriate laboratory and radiographic studies (11,12 and 13).

History

The following information should be obtained from the patient. Is the pain localized to one or a few joints, or is it more generalized? Is joint involvement symmetrical? Are peripheral joints primarily involved, or is the axial skeleton the primary site of involvement? What is the pain in the joint like? How rapidly does it appear, how intense is it, how long does it last, what is the quality of the pain, and what is its pattern of radiation? Is the pain produced by physical activity and relieved by rest? Is there morning stiffness, and how long does it last? Morning stiffness of greater than 30 minutes usually suggests an inflammatory arthritis. Symmetric polyarthritis persisting longer than 6 weeks raises the possibility of rheumatoid arthritis.

Migratory polyarthritis is defined as arthritis occurring in one joint and then moving to another joint while inflammation in the previously involved joint subsides. This type of arthritis is more characteristic of a viral infection or rheumatic fever. Arthritis that is additive or progressive continues in the initially involved joints as new joints become affected. Additive arthritis is more likely to occur in inflammatory arthritides such as rheumatoid arthritis.

Development of an acute arthritis involving one or a few joints suggests a crystal-induced arthritis, such as gout or pseudogout or bacterial arthritis. In a young man, low back pain radiating into the buttock and posterior thigh, along with morning stiffness, raises the possibility of ankylosing spondylitis, which can be incorrectly diagnosed as a herniated intervertebral disk. One should search for subcutaneous nodules, which are seen in rheumatoid arthritis or gout. Nodules occur most often over bony prominences such as the elbows. Patients with disorders such as rheumatoid arthritis, psoriatic arthritis, gout, or ankylosing spondylitis often have a

positive family history for that type of arthritis.

The patient should be questioned for constitutional symptoms. Weight loss and fatigue in a patient with polyarthritis and morning stiffness lasting more than 30 minutes point to rheumatoid arthritis. Skin lesions such as those caused by psoriasis should be noted. An acute oligoarthritis in a sexually active young man in association with urethritis, conjunctivitis, or mucocutaneous lesions (or any combination of these symptoms) is most likely Reiter's syndrome. A patient with acute arthritis in one or two joints in the lower extremities and chronic diarrhea should be evaluated for arthritis associated with inflammatory bowel disease.

Physical Examination

When evaluating a patient with musculoskeletal complaints, it is important to distinguish arthritis from soft tissue inflammation and muscle disease. Joints should be examined for evidence of synovial proliferation, fluid, and bony enlargement. Tenderness, warmth, and any limitation of range of motion should be noted. Pain on passive motion of a joint suggests the possibility of inflammation in the joint or periarticular structures.

Muscles should be evaluated for tone, strength, and size. Muscle atrophy and weakness develop in patients with painful chronic joint disease. Proximal muscle weakness is observed in polymyositis, dermatomyositis, and hyperthyroidism. An elderly patient with pain and stiffness in the shoulder and hip girdle should be evaluated for polymyalgia rheumatica. Muscle weakness is usually not prominent, and the erythrocyte sedimentation rate is elevated. Fatigue, persistent aching of the arms, legs, and shoulders throughout the day, and tenderness over specific sites such as the lateral epicondyles, upper shoulders, interscapular region, posterior iliac spines, and medial aspect of the knees are seen in patients with fibromyalgia.

Laboratory Examination

Examination of the joint fluid is essential in patients who have undiagnosed arthritis. Diagnosis of infectious or crystal-induced arthritis is established only by examination of joint fluid. Characteristics of the joint fluid in various rheumatic conditions are shown in Table 27-1. In inflammatory effusions, the cell count is usually elevated, with predominantly polymorphonuclear white cells. The fluid is cloudy, has reduced viscosity, and forms a fibrin clot. Normal joint fluid does not spontaneously clot because it contains no fibrinogen. Viscosity is reduced in inflammatory arthritis because of the breakdown of hyaluronate. A rough assessment of viscosity can be made by forcing a drop of fluid through the end of the syringe. Fluid with poor viscosity drops like water. In normal joint fluid or noninflammatory conditions, a string trails the drop; the longer the string, the higher the viscosity. The mucin clot test has been used for years in the examination of joint fluid. The addition of a drop of synovial fluid from a normal or OA joint to a tube of dilute acetic acid results in the formation of a tight, ropy precipitate of hyaluronate and protein. The mucin clot in inflammatory joint disease is loosely formed, and it fragments readily when shaken gently. A good mucin clot correlates with normal viscosity of joint fluid. The mucin clot test is not essential for the examination of joint fluid because the degree of inflammation can be determined by other methods.

Diagnosis	Appearance	Mucin clot*	White blood count (per mm³ leukocytes)	Polymorphonuclear white cells	Glucose† (%) of blood
Normal	Clear, straw-colored	Good; firm	<200	<25	~100
Osteoarthritis	Straw-colored	Good; firm	<2,000	<25	~100
Rheumatoid arthritis	Yellow	Fair to poor; friable	5,000–25,000 or greater	>65	~75‡
Gout or pseudogout	Yellow, slightly cloudy	Fair to poor; friable	2,000–75,000	>70	[illegible]
Spondyloarthropathies	Yellow, slightly cloudy	Fair to poor; friable	2,000–75,000	>60	[illegible]
Bacterial arthritis	Cloudy to purulent	Poor; friable	10,000, often >100,000	>75	<50
Tuberculous arthritis	Yellow, cloudy	Poor; friable	10,000–20,000§	Variable	[illegible]
Traumatic arthritis	Straw-colored, xanthochromic, bloody	Good; firm	2,000	<25	~100

*Mucin clot correlates with viscosity except with grossly purulent fluid.
†[illegible]
‡May be less than 50%.
§[illegible]
[illegible]

TABLE 27-1. Synovial fluid findings in arthritis

Normal joint fluid usually contains fewer than 200 white cells per cubic millimeter and these cells are predominantly mononuclear. Cell counts greater than 50,000 per cubic millimeter, and in which the cells are predominantly polymorphonuclear, suggest an infectious arthritis, but cell counts of this magnitude are also seen in noninfectious inflammatory joint diseases such as Reiter's syndrome.

The joint fluid glucose approximates the blood glucose when the two compartments are in equilibrium, which is reached 6 hours after a meal. In bacterial arthritis, the glucose in joint fluid is less than 50% of the serum glucose. In rheumatoid arthritis, joint fluid glucose can also be less than 50% of a simultaneously obtained serum glucose because of a defect in glucose transport across the synovium.

Biopsy of the synovium is often needed to diagnose conditions such as tuberculous, sarcoid, or amyloid arthritis. Arthroscopy and arthrography might be required to search for evidence of mechanical derangements such as a torn meniscus, tendon, or ligament. Computed tomography and nuclear magnetic resonance imaging add another dimension to conventional radiography for examination of the musculoskeletal system, especially the spine.

CLINICAL CONSIDERATIONS

Osteoarthritis

OA is characterized by progressive loss of articular cartilage leading to joint pain and limitation of movement. Weight-bearing and frequently used joints are most often affected. The disease is divided into a primary (idiopathic) form, in which no predisposing factors are apparent, and a secondary form, which is associated with trauma, a metabolic disorder, or a congenital abnormality.

Primary OA is the more common form. Pathologically, the two forms are indistinguishable.

Epidemiology and Pathophysiology

OA is the most common form of arthritis worldwide. The disease occurs in all races and geographic areas. Prevalence and severity increase with age. Under age 55 years, the frequency and joint distribution of OA in men and women are approximately the same. After age 55 years, OA of the knee is more common in women and OA of the hip in men (14). OA can be demonstrated radiographically in almost all persons over the age of 75 (15). Weight-bearing joints such as the hips, knees, feet, and cervical and lumbosacral joints are most often affected. The distal and proximal interphalangeal joints of the hands are also commonly involved. Certain occupations have been shown to predispose a person to OA. In coal miners, for example, OA of the shoulders and knees is more frequent, presumably because of the forces placed on these joints during work. Prize fighters are more likely to develop OA of their metatarsophalangeal joints, football players of their knees, and ballet dancers of their ankles. Hereditary factors also exist: Heberden's nodes are twice as frequent in mothers of affected persons and three times more frequent in sisters (16). A single point mutation in the cDNA coding for type II collagen was found in family members with an inherited form of OA associated with a mild chondrodysplasia (17,18). Previous major trauma and repetitive use of a joint increase the risk of developing OA. Age alone is a risk factor, with the prevalence of OA increasing after age 45 years. Obesity has been shown to be a definite risk factor for developing OA of the knees (19).

The process of OA may begin with a decrease in the energy-absorbing property of the subchondral bone (20). This change means that the energy of weight bearing is absorbed mainly by the articular cartilage and chondrocytes. In response to this impact, the chondrocytes multiply and increase their synthesis of degradative enzymes as well as collagen and proteoglycans. Chondrocytes produce a family of metalloproteinases that include stromelysin, collagenase, and gelatinase. These enzymes can degrade all the components of cartilage. Cytokines (interleukin-1 and tumor necrosis factor-a) secreted by mononuclear cells of the synovium and by chondrocytes stimulate the release of metalloproteinases. These enzymes are inhibited by tissue inhibitors of metalloproteinase, which are also made in chondrocytes and serve to protect against excessive degradation of cartilage. Eventually, this protection is lost, resulting in loss of cartilage. In addition, antibodies to proteoglycans

and other degradative products induce an inflammatory response that may further injure the joint.

The cartilage initially shows fissuring and pitting, which eventually progress to erosions and denuded areas. The proteoglycan content of cartilage and the number of chondrocytes decrease in proportion to the degree of disease. Subchondral bone becomes thickened and has an eburnated, or ivorylike, appearance. Cysts appear in the subchondral bone, and the formation of new bone at the joint margins produces osteophytes or spurs. The synovium is thickened and contains a modest infiltration of lymphocytes, plasma cells, and an occasional multinucleated giant cell. The joint capsule and ligaments are hypertrophied.

Symptoms and Signs

OA may be limited to one or two joints or may occur in a generalized form involving many joints. Symptoms usually begin insidiously as a deep aching pain that is poorly localized. Pain occurs during use of the involved joint and is relieved by rest. Involved joints are stiff for 30 minutes or less in the morning and after periods of inactivity. The involved joints often ache at night, and the ache can keep the patient awake. Night pain is caused in part by increased intraosseous venous pressure. As the disease progresses, pain becomes a constant feature of physical activity and can persist for several hours afterward. Eventually, restricted motion and joint deformities develop.

OA most frequently affects the distal interphalangeal joints, the first carpometacarpal joint, and the scaphotrapezoid joint. The proximal interphalangeal joints are less frequently involved. OA of the metacarpal phalangeal joints, especially the second and third joints, is unusual and when present is caused by previous trauma, calcium pyrophosphate deposition disease (CPDD), or hemochromatosis. Patients experience aching pain in the involved joints during and shortly after using their hands. With vigorous activities, such as gardening, golf, or tennis, the joints swell and ache for several hours or even days. Heberden's nodes usually develop after age 40 and are associated with OA of the distal interphalangeal joints. Similar nodes, called *Bouchard's nodes*, appear at the proximal interphalangeal joints. At times, these nodes become red and painful to touch. Bony enlargement, small effusions, restricted motion, and angulation can be seen on physical examination. Radial subluxation of the first carpal metacarpal joint gives a square appearance to this joint (shelf sign).

A form of OA, referred to as *primary generalized OA*, appears most often in middle-aged women and affects the distal interphalangeal and proximal interphalangeal joints of the hand, the first carpal metacarpal joint, knees, hips, and the first metatarsal phalangeal joint. Episodes of inflammation are characterized by warmth, pain, and swelling of these joints.

OA of the hip is usually unilateral, but the opposite side is also affected in approximately 20% of patients (21). Congenital or developmental abnormalities such as slipped capital femoral epiphysis, Legg-Calvé-Perthes syndrome, or hip dysplasia underlie many of the cases. OA follows avascular necrosis, which can be related to deep-water diving, glucocorticosteroid therapy, alcohol, or sickle cell disease. Hip pain is experienced in the groin, over the greater trochanter, in the buttock, or down the anterior and inner thigh. Pain might be referred to the distal thigh and upper knee because the obturator nerve and its branches supply both hip and knee. Hip disease can be mistaken for knee arthritis or trochanteric bursitis because hip pain can be referred to those locations. The pain of hip disease is often described as dull and aching and is initially experienced with physical activity. Later, night pain is also experienced. Patients might limp and have difficulty rising from a sitting position. Functional shortening of the leg caused by adduction and flexion contractures causes the patient to walk with a shuffling gait. Examination of the hip shows initially decreased internal rotation that is followed later by decreased extension, abduction, and flexion, as well as a flexion contracture.

The cause of OA of the knee is not known in most patients. Previous injury such as a torn meniscus or ligament predisposes the knee to secondary OA. The presence of genu varum (bow legs) or genu valgum (knock knees) increases the force directed through either the medial or lateral side of the knee and can lead to OA. These deformities are also acquired in OA as a result of destruction of either the medial or lateral articular cartilage. Obesity predisposes the knees to OA by the additional weight and by the thigh thickness, which places the legs in a genu varus position and increases the pressure on the medial compartment.

The first symptom is usually pain with activity. The pain is dull and aching and usually poorly localized in and around the knee. Pain also can be localized to either the medial or lateral aspect of the joint. Stiffness lasting less than 30 minutes is present in the morning or after prolonged rest during the day. Stiffness improves with activity but might return later in the day. Atrophy and weakness of the quadriceps muscle develop with progression of the arthritis. Crepitus might be noted with bending of the knee. With loss of ligamentous and muscle support, the knee becomes unstable, and the patient may be hesitant to walk on uneven surfaces. The knee might suddenly give way because of a pain reflex. A loose cartilaginous fragment, sometimes referred to as a *joint mouse*, can prevent the joint from being fully extended.

On examination, a small joint effusion might be present. Presence of a large effusion suggests the possibility of associated CPDD or recent trauma. Ligamentous laxity, limitation of motion, and flexion contractures might be present.

Patellofemoral arthritis occurs alone or in conjunction with arthritis of the other knee compartments, especially in older patients. The term *chondromalacia patellae* is often used interchangeably with patellofemoral arthritis, although some restrict this term to a self-limiting disorder occurring in adolescents and young adults. Patellofemoral arthritis is caused in some patients by improper tracking of the patella through the patellofemoral groove (trochlea). The patella is pulled to the lateral margin of the groove by a tight lateral patellar retinaculum or a relative weakness of the vastus medialis compared with the vastus lateralis of the quadriceps muscle. Lateral subluxation of the patella can also be caused by an increased Q angle resulting from rotational malalignment of the femur and tibia.

In the spine, intervertebral disks and apophyseal (facet) joints are sites for OA. Involvement of intervertebral disks is referred to as *spondylosis*, whereas disease in the apophyseal joints is considered true OA. OA also affects the joints of Luschka (uncovertebral joints), which are located in the cervical spine between the superior process of one vertebral body and the inferior process of the vertebral body above it.

Symptoms of spine involvement are localized pain and stiffness, referred or dermatomal pain, and radicular pain from nerve root compression. Nerve root involvement produces paresthesias, decreased sensation, loss of muscle strength, and diminished or absent deep tendon reflexes. OA of the cervical spine causes either localized pain or pain referred to the occiput, shoulder, interscapular area, or arm, depending on the level affected. With upper cervical disease, the pain tends to be referred to the occiput or upper interscapular area, and with lower cervical involvement it is referred to the shoulder and upper arm. Neurologic manifestations are also caused by compression of the spinal cord by posteriorly directed osteophytes and by occlusion of the anterior spinal artery by a herniated disk. Cervical spine diseases are discussed in Chapter 55; lumbar spine in Chapter 75 and Chapter 76.

Secondary Osteoarthritis

OA can develop in joints that have been damaged. A torn knee meniscus or ligament can lead to incongruity of the joint surfaces resulting in OA. OA may follow joint damage produced by infectious arthritis or an inflammatory arthritis such as rheumatoid arthritis. Neuropathic joint disease is a severe form of OA resulting from the loss of pain sensation, proprioception, or both (22). Without these protective mechanisms, joints are subjected to repeated trauma, leading to progressive cartilage damage. Diabetes is the most common cause of neuropathic joint disease. Other causes include tabes dorsalis, syringomyelia, amyloidosis, meningomyelocele in children, and leprosy.

OA occurs in patients with excessively hypermobile joints. Patients with Ehler-Danlos syndrome, a hereditary disorder of connective tissue, develop OA of their hands, shoulders, knees, and ankles usually before age 40 years (23). Debate exists regarding whether patients with idiopathic joint hypermobility are at risk of developing premature OA (24).

Several metabolic disorders are associated with the development of OA. These include hemochromatosis, ochronosis, and acromegaly. Arthritis occurs in 20% to 50% of patients with hemochromatosis and may appear before other overt clinical manifestations (25). Hands, knees, and hips are most commonly affected. A particularly characteristic finding is involvement of the second and third metacarpophalangeal joints, which are rarely affected in primary OA. Ochronosis is a rare disorder caused by a hereditary deficiency of homogentisic acid oxidase, leading to accumulation of homogentisic acid in connective tissue. Deposits of homogentisic acid impart a blue-black hue to the sclerae and external cartilage of the ears. Arthritis appears in middle age and involves most often the knees, shoulders, hips, and spine (26). Approximately 60% of patients with acromegaly develop OA, which most often involves the spine, knees, hips, shoulders, and, occasionally, ankles (27). The increased growth of articular cartilage causes joint surface incongruity and abnormal wear.

Laboratory Findings. Routine laboratory work is normal in patients with primary OA and reflects the underlying metabolic disorder in secondary OA. The synovial fluid is straw colored and has good viscosity. The cell count is usually less than 2,000 white cells per cubic millimeter, and the cells are predominantly mononuclear. Radiographs in early OA are usually normal, but as the disease progresses joint space narrowing, subchondral bone sclerosis, and osteophytes are observed.

Erosive OA is characterized by erosions on the joint surface, sclerosis of subchondral bone, and later by bony ankylosis. Radiographic abnormalities do not always correlate with clinical symptoms.

Treatment. The first-line therapy for OA is over-the-counter analgesics (e.g., acetaminophen, 1,000 mg four times a day, or even less if it is effective). If the patient remains symptomatic after 2 to 4 weeks, low-dose ibuprofen or nonacetylated salicylates are indicated. If the response is still inadequate after 2 to 4 weeks, the patient should be placed on a full dose of a nonsteroidal drug (Table 27- 2). In the patient with risk factors for upper gastrointestinal bleeding or ulcer disease, misoprostol or a proton pump inhibitor should also be taken. Intraarticular corticosteroid injections should be used judiciously in weight-bearing joints and those subjected to vigorous activity because in the absence of pain, the joint may be overused, leading to accelerated joint damage. No more than three injections per year should be placed into a weight-bearing joint. Corticosteroid injection of the first carpal metacarpal joint, a frequently symptomatic joint, often provides significant relief of pain and improvement of function. Injectable hyaluronan is approved for use on OA of the knee, and it has been shown to reduce the level of pain with few side effects in controlled studies (28). Glucosamine sulfate is also reported to be of benefit in OA and at least one animal model of OA suggests disease modification (29,30).

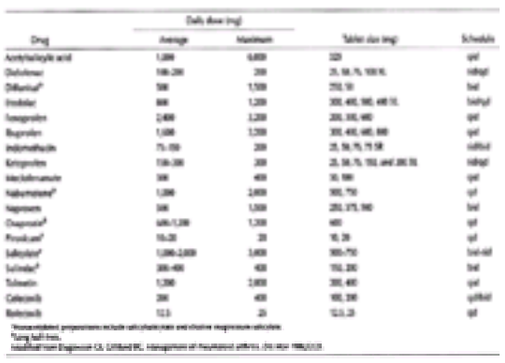

TABLE 27-2. Nonsteroidal antiinflammatory drugs for arthritis

Physical therapy plays an important role in improving muscle strength and range of motion. Affected joints should not be overused, especially in high-impact exercises. It is important to build up the muscles before using a joint that has been injured. Overweight patients benefit from weight reduction. Splinting a painful first carpal metacarpal joint is often quite helpful.

When a joint is severely damaged and painful, joint replacement should be considered. Total hip replacement has provided dramatic relief of pain and improvement of function. Placement of a knee, shoulder, or ankle prosthesis can also be quite helpful. Correction of a valgus or varus deformity by osteotomy of the knee, shoulder, or ankle improves weight distribution and extends the functional life of the joint. A prosthesis at the carpal metacarpal joint of the thumb helps some patients.

Rheumatoid Arthritis

Rheumatoid arthritis is an inflammatory polyarthritis of unknown etiology and typically involves peripheral joints in a symmetric distribution. The worldwide prevalence varies from 0.097 to 2.900 per 1,000 (31). In the United States, the prevalence is 1% to 2% (32). Women are more commonly affected: The average ratio is 3:1. An association also exists with HLA-DR4, the prevalence being 48% to 59% in persons with this genetically determined antigen compared with 8% to 16% in the general white population (33).

Etiology and Pathophysiology

Even though the etiology of rheumatoid arthritis remains unknown, significant advancements have been made in the understanding of the inflammatory events leading to joint injury and extraarticular manifestations. The hallmark of rheumatoid arthritis is the proliferation of synovium, which spreads over the articular surface as a pannus and damages cartilage, bone, and joint capsule. Harris has classified the pathophysiology of rheumatoid arthritis into four phases (34). Stage I is characterized by the presentation of an as yet unknown antigen or antigens to T cells. In stage II, proliferation of T and B cells, as well as synovial angiogenesis, occurs. In stage III, synovial hypertrophy begins and neutrophils accumulate within the joint in response to chemotactic factors produced by the fixing of complement and the production of cytokines by macrophages and synoviocytes such as tissue necrosis factor-a, interleukin-1 and -6, and granulocyte macrophage cell-stimulating factor. Of interest, cytokines from macrophages and synoviocytes are present in abundance in the rheumatoid joint but typical T-cell cytokines such as interleukin-2 and interferon-g are notably absent in established disease. Finally, stage IV is characterized by pannus formation and joint destruction.

B cells in the synovium have been shown to synthesize immunoglobulins, some of which have anti-IgG (rheumatoid factor) activity. Immune complexes consisting of IgG and anti-IgG form in the joint fluid and activate the complement system, which results in the formation of vasoactive and chemotactic factors. Polymorphonuclear white cells attracted to the joint by chemotactic factors phagocytize these immune complexes and secrete proteolytic enzymes within the synovial fluid. The most common form of rheumatoid factor is an IgM molecule directed against the *Fc* portion of IgG. IgG and IgA rheumatoid factors can also be found in patients with rheumatoid arthritis, and IgA rheumatoid factors in particular have been noted to be associated with more severe disease (35).

In addition to the complement system and cytokines, other inflammatory mediators are also involved. These include prostaglandins, leukotrienes, and free oxygen radicals. Prostaglandin E_2 is a potent vasodilator and enhances the action of histamine and bradykinin to produce edema and pain (36). Leukotrienes, another product of arachidonic acid metabolism, produce smooth muscle contraction, neutrophil chemotaxis, and vasodilatation (37). Superoxide anions released from neutrophils and macrophages during phagocytosis and oxygen radicals formed during metabolism of arachidonic acid also produce tissue damage (38).

The etiology of rheumatoid arthritis is uncertain, but research for many years has focused on the possibility of an arthrotropic infectious disease either triggering the inflammatory cascade or persisting in some form in the joint. An interesting piece of evidence in this light is the fact that rheumatoid arthritis was rare in the Old World before European exploration of the New World and seems to have appeared in Europe after this period (39). Rheumatoid arthritis has been diagnosed via skeletal remains in certain Native American population antedating the age of exploration, leading some to speculate that the disease is a New World phenomenon that was transmitted back to the Old World.

Symptoms and Signs

The typical patient with rheumatoid arthritis is a young to middle-aged woman who presents to her physician with a history of 2 to 3 months of joint pain and stiffness in her hands. Constitutional symptoms of fatigue, weight loss, and low-grade fever might also be present. The hands and other involved joints are stiff on arising in the morning. Stiffness might last from 30 minutes to 2 hours or longer. In severe disease, the patient might remain stiff most of the day.

Patients with involvement of the hands and wrists might have difficulty performing tasks such as lifting pots, washing their hair, and opening jars or doors. A firm handshake can be quite painful. Tingling and numbness of the thumb and index and middle fingers, which often occur at night, indicate compression of the median nerve by synovial tissue in the carpal tunnel (carpal tunnel syndrome). At times, the carpal tunnel syndrome produces pain radiating up the forearm and down into the hand. Rheumatoid arthritis can begin in the feet in the metatarsal phalangeal joints. It is not unusual for a patient to attribute metatarsalgia to improperly fitting shoes before seeking medical attention.

On physical examination, the joints are swollen, tender to palpation, and warm but not hot. The combination of synovial proliferation and fluid gives the joint a boggy sensation on palpation. Synovial proliferation in the flexor tendons of the fingers fills in the palm, giving it a flat appearance. The skin over the small joints often has a bluish discoloration resulting from venous engorgement. The hands may be cool and clammy. Hand grips are significantly reduced. Measurement of the hand grip provides a quantitative tool for assessing response to treatment. The range of joint motion is initially limited by pain and later by contractures. Ulnar deviation of the fingers at the metacarpal phalangeal joint is a common deformity in established disease and results from radial deviation of the wrist and slippage of the extensor tendons to the ulnar side of the metacarpal phalangeal joints. Another common deformity of the hand that develops in chronic disease is the swan-neck deformity.

This appearance results from flexion of the distal interphalangeal joint and metacarpal phalangeal joint with hyperextension of the proximal interphalangeal joint. The boutonniere deformity is caused by avulsion of the extensor hood over the proximal interphalangeal joint, leading to a flexion deformity of this joint and hyperextension of the distal interphalangeal joint. In advanced disease, subluxation and flexion deformities are common and involve the knees, ankles, elbows, wrists, shoulders, hands, and feet.

The course of rheumatoid arthritis is highly variable. Fifteen percent of patients have complete remission, whereas 10% or less go on to destructive disease that responds poorly to all forms of therapy. Most patients fall between these two groups with variable periods of remission and relapse. Some patients experience significant disability, whereas others respond to treatment and function quite well throughout their lifetimes. Prognostic factors for more severe disease include the presence of high titers of rheumatoid factor, presence of HLA-DR4, and more joints initially involved.

Laboratory Findings

Patients often have a normocytic normochromic anemia and an elevated erythrocyte sedimentation rate. Approximately 80% of patients have a positive rheumatoid factor test result. Radiography in early disease reveals only juxtaarticular osteopenia and soft tissue swelling. In more advanced disease one finds narrowing of joint spaces, erosions at the margins of the joint, and eventually subluxation. The synovial fluid usually has a white blood cell count that varies from 5,000 to 25,000 cells per cubic millimeter (most of the cells are neutrophils), decreased viscosity, and a low glucose level (see Table 27-1).

Treatment Philosophy. The goal of treatment is to reduce pain and swelling to preserve joint function and activities of daily living. Management of patients with rheumatoid arthritis requires coordinated, comprehensive care involving rheumatologists, the patient's primary care physician, orthopedic surgeons, rehabilitation physicians, occupational therapists, and physical therapists.

Medications remain the mainstay of the treatment of rheumatoid arthritis. Drug treatment can be separated into two broad categories (see Table 27-2). The first consists of drugs that have a rapid onset of action and do not significantly alter the ultimate course of rheumatoid arthritis. These drugs include salicylates and other nonsteroidal antiinflammatory agents. The second category consists of drugs that have a slow onset of action varying from weeks to 6 months or longer. These drugs have been referred to by many descriptions, including remitting drugs, slow-acting drugs, and disease-modifying antirheumatic drugs (DMARDs). These drugs have the potential to bring about complete or substantial improvement in clinical symptoms and signs. These drugs also bring about improvement of the laboratory indices, and roentgenography shows a decreased progression of joint destruction and, in some cases, actual disappearance of erosions. The drugs in this group include antimalarials, sulfasalazine, methotrexate, cyclosporine, and gold salts. The cytotoxic agents azathioprine and cyclophosphamide have also been shown to be remitting, but they are placed in a separate category because of their toxicity and concerns about their long-term safety.

The treatment of rheumatoid arthritis has undergone considerable rethinking over the years. The time-honored approach to the treatment of rheumatoid arthritis has been based on the *pyramid*, in large part because of the philosophy that rheumatoid arthritis was a disabling but otherwise benign disease. Via the treatment pyramid, patients would receive nonsteroidal antiinflammatory drugs (NSAIDs) or salicylates along with education and physical and occupational therapy and, as the disease progressed, more aggressive therapy with DMARDs of increasing toxicity would be used. In 1965, up to 120 months would pass before a DMARD would be started (40). Because a majority of patients with rheumatoid arthritis develop erosions by 2 years of disease and it has been found not to be the benign disease it was once thought to be, it has been suggested that we invert the pyramid (i.e., begin with aggressive therapy up front to prevent erosive changes to joints that are generally not reversible and thus prevent the disability and potentially the mortality caused by unchecked rheumatoid arthritis) (41,42 and 43). Currently, most rheumatologists start a DMARD at approximately 3 months of persistent synovitis, especially in a patient with a positive rheumatoid factor. In addition, combination therapy with more than one DMARD has been shown to be more effective and no more toxic than single-agent therapy (see following discussion).

Current Management of Rheumatoid Arthritis

Nonsteroidal Antiinflammatory Drugs. NSAIDs are usually given to most patients early on in the course of rheumatoid arthritis. NSAIDs are antiinflammatory and analgesic drugs and should be given at least 2 to 3 weeks before their clinical effectiveness can be fully evaluated. It is usually possible to find one of these drugs that will help the patient. Salicylates or NSAIDs usually can be continued when a disease-modifying drug is administered. The currently available NSAIDs, along with their daily doses, are shown in Table 27-2.

The side effects of NSAIDs are somewhat similar (44). These agents can cause gastritis and are associated with peptic ulcer disease. Other gastrointestinal manifestations include flatulence, bloating, and diarrhea, which tend to be more common with indomethacin and sodium meclofenamate. Mild elevations of the liver enzymes occur, but use of these drugs seldom leads to serious liver damage. Asthma can be exacerbated. Many of these drugs also cause urticaria or angioedema and, rarely, an anaphylactic reaction. Interstitial nephritis has also been observed. NSAIDs reduce renal blood flow by inhibiting renal prostaglandin synthesis and can precipitate renal failure. Rashes, including Stevens-Johnson syndrome, have been reported. NSAIDs can be associated with headache, confusion, and dizziness. Aseptic meningitis is a rare complication, reported most often with ibuprofen. NSAIDs interfere with platelet function, which returns to normal within five half-lives after stopping the drug. The anticoagulant effect of warfarin (Coumadin) is also enhanced by several of the NSAIDs.

Disease-Modifying Agents. Patients with early mild synovitis are generally started on hydroxychloroquine (45). This agent takes 8 to 12 weeks before it begins to affect the synovitis and may take up to 6 months in some patients. Its mechanism of action is thought to be on the basis of increasing the pH of the vacuoles in antigen-presenting cells and gently disrupting the interaction of the major histocompatibility complex, with antigen thus affecting the way antigen is presented to T cells (46).

Hydroxychloroquine is dosed by weight at 6.5 mg per kg per day in divided doses. Doses higher than this increase the risk for ocular toxicity. Common side effects include diarrhea, gastrointestinal upset, and rash. Serious side effects are listed in Table 27-3 as well as a monitoring schedule. Improvement in morning stiffness and pain, as well as a decrease in the number of tender and swollen joints, and a reduction in acute-phase reactants (i.e., erythrocyte sedimentation rate or C-reactive protein) are measures of success. Patients with more significant synovitis may be candidates for either sulfasalazine or methotrexate as single agents.

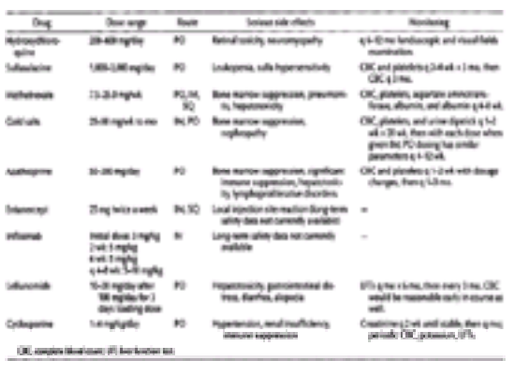

TABLE 27-3. Disease-modifying antirheumatic drugs

Sulfasalazine is a combination of sulfapyridine and 5-aminosalicylic acid, which is cleaved by gut bacteria into two compounds. It is thought that the sulfapyridine moiety is the active one in rheumatoid arthritis. It is dosed generally at 2,000 mg in two divided doses and monitored as noted in Table 27-3. It takes 4 to 8 weeks for an effect to be apparent in most patients and in some may be up to 12 weeks. Common side effects include gastrointestinal upset, diarrhea, and rash. Severe agranulocytosis can occur and is idiosyncratic. Drug cessation resolves the cytopenias in most cases, but there have been a few cases requiring granulocyte colony-stimulating factor therapy. G6PD deficiency may lead to severe anemia in affected patients and should be checked before starting therapy if suspected.

The other commonly used DMARD in single therapy is methotrexate. The dose range and other characteristics are presented in Table 27-3. Methotrexate is a dihyrofolate reductase inhibitor. Its mode of action is uncertain but may be caused by an increase in adenosine, an antiinflammatory compound (47). Methotrexate has the advantage of being given once a week and can be given both orally and intramuscularly. Methotrexate begins to be effective generally in 3 to 8 weeks after

initiation of therapy. Common side effects include stomatitis, nausea, gastrointestinal upset, and mild hair thinning. Stomatitis in particular might respond to the addition of 1 mg of folic acid daily without affecting its activity in rheumatoid arthritis. The response rate in studies is approximately 75% and approximately 50% of patients are still on methotrexate at 5 years of therapy compared with 20% or less for the other DMARDs (48).

For those who have a partial response to a single DMARD, the DMARD is not typically stopped but additional DMARDs are added. Combinations found useful include hydroxychloroquine, sulfasalazine, and methotrexate or cyclosporine added to methotrexate (49,50). Azathioprine is typically used in some form of combination therapy and cyclophosphamide is given to patients with severe unresponsive disease and to those with rheumatoid vasculitis (see following discussion). Most of the combination regimens are given under the direction of a rheumatologist.

Two medications have recently been approved for the treatment of rheumatoid arthritis. Entanercept and infliximab are anti–tumor necrosis factor-a agents that have been shown to be quite effective in reducing joint counts and acute-phase reactants. Etanercept is administered intramuscularly twice weekly, and infliximab is given intravenously at 0, 2, and 6 weeks, and then every 8 weeks thereafter. Both medications reduce joint swelling and pain, and decrease morning stiffness and fatigue. They are usually given to patients on methotrexate who have had only a partial response. Leflunomide is a pyrimidine synthesis inhibitor also shown to be effective in reducing joint counts, acute-phase reactants, and retarding joint erosions. After an initial loading dose of 100 mg for 3 days, the usual daily dose is 20 mg per day.

Glucocorticoids. The antiinflammatory mechanisms of glucocorticoids include altering leukocyte traffic and function, stabilizing lysosomal membranes of neutrophils and monocytes, and inhibiting the secretion of destructive enzymes including collagenase and elastase (51). They also inhibit the products of arachidonic acid metabolism including prostaglandins and leukotrienes.

Studies have shown that low-dose glucocorticoids (defined as 7.5 mg or less of prednisone or the equivalent of another short- acting glucocorticoid) given in the morning by 10 am reduces the progression of joint damage (52). Also, the hypothalamic-pituitary-adrenal axis remains intact when low doses of prednisone are used. Low-dose prednisone treatment can be especially beneficial during initiation of treatment with a DMARD. The prednisone dose can be tapered once the patient has had a response to the remitting agent.

In patients on corticosteroids, it is important to give calcium in the range of 1,000 to 1,500 mg per day, and vitamin D, 400 units a day. Patients should be monitored closely for evidence of hypercalcemia and hypercalcinuria. A bisphosphonate (e.g., alendronate) may also reduce the bone loss of calcium in patients on corticosteroids.

Judicious intraarticular administration of corticosteroids can be quite useful in the treatment of rheumatoid arthritis. It is recommended that an individual joint be injected no more than three times at intervals of 6 months or longer. In a badly damaged joint or one that is soon to be replaced by a prosthetic joint, corticosteroids may be injected more frequently.

Surgery

Indications for orthopedic surgery in rheumatoid arthritis are twofold: pain unresponsive to medical management and loss of function. Synovectomy of selected joints provides alleviation of symptoms and improvement of function in the first year after operation, but may not provide a long-term effect (53). Removal of synovial tissue from the wrist and dorsal tendon sheath and resection of the ulnar head might prevent rupture of the extensor tendon. Patients with severely deformed hands can benefit from metacarpal phalangeal arthroplasty. Patients with severe pain and loss of function can benefit from total joint replacement, especially the knee or hip. Metatarsal head resection can be of tremendous help in patients with painful metatarsal heads. Intermittent splinting of selected joints is beneficial.

Important Complications of Rheumatoid Arthritis Presenting with Pain

Carpal Tunnel Syndrome. Carpal tunnel syndrome is a common problem in rheumatoid arthritis caused by wrist synovitis that can lead to median nerve compression. Therapy is generally directed at the rheumatoid synovitis with DMARDs and antiinflammatory agents. A wrist injection with corticosteroids may be helpful in many cases. Carpal tunnel release may be necessary in some cases.

Rheumatoid Vasculitis. This is a potentially life-threatening complication. Patients with long-standing, seropositive, erosive rheumatoid arthritis are generally at risk for this small to medium vessel vasculitis similar to polyarteritis nodosa. Patients may present with digital gangrene or symptoms of mononeuritis multiplex (i.e., footdrop). More serious complications include intestinal perforation or cardiac involvement. Kidneys are less commonly involved than in polyarteritis nodosa. Treatment is with cyclophosphamide and high-dose prednisone.

Cervical Spine Disease. The synovial portions of the cervical spine can be involved in rheumatoid arthritis. This can lead to C1-2 instability or subaxial instability. Symptoms may be caused by cord or vascular compression and may include neck pain, shocklike sensation up or down the spine, and intermittent loss of consciousness when vertebral artery compression occurs. Before surgery, all patients with long-standing rheumatoid arthritis should have a set of lateral flexion and extension views of the cervical spine taken to evaluate the cervical spine for C1-2 subluxation.

Septic Arthritis. Patients with rheumatoid arthritis are at increased risk of septic arthritis caused by abnormal joint architecture, use of immunosuppressive drugs, and skin breakdown over high-pressure, biomechanically abnormal sites such as the feet. Patients often present with one joint out of proportion to the others in terms of pain or swelling and may have a paucity of systemic symptoms typical in nonrheumatoid patients. Detection is imperative because of the high mortality in such patients (i.e., 20% mortality if a single joint is infected and over 50% in patients with multiple joints involved) (54).

Ankylosing Spondylitis

Ankylosing spondylitis is an inflammatory arthritis involving sacroiliac joints and the spine (55). Inflammation also occurs at sites of tendon and ligament insertions (enthesitis). Hips and shoulders can also be affected. Peripheral arthritis is less common. Onset of disease is usually in the second or third decade, and men are predominantly affected. The histocompatibility antigen HLA-B27 is found in 90% or more of patients, fulfilling clinical criteria for ankylosing spondylitis (56). The normal frequency of HLA-B27 in the white population is approximately 7%.

Pathophysiology

Synovitis in the apophyseal and costovertebral joints of the spine and peripheral joints is characterized by synovial hyperplasia with focal accumulation of lymphoid and plasma cells. Inflammation also involves cartilaginous joints, which include the intervertebral disks, manubriosternal joint, and symphysis pubis. Ossification of the outer layers of annulus fibrosus of the disk and the inner layers of the longitudinal ligaments forms syndesmophytes that eventually interconnect to give the spine the appearance of bamboo.

A common site of inflammation is at the insertion of tendons, ligaments, and joint capsule to bone. New bone formation can occur at these sites, particularly at the greater trochanter, pelvis, and heels. Focal medionecrosis of the proximal aorta leads to dilation of the aortic valve and aortic regurgitation. Inflammation of the atrioventricular bundle produces cardiac conduction abnormalities.

Symptoms and Signs

The onset of the disease is usually in the second and third decades. The patient initially notes low back pain and stiffness, especially on arising in the morning. The stiffness of the back lasts for several hours in the morning and occurs after periods of activity during the day. The pain might radiate into either buttock, extend down the back of the leg to the knee, and can be mistaken for the pain caused by herniated disk. The pain might alternate from side to side. Involvement of the hips and shoulders causes pain, stiffness, and decreased motion. Peripheral joints other than the hips or shoulders are affected relatively infrequently. Costovertebral joint arthritis can cause chest pain similar to that of angina pectoris or pleurisy. The entire spine can become ankylosed. Atlantoaxial subluxation (with the potential danger of spinal cord compression) can occur, but this is observed less often in ankylosing spondylitis than in rheumatoid arthritis. The fused spine, especially the neck, is susceptible to fractures with trauma.

Cardiac abnormalities include aortic regurgitation caused by aortic root dilatation and varying degrees of heart block. Acute iritis occurs in approximately one-third of

the patients. A rare manifestation is fibrosis of the upper lobes of the lung, which occurs late in the course of the disease. Patients occasionally have significant constitutional symptoms of fever and weight loss.

Ankylosis develops over several years, usually 10 years or more. The extent of involvement varies among patients and ranges from bilateral sacroiliitis to complete ankylosis of the spine. The spondylitis sometimes skips segments of the back.

On physical examination, sacroiliac tenderness is elicited by direct palpation or by maneuvers that stress the joint. A loss of normal lumbar lordosis occurs, giving the lumbar area an ironed-out appearance. Flexion is limited. Tenderness can be present over costovertebral joints, iliac crests, greater trochanter, and heels. Chest expansion is limited. In advanced disease the spine becomes rigid, fusing in varying degrees of flexion.

Laboratory Findings

The sedimentation rate can be elevated, and a mild hypoproliferative anemia can occur. The rheumatoid factor test result is negative. The synovial fluid is inflammatory (see Table 27-1). Radiography of the sacroiliac joints in early disease shows blurring and irregularity of the joint margins, followed later by subchondral erosions, sclerosis, and eventually fusion. Bony spurs appear at tendinous insertions such as the sites of attachment of the Achilles tendon and plantar fascia. Radiography shows a straight lumbar spine, squared vertebrae, and syndesmophytes. Syndesmophytes extend along the outer aspect of the intervertebral disk and eventually form a bridge between adjacent vertebrae (bamboo spine).

Treatment

Nonsteroidal Antiinflammatory Drugs. NSAIDs (see Table 27-2) are especially useful in reducing inflammation and relieving pain, but they may not change the course of the disease. It is speculated, but not proven, that NSAIDs may encourage the patient to be more mobile and possibly lessen the chance of spine fusion. Preferred agents include indomethacin or a once-a-day agent such as piroxicam because of their antiinflammatory activity. Any antiinflammatory agent chosen usually needs to be dosed at an antiinflammatory level (i.e., upper limit of dosing range) for benefit.

Disease-Modifying Antirheumatic Drugs. Sulfasalazine has been shown to be beneficial in ankylosing spondylitis, especially when peripheral joints are involved (57,58). It can also lower levels of acute-phase reactants, suggesting disease-modifying activity. Methotrexate has also been used for ankylosing spondylitis, but controlled trails are lacking.

Physical Therapy. Physical therapy is directed at maintaining the erect posture of the patient. Patients should be encouraged to sleep in the prone position and to avoid using a pillow when sleeping on their backs. Anterior uveitis or iritis can be treated with intraocular corticosteroids. Patients with severe destructive hip disease can benefit from total hip replacement.

Important Complications of Ankylosing Spondylitis Presenting with Pain

Cauda Equina Syndrome. Patients with cauda equina syndrome generally have long-standing ankylosing spondylitis. The patient generally presents with progressive lower extremity weakness, pain, and loss of sensation in the lower extremities and perineum. Impotence and overflow incontinence are also frequently occurring problems. Radiographically, large dorsal diverticula are seen on myelography or magnetic resonance imaging (59). Electromyography demonstrates multiroot involvement. Therapy with high-dose corticosteroids and surgery both have been disappointing.

Spondylodiskitis. Spondylodiskitis is a rare complication of long-standing ankylosing spondylitis. Patients have persistent mechanical-type back pain (pain with activity) rather than inflammatory low back pain (pain in the morning or with rest). It is caused by a mobile vertebral segment surrounded by fused segments. The focus of activity at the one segment may lead to significant inflammation and damage to the adjacent vertebral bodies, simulating infection. Infection generally needs to be ruled out and treatment is directed to immobilizing the segment either via brace and allowing it to fuse or refuse; occasionally it may need to be surgically fused (60).

Vertebral Fracture. Vertebral segments connected by syndesmophytes are subject to fracture with even minor trauma (60). The usual location for such fractures are the C-5–7 vertebral segments; the fractures are typically caused by a hyperextension injury. Patients suspected of fracture should be evaluated by computed tomographic scan or bone scan to try to identify a potential fracture site, as plain radiography may not be able to demonstrate the fracture. Patients with such fractures have a relatively high morbidity and mortality even if identified, because of surgery or prolonged immobilization usually required for treatment. Only 40% of such patients return to their former level of activity.

Chronic Enthesitis. Enthesitis of Achilles tendon, plantar fascia, and occasionally the ribs can be a chronic source of pain and may be more resistant than spondylitis to usual therapies (61). In such cases indomethacin at maximum dose, or use of a DMARD such as methotrexate or sulfasalazine may be warranted. Refractory patients may benefit from low-dose radiation to the heel (62).

Reiter's Syndrome

Reiter's syndrome is defined as an asymmetric arthropathy involving predominantly joints of the lower extremities plus one or more of the following: urethritis or cervicitis, dysentery, mucocutaneous lesions, and inflammatory eye disease. It is also defined as an episode of arthritis lasting longer than 1 month that is associated with urethritis or cervicitis (63,64). The histocompatibility antigen HLA-B27 is present in approximately 80% of patients (65).

There appears to be a relationship between certain infections and a specific genetic background. Reiter's syndrome can follow infections with *Shigella*, *Salmonella*, *Campylobacter,* or *Yersinia* (64,66). An association also exists with urethritis associated with *Chlamydia* or *Mycoplasma* infections. In addition, Reiter's syndrome has been associated with human immunodeficiency virus (HIV) infection. Reiter's syndrome develops in patients without these infections, however, and most patients with nonspecific urethritis do not develop this syndrome. The risk of an individual who has a positive result for HLA-B27 with nonspecific urethritis developing Reiter's syndrome is in the range of 20%. Up to 3% of individuals with nonspecific urethritis have been shown to develop a reactive arthritis. Reiter's syndrome has a worldwide distribution and occurs more often in men. In postdysenteric Reiter's syndrome, the gender distribution is equal.

Symptoms and Signs

Arthritis affects several joints in an asymmetric fashion; knees and ankles are most often involved. Patients also experience pain in the feet and ankles secondary to inflammation at the insertion of the Achilles tendon and plantar fascia. Joints can remain swollen for several months. Swelling of two adjacent interphalangeal joints and adjoining tendon sheath results in a sausage digit or dactylitis. In approximately 20% of patients, spinal involvement occurs. Sacroiliitis is usually unilateral and spine involvement mild. Patients can also experience chest pain caused by inflammation at the tendinous insertions of the intercostal muscles.

The mucocutaneous lesions of Reiter's syndrome include oral ulcers, balanitis, and keratoderma blennorrhagica. The oral ulcers are shallow and irregular, and have a slightly erythematous base. These lesions are only present for several days. Balanitis usually begins as small painless vesicles that become hyperkeratotic. These lesions are painless and remain crusted in the circumcised patient. In the uncircumcised patient, lesions are moist and can become secondarily infected. Keratoderma blennorrhagica most commonly involves the feet. Sometimes it involves the hands, but it can be present almost any place on the body.

Conjunctivitis involves one or both eyes. Uveitis also occurs. Urethritis can precede or accompany the arthritis. Prostatitis is present in approximately 80% of patients.

As with ankylosing spondylitis, some patients may develop dilatation of the proximal aorta leading to aortic valve insufficiency.

The course of Reiter's syndrome is recurrent or persistent, with only an occasional patient experiencing transient, self-limited disease. In some patients sexual intercourse with a certain partner appears to lead to an exacerbation of Reiter's syndrome. These patients should be advised to use a condom even though the benefit of this practice is questioned by some. No evidence exists that the use of an antibiotic prevents or alters the course of Reiter's syndrome.

Laboratory Findings

Routine laboratory test results are usually normal. The sedimentation rate is quite variable and does not correlate with disease activity. Synovial fluid shows an elevated white cell count ranging from 5,000 to 50,000 cells per cubic millimeter, predominantly neutrophils. Radiography shows juxtaarticular osteopenia, joint space narrowing, and bone erosions. Periostitis is present adjacent to the involved joints and at the insertion of tendons and fasciae. Erosions, sclerosis, and irregularity of the sacroiliac joint can be present and are usually unilateral. Changes of spondylitis are usually asymmetric, occur at various levels of the spine, and are similar to those seen in psoriatic arthritis. Testing for HLA-B27 is not necessary for diagnosis. This test should be reserved for patients who have asymmetric arthritis without other evidence of Reiter's syndrome.

Treatment

Treatment of Reiter's syndrome is similar to that of ankylosing spondylitis. NSAIDs are first-line therapy followed by sulfasalazine in refractory cases. Methotrexate or azathioprine can be used in more severe disease. Intraarticular corticosteroid can also be useful. Data also exist to suggest that treatment of Reiter's syndrome or reactive arthritis with several weeks of antibiotics useful against *Chlamydia* may affect the course of the subsequent illness (67).

Complications of Reiter's Syndrome Associated with Chronic Pain

Rare patients may have more persistent inflammatory eye disease requiring continuous ophthalmology care.

For a discussion of chronic enthesitis, see Ankylosing Spondylitis.

Psoriatic Arthritis

Arthritis appears in up to 20% of patients with psoriasis (68). Hereditary factors play a role: An increased prevalence of psoriatic arthritis occurs in first-degree relatives. The epidemiology and pathogenesis of psoriatic arthritis are not known. An association with HLA-B27 is seen in psoriatic arthritis with spondylitis, but not in patients with peripheral arthritis. Onset of psoriatic arthritis is usually in the third or fourth decade, and the gender ratio is approximately equal. In most patients, psoriasis precedes the arthritis by several years. Most patients with psoriatic arthritis have only a few joints that are involved, and, overall, the prognosis tends to be better than in rheumatoid arthritis. Psoriatic arthritis has been noted in patients with HIV infection.

Symptoms and Signs

Several patterns of arthritis are observed in patients with psoriasis. The majority of patients have an asymmetric oligoarthritis involving the proximal joints of the hands and feet. In approximately 10% of patients, arthritis affects predominantly the distal interphalangeal joints and is usually accompanied by psoriasis of the adjacent nail. Other patients have a symmetric polyarthritis similar to that seen in rheumatoid arthritis. These patients usually have negative results for rheumatoid factor. If the rheumatoid factor test result is positive, the patient probably has both rheumatoid arthritis and psoriasis. Patients can also manifest sacroiliiitis, usually unilateral, and variable degrees of spondylitis. In some patients the spine becomes ankylosed. A few patients have a severe, destructive, and deforming polyarthritis referred to as *arthritis mutilans*.

Joints are swollen, warm, and tender, and a digit may have the appearance of a sausage. Contractures and ankylosis of joints occur with long periods of persistent joint inflammation. In most cases there appears to be no definite correlation between the degree of skin involvement and joint disease.

Laboratory Findings

Laboratory findings include an elevated sedimentation rate and a hypoproliferative anemia. The rheumatoid factor test result is negative. The synovial fluid shows evidence of inflammation with elevated white cell counts; the cells are predominantly polymorphonuclear. A somewhat characteristic radiographic finding is that of the pencil-in-cup deformity caused by osteolysis, or whittling of the distal end of the middle phalanx, which produces a pencil point that projects into a widened cuplike erosion in the adjacent surface of the distal phalanx. Radiography shows joint space narrowing, erosions, osteolysis, and ankylosis, depending on the degree of clinical severity. The radiographic findings of the spine are similar to those found in patients with Reiter's syndrome.

Treatment

Initial treatment of psoriatic arthritis is aspirin or other NSAIDs (see Table 27-2). In patients with progressive disease, gold, sulfasalazine, and even hydroxychloroquine have been used successfully (69). Methotrexate and cyclosporine have also been used to treat both the arthritis and the skin disease. Low-dose oral corticosteroids as well as intraarticular corticosteroids can also be used. The tapering of corticosteroids in patients who have been on moderate to large doses may exacerbate the skin disease. Recently, statistics have shown that psoriatic arthritis responds well to etanercept, a TNF-a antagonist.

Important Complications of Psoriatic Arthritis Presenting with Pain

See Ankylosing Spondylitis for a discussion of chronic enthesitis. For a discussion of carpal tunnel syndrome, see Rheumatoid Arthritis.

Arthritis Associated with Inflammatory Gastrointestinal Disease

Both ulcerative colitis and regional enteritis (Crohn's disease) are associated with peripheral arthritis and spondylitis (70). Peripheral arthritis occurs in approximately 10% to 20% of patients with inflammatory bowel disease. Onset of peripheral arthritis is usually in the third or fourth decades. Both genders are equally affected. The arthritis usually follows the onset of colitis by months to years and involves only one or two joints. Arthritis is acute, lasts several days to several weeks, and leaves no residual damage. The knees and ankles are most frequently affected.

Ankylosing spondylitis is also associated with inflammatory bowel disease. The gender distribution is equal, in contrast to the male predominance observed in primary ankylosing spondylitis. The majority (70%) of patients with spondylitis associated with inflammatory bowel disease has positive results for HLA-B27. Asymptomatic bilateral sacroiliiitis can be found in up to 15% of patients with inflammatory bowel disease. Frequency of HLA-B27 is not increased in patients with only peripheral arthritis. Synovial fluid analysis shows an inflammatory effusion.

Treatment

Peripheral joint symptoms are managed with salicylates or other NSAIDs (see Table 27-2). NSAIDs, however, may lead to an exacerbation of the inflammatory bowel disease. Peripheral arthritis often disappears after colectomy. Treatment of the spondylitis is similar to that described for ankylosing spondylitis.

Arthritis Caused by Deposition of Calcium Pyrophosphate

Deposition of calcium pyrophosphate dihydrate in the joint produces both an acute and chronic form of joint disease (71,72). The acute or subacute form is referred to as *pseudogout* because of its similarity to gout. *Chondrocalcinosis* refers to calcium pyrophosphate deposits in articular tissue that are detectable radiographically and occurs in the absence of inflammatory arthritis. Pseudogout affects persons over the age of 40, men predominately. The knee is the most frequent site of acute arthritis, but the hip, shoulder, ankle, wrists, and bursae can be affected. Approximately 3% to 5% of the adult population have calcium pyrophosphate deposits in knee joints at the time of death. This disorder is associated with OA.

Three forms of CPDD are recognized: a hereditary form, CPDD associated with metabolic and other diseases, and an idiopathic form. The frequency of OA in CPDD varies from 40% to 70%. CPDD occurs in 41% of patients with hemochromatosis and in 5% to 15% with hyperparathyroidism (73). An association is suspected in patients with diabetes mellitus, hypophosphatemia, Wilson's disease, ochronosis, and hypothyroidism.

Pathophysiology

The initial site of crystal formation is in articular cartilage. In idiopathic CPDD it is not clear whether the primary event is deposition of crystals in cartilage or whether the crystals develop as a consequence of disturbed cartilage metabolism. Increased inorganic pyrophosphate is found in the synovial fluid and probably reflects a local disorder of pyrophosphate metabolism leading to deposition of calcium pyrophosphate crystals in the joint (74,75). Elevated levels are also found in patients with OA. Acute arthritis is brought on by shedding of crystals into the joint space. The mechanism for crystal shedding is the lowering of either calcium or pyrophosphate ions in synovial fluid (76,77). The decreased concentration of ionized calcium results in movement of crystals from cartilage into synovial fluid. Crystals can also be shed into the synovial fluid as a consequence of mechanical disruption of cartilage. Attacks can follow trauma. In addition, crystals can be released as a result of degradation of cartilage by enzymes from polymorphonuclear white cells during episodes of bacterial arthritis or other forms of inflammatory arthritis. Increased enzyme activity is also present in OA.

Calcium pyrophosphate dihydrate crystals are capable of inducing an inflammatory response. Injection of these crystals into a normal joint produces an inflammatory response (78). Crystals bind IgG and are phagocytized by polymorphonuclear white cells, resulting in the release of cytoplasmic and lysosomal enzymes.

Symptoms and Signs

Several patterns of joint disease are recognized (71). In approximately 25% of patients, CPDD presents as an acute arthritis involving a single joint or a few joints at any given time. The clinical picture mimics that of acute gout, which accounts for the term *pseudogout*. The onset of joint swelling and pain is abrupt and severe and usually reaches a peak within 24 to 36 hours. An attack can last up to 14 days. The joint is swollen, red, and tender. The most common site of involvement is the knee, but attacks can involve other large joints such as the ankles, wrists, elbows, or hips. Also, the lumbar and cervical spine can be involved. Trauma, surgery, or severe medical illness can precipitate an attack. The same joint is often involved in subsequent attacks. Radiographic evidence of chondrocalcinosis may be present in affected joints.

Approximately 5% of patients with CPDD have a form of disease that mimics rheumatoid arthritis (*pseudorheumatoid disease*). Involvement of multiple joints, synovial proliferation, limitation of joint motion, and joint deformity can develop. Patients experience fatigue and morning stiffness. To further confuse the issue, calcium pyrophosphate deposition can occur in rheumatoid arthritis.

CPDD also occurs in a chronic form that is similar to OA. Multiple joints are involved and include the knees, wrists, metacarpal phalangeal joints, hips, shoulders, elbows, and ankles. The disease involves middle-aged to elderly patients, predominantly women. CPDD can mimic neuropathic arthropathy and can also occur in patients with neuropathic joint disease.

The diagnosis of calcium pyrophosphate disease is established by identification of calcium pyrophosphate crystals in synovial fluid, both free and in polymorphonuclear white cells. The crystals appear as short rods, rhomboids, and cuboids, and they have a sign of weakly positive birefringence under compensated polarized light. Radiography shows calcification in articular hyaline cartilage that is parallel to and separated from the subchondral bone. Calcifications in fibrocartilage are thick and irregular densities and are found in the menisci of the knee, symphysis pubis, annulus fibrosus, and the triangular cartilage of the wrist. Calcifications also occur in the Achilles, supraspinatus, and triceps tendons, but can involve any tendon. Changes in the joint are similar to those seen in OA with sclerosis of subchondral bone, joint space narrowing, and large subchondral cysts.

Treatment

The NSAIDs (see Table 27-2) are effective in the treatment of acute and chronic joint disease. An NSAID is given for 10 to 14 days in patients with acute pseudogout. The drug can be continued indefinitely in patients with chronic calcium pyrophosphate disease associated with OA. When an NSAID is contraindicated, another method of treatment for an acute attack is prednisone, starting with 40 mg the first day and gradually tapering over a 7-day period. Colchicine, 0.6 mg twice a day, is started on day 3 or 4 and continued for several weeks to avoid a flare of arthritis after prednisone is discontinued. Colchicine, 0.6 mg twice a day, can also be given prophylactically to reduce the number and length of attacks (see colchicine in section on gout). Aspiration of the involved joint followed by an injection of glucocorticoids reduces pain and swelling.

Hydroxyapatite Arthropathy

Arthritis is caused by deposition of calcium hydroxyapatite crystals in the joint (71). Knees and shoulders are most frequently involved. The Milwaukee shoulder, also known as *cuff tear arthropathy*, is an entity observed in elderly women with glenohumeral OA, rotator cuff tears, and joint effusions. Joint fluid from the shoulder has few white cells, but it has elevated levels of collagenase and neutral proteases. Calcium hydroxyapatite and calcium pyrophosphate crystals are often found together in the joint. Hydroxyapatite crystals are extremely small, ranging from 0.1 to 1 mm in length. The calcium components in the synovial fluid can be detected by staining with alizarin red S (79). Definitive diagnosis depends on electron microscopy or x-ray diffraction studies. Radiographically, intraarticular calcifications of hydroxyapatite have a diffuse and amorphous pattern. Treatment of hydroxyapatite disease is with NSAIDs, repeated joint aspirations, and rest of the involved joint.

Gout

Gout is characterized by elevated serum urate levels, recurrent attacks of acute arthritis involving a single joint or a few joints at any given time, and deposition of monosodium urate dihydrate (tophi) in and around joints, leading in some patients to a deforming and crippling arthritis. Renal stones also may form. These features are present in varying combinations (80).

Recognized since ancient times, gout has been depicted in caricatures as affecting well-fed aristocrats overindulging in rich foods and wines. The disease has been referred to as the *king of diseases* and the *disease of kings* (80,81).

The normal serum urate concentration is 5.1 ± 1.0 mg per dL in men and 4.0 ± 1.0 mg per dL in premenopausal women. After menopause, the level in women approximates that of men. The level in young boys is 3 to 4 mg per dL and increases to adult levels at puberty. Serum urate levels show a positive correlation with weight and surface area in various racial groups (82). The prevalence of gout varies from 0.20 to 0.35 per 1,000 (83,84). The prevalence of gout increases with age and increasing levels of serum urate. In one study of men whose ages ranged from 35 to 44 years old, the prevalence was 15 per 1,000 men (85).

The familial incidence of gout varies widely. In one study, approximately 40% of the patients gave a positive family history of gout (86). Serum urate levels appear to be controlled by multiple genes. Both genetic and environmental factors play a role in the expression of hyperuricemia and gout. For example, higher serum urate levels are found in Filipinos living in the United States compared with racially identical persons living in the Philippines. These persons are unable to excrete the greater uric acid load resulting from the higher purine content of the diet eaten in the United States (87).

Etiology and Pathophysiology

Uric acid is a product of purine metabolism (80). The serum urate concentration depends on the rate of uric acid production and excretion. Approximately two-thirds of uric acid is excreted in the urine and one-third into the gastrointestinal tract. Normally, uric acid is completely filtered through the glomeruli and completely reabsorbed in the proximal tubule. Secretion of uric acid occurs in the proximal tubule, followed by a second reabsorption in the proximal tubule.

Primary gout is defined by the absence of other diseases or conditions such as drugs that lead to hyperuricemia and gout. Approximately 90% of patients with primary gout have decreased renal clearance of uric acid resulting from reduced glomerular filtration, increased tubular reabsorption, reduced tubular secretion, or combinations of these factors. Evidence for a molecular renal defect is still lacking in the majority of patients.

Approximately 10% of patients are overproducers of uric acid. Overproduction is defined as the urinary excretion of more than 800 to 1,000 mg of uric acid in 24 hours while the patient is on a regular purine diet.

Two inborn errors of purine metabolism make up a small number of primary gout patients who are overproducers of uric acid. The first disorder is caused by a partial

deficiency of the enzyme hypoxanthine-guanine phosphoribosyltransferase, which catalyzes conversion of hypoxanthine to inosinic acid and guanine to guanylic acid (80). These patients usually experience the onset of gouty arthritis in the second or third decade and have a high frequency of uric acid stones. The disease is inherited as an X-linked disorder, therefore affecting male subjects, with women as carriers. Some of these patients also have dysarthria, hyperreflexia, lack of coordination, and mental retardation. A severe form of this disorder with almost a complete deficiency of this enzyme, referred to as the Lesch-Nyhan syndrome, is characterized by self-mutilation, choreoathetosis, and mental retardation (88,89). This disorder is classified under secondary hyperuricemia or gout because the neurologic disorder is predominant.

The second disorder is caused by increased 5-phosphoribosyl-1-pyrophosphate synthetase activity leading to elevated levels of intracellular 5-phosphoribosyl-1-pyrophosphate and overproduction of uric acid (80,90). This disorder is also genetically X- linked. The onset of gouty arthritis is in the second or third decade, and a high frequency of uric acid stones occurs.

Secondary gout is defined as gout or hyperuricemia occurring in patients with other disorders. Overproduction of uric acid results in hyperuricemia in patients with disorders associated with increased cell proliferation and turnover of nucleic acids. These disorders include myeloproliferative and lymphoproliferative diseases, multiple myeloma, polycythemia, pernicious anemia, hemoglobinopathies, and some carcinomas. The hereditary disorder glucose 6-phosphatase deficiency (von Gierke's glycogen storage disease) is also manifested by overproduction of uric acid.

Secondary hyperuricemia can also result from renal failure or the effects of drugs or toxins on renal clearance of uric acid. Diuretic agents, low doses of aspirin (less than 2 g per day), alcohol, ethambutol, cyclosporine, and lead are some of the agents that decrease the clearance of uric acid and thereby raise the serum urate level.

Pathophysiology of Acute Gouty Arthritis

Acute gouty arthritis results from the inflammatory reaction to urate crystals that form in the joint space or are released into the joint from synovium or articular cartilage. Plasma becomes supersaturated with urate at concentrations of approximately 7 mg per dL (91). Factors in addition to supersaturation of plasma urate are necessary for crystal precipitation because most patients with hyperuricemia do not develop gout. The lower temperatures found in peripheral joints or tissues might contribute to urate precipitation at these sites. Urate is less soluble at 32°C, which is the temperature observed in a normal knee, compared with the core body temperature of 37°C (92). Another mechanism for urate precipitation might be the faster reabsorption of extracellular fluid than urate from the joint space, resulting in a transient increased urate concentration and crystal formation (93). Trauma or impact loading of a joint that breaks crystals loose from the joint surface is yet another possible mechanism and might explain the high frequency of gout at the base of the great toe, which is a joint subjected to great stress.

Urate crystals induce inflammation by several mechanisms (80). Urate crystals activate Hageman's factor in joint fluid, leading to the formation of kinins that induce vasodilatation and increased vascular permeability. Urate crystals activate the complement system with the generation of leukocyte chemotactic factors and also stimulate the formation of leukotrienes from arachidonic acid. Furthermore, urate crystals can activate platelets, which secrete several inflammatory mediators including prostaglandins. Urate crystals can also stimulate synovial lining cells and macrophages that secrete prostaglandins and collagenase.

The key to urate-induced inflammation is the polymorphonuclear white cell. Urate crystals bind IgG, leading to their attachment to and phagocytosis by polymorphonuclear white cells. This process mediates the production of superoxide anions, which damage tissue (94). In addition, ingestion of crystals results in the release of chemotactic factors from the polymorphonuclear white cells, thus attracting more polymorphonuclear white cells (95). On ingestion by polymorphonuclear white cells, crystals are incorporated into phagosomes, which fuse with lysosomes. The rupture of phagolysosomes inside polymorphonuclear white cells damages these cells. Lysosomal and cytoplasmic enzymes are released into the joint space, resulting in tissue inflammation and injury.

Gouty arthritis often develops with fluctuation of serum urate levels. A rapid increase in serum uric acid results in precipitation of crystals in tissue or fluid. A rapid decrease in serum urate brings about release of urate from the joint surface into the joint space.

Drinking of alcohol is also associated with the precipitation of gouty attacks. Metabolism of ethanol results in an increased concentration of blood lactate, which blocks the renal excretion of uric acid by inhibiting tubular secretion and raising the serum urate level. Alcohol consumption also leads to accelerated degradation of adenosine triphosphate to adenosine monophosphate with accumulation of adenine nucleotides that are degraded to uric acid and other purine metabolites (96). The drinking of moonshine whiskey is associated with gouty arthritis and is referred to as *saturnine gout* (97). Moonshine whiskey is often distilled in automobile radiators containing a lead core. Lead reduces the excretion of urate and decreases its solubility. In addition, lead may affect renal mechanisms for handling urate, leading to elevated levels.

Gout follows periods of fasting. During fasting the increased plasma level of acetoacetate and b-hydroxybutyrate interferes with renal excretion of urate (98). Overindulgence of food and wine has often been associated with gout. When a large protein- and purine-rich diet is ingested along with copious amounts of wine or other liquor, the uric acid serum concentration rises because of increased formation and decreased excretion of sodium urate. Acute gouty arthritis attacks occur when drugs increase or lower the serum uric acid level. Attacks are precipitated by allopurinol, which lowers the uric acid concentrations, and thiazides or low doses of aspirin, which raise the level. Cyclosporine interferes with the renal excretion of uric acid and induces hyperuricemia and gout (99). An increased frequency of gout is seen in transplant recipients receiving cyclosporine and may affect atypical joints such as the hips, sacroiliac joints, or shoulders.

Symptoms and Signs. Gouty arthritis occurs mainly in middle-aged and older men and after menopause in women. Approximately one-fourth of the patients have a family history of gout. Nephrolithiasis precedes the first attack of arthritis in approximately 10% of patients. The first attack occurs most often in the metatarsal phalangeal joint of the great toe (podagra). Subsequent attacks might be separated by several months or even years. The involved joint usually returns to normal between attacks. In untreated cases, the attacks become more frequent and involve other joints, such as wrists, elbows, olecranon bursae, and the small joints of the hand. Gouty arthritis can occur in distal interphalangeal joints already involved with OA and Heberden's nodes (100). Gout can be overlooked in these joints because acute inflammation can also occur with Heberden's nodes. Gouty arthritis of intervertebral joints, sacroiliac joints, and shoulders and hips is uncommon.

The typical attack of gout comes on acutely, often during the early hours of morning. Attacks also occur after surgery. Pain and swelling reach a peak within 24 hours. The joint is exquisitely tender, and overlying soft tissue is swollen and erythematous even to the degree that it could be mistaken for cellulitis. Pain is intense and throbbing. Patients are unable to tolerate even a light sheet touching the involved great toe. Jarring of the bed can make the patient wince with pain. The patient might even dread the landing of a fly on the involved toe. Both a low-grade fever and leukocytosis can accompany the attack, especially in polyarticular gout. An untreated attack of gout usually lasts for 1 to 2 weeks. Less severe attacks also occur that last only a few days.

Chronic tophaceous gout develops in some patients. Before the effective control of hyperuricemia, approximately one-half of the patients with episodes of gouty arthritis eventually developed deposits of monosodium urate dihydrate in and around joints as well as in other tissues. These deposits, referred to as *tophi*, usually become apparent at least 10 years after the onset of gouty arthritis. They develop in the olecranon, infrapatellar and prepatellar bursae, Achilles tendons, synovium, subchondral bone, and, infrequently, in the cartilage of the ear. Tophi can ulcerate and drain material that contains microscopic needle-shaped crystals of monosodium urate. Patients with tophaceous gout have frequent episodes of acute gouty arthritis. Joint deformity and disability can be quite severe in the untreated patient.

Significant renal disease secondary to gouty nephropathy is rare. Proteinuria, decreased concentrating capacity, and a decrease in creatinine clearance might be present. Small deposits of urate are observed in the interstitium of the renal medulla. Nephrosclerosis and hypertension are frequently associated with gout.

Treatment of patients with underlying myeloproliferative or lymphoproliferative disorder results in extremely high levels of serum urate that can precipitate in the renal tubules, producing obstruction and oliguria. Patients should be treated with allopurinol and colchicine before treatment of the blood dyscrasia.

Renal calculi develop in approximately 20% of patients with gout (101). Hypertension, diabetes mellitus, and hypertriglyceridemia occur more frequently in patients with gout.

Laboratory Findings. Radiography of the affected joint in acute gouty arthritis is usually normal. When the first metatarsal phalangeal joint is involved, radiography might show underlying changes of OA. The typical erosion caused by urate deposition is sharply defined and has a thin shell-like overhanging edge at the margins of the erosion. The diagnosis of gout is established by demonstration of the characteristic crystal of monosodium urate monohydrate in the synovial fluid or from tissue deposits. Crystals are found both in the polymorphonuclear white cells and free in fluid. The crystals in joint fluid are usually rod shaped and 7 to 10 µm in length. They are identified by use of polarized microscopy. With use of a first-order red compensator, crystals have a sign of strongly negative birefringence (102). Crystals

from tophi are long and needle shaped and are not usually found in white cells.

Treatment. Treatment of a patient with gout has two components: treatment of the acute gouty arthritis and treatment of hyperuricemia (80). Each is treated independently. Even though they are closely interrelated, the drugs used for each are different. In fact, the indiscriminate use of a drug to lower the uric acid can exacerbate or prolong an attack of gouty arthritis.

Antiinflammatory Drugs. For the acute attack of gouty arthritis, the patient is given indomethacin, 200 mg in four divided doses (50 mg every 6 hours) the first 24 hours, followed by 150 mg every day for 7 to 10 days. Other NSAIDs (see Table 27-2) can also be used. NSAIDs for the treatment of acute gout should be avoided or used with caution in patients with symptomatic heart failure, renal failure, oliguria, or peptic ulcer disease. Glucocorticoids are also quite effective in treatment of acute gout. Prednisone is given over a 7-day period with an initial dose of 40 mg as a single dose and then gradually tapered over a 7-day period. To avoid a flare of arthritis when prednisone is discontinued, the patient is started on 0.6 mg of colchicine or an NSAID beginning on day 3 or 4 of prednisone therapy and continuing for several weeks. Methylprednisolone can be given intravenously to patients unable to take oral medications. The dose schedule for oral prednisone is followed. Intraarticular corticosteroids can also be used to treat gout in a large joint such as the knee.

In patients who experience frequent attacks of acute gouty arthritis, colchicine, 0.6 mg once or twice a day, is quite effective in preventing attacks. Patients on this prophylactic regimen can abort an acute attack by taking colchicine, 0.6 mg every hour for four to six doses, when they experience the first twinge of joint pain.

Myopathy and polyneuropathy may occur on maintenance doses of colchicine in patients who have renal insufficiency (103). Myositis manifests as proximal muscle weakness and serum creatine kinase becomes elevated. These abnormalities return to normal 3 to 4 weeks after stopping the drug. Polyneuropathy also disappears on discontinuing colchicine. In addition, agranulocytosis or aplastic anemia can occur in patients with renal insufficiency who are on regular doses of colchicine because the plasma drug levels in these patients greatly increase.

Antihyperuricemic Drugs. Treatment of hyperuricemia in patients with gout is directed at preventing the formation of tophaceous deposits. It is not uniformly agreed that all patients with elevated uric acids and gouty arthritis require medications to lower their uric acid. If the patient already has tophaceous deposits in joints or subcutaneous tissue, then the uric acid should be lowered. On the other hand, an elevated uric acid of less than 10 mg per dL in a patient without tophi or frequent gouty attacks might not require treatment. Whether they have gout or not, persons with uric acid levels above 10 mg per dL are usually treated because of their higher risk of developing gout.

The uric acid concentration can be lowered by probenecid, which is a uricosuric agent (104). In patients with normal renal function and no renal stones, probenecid is an effective agent. The dose of probenecid is 1 to 3 g per day given twice a day. The urine should be alkalinized to prevent precipitation of urate in the urinary tract. Sulfinpyrazone is another uricosuric drug. The usual daily dose is 300 to 400 mg per day, administered in 3 or 4 divided doses.

Serum uric acid level is effectively reduced by allopurinol, which is a potent inhibitor of xanthine oxidase (104). This drug blocks the conversion of hypoxanthine to xanthine and xanthine to uric acid. This leads to the accumulation of other oxypurines in the blood. The daily dose of allopurinol is 300 to 800 mg per day, which is regulated to reduce uric acid to a concentration below 6 mg per dL. Allopurinol administration can precipitate an acute attack of gout, presumably because of fluctuation of sodium urate between tissue and blood. To prevent an acute gouty attack, allopurinol is started in a low dose and gradually increased. Colchicine, 0.6 mg twice a day, is given along with the allopurinol to prevent an acute attack.

The most significant side effect of allopurinol is a rash that occasionally progresses to a severe life-threatening exfoliative dermatitis. Transient leukopenia and abnormalities of liver function are observed in some patients. In patients treated for many years, xanthine stones may occur. These tend to occur in patients who are overproducers and hyperexcretors of uric acid.

Allopurinol is the drug of choice in patients with renal insufficiency who are unable to excrete a uric acid load. This drug is also indicated in patients with uric acid renal calculi. Allopurinol is more effective than probenecid in reducing tophi in patients with severe tophaceous gout. The addition of probenecid, however, further enhances the lowering of serum acid level.

Allopurinol is also indicated in patients with gout who are overproducers and hyperexcretors of urate (urine acid excretion greater than 1,000 mg for 24 hours) because these patients are at greater risk for developing renal stones. No clear evidence exists that treatment of asymptomatic hyperuricemia in a person who is not a hyperexcretor is beneficial.

Allopurinol potentiates the action of 6-mercaptopurine and azathioprine (104). The dose of the cytotoxic agent is usually reduced by at least one-third in patients on allopurinol.

Infectious Arthritis

Nongonococcal Bacterial Arthritis

Acute bacterial or septic arthritis is a serious problem that requires prompt treatment to avoid joint damage (105,106). Bacteria usually reach the joint by hematogenous spread from a primary infection elsewhere. Often, however, no primary source of infection is found. An infection in the adjacent bone or soft tissue can extend directly into the joint. Acute bacterial arthritis is most often caused by *Neisseria gonorrhea*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Staphylococcus pyogenes*, or *Haemophilus influenzae*, with *Staphylococcus* spp. being the most common causative organisms. Gram-negative organisms include *Escherichia coli*, *Salmonella*, and *Pseudomonas* and are usually seen in patients who are immunosuppressed or use intravenous drugs.

Patients with diabetes mellitus or blood dyscrasias or those receiving glucocorticoids or immunosuppressive drugs are more susceptible to joint infection. Septic arthritis is more likely to occur in joints previously damaged by trauma or inflammatory arthritis (e.g., rheumatoid arthritis).

Pathophysiology. The synovium is edematous and infiltrated by neutrophils. As the disease progresses, small abscesses are present in the synovium and subchondral bone. Proteolytic enzymes from neutrophils damage the cartilage, bone, and joint capsule. Healing is manifested by proliferation of fibroblasts, which can lead to ankylosis.

Symptoms and Signs. The onset of bacterial arthritis is usually abrupt and associated with severe pain and fever. A shaking chill occasionally accompanies the onset. Any motion of the joint causes excruciating pain. The overlying skin is usually erythematous. In elderly patients and those who are on glucocorticoids, the symptoms can be less severe.

The joint affected most frequently by septic arthritis is the knee, which is involved in at least one-half of the cases. Other commonly involved joints are hips, shoulders, wrists, ankles, elbows, and sternoclavicular and sacroiliac joints. Involvement of the latter two joints has been noted in intravenous drug abusers. In the spine, the intervertebral disk space and adjacent vertebral bodies are infected. Infection in the hip is more difficult to recognize because swelling is less evident. Patients with hip infection might hold the thigh in adduction, flexion, and internal rotation. Pain is felt in the groin or thigh and is also referred to the anterior surface of the knee.

An overlying infected bursa or cellulitis can be mistaken for septic arthritis. It is important in aspirating a joint not to insert the needle through an infected bursa or cellulitis and possibly infect a normal joint.

Laboratory Findings. Joint fluid usually shows increased numbers of neutrophils ranging from 10,000 to greater than 100,000 per cubic millimeter. The white cell count in infected bursa fluid is not as high as observed in the joint. A peripheral blood leukocytosis might also be present. The synovial fluid glucose is usually less than 20% of a simultaneously drawn blood glucose when these two compartments are in equilibrium. Equilibrium is usually reached 6 hours after a meal. In gonococcal arthritis, however, the synovial fluid glucose is not significantly reduced. Gram's stain performed on synovial fluid often shows bacteria except in gonococcal infections. Culture results of synovial fluid as well as blood are also often positive.

Radiography of the joint initially shows soft tissue swelling and distension of the joint capsule, followed later by juxtaarticular osteoporosis and periosteal elevation. As the process continues, destruction of articular cartilage leads to joint space narrowing followed by bony erosions. Juxtaarticular bone destruction might indicate

osteomyelitis. In the spine, the initial change consists of narrowing of the disk space and proliferation of bone at vertebral margins. Osteolytic lesions in adjacent vertebrae are seen later. Radioisotope scans can be helpful in identifying infection in certain joints such as the hip, shoulder, spine, and sacroiliac joints, but inflammatory arthritides and degenerative joint disease also give a positive scan result.

Treatment. An infected joint requires immediate aspiration and rapid initiation of parenteral antibiotic therapy. It has been reported that joint outcome is best when patients are seen within 7 days of initial symptoms (107). Joint fluid should be immediately cultured and a Gram's stain performed. When organisms are seen on Gram's stain, a penicillinase-resistant penicillin or cephalosporin plus aminoglycan should be given immediately and adjusted appropriately when the organism is identified and antibiotic sensitivities are determined. Antibiotics should be given intravenously for at least the first 2 weeks. A total of 6 weeks of antibiotic therapy is indicated. Antibiotics do not need to be infused into the joint. The joint should be adequately drained to prevent damage. Usually drainage can be accomplished with a large-gauge needle. Drainage reduces intraarticular pressure and removes pus, which is a source of proteolytic enzymes. Repeated aspirations are only necessary during the first few days of treatment. Surgical drainage is required when the joint cannot be adequately aspirated and irrigated by needle or when the cell count in the synovial fluid does not decline in spite of what appears to be adequate drainage. Surgical drainage via arthroscopy should also be considered in patients with underlying arthritis and those with prolonged symptoms (i.e., longer than 7 days) (54). During the first few days of treatment, splinting of the involved joint in extension makes the patient more comfortable and reduces the possibility of a flexion contracture. Daily physical therapy, once the acute process has resolved, improves the range of motion. In a severely damaged joint, bony fusion might be required.

Gonococcal Arthritis

Gonococcal arthritis is a frequent cause of bacterial arthritis in young adults (105,106). Women are more susceptible to gonococcal arthritis during menses and pregnancy. Persons who have a homozygous deficiency of complement component C5, C6, C7, or C8 are also susceptible to disseminated neisserial infections (108). Patients with low complement levels caused by consumption of complement might also be more susceptible to disseminated neisserial infections (108).

Symptoms and Signs

Patients typically present with fever and migratory arthritis or arthralgias that evolve in several days into a monoarticular arthritis. Patients also directly present with monoarticular arthritis. Wrists and knees are common sites of involvement, but any joint can be affected. Arthritis is manifested by swelling, erythema, and severe pain as in other bacterial arthritides. Skin lesions can accompany gonococcal arthritis. These lesions can be pustular, vesicular, or hemorrhagic and can ulcerate.

Laboratory Findings

Joint fluid shows increased numbers of polymorphonuclear white cells, but the white cell count might not be as high as in other bacterial infections. The joint fluid glucose is also not decreased to the low levels found in other bacterial joint infections.

Diagnosis

Gonococcal arthritis is suspected in a patient presenting with fever, typical skin lesions, and polyarthralgias or arthritis that evolves into a monoarticular arthritis. Diagnosis is confirmed by positive culture results from synovial fluid or from blood, but culture results from these sites are positive in fewer than 50% of cases. Cultures from skin lesions are also usually negative. Gram's stain or culture results from cervix, urethra, or rectum might be positive when joint, skin, and blood culture results are negative.

Treatment

The patient should be admitted to the hospital and receive parenteral antibiotics. Currently, the recommendation is to start a third-generation cephalosporin such as ceftriaxone until susceptibilities are determined, as 5% of strains are penicillin resistant (109). Most patients are still candidates for aqueous crystalline penicillin G, 10 million U per day given intravenously for 3 to 4 days. If substantial improvement has occurred, the patient can be discharged on oral ampicillin or amoxicillin, 500 mg 4 times daily for an additional 7 days. In most patients this regimen is adequate, but in some patients with severer joint involvement, treatment is continued for 3 to 4 weeks. Unlike other bacterial infections, gonococcal infection seldom requires that antibiotics be given for 6 weeks.

The patient is placed at bed rest for the first 2 days. Splinting of the affected joint provides pain relief. The infected joint should be immediately aspirated. The frequency of aspirations depends on the degree of inflammation. In most patients residual joint damage does not occur.

Tuberculous Arthritis

Pathophysiology

Infection of a joint with *Mycobacterium tuberculosis* causes a destructive arthritis (110). Arthritis and tenosynovitis can also be caused by atypical mycobacteria such as *M. kansasii*, *M. marinum*, and *M. intracellulare*. Approximately 1% of patients with tuberculosis have arthritis. Patients with arthritis might have no evidence for active or even inactive pulmonary involvement. Joints are infected by direct hematogenous spread or by extension from a tuberculous process in adjacent bone. As the disease evolves, the cartilage is destroyed and erosions appear in the subchondral bone. Infection can extend from the joint to soft tissues, producing cold abscesses and draining sinus tracts. Tendon sheaths are also involved.

Tuberculosis of the spine (Pott's disease) involves the margins of the vertebral bodies and spreads into the adjacent disk space. Collapse of vertebral bodies in the thoracic spine results in kyphosis or a gibbus. Infection can also spread into the adjacent paraspinal muscles, extend up and down the spine, and eventually emerge as a cold abscess in the groin. Extension into the meninges results in tuberculous meningitis or, into the spinal cord, cord compression and paraplegia.

Symptoms and Signs

The patient with tuberculous arthritis might have low-grade fevers and night sweats. The involved joint is warm, swollen, and painful. An effusion is usually present. Tuberculous tenosynovitis of the flexor tendons in the wrist can compress the median nerve and produce a carpal tunnel syndrome. Tuberculous tenosynovitis should be excluded in patients presenting with unilateral carpal tunnel syndrome and low-grade fevers. Symptoms of spine involvement depend on the level of involvement.

Laboratory Findings

The white cell count in synovial fluid is usually greater than 10,000 per cubic milliliter, with approximately 50% to 60% polymorphonuclear white cells. The synovial fluid glucose is low. The tubercle bacilli might be seen on smear, but the diagnosis often requires biopsy and culture of synovial tissue.

Treatment

The antibiotic treatment of tuberculous arthritis is the same as for pulmonary tuberculosis except that a longer duration of therapy may be necessary, depending on the clinical and radiographic response. For adults, isoniazid, 300 mg per day (5 mg per kg), and rifampin, 600 mg per day (10 mg per kg), are given for at least 9 months (110). Some patients with tuberculous arthritis may require 12 to 18 months of therapy. When isoniazid resistance is documented, ethambutol, 15 to 25 mg per kg per day, is given with rifampin for a minimum of 12 months. In these patients, pyrazinamide, 15 to 30 mg per kg per day, can be added for the initial 2 months of therapy.

The joint should be placed at rest and adequately drained. In severe destructive disease, debridement and fusion of the joint might be required.

CHAPTER 28

Neuropathic Myofascial Pain Syndromes

C. Chan Gunn

Myofascial pain syndromes are a large and diverse group of painful conditions that occur in the musculoskeletal system. They affect muscles and their connective tissue attachments in any part of the body, and are therefore customarily named according to the location of the painful part (e.g., lateral epicondylitis, Achilles tendonitis, frozen shoulder, bicipital tendonitis, and even low back pain) (Table 28-1). They are puzzling because they seem to arise and persist in the absence of any detectable injury or inflammation. Myofascial pain syndromes are often difficult to treat because medications and the commonly available physical therapies give only temporary relief. Innumerable patients, therefore, wander from provider to provider in a vain search for relief.

TABLE 28-1. Common myofascial pain syndromes caused by shortened muscles[a]

The term *myofascial pain syndrome* is presently used in a vague and indeterminate way to denote any regional musculoskeletal pain syndrome without regard to its source or cause. However, careful examination of these syndromes often reveals them to be the effects of neuropathy appearing in the musculoskeletal system. The initial and underlying problem is malfunction of the peripheral nervous system, and pain is just one possible although not inevitable downstream product of the neuropathy. The key to successful management of this important and widespread category of chronic pain is to understand neuropathy, how it can cause pain, and recognize it in its many guises.

PERIPHERAL NEUROPATHY AND PAIN

Medical diagnosis traditionally presumes that pain is a signal of tissue injury conveyed to the central nervous system via a healthy nervous system. The definition of pain, as given by the International Association for the Study of Pain, underscores this: “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described by the patient in terms of such damage” (see Chapter 2). The traditional model, however, fails to explain many pain syndromes associated with damage to the peripheral nerve, or to the pathways coursing through the dorsal horn and spinal cord. Although pain may be linked causally to tissue injury, it is not necessarily so. Injury does not always generate pain, nor does pain always signal injury. Persistent pain can occur in the presence of the following conditions: (a) ongoing nociception (e.g., an unhealed fracture) or persistent inflammation (e.g., rheumatoid arthritis). Inflammation results in the local release of algogenic substances such as bradykinin, serotonin, histamine, H^+, K^+, prostaglandins, leukotrines, nerve growth factors, and neuropeptides; (b) psychological factors such as somatization disorders, depression, or adverse operant learning processes; (c) abnormal functioning in the nervous system. Pain can arise from nonnoxious input, or from within the body when there is some functional disturbance in the nervous system (e.g., peripheral neuropathy). *Neuropathic* pain is generally used to refer to any acute or chronic pain syndrome in which the mechanism that sustains the pain is inferred to involve aberrant somatosensory processing in the peripheral nervous system or central nervous system. In neuropathic myofascial pain, structural factors exist as well, such as muscle shortening, degraded and weakened collagen, and trophic changes that contribute to the pain.

How the Concept of Neuropathic Pain Originated

It is well accepted that pain can follow gross nerve injury, but the many and varied effects of dysfunction in the peripheral nervous system are recent concerns. I proposed the concept of neuropathic pain when it became evident from clinical observations and research carried out at the Workers' Compensation Board of British Columbia that pain is not always a signal of injury, but can be a product of abnormal nerve function (1).

In 1970, my examination of patients who had back pain, but no signs of injury, showed that those who were disabled for long periods had tenderness over muscle motor points in affected myotomes. Tender motor points, I found, are sensitive indicators of radicular involvement or irritation at the nerve root. Tender points differentiate a simple mechanical low back strain, which usually heals quickly, from one that is slow to improve (2). Next, a study of patients with *tennis elbow* showed that tender points at the elbow were secondary to cervical spondylosis and radiculopathy (i.e., neuropathy originating at the nerve root). Treating the neck, but not the elbow, was able to provide relief (3). A study of pain in the shoulder likewise implicated neuropathy at the cervical spine (4).

A pattern began to emerge: Patients who have pain, but no signs of injury, generally have sensory, motor, and autonomic manifestations of peripheral neuropathy. Peripheral neuropathy may be defined as a disease that causes disordered function in the peripheral nerve. Although sometimes associated with structural changes in the nerve, a neuropathic nerve can, deceptively, appear normal. It still conducts nerve impulses, synthesizes and releases transmitted substances, and evokes

action potentials and muscle contraction.

In 1978, I presented a paper to the Royal College of Physicians and Surgeons of Canada reporting that following neuropathy and denervation, “many diverse pain syndromes of apparently unrelated causation may be attributed to supersensitive receptors (nociceptors) and hyperreactive control systems at internuncial pools.” The concept of neuropathic pain is well accepted today, but at that time, not all physicians were familiar with peripheral neuropathy, and some vigorously denied its existence (Merskey H, *personal communication*, 1986).

The following attributes generally are associated with neuropathic pain (5,6):

- Pain when no ongoing tissue-damaging process exists.
- Delay in onset after precipitating injury. It generally takes approximately 5 days for supersensitivity to develop (7).
- Dysesthesia, unpleasant burning or searing sensations, or deep, aching pain that is more common than dysesthetic pain in musculoskeletal pain syndromes.
- Pain felt in a region of sensory deficit.
- Neuralgic pain, paroxysmal brief shooting or stabbing pain.
- Severe pain in response to a noxious stimulus (hyperalgesia).
- Severe pain in response to a stimulus that is not normally noxious (allodynia).
- Pronounced summation and afterreaction with repetitive stimuli.

Peripheral Mechanisms in Neuropathic Pain

Neuropathic pain is customarily perceived as beginning with peripheral sensitization. In peripheral sensitization, increased transduction sensitivity of nociceptors is associated with alteration of ionic conductances in the peripheral terminal (see Chapter 3). Sensitization can occur following tissue inflammation or damage to a peripheral nerve. Inflammatory cells also produce growth factors and cytokines that contribute to the increased sensitivity of nociceptors. However, damage to the peripheral nerve is most commonly caused by spondylosis at the root level (i.e., *radiculopathic* pain) when all fibers of the peripheral nerve can be damaged and can lead to any or all of the following effects:

- Motor: Muscle shortening is the most significant feature of radiculopathy; pain caused by the mechanical effects of muscle shortening.
- Autonomic: Increased vasoconstriction; hyperhidrosis; trophedema; and causalgic pain, reflex sympathetic dystrophy, or now, better labeled c *omplex regional pain syndrome*.
- Trophic: Dermatomal hair loss; collagen degradation and frailty leading to enthesopathic tendons.

Inflammation is clinically obvious, but minor damage to the nerve root is not. Early radiculopathy is universal, but it is usually unsuspected in prespondylosis when painless muscle shortening precedes peripheral sensitization. Damaged primary afferent fibers demonstrate three electrophysiologic features: (a) spontaneous activity; (b) exaggerated response to stimulus; and (c) sensitivity to catecholamines. These can be explained by a fundamental physiologic law.

Cannon and Rosenblueth's Law of Denervation

This law is seldom cited to explain neuropathic pain; it deserves to be better known. It points out that the normal physiology and integrity of all innervated structures are dependent on the arrival of nerve impulses via the intact nerve to provide a regulatory or *trophic* effect. When this flow, which is probably a combination of axoplasmic flow and electrical input, is blocked, innervated structures are deprived of the trophic factor, which is vital for the control and maintenance of cellular function. *A-trophic* structures become highly irritable and develop abnormal sensitivity or supersensitivity according to Cannon and Rosenblueth's Law of Denervation (7): “When a unit is destroyed in a series of efferent neurons, an increased irritability to chemical agents develops in the isolated structure or structures, the effect being maximal in the part directly denervated.”

All denervated structures develop supersensitivity (including skeletal muscle, smooth muscle, spinal neurons, sympathetic ganglia, adrenal glands, sweat glands, and brain cells). Cannon and Rosenblueth's original work was based on total denervation or decentralization for supersensitivity to develop; accordingly, they named the phenomenon *denervation supersensitivity*. But it is now known that physical interruption and total denervation are not necessary. Any circumstance that impedes the flow of motor impulses for a period of time can rob the effector organ of its excitatory input and cause disuse supersensitivity in that organ and, significantly, in associated spinal reflexes (8).

The importance of disuse supersensitivity cannot be overemphasized. When a nerve malfunctions, the structures it supplies become supersensitive and behave abnormally. These structures overreact to many forms of input, not only chemical, but physical inputs as well, including stretch and pressure. Supersensitive muscle cells can generate spontaneous electrical impulses that trigger false pain signals or provoke involuntary muscle activity (9). Supersensitive nerve fibers become receptive to chemical transmitters at every point along their length instead of only at their terminals. Sprouting may occur, and denervated nerves are prone to accept contacts from other types of nerves including autonomic and sensory nerve fibers (10). Short circuits are possible between sensory and autonomic (vasomotor) nerves and may contribute to complex regional pain syndrome.

Disuse supersensitivity is basic and universal, yet not at all well known or credited. The important role of supersensitive structures after neuropathy or denervation was previously neglected. Many diverse pain syndromes of apparently unknown causation may be attributed to the development of hypersensitive receptor organs and supersensitivity in pain sensory pathways. Instead of nociception, there can be severe pain in response to a noxious stimulus (hyperalgesia) or severe pain in response to a stimulus that is not normally noxious (allodynia).

RADICULOPATHY: ITS FREQUENT RELATIONSHIP TO SPONDYLOSIS

It is not unusual for the flow of nerve impulses to be obstructed. Peripheral neuropathy, often accompanied by partial denervation, is not exceptional in adults. Of the innumerable causes of nerve damage, such as trauma, metabolic, degenerative, toxic, and other conditions, chronic attrition from spondylosis (the structural disintegration and morphologic alterations that occur in the intervertebral disk, with pathoanatomic changes in surrounding structures) is by far the most common. The spinal nerve root, because of its vulnerable position, is notably prone to injury from pressure, stretch, angulation, and friction. Other causes of radiculopathy (i.e., neuropathy at the nerve root), such as arachnoiditis, neuroma, and intraspinal tumors, are much less common. Spondylosis increases with age; therefore, spondylotic pain is more common in middle-aged individuals who have accumulated an *injury pool*, an accumulation of repeated major and minor injuries to a segment leading to unresolved clinical residuals that may, or may not, produce pain (11).

Ordinarily, spondylosis follows a gradual, relapsing, and remitting course that is silent, unless and until symptoms are precipitated by an incident often so minor that it passes unnoticed by the patient. All gradations of spondylosis can exist, but early or incipient spondylotic changes, even when unsuspected, can nevertheless irritate and upset function in the segmental nerve. The emphasis on radiculopathy is not without reason. With an acute injury to a healthy nerve, there is no prolonged discharge of pain signals, whereas the same injury to a neuropathic nerve can cause a sustained discharge (12). In other words, for pain to become a persistent symptom, the affected fibers must be previously irritated or defective. That is why some people develop severe pain after an apparently minor injury, and why that pain can continue beyond a *reasonable* period.

The manifestations of neuropathic dysfunction are motor, sensory, and autonomic. In our studies, early and subtle signs of peripheral neuropathy were found in a significant number of young (under 30 years), apparently normal, and asymptomatic individuals (13). Brief and transient motor manifestations are the first to appear, and radiculopathy can occur without pain. Muscle shortening is an early and regular feature of radiculopathy, because large diameter nerve fibers at the nerve root—axons of motoneurons and myelinated primary afferents (muscle proprioceptors)—are the first to suffer physically. Painless, reversible, tight muscle knots can be felt in most individuals; not uncommonly, even in toddlers. Pain is not therefore a feature of radiculopathy unless nociceptive pathways are involved. Many neuropathies are pain free, such as sudomotor hyperactivity in hyperhidrosis, and muscle weakness in ventral root disease.

Degradation of Collagen

Ironically, neuropathy itself contributes to degenerative conditions (including spondylosis). Neuropathy degrades the quality of collagen, causing it to have fewer cross-links; it is, therefore, more frail than normal collagen (14). The amount of collagen in soft and skeletal tissues is also reduced. Because collagen lends strength to ligament, tendon, cartilage, and bone, neuropathy can expedite degeneration in weight-bearing and activity-stressed parts of the body, which include the spine and

joints, and become a source of pain. Enthesopathic thickening in a tendon is possibly a compensation for this weakness.

CENTRAL MECHANISMS IN NEUROPATHIC PAIN

Interactions between peripheral and central mechanisms occur to produce postinjury hypersensitivity and neuropathic pain. The spinal cord is not simply a passive conveyer of peripheral sensation to the brain. It can modify or amplify incoming signals. Central sensitization, a state of hyperexcitability of the dorsal horn neuron, can occur after damage to a peripheral nerve (e.g., irritation of a nerve root by spondylosis) or after low-frequency repetitive C fiber nociceptor input (e.g., from peripheral tissue inflammation, as in arthritis). Central sensitization has several aspects: increased spontaneous activity of dorsal horn neurons, increased response to afferent input, expansion of receptive field size, reduction in threshold, and prolonged afterdischarges. Central sensitization leads to a cascade of molecular events, such as activation of the *N*-methyl-d-aspartate (NMDA) channel, increase in intracellular Ca^{2+}, wind-up/wide dynamic range (WDR) neuron sensitization, and other phenomena (15,16,17,18,19,20 and 21).

Altered Sensitivity in the Dorsal Horn

Central sensitization may be maintained by ongoing primary afferent input, by altered central neural circuitry, or both. Woolf has identified four stimulus-processing states (22,23):

1. Normal state: In this state, low-intensity A-b stimulation, such as touch, is perceived as innocuous, but high-intensity A-d and C noxious stimulation is perceived as pain.
2. Suppressed state: High-intensity stimulation is not painful because of inhibition from segmental inhibition or descending inhibition from higher centers.
3. Sensitized state: Low-intensity stimulation is perceived as painful mechanical allodynia, and high-intensity stimulation, which is normally painful, leads to hyperalgesia.
4. Reorganized state: There may be structural changes and reorganization of the dorsal horn circuitry. Inappropriate synapses may form. A-b fibers from layer 3 can sprout into layers 1 and 2, causing low-threshold afferent input to be misinterpreted as pain. A-b afferents acquire the capacity, after inflammation, to produce central excitability, something they cannot normally do.

Expansion of Receptive Field Size

The clinical observation that pain radiates several segments above and below the level of nociceptive stimulation may be explained by dispersion of the primary afferent input through propriospinal connections in adjacent layers 5 and 6 of the dorsal horn. This area also contains WDR neurons (so called because they can encode a range of stimuli from light touch to intense pain). The WDR receptive field is immense compared with that of the primary afferent neuron; therefore, any increase in nociceptive stimulation can lead to the recruitment of many more WDR neurons.

Prolonged Afterdischarges

Perceived pain often outlasts the stimulus. In neuropathy, a brief discharge from A-d or C fibers generates prolonged activity of WDR neurons because the normal inhibitory effects of A-b fibers on A-d and C activity is lost.

Wind-Up

Wind-up is a frequency-dependent phenomenon. Low-frequency (0.1-Hz) C fiber input gives a constant response from dorsal horn neurons. But frequencies greater than 0.5 Hz can give rise to hyperexcitability lasting for many minutes after the stimulus. In wind-up, C fibers release substance P, neurokinin A, and excitatory amino acids (glutamate and aspartate) onto dorsal horn neurons. There are two types of receptors at the dorsal horn, a neurokinin receptor and an NMDA receptor for amino acids. The binding of amino acids to the NMDA receptor depends on its prior activation by the binding of substance P to the neurokinin receptor. Thus, the release of substance P may lead to the recruitment of a second receptor type (NMDA) and an exaggerated response to further stimulation. The sensitized cell undergoes other biochemical changes, as indicated by the expression of the gene c-*fos*. Products of c-*fos* expression are involved in the regulation of neurotransmitter and nerve growth factor synthesis.

CHALLENGES IN DIAGNOSIS AND TREATMENT

Diagnosis

Diagnosing pain and dysfunction caused by radiculopathy depends almost entirely on the examiner's clinical experience and acumen. The history gives little assistance. Pain often arises spontaneously with no history of trauma, or else the degree of reported pain far exceeds that consistent with the injury. Laboratory and radiologic investigations are generally not helpful. Thermography reveals decreased skin temperature in affected dermatomes and this can be an indication of neuropathy, but does not necessarily signify pain. Radiculopathies are difficult to document with routine nerve conduction studies, which measure only the few fastest conducting and largest fibers and take no account of the majority of smaller fibers. In focal neuropathy, nerve conduction velocities remain within the wide range of normal values, but F-wave latency may be prolonged. Electromyography is not specific either.

The physical signs of neuropathy are distinctive and different from the well-known ones of outright denervation, such as loss of sensation and reflexes. They are important to look for because they indicate early neural dysfunction for which no satisfactory laboratory or imaging test exists. A careful inspection for signs of motor, sensory, and autonomic (vasomotor, sudomotor, and pilomotor) dysfunction in the skin and affected muscles is necessary. Vasoconstriction differentiates neuropathic pain from inflammatory pain: In neuropathic pain, affected parts are perceptibly colder. There may be increased sudomotor activity and the pilomotor reflex is often hyperactive and visible in affected dermatomes as goose bumps (Fig. 28-1). There can be interaction between pain and autonomic phenomena. A stimulus such as chilling, which excites the pilomotor response, can precipitate pain; conversely, pressure on a tender motor point can provoke the pilomotor and sudomotor reflexes.

Figure 28-1. A readily seen signal of neuropathy affecting the autonomic system is an isolated patch of *goose bumps* created by a super-sensitive pilomotor reflex responding to exposure while undressing. Here it appears locally at the shoulder and arm, indicating trouble related to segments C-5 and C-6.

Increased permeability in blood vessels can lead to local subcutaneous tissue edema (neurogenic edema or trophedema). This can be seen as *peau d'orange* skin (Fig. 28-2) and confirmed by the match stick test. Trophedema is nonpitting to digital pressure, but when a blunt instrument such as the end of a match stick is used, the indentation produced is clear-cut and persists for many minutes (Fig. 28-3). This quick and simple test can demonstrate neuropathy earlier than electromyography. Trophic changes such as dermatomal hair loss may also accompany neuropathy.

Figure 28-2. **A:**Wrinkling of normal skin when gently squeezed together. **B:** Trophedematous skin when gently squeezed together, the *peau d'orange* effect. (From Gunn CC, Milbrandt E. Early and subtle signs in low-back sprain. *Spine* 1978;3:267 –281.)

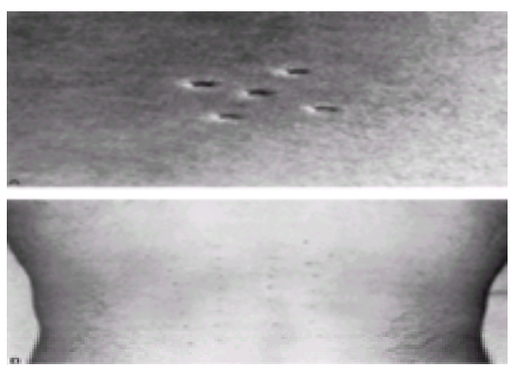

Figure 28-3. **A:** The matchstick test. Trophedema may be found by pressing on the suspected area using the end of a matchstick. The deeper the indentations, and the longer they last (up to many minutes), the more severe the neuropathy. **B:** In low back pain, the matchstick test result is often positive over an area that is more widespread than the painful area. This patient had symptoms only in the low lumbar back, but indentations are seen at all lumbar levels, which indicates that even though pain is limited to one level the neuropathy is more extensive. (**A** from Gunn CC, Milbrandt E. Early and subtle signs in low-back sprain. *Spine* 1978;3:267–281.)

Knowledge of the Segmental Nerve Supply to Muscles Is a Clue to Diagnosis

Neuropathic changes are primarily in muscle. Even when symptoms appear to be in joints or tendons, signs in the muscles are the most consistent and relevant: increased muscle tone; tenderness over motor points; and taut and tender, palpable contracture bands and restricted joint range. Each constituent muscle must be palpated and its condition noted. Palpation requires detailed knowledge of anatomy, and clinical skill comes only with practice. Moreover, because many paraspinal muscles are compound (e.g., the longissimus) and extend throughout most of the length of the vertebral column, the entire spine must be examined even when symptoms are localized to one region.

Muscle Shortening from Contracture

Muscle contracture is a fundamental feature of musculoskeletal pain (Fig. 28-4). Of all structures that can develop supersensitivity, the most widespread is striated muscle. Contracture can physically give rise to pain by its relentless pull on sensitive structures (24) (Fig. 28-5). *Classic contracture* refers to the evoked shortening of a muscle fiber in the absence of action potentials. According to Cannon and Rosenblueth (7), skeletal muscle can become supersensitive in several ways: (a) by increased susceptibility; lessened stimuli, which do not have to exceed a threshold, can produce responses of normal amplitude; (b) by hyperexcitability; the threshold of the stimulating agent is lower than normal; (c) by superreactivity; the capacity of the muscle to respond is augmented; and (d) by superduration of response; the amplitude of response is unchanged but its time course is prolonged.

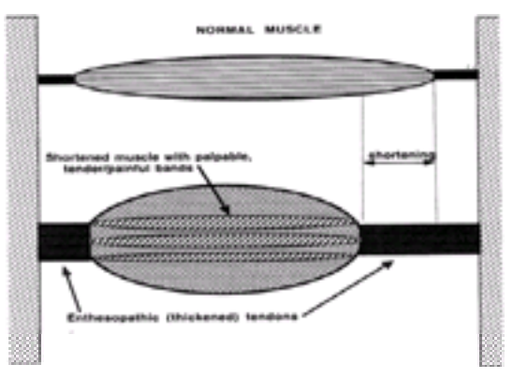

Figure 28-4. Neuropathy can cause muscle contracture and shortening. (From Gunn CC. *The Gunn approach to the treatment of chronic pain.* New York: Churchill Livingstone, 1996, with permission.)

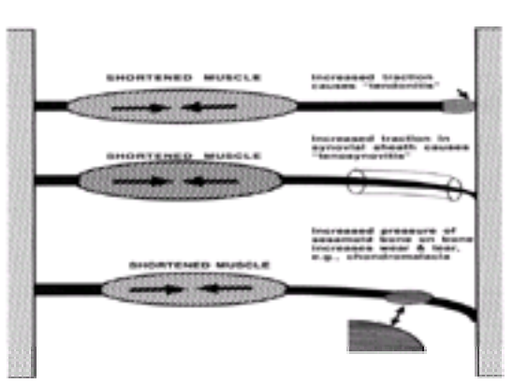

Figure 28-5. Shortening creats tension in tendons and their attachments and can cause syndromes as epicondylitis, tendonitis, or chondromalacia patellae. (From Gunn CC. *The Gunn approach to the treatment of chronic pain.* New York: Churchill Livingstone, 1996, with permission.)

Supersensitive skeletal muscle fibers, furthermore, overreact to a wide variety of chemical and physical inputs, including stretch and pressure. Furthermore, they have a lowered threshold to acetylcholine, which is itself increased from reduced levels of acetylcholinesterase. Acetylcholine slowly depolarizes supersensitive muscle

membrane, inducing an electromechanical coupling in which tension develops slowly without generating action potentials. In normal muscle, acetylcholine acts only at receptors that are situated in the narrow zone of innervation, but in neuropathy, it acts at newly formed extrajunctional receptors (*hot spots*) that appear throughout the muscle (Fig. 28-6).

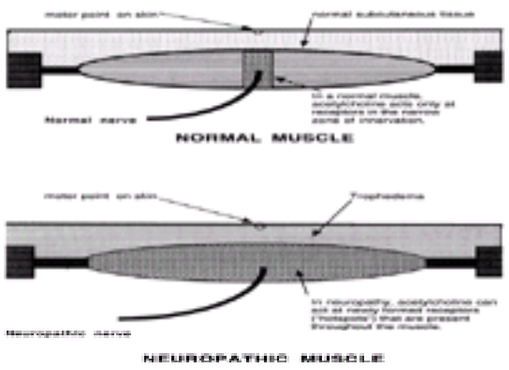

Figure 28-6. In comparison to normal muscle, widespread newly formed acetylcholine receptors are present throughout neuropathic muscle. (From Gunn CC. *The Gunn approach to the treatment of chronic pain.* New York: Churchill Livingstone, 1996, with permission.)

TREATMENT

Pharmacologic Management Is Difficult

A critical review of controlled clinical trials for peripheral neuropathic pain concluded that the pharmacologic management of neuropathic pain is difficult (25). Further trials are needed to establish the efficacy for all treatments currently in use. The review gave support to corticosteroids, which had long-term effectiveness, and limited support to tricyclic antidepressants, intravenous and topical lidocaine, intravenous ketamine, carbamazepine, and topical aspirin. There was also limited support for oral, topical, and epidural clonidine and for subcutaneous ketamine. Data were contradictory for mexiletine, phenytoin, topical capsaicin, oral nonsteroidal antiinflammatory medication, and intravenous morphine. Codeine, magnesium chloride, propanol, lorazepam, and intravenous phentolamine all failed to provide pain relief. There was also limited support for the effectiveness of topical dimethyl sulfoxide, epidural clonidine, and intravenous regional blocks with bretylium and ketanserin. Data were contradictory for intranasal calcitonin and intravenous phentolamine. Guanethidine, reserpine, and droperidol intravenous regional blocks were ineffective. No data were available to evaluate sympathetic ganglion blocks with local anesthetics. Regional and systemic adrenergic blockages gave limited success. Overall, there were no long-term data to support the effectiveness of any drug in treating this condition.

Physical Therapy and Stimulation-Induced Analgesia

Physical therapy is widely used as a first-line treatment for peripheral neuropathic pain. Early physical treatment is advocated, because earlier treatment is said to correlate with better outcome. Neuropathic pain is a supersensitivity phenomenon, and its treatment requires desensitization. Lomo has shown in animal experiments that supersensitivity and other features of denervated muscle can be reversed by electric stimulation (26). Physical therapy also achieves its effect by stimulation. Local therapy excites receptors (in skin and muscle); for example, massage activates tactile and pressure receptors; exercise, manipulation, and dry needling stimulate muscle spindles and Golgi organs; heat and cold act on thermal receptors. These stimuli are sensed by their specific receptors, transduced into nerve impulses, and relayed to the dorsal horn. All forms of physical therapy, including dry needling, are effective only when the nerve to the painful part is still intact. A dry needling technique called *intramuscular stimulation* (see Chapter 97) is often effective. In intramuscular stimulation, diagnosis, treatment, as well as progress during therapy are determined according to physical signs of neuropathy. The effective application of intramuscular stimulation therefore requires a sound background both in anatomy and neurophysiology (27).

Stimulation also can be applied directly to the spinal cord (28) (see Chapter 100). Cui and colleagues have reported that neuropathic pain may be effectively relieved by electric stimulation of the spinal cord. Stimulation of the spinal cord has been shown to normalize withdrawal response thresholds in a rat model. The effect of stimulation of the spinal cord on neuropathic pain and allodynia is believed to be caused by inhibition of glutamate and aspartate release at NMDA receptor sites, and activation of local GABAergic mechanisms.

Removing the Cause of Neuropathy Is Key to Treatment

Spondylosis is, by far, the most common cause of radiculopathy, and treatment should be aimed at relieving the cause of impingement or entrapment of the nerve root. Local treatment (starting with simple measures such as massage, and, if necessary, escalating to more effective modalities such as dry needling) should be given to all tender and shortened muscles in the affected myotome(s), including paraspinal muscles. The outcome of treatment depends on the modality used and the skill of the therapist.

The fine, flexible, acupuncture needle used in intramuscular stimulation is a unique tool for finding and releasing contractures. Contracture is invisible to radiography, computed tomographic scans, or magnetic resonance imaging, and in deep muscles beyond the finger's reach. Deep contracture can only be discovered by probing with a needle. The needle transmits feedback information on the nature and consistency of the tissues it is penetrating. When penetrating normal muscle, it meets with little hindrance; when penetrating a contracture, there is firm resistance, and the needle is grasped by the muscle. This causes the patient to feel a peculiar cramplike or grabbing sensation, which is referred to in acupuncture literature as the *Deqi* or *Teh Ch'i response*. The *Deqi* response is an important finding: It is a sign of muscle contracture and confirms the status of neuropathy.

Myofascial muscle pain is not merely dull and aching. It has a peculiar cramplike quality that is associated with muscle tenderness and shortening. Any experienced dry-needling therapist or acupuncturist would be aware of this distinctive sensation produced by needling a contracture. The classic acupuncturist painstakingly differentiates between pain that has the *Deqi* response (therefore, the muscle is shortened and neuropathic), and pain that does not (nociceptive). This distinction is important because of the difference in the nature and treatment of the two pains. According to Fields, the strange quality of neuropathic pain probably results from disruption of the sensory apparatus so that a normal pattern of neural activity is no longer transmitted to the perceptual centers. He allows that neuropathic pain probably activates nociceptive neurons, because the message that gets through to the perceptual centers is clearly unpleasant, but he astutely notes that patients distinguish the peculiar sensations from *normal* pain sensations (29).

Chronic myofascial pain is not ordinary nociception. *Deqi* pain sensations are not normal because they are associated with receptors that sense muscle shortening (proprioceptors). The classic acupuncturist demonstrates this by the needle grasp occurring at the site of penetration when a neuropathic muscle is needled. Needling is usually pain free when an acupuncture needle enters a normal muscle, but when the needle pierces a shortened muscle, it produces a cramp, and the needle is observed to be firmly grasped by the shortened muscle. The intensity of the needle grasp parallels the degree of muscle shortening, and it gradually eases off during treatment as muscle shortening is released: Release frequently occurs in minutes. Because muscle pain eases concurrently with the release of the needle grasp, patients soon become aware of the importance of eliciting the *Deqi* sensation and releasing needle grasp during treatment.

Progressive Tactile Hypersensitivity

Laboratory investigators presently pursue A-d and C fiber nociceptive pathways but give little consideration to large-diameter fibers. However, Ma and Woolf have described a noteworthy phenomenon, *progressive tactile hypersensitivity* (30). They have found that repeated light touch to an inflamed paw produced cumulative allodynia. Progressive tactile hypersensitivity can only be induced in inflamed tissue and persists for several hours. It is different from central sensitization induced by C fiber stimulation, which can be induced in noninflamed tissue and lasts only for minutes. Progressive tactile hypersensitivity demonstrates that A-b afferents have the capacity to produce wind-up of spinal cord neurons, normally a C fiber–mediated effect.

Myofascial pain is not solely A-d and C fiber nociceptive pain. Muscle shortening is an essential component; by simply releasing a shortened muscle, pain is

banished. If large-diameter A-b primary afferents from the cutaneous nerve can contribute to hyperalgesia, is it possible for large-diameter proprioceptor fibers from the muscle nerve to likewise contribute to myofascial pain? Fibers from muscle fascia and other deep tissues must now be studied, in particular group I and II fibers, which sense muscle length and tension, and group III and IV fibers, which sense muscle pain.

In chronic pain, fibrosis eventually becomes a major feature of the contracture; response to dry-needle treatment is then much less dramatic. The extent of fibrosis does not correlate with chronologic age. Scarring can occur after injury or surgery, and many older individuals have sustained less wear and tear than younger ones who have subjected their musculature to repeated physical stress. The treatment of extensive fibrotic contractures necessitates more frequent and extensive needling. To relieve pain in such a muscle, it is necessary to needle all tender bands. It is uncommon to encounter a muscle that is totally fibrotic and cannot be released by vigorous needling.

For long-lasting pain relief and restoration of function, it is essential to release shortened paraspinal muscles that may be compressing a disk and disperse fibrotic tissue that may be entrapping a nerve root (Fig. 28-7). Surgical release is rarely necessary as the needle can reach deeply located shortened muscles.

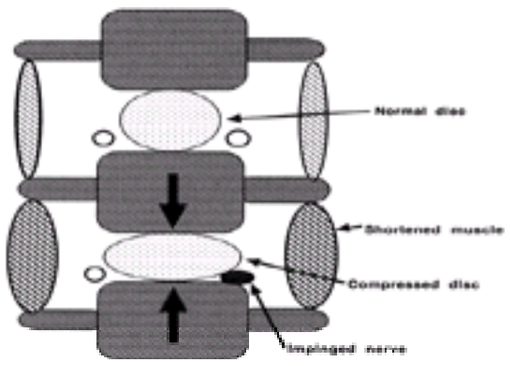

Figure 28-7. Shortened paraspinal muscles across an intervertebral disk space can compress the disk. (From Gunn CC. *The Gunn approach to the treatment of chronic pain.* New York: Churchill Livingstone, 1996, with permission.)

DISCUSSION

Myofascial pain syndromes frequently become medical riddles when they are not recognized as the effects of neuropathy presenting primarily in the musculoskeletal system. The primary problem is peripheral neuropathy, and pain is just one of its many possible presentations. Pain is not a feature unless nociceptive pathways are involved. Many neuropathic conditions are pain free. It is helpful to remember the following points:

- Because pain is a manifestation of neuropathy, therapy should aim at the cause of the neuropathic condition.
- Spondylosis is, by far, the most common cause of radiculopathy. Myofascial pain syndromes are almost invariably segmental; symptoms are found in dermatomes, myotomes, and sclerotomes. Examination and treatment must always include the spine.
- Establish that neuropathy is present. Signs of neuropathy are subtle and differ from those of outright denervation. Look for vasoconstriction and trophedema.
- Neuropathic pain has a proprioceptive component; it cannot exist without muscle shortening. Look for tender, shortened muscles in myotomes.
- Neuropathic pain is often the unsuspected cause of many other conditions (e.g., tension headache, frozen shoulder, tennis elbow, and even low back pain). Muscle shortening upsets joint alignment and increases pressure on articular surfaces. Neuropathy degrades the quality of collagen and contributes to degeneration in weight-bearing and activity-stressed parts of the body.
- Radiculopathy is perpetuated when shortened paraspinal muscles draw adjacent vertebrae together to compress the disk and irritate the nerve root. The vicious circle must be treated at the spine.

CONCLUSIONS

It is only through hands-on examination of patients, explicitly searching for neuropathic signs, that one is able to understand and treat neuropathic myofascial pain. Drug treatment is difficult, and physical therapy is the first approach. The efficacy of intramuscular stimulation for chronic low back pain has been demonstrated by a randomized clinical trial involving a large group of Workers' Compensation Board patients. At their 7-month follow-up, the treated group was clearly and significantly better than the control group (27). It is a most convincing experience to diagnose neuropathic pain by finding its unmistakable physical signs and then to treat the patient with intramuscular stimulation and witness the signs disappear, often within minutes.

CHAPTER 29

Myofascial Pain Syndromes

Anders E. Sola and John J. Bonica

Myofascial pain syndromes constitute a large group of muscle disorders characterized by the presence of hypersensitive points, called *trigger points* (TPs), within one or more muscles, the investing connective tissue, or both, together with a syndrome of pain, muscle spasm, tenderness, stiffness, limitation of motion, weakness, and occasionally autonomic dysfunction. The symptoms are usually referred to an area distant from the TPs, although local pain may also be present. These syndromes have been previously described as, among other terms, *myalgia*, *myositis*, *fibrositis*, *myofascitis*, *fibromyositis* (or *myofibrositis*), *muscular rheumatism*, and *muscular strains*.

Management of patients with myofascial pain syndromes constitutes one of the most important problems encountered in clinical practice. This importance stems from several interrelated factors. First, they are the most common musculoskeletal disabilities of the shoulder girdle, neck, low back, and, to a lesser extent, the chest and ribs. They are certainly among the most frequent causes of severe disabling pain. Moreover, because of the peculiar symptoms associated with these syndromes, they were not generally recognized until recently. Consequently, they were often misdiagnosed and treated as bursitis, arthritis, or visceral disease.

Once recognized, however, these disorders are relatively simple to manage. Most of the therapeutic procedures can be carried out in the physician's office, and in many cases, a short series of treatments can relieve conditions that might otherwise result in continued pain and disability.

In this chapter we present the epidemiology, etiology, pathophysiology, symptoms and signs, diagnosis, and treatment of these syndromes. A more detailed discussion of syndromes affecting each part of the body is presented in the various sections of Part IV of this book. Comprehensive discussions of this subject can be found in an excellent monograph by Travell and Simons (1) and in a number of review articles (2,3,4,5,6,7,8,9,10 and 11).

BASIC CONSIDERATIONS

The TP phenomenon was first recognized in the mid–nineteenth century by physicians in Germany, Sweden, and Britain (1,2,3,4,5,6,7,8,9,10 and 11). The early German writers referred to conditions with symptoms and signs characteristic of myofascial syndromes as *myogelosis* (*myogelosen*) and as *muscular rheumatism* and later as *muscle hardenings* or *muskel schmerzen* and noted the presence of tender spots in various muscle groups. Swedish writers used the term *myositis* for myofascial syndromes, whereas British writers used a number of terms, including *myalgic spots*, *myalgia*, *myofascitis*, *myositis*, and especially *fibrositis*. Unfortunately the term has been used interchangeably with such terms as *nonarticular rheumatism*, *muscular rheumatism*, *fibromyositis*, *fibrofascitis*, and *muscular strain*.

A number of writers, especially Good (12), in Britain, and Kelly (13), in Australia, have used the term *fibrositis* for symptoms that describe myofascial pain syndromes. At about the same time, Travell (14), who has made immeasurable contributions to this field, published her first paper on the subject and used the terms *idiopathic myalgia* and *myalgia*. Later, she began to call these conditions *myofascial pain syndromes* (15).

In the first edition of this book, Bonica, in conformance with the widespread literature of the 1940s, considered fibrositis separate from myofascial pain syndromes. For a number of years he continued to consider these two conditions separately, although he emphasized the importance of myofascial syndromes (16). At about the same time, Sola, following his experience with Bonica, also published reports on myofascial pain syndromes (17,18). In recent years some authorities (19) have come to believe that fibrositis is similar to myofascial pain syndromes and have suggested that the term be abandoned. Others, however, have continued to insist and have provided evidence that fibrositis, now commonly known as *primary fibromyalgia syndrome* (PFS), can be differentiated from myofascial pain syndromes. The difference is based on the fact that myofascial pain syndromes are characterized by presence of specific TPs in one or several muscles, whereas PFS is characterized by local tenderness in more than 11 specified sites, with widespread aching of more than 3 months' duration. This difference has been recognized by the Committee on Taxonomy of the International Association for the Study of Pain and therefore will be respected here. PFS is discussed in Chapter 30.

Epidemiology

As in most other acute and chronic painful disorders, there are no data from national epidemiologic studies on the incidence and prevalence of myofascial pain syndromes. These syndromes, with their characteristic TPs, exist as primary conditions and also as secondary conditions, in conjunction with musculoskeletal injuries, arthritis, nerve injuries, and visceral diseases. Further complicating the data is the fact that TPs, which can develop in any muscle of the body, can be active or latent. An active TP is associated with spontaneous pain at rest or with motion that stretches or overloads the muscle. A latent TP does not cause spontaneous pain, but it can be diagnosed by applying discrete pressure on the TP, which is likely to cause pain locally and in the area of reference. Consequently, we must rely on local surveys to estimate the incidence and prevalence of TPs in the population.

In a survey of 200 unselected young adults, Sola and associates (20) found latent TPs in the muscles of the shoulder girdle in 54% of the females and 45% of the males. In a survey of 1,000 ambulatory patients, Sola (unpublished data, 1985) found hyperactive TPs with classic myofascial syndromes in 32%. The prevalence was 36% among the 598 women and 26% among the 402 men seen. Table 29-1 lists the distribution of the pain syndromes according to the age group of female and male patients. As may be noted, the highest prevalence was in patients who were between 30 and 49 years of age. Table 29-2 lists the location of the TPs in 214 female and 103 male patients. A significantly greater incidence of myofascial syndromes among female patients has also been reported by others (1). Moreover, Sola's personal observations confirmed the impression of many clinicians that myofascial pain syndromes affect the head and neck, the shoulder girdle, and the lumbar and low back regions more frequently than other regions.

	Females (n = 214)		Males (n = 103)	
Age (yr)	Number	Percent*	Number	Percent*
≤19	2	1	3	3
20–29	34	16	14	14
30–39	48	22	21	21
40–49	40	19	22	22
50–59	30	14	17	17
60–69	33	15	12	12
70–79	22	10	14	14
≥80	5	2	0	0

*Percentage of patients by age group.

TABLE 29-1. Distribution of cases of myofascial syndromes by age and gender

Location	Females (n = 214)		Males (n = 103)	
	Number	Percent*	Number	Percent*
Cervical (approximately one-third with torticollis)	72	34	30	29
Hip(s)	60	28	52	51
Shoulder	44	21	36	35
Lumbar region	34	16	23	22
Generalized	11	5	4	4
Low back	6	3	9	9
Ipsilateral	6	3	0	0
Leg, thigh, knee	5	2	6	6
Upper extremity	3	1	4	4
Thoracic region	2	0.9	3	3
Back	0	0	2	2
Abdominal region	0	0	2	2
Groin	0	0	1	1
Upper and lower trunk	23	11	9	9

*Percentages total more than 100% because several areas may have been noted for each patient.

TABLE 29-2. Locations of sensitive trigger points

In another survey, Sola (*unpublished data*, 1954) found that laborers who exercise their muscles heavily every day are less likely to develop active TPs than sedentary workers who tend to indulge in occasional sessions of vigorous physical exercise. Similar observations have been made by Travell and Simons (1,2 and 3).

The most comprehensive and most revealing overview of the incidence and prevalence of muscle pain can be found in the Nuprin Report (21). This publication contains data derived from the first nationwide survey on the prevalence of pain, which was carried out in 1985 by Lou Harris Associates under the sponsorship of Bristol Myers Company. The survey suggests that 53% of the American population experiences muscle pain. Among the respondents with muscle pain, approximately one-third had pain for 11 or more days and 10% had pain for 100 or more days. The data do not indicate what percentage of these respondents had myofascial pain syndromes, but it is likely that these conditions were present in a significant percent of this population.

Etiology

The most easily identified causes of myofascial pain syndromes are trauma to myofascial structures and acute overload of muscles (Fig. 29-1). After acute injury, TPs (small, circumscribed, hypersensitive regions in muscles or connective tissue) can be identified in some individuals. These TPs are also known as *trigger areas*, *trigger zones*, and *myalgic spots* (1,4,9,18). Impulses arise from these points and bombard the central nervous system to produce local or referred pain, or both, and associated phenomena in the area of reference. The TP is so named because its stimulation, with pressure or activation of the muscle, is like pulling the trigger of a gun, producing effects at another place (a target), called the *reference zone* or *area of reference*. The term, then, implies the existence of a relationship between two different topographic areas, the trigger and the target.

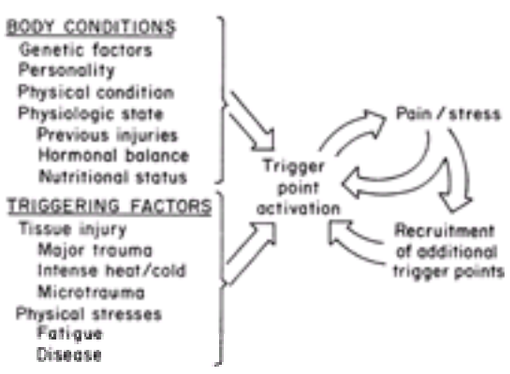

Figure 29-1. Stress and body conditions. A variety of stress-inducing stimuli have been implicated in the onset of myofascial pain. The power of these stimuli to induce pain in an individual is moderated by the genetics, personality, conditioning, and physiologic state of that individual. Once established, however, a painful event may sustain itself in spite of control or elimination of the initiating stimuli. (Modified from Sola AE. Myofascial trigger point therapy. *Med Times* 1982;110:70–75.)

TPs often remain in muscle in a latent form for many years after an injury, contributing to an “injury pool” (6,7 and 8). The only manifestation may be minimal loss of range of motion (ROM), coolness, quick fatigability, slight loss of dexterity in the upper extremities, or a combination of these. Residual clinical stigmata are seen most often in conjunction with injuries to the extremities in association with cervical or lumbar/sacral pathology. In the presence of an injury pool, any additional injury or stress involving the same segment can cause a flare-up of latent TPs. Under these conditions, an insignificant event can initiate bizarre responses, including intense severe pain, prolonged edema, loss of ROM, and slow recovery—many of which could be construed as psychosomatic.

Latent TPs can also be activated by intense heat or cold or by prolonged chilling, as occurs with air conditioning or chilly, damp weather. In these cases, the precipitating factor is not readily identified, or the relationship might be overlooked because the painfulness of the myofascial syndrome is disproportionate to the significance of the incident. A third etiologic pattern for myofascial syndrome is slow onset, in which the microtraumas of daily activities or repetitive movements while working, such as prolonged typing, result in overload fatigue.

In addition to these precipitating factors, a number of factors can make a person vulnerable to development or activation of latent TPs. These include mechanical stresses that overload muscles, such as occurs with a short leg, small hemipelvis, poor posture, and prolonged immobility. Travell and Simons (1) also mention that a variety of nutritional and metabolic and endocrine factors, including vitamin deficiencies, mineral inadequacy, hypometabolism, and endocrine dysfunction (particularly estrogen deficiency and hypothyroidism) are important predisposing and perpetuating factors. They also list chronic infection due to viral or bacterial disease and parasitic infestation as predisposing or perpetuating factors.

An acute episode of myofascial pain often follows overuse of unconditioned muscles (the weekend athlete); excessive zeal in fitness programs; prolonged stresses on musculoskeletal structures due to poor posture during activities such as computer-oriented work or television watching; sports injuries; automobile accidents involving cervical or lumbar sprain, or both; or a period of intense emotional stress. Travell and Simons (1) point out that there is a difference between soreness after exercise and the TP phenomenon. They note that muscles that are stiff and sore from exercise do contain tender points, but the tenderness is not similarly referred to other areas and it is distributed “as if it were caused by sensitization with a different noxious agent, or by the sensitization of a different neural structure than that responsible for the trigger point phenomenon.”

The precipitating factor for primary myofascial pain is often a seemingly innocent activity (1,8). Among the more common of these is a change in heel height from high heels worn during the day to slippers in the evening. Other examples are working at a table or counter that is too low, sitting in an overstuffed chair, and riding in an airplane or car (in these instances, vibration is added to the postural and environmental stressors, which include the handling of heavy luggage).

An afternoon of shopping can be the precipitating event, particularly when the person has been walking in leather-soled shoes on highly waxed floors, which are common in shopping malls and many other public areas and institutions (e.g., nursing homes, convention centers, schools). The muscular accommodation necessary to maintain balance in these conditions, plus abnormal adjustment of gait, can aggravate muscles with existing TPs, causing acute onset of pain in hips, knees, ankles, feet, low back, head, or neck.

Frequently, more than one TP area is found in pain syndromes, each having a site of reference comprising a portion of the pain pattern. A prolonged barrage of noxious impulses from a TP area is conducive to the creation of secondary tender areas in the zone of reference. In such instances, the more recent secondary foci can be a major source of pain, and it is not until these are eliminated that the primary focus becomes evident. Although trigger areas can develop anywhere in the

body, they occur most frequently in the neck, shoulder girdle, low back, and extremities.

Pathophysiology

Present knowledge of myofascial pain syndromes and TP phenomena depends heavily on clinical observations and theories that relate limited physiologic data to physical findings. Although TPs can sometimes be palpated, their presence is more commonly established by the pain response of the patient when pressure is applied to them—Travell calls this response the “jump” sign (1,2). By probing and observing pain responses, Travell and Simons (1) have estimated the size of a single TP to be between 3 mm and 6 mm.

Hypersensitive TPs have been studied histologically, but there is little experimental evidence to substantiate their role in causing or perpetuating pain. Henriksson and associates (19) reported that muscle tissue biopsied from tender areas in patients with primary “fibromyalgia” had a “moth-eaten” appearance. In these patients, adenosine triphosphate and phosphocreatine levels were reduced, lactate values were normal, and glycogen concentrations were below normal. These findings led Henriksson et al. to conclude that the TP phenomenon could be caused either by a primary metabolic disturbance or by overload secondary to muscle tension.

There is little doubt as to the reality of TPs, but there is great diversity of opinion as to how these points become hypersensitive and how they produce pain. Cailliet (22) suggested that TPs are caused by the presence of blood and extracellular material that are not reabsorbed after damage of any type to soft tissue. The resulting adhesions limit the gliding action of muscles, resulting in tension, spasm, and further development of irritants. Travell and Simons maintain that the principal causes of TPs are microtrauma and overload (1).

According to Gunn (23), the cause of TP hypersensitivity is neuropathy of the nerve serving the affected muscle (see Chapter 28). Cannon's law of denervation states that any structure affected by denervation responds with supersensitivity, which is translated as hyperactivity of its normal function (24). Neurologic deficit to the muscle therefore results in supersensitivity of the muscle to biochemical agents and to impulses to contract (25,26,27,28 and 29). Supersensitivity associated with neuropathy has been supported by studies of Lomo (30), which show increased sensitivity of muscle to acetylcholine and a broadened distribution of acetylcholine receptors—a condition that was reversible in laboratory animals.

Clinical findings confirm that TP formation, with the associated potential for pain, occurs subsequent to injury or stress (1). The muscle fibers “hosting” the TP are contracted for an extended period of time, and muscle fatigue develops. Local ischemia occurs, leading to changes in the extracellular environment of the affected cells, including release of such algogenic agents as histamine, kinins, and prostaglandins (27). These changes feed into a cycle of increasing motor or sympathetic activity, or both, which leads to increased pain (Fig. 29-2), with the TP as the focus of distress signals to the central nervous system. Once established as a cycle, a painful event can sustain itself in this way after the initial stimulus has been controlled or treated.

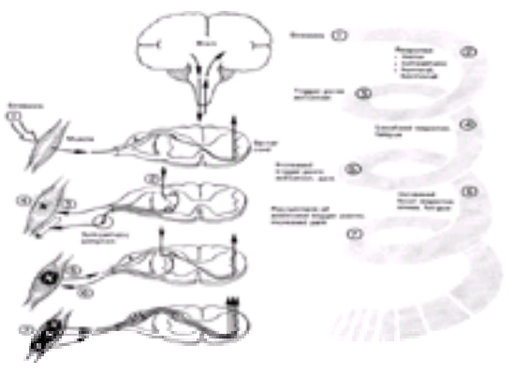

Figure 29-2. Mechanisms in myofascial pain syndrome. (*1*) The individual, subjected to the physical and emotional stresses of daily living, responds with defense mechanisms that include various physiologic changes, such as splinting and bracing of muscles, vasomotor changes, increased sympathetic discharge, and hormonal and other humoral changes in the plasma and extracellular fluids. (*2,3*) A particular point in a braced, stressed muscle or fascia that is more sensitive than the surrounding tissue—perhaps due to previous injury or genetic mandate—fatigues and begins to signal its distress to the central nervous system. (*4*) A number of responses are possible. The most readily understood involves the motor reflexes. Various muscles associated with the trigger point become more tense and begin to fatigue. Sympathetic responses lead to vasomotor changes within and around the trigger point. Local ischemia following vasoconstriction or increased vascular permeability following vasodilation can lead to changes in the extracellular environment of the affected cells, release of algesic agents (bradykinins, prostaglandins), osmotic changes, and pH changes, all of which can increase the sensitivity or activity of nociceptors in the area. Sympathetic activity can also cause smooth muscle contraction in the vicinity of nociceptors, thus increasing their activity. (*5,6*) Increased nociceptor input contributes to the cycle by increasing motor and sympathetic activity, which in turn leads to increased pain. The pain is shadowed by growing fatigue, which adds an overall mood of distress to the patient's situation and feeds back to the cycle. (*7*) As tense muscles in the affected area begin to fatigue in an environment of sympathetic stimulation and local biochemical change, latent trigger points within these muscles also begin to fire, thus adding to the positive feedback cycle and spreading the pain to these adjacent muscle groups. Finally, the stress of pain and fatigue, coupled with both increased muscle tension and sympathetic tone throughout the body (conceivably with ipsilateral emphasis through the sympathetic chain), leads to flare-ups or trigger points in other muscles remote from the initial area of pain. (Modified from Sola AE. Myofascial trigger point therapy. *Med Times* 1982;110:70–75.)

An important characteristic of a TP is that stimulating it with dry needling or injecting it with a local anesthetic that has only transitory pharmacologic action (1,4,16,31), or with a cooling spray (1,2), can render it nonexcitable, and the pain cycle can be terminated for a period of time or even permanently.

In many cases the hyperactivity of TPs remains at a subclinical level, particularly after minor or moderate injuries to the shoulder girdle and upper extremities. In these instances the TPs remain undiagnosed and untreated. These points remain as latent, or “weak,” points, with increased sensitivity of slow nerve fibers, associated vasoconstriction, and low-grade hypersympathetic activity, resulting in the “injury pool” phenomenon (6,23,32). The significance of the injury pool is that subsequent injury, stress, or fatigue can initiate an accrued response that is vastly disproportionate to the immediate circumstances, because latent points throughout the body can easily be activated by subsequent sympathetic nervous system activity.

CLINICAL CONSIDERATIONS

Symptoms and Signs

Patients with myofascial disorders usually present with persistent pain, tight or aching muscles, limited ROM, general fatigue, or a combination of these. The patient might not be aware of the muscular involvement, however, and might complain instead of headache, neck pain, joint pain, backache, or sciaticalike pain in the buttocks or lower extremities (5,7,33,34).

The intensity of myofascial pain ranges from a low level, felt as a mild ache, to excruciating aching or burning pain, or both. The pain can be either continuous or periodic, but it is usually persistent, debilitating, and limiting. It is usually elicited explosively and spontaneously as soon as the trigger area is touched. The extent of the area of focal and referred pain apparently depends on the sensitivity of the trigger areas: If the trigger area is very sensitive, there is a wide radiation of pain to include the essential zone of reference as well as a spillover zone (Fig. 29-3), whereas if the trigger area is not sensitive, pain is present only in the essential zone. Associated with pain are deep hyperalgesia or tenderness in the reference zone, often continuous hyperalgesia, and, as previously mentioned, limited ROM, general fatigue, or both.

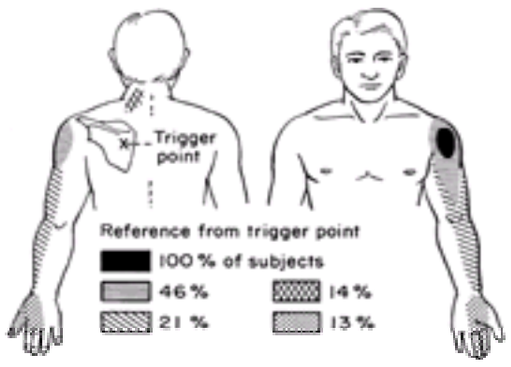

Figure 29-3. Pain reference pattern of trigger area in the upper portion of infraspinatus muscle as mapped in 193 patients with shoulder pain. The black area is called the *essential reference zone* because 100% of the subjects felt pain there; the shaded and stippled areas are collectively labeled the *spillover reference zone* because not all patients felt pain in these areas. (Modified from Travell JG. Basis for the multiple uses of local block of somatic trigger areas. *Miss Valley Med J* 1949;71:13–22.)

The pattern of this referred pain and associated phenomena is relatively constant and predictable, which indicates that impulses concerned in the unfamiliar reference of somatic pain, like that of visceral pain, follow fixed anatomic pathways (1,2,3,4,5,6,7,8 and 9,16). This predictability of pain patterns enables one to use a known reference pattern by which to locate the myofascial source of the pain. It must be added, however, that the distribution of referred somatic pain, although remarkably constant for the structure stimulated, does not follow a dermatomal pattern or nerve root distribution. This lack of neurotomal distribution of symptoms and signs has been perhaps the most important factor delaying recognition of this group of disorders as clinical entities and has misled physicians to misdiagnose them as bursitis, tendinitis, or arthritis or as functional. Figure 29-4 shows some of the common myofascial pain syndromes in different parts of the body.

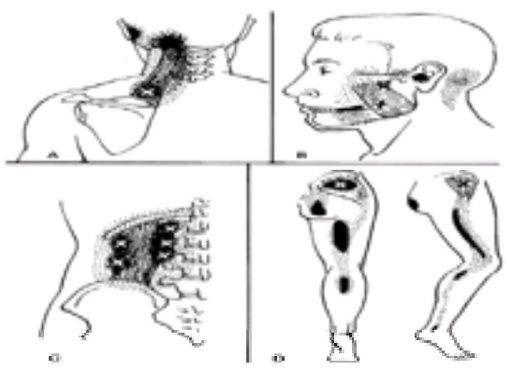

Figure 29-4. **A:** Pain pattern and trigger points of the levator scapulae muscle. **B:** Masseter muscle with some of its characteristic pain reference sites. **C:** Quadratus lumborum muscle with common trigger points and local pain reference pattern. **D:** Gluteus medius trigger point (one of the most powerful trigger points in the body, with its local pain and reference referral patterns to the thigh and legs), and tensor fascia lata trigger point and characteristic hip pain and lateral thigh and leg reference zones.

In a minority of patients, the presenting complaint is not pain but limited ROM or conditions associated with shortened or guarded muscles. One example of this is short-leg syndrome, in which the shortening of the leg can be attributed to extreme muscle tightness involving hyperactive TPs, particularly in the ipsilateral quadratus lumborum and into the ipsilateral extremity. Compensation for the shortened leg then creates another set of symptoms that bring the patient in for treatment. Another common example is patients who have limited ROM in one shoulder, for which they have compensated to the extent that they are no longer aware of the condition as a source of pain. Their presenting complaint might be muscle weakness in the forearm or hand. On examination, affected muscles do not extend to full range and resistance is exquisitely painful. Maximum contractile force is weakened, and muscle strength is unreliable.

Severe hip pain associated with pregnancy is often myofascial in origin. In a study by Sola (unpublished data, 1986) of 32 gravidas referred for treatment because of moderate to severe hip and low back pain, 29 had symptoms and signs characteristic of myofascial pain syndromes. All 29 responded positively to treatment, and follow-up revealed that pain relief persisted during the remainder of the pregnancy. In most cases relief occurred after one or two treatments consisting of TP injections with normal saline and hot packs.

When the pain is of long duration, it is extremely common for patients to indicate involvement of several areas—for example, pain and ache in one upper extremity, associated with edema in the hand or wrist, might be associated with stiffness or discomfort in the hip and lower limb on the ipsilateral side (4,7,16). Both active and latent TPs are hypersensitive to pressure on examination, but only active TPs cause pain. Latent TPs can result in involuntary guarding of muscles, including involuntary limitation of ROM. Such patterns of guarding and disuse contribute to arousal of the latent TP to a level of activity resulting in achiness in the ipsilateral limb.

Secondary myofascial syndromes are usually associated with a known condition. A reliable indicator of secondary myofascial involvement is a history of pain that is disproportionate to what might be expected or pain that persists after the normal treatment period for the primary clinical disorder. In some instances of severe, generalized pain, treatment for myofascial syndrome can accomplish sufficient pain relief to reveal and permit localization of the primary pain source, thereby assisting in the diagnosis. (TPs, both in the upper and lower body, are also frequently found in association with herpes zoster and in stress-related disorders.)

Myofascial syndromes may complicate recovery from surgical procedures, causing intense pain near the incision (Sola, unpublished data, 1975). Latent points can also be activated by adjunct therapies after surgery or injury, such as physical therapy, massage, exercise, and, particularly, ultrasound or electrical stimulation. If any of these treatments increases patient suffering, it should be discontinued until a thorough evaluation has been made for myofascial supersensitivity.

Undiagnosed and untreated, myofascial syndromes can delay recovery from uncomplicated stressful incidents and injuries and can perpetuate a state of disability with chronic pain as the primary symptom. In a study of workers disabled by low back pain, Gunn and Milbrandt (34) found that patients with “low back sprains” without tender myofascial points were disabled an average of 6.9 weeks. In contrast, those with “low back sprains” who also had tender myofascial points were disabled for an average of 22.4 weeks, almost as long as those who had signs of radiculopathy, who were disabled for an average of 25.7 weeks.

Most of the current pain literature associates prolonged symptoms and disability with abnormal illness behaviors caused by emotional, psychological, or environmental factors (35). As mentioned in Chapter 10 and Chapter 18, this conclusion is neither surprising nor inaccurate because most of the reports on chronic pain originate in major comprehensive multidisciplinary referral pain programs. Clinical studies have demonstrated that the psychological profiles of patients in such programs are different from those of the general population (36,37). In one study in which 200 patients from the university clinical population were compared with 200 patients from a private pain management practice, there were significant differences in illness behaviors and personality factors between the two populations (37). These data suggest that there is potential danger in generalizing knowledge about the psychological profiles of tertiary referral clinic patients to private-practice settings. Physicians in private practice are much more likely to encounter patients with medical causes of their pains and less likely to encounter moderate or severe depression in association with chronic pain (see Chapter 10). Evaluation of the patient for myofascial syndromes will frequently provide the practitioner with the medical explanation for persistent pain.

Of course, it is possible that TPs are a physiologic mechanism through which a psychophysiologic process manifests and perpetuates itself. Regardless of the causative factor—that is, whether a TP is the result of injury, psychological stress, or environmental factors—once it has formed its own hypersensitivity it is sufficient to generate progressively greater responses that are painful and physically limiting. Although the family physician or the average clinical specialist might not be able

to treat the psychopathologic processes that might account for some of the symptoms, the myofascial syndrome can be readily relieved through TP therapy.

Diagnosis

Diagnosis of myofascial syndrome requires a detailed history of the pain problem, the patient's personal and family history, a general physical examination (which might include neurologic and orthopedic evaluation), and a systematic search for the TP (see Chapter 12).

A detailed history of the pain problems should be taken. Briefly, this entails eliciting a history of the cause and characteristics of the pain at onset, subsequently, and at the time of interview. As previously mentioned, myofascial syndromes caused by sudden trauma are usually easily remembered so that the patient can describe what activity was associated with the onset of pain. In the absence of recent trauma and when onset of pain has been gradual, the physician must inquire about daily activities that might involve repeated movements of muscle groups that could result in chronic overload of muscles.

Physical examination should focus on observation of abnormalities of gait, postural deviation, body asymmetries, and any protective and restricted movements as the patient moves about or disrobes. Normal ROM does not preclude the presence of TPs, but TPs are invariably present if ROM is limited. The involved muscles, as identified by screening for restricted motion and by palpation, usually reveal no sensory deficit or changes in reflexes. Areas distal to the affected muscle, however, might show subtle signs of denervation (26).

To systematically search for the trigger zones, it is essential to know the reference pattern of various myofascial pain syndromes, or at least to have a source to consult to refresh one's memory. As an example, pain in the head and face is often associated with TPs in the cervical muscles (Fig. 29-5). The area of pain reported by the patient can be helpful in attempting to ascertain the pain pattern and tentatively identifying the TPs. The examiner then palpates the suspected muscle for tender TPs and tight bands. The search for TPs is best accomplished by palpating the area with the tip of the finger.

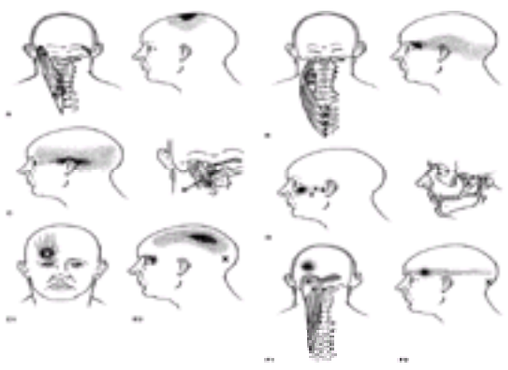

Figure 29-5. Patterns of pain related to trigger points in the head and neck. **A:** Splenius capitis. **B:** Cervicis. **C:** Suboccipital muscles. **D:** Lateral pterygoid muscles. **E:** Occipitofrontalis muscles: 1. frontalis, 2. occipital. **F:** Medial posterior cervical muscles: 1. semispinalis cervicis, 2. semispinalis capitis. *Note: These regions must be approached with extreme caution due to the proximity of underlying nerves and vessels.* (Modified from Travell JG, Simons DG. *Myofascial pain and dysfunction: the trigger point manual*. Baltimore: Williams & Wilkins, 1983.)

The palpation should be systematic so that every square centimeter of the surface overlying the suspected sensitive zone or site from which the pain arises is palpated. The patient is instructed to indicate when the point of exquisite tenderness is not only locally painful, but also aggravates or reproduces the pain in the reference zone. The patient is observed closely during the palpation, because pressure on the exquisitely tender TP usually causes the patient to jump, wince, or cry out. Often seemingly remote TPs contribute to the problems in reported painful areas. Thus, the search for hypersensitive areas should extend to large ipsilateral muscles, particularly in the gluteal region (Fig. 29-6).

Figure 29-6. Ipsilateral pain, a diagnostic key to treatment of refractory local pain. An ipsilateral pattern of pain is very common, with simultaneously active painful trigger points (TPs) in the neck and shoulder, quadratus lumborum, and gluteal muscles (m.) and frequently in the calf muscles. The patient may not be aware of pain in the lumbar gluteal region or lower extremity but may confirm achiness or stiffness in the hip area, sciaticalike pain, or fatigue in the lower back and extremities. Hyperactive TPs in the lumbar gluteal muscles must be treated before positive results can be expected from treatment of TPs in the head, neck, or extremities.

Once the suspected TP has been found and marked with a skin pencil, the palpation is varied so that the patient is required to assist in identifying the particular spot. Uncertainty on the part of the patient suggests that a spot is not a true TP. When several areas of exquisite tenderness are found, it is important to initiate treatment at the most sensitive point.

Search for Tight Bands

To examine the suspected muscle for the objective sign of a tight band, it is placed on stretch. This maneuver places the fibers in a tight band under increased tension, while uninvolved adjacent fibers remain slack. This tight band can be felt most readily by rubbing the tip of the finger (rather than the flat pad) across (perpendicular to) the direction of the fibers (Fig. 29-7). As the fingertip passes over the tight muscle, it feels tense as a nodule. Another technique of palpating the tight muscle and the TP is to grasp the belly of the muscle between thumb and forefinger and squeeze the fibers with a back-and-forth rolling motion to locate taut bands. Tense nodules promptly disappear after effective treatment of the TP.

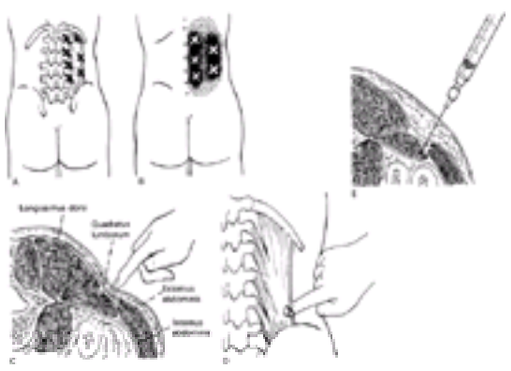

Figure 29-7. Quadratus lumborum myofascial pain syndrome. **A:** Anatomy of the quadratus lumborum and its attachment. Trigger points (TPs) are shown by *X*. **B:** Pattern of pain caused by TPs in the lateral part of the muscle and in its attachment to the transverse processes of the lumbar vertebrae. In the black areas (the essential zones) the pain is most intense and is felt by all patients; in the stippled areas (the spillover zones) not all patients experience pain, and if they do, it is of lesser intensity. **C,D:** Palpation of the area to locate the TP. **E:** Techniques of injecting the TP.

Local Twitch Response

Another objective sign recommended by Travell and Simons (1) is the local twitch response (LTR), which is readily observed in superficial muscles when rapidly changing pressure is applied to the TP by snapping palpation. They cite electromyographic studies showing that this response represents a transient (usually less than 1 second) contraction of a circumscribed group of fibers that correspond closely to the palpable band. The greatest LTR is observed when the TP itself is stimulated, and generally, the more active (hyperirritable) the TP, the stronger its LTR. As one moves further from the TP, stronger pressure is required and the LTR becomes less and less vigorous.

Although the LTR can be useful, the most reliable technique is to systematically search for the TP, and once the point is found, apply sustained pressure sufficient to cause mild local pain that invokes the referred pain pattern in 5 to 10 seconds. If very strong pressure is applied, the local pain can overshadow the referred pain. The referred pain pattern caused by stimulation of a TP is also invoked when a needle penetrates a TP during injection.

TPs are most commonly found in the mid-portion of the muscle belly, coinciding with the motor point in many cases. They are also found at the attachment to the bone, however, and they can develop at other points along the muscle. The size or significance of the host muscle is unrelated to the amount of pain generated by activation of the TP. Once a TP is identified, its sensitivity should be determined by comparing the affected muscle with contralateral muscles in the same segment.

The patient's report of pain should never limit the area of search for TPs. Some patients are acutely aware of pain in only one portion of the body (head, neck, extremity). Examination might reveal hyperactive points in the lower trunk or shoulder girdle that are more important in achieving pain relief. The search should proceed to include the predicted patterns discussed below, with particular emphasis on the erector spinae and the gluteal muscle.

Segmental Clusters

We have found that several different muscles supplied by a specific nerve or nerves frequently contain clusters of hypersensitive TPs. The spread from a single point of stress into clusters is assumed to be associated with local pain response and muscle fatigue. Clusters of myofascial syndromes are common in the neck and shoulder area and include most frequently the trapezius, levator scapula, and infraspinatus. As the severity and duration of pain increase, so do clinical findings of progressively greater involvement of all other muscles innervated by the same spinal segment(s). Hypersensitivity at one level readily involves other muscles with overlapping segmental innervation. For example, the innervation of the splenius capitis muscle starts at the C-2 level and reaches the mid-thoracic level. Therefore, progressive involvement of TPs can be anticipated in all of the muscles with the common spinal nerve supply.

If a TP with referred pain is found in a muscle innervated by the anterior division of the spinal nerve, palpation of the muscles innervated by the posterior division of the same nerve frequently reveals latent TPs that are hypersensitive to pressure and can cause muscle tightness with pain. Thus, TPs in the posterior abdominal muscles may be accompanied by somatic-visceral symptoms related to anterior abdominal muscles in the same segment(s) (38,39). Effective treatment would then involve both the muscles of the lower back and the anterior abdominal muscles, including the rectus abdominis. Contralateral muscles as well as muscles in neighboring segments can also be involved, although usually to a lesser extent.

Multiple Segmental Clusters

As the self-perpetuating myofascial disturbance continues and progresses, TPs develop further and further from the initial area of stress or injury. Although it is generally appreciated that there can be contralateral involvement along segmental lines, it is not generally realized that TPs tend to develop with a higher frequency in ipsilateral muscle groups. Careful examination is likely to reveal that at least 50% more hypersensitive points are found in muscles of the same side as compared with muscles of the contralateral side. Thus, TPs in the upper trunk or shoulder area are likely to be accompanied by TPs in ipsilateral gluteal or lumbar muscles, or both. Activation of TPs in these lumbar and gluteal muscles can adversely affect TPs involving the shoulder, neck, and head or those in the lower limb.

Treatment

General Considerations

Treatment of myofascial pain syndromes revolves around interruption of the pain cycle by eliminating the TP. This may be accomplished by penetrating the TP with a needle; injecting a local anesthetic, a weak steroid solution (38), or saline alone; or spraying the skin overlying the muscle containing the trigger area with a vapocoolant (preferably chlorofluoromethane, although some clinicians use ethyl chloride). In addition, stretch of the muscle is used after TP therapy. Indeed, some clinicians (1,9) believe that stretch of the muscle is as important as the injection or spray. Although we use passive stretch alone in mild cases of myofascial syndromes and we use it in combination with needle penetration of the trigger area in a number of patients, we do not use it routinely, as advocated by Travell and Simons (1,9). Although the latter clinicians consider “stretch and spray” the “workhorse of myofascial therapy,” extensive experience with thousands of patients suggests that penetration of the TP with a needle or injection of a local anesthetic, a weak steroid solution, or saline remains the most effective therapy (4,6,7,16,31). The limited use of low- dose steroids [0.05% dexamethasone (DMSO) in saline] is a more recent approach that shows particular promise in older patients or in those with an extended history of myofascial pain.

Although good results have been reported with injections of saline or with dry needling (1,9,33,40,41), the use of local anesthetics diminishes the local discomfort associated with the injection. In my experience, the optimal concentrations of local anesthetics for injections of TPs are 0.5% procaine, 0.25% to 0.5% lidocaine, and 0.125% or 0.25% bupivacaine in 2 mL. Using these concentrations and volumes virtually eliminates the risk of systemic toxic reactions and local damage to muscle. Thus, injection of 20 mL to treat 10 TPs involves a maximum of 100 mg of procaine, 50 to 100 mg of lidocaine, or 25 to 50 mg of bupivacaine. It is of interest to note that lidocaine, in doses of 50 to 100 mg injected as a bolus, is frequently used for the treatment of cardiac arrhythmia without systemic toxicity. Although procaine was long considered the standard of reference as the best drug, lidocaine has the advantage of more rapid and longer action; bupivacaine produces analgesia that lasts four to six times longer than procaine and two to three times longer than lidocaine.

The theory underlying treatment is that the entire symptom complex is an expression of reflex mechanisms, provoked by the TP, and that once it is initiated, it is self-sustaining by implication of closed, self-exciting chains of internuncial neurons in the central nervous system. Interruption of this pain cycle by eliminating the TP, using dry needling; injection with local anesthetic, a weak steroid solution, or saline alone; or stretch and spray, interrupts the reflex and can produce prolonged relief.

Treatment of myofascial syndromes secondary to ligamentous injuries is somewhat difficult. Injuries associated with physical labor (impact, heavy lifting, twisting) and automobile accidents might not respond to the initial course of TP therapy. If no response is apparent, attention should be turned to the adjunctive therapies and TPs should be reevaluated periodically over the course of treatment.

Trigger Point Injection Technique

To apply the injection technique successfully, it is necessary to have knowledge of the patterns of various myofascial syndromes and the locations of the trigger areas. Application of this knowledge requires a thorough history and physical examination. Treatment must be directed primarily toward the trigger area and not to the zone of reference. Although infiltration of the spastic muscle and application of heat and other physical therapeutic procedures that produce spasmolysis are of benefit, blocking of the TP or trigger area is more efficacious because it eliminates the cause of the referred pain and the associated phenomena. It is also important to remember that more than one trigger may be, and usually is, present. Therefore, for optimal results, it is necessary to examine all of the muscles for TPs that could be producing the pain pattern so that all of the abnormal foci of pain can be interrupted. Finally, it is important to recognize sites that include crucial underlying structures such as nerves or vessels that must be avoided. Great care must be taken when treating the head and neck (see Fig. 29-5); the inguinal, axillary, or

popliteal areas; and the scapular region (apex of lung).

Preparation of the Patient. Before the first treatment, whether by penetration of TPs or by stretch and spray, it is important to provide the patient with information about the purpose of the treatment, a detailed description of the procedure, and what is expected to be accomplished. The patient must understand clearly why the therapy is directed toward the TP rather than the area of pain reference. This understanding can be enhanced by again exerting pressure on the TP and reminding the patient that the pain provoked by the pressure is referred to another area. Because in many instances the period of relief produced by the treatment is followed by pain that may be even greater than the original complaint, the patient should be informed that such a reaction is not uncommon. Unless this information is provided in advance of the therapy, the patient might become discouraged and not return for a second treatment. The patient's full cooperation is required if optimal results are to be obtained.

For needle preparation, the patient is placed in the recumbent position to prevent or minimize attacks of psychogenically induced arterial hypotension and syncope, which are likely to occur in apprehensive patients who are upright. The patient should be repeatedly reassured and informed of each maneuver before treatment. It is essential to have a source of oxygen in the office to treat vasovagal or psychogenic reactions. This need not be a complicated piece of equipment, but merely a tank, regulator, and mask.

Technique of Injection. Just before initiating the treatment, the precise site is marked with a skin pencil or gentian violet and the skin is washed with soap and water and then with antiseptic solution. Sterility must be strictly maintained to preclude infection. Immediately before insertion of the needle, the TP is again identified with the finger (Fig. 29-8). Penetration is accomplished with a 25-gauge, 5-cm needle for deep muscles or a 27-gauge, 2-cm needle for superficial muscles. The use of such fine needles makes preliminary intracutaneous injection of the local anesthetic unnecessary and even undesirable because the pain caused during injection is usually more than that caused by the deliberate insertion of a fine needle through the skin. Although some clinicians advocate the use of 22-gauge needles for fear of breaking finer needles, we believe that proper insertion of a good needle virtually eliminates the danger of breakage and has the advantages of making insertions almost painless and avoiding trauma to tissues.

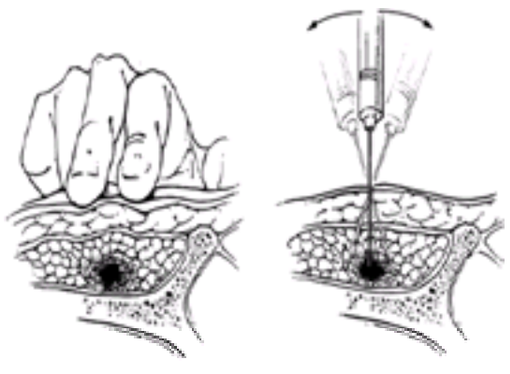

Figure 29-8. **A:** Technique of locating trigger point for injection. **B:** Fanning technique for injection.

The needle is attached to a 10-mL Luer-Lok control syringe filled with a local anesthetic solution, saline, or a weak solution of saline and 0.05% DMSO. Although some clinicians use a smaller syringe (3 or 5 mL), the larger syringe acts as a reservoir and avoids the necessity of refilling the syringe several times if many TPs are to be injected. Saline only is very effective and preferable in young patients and is the only choice for pregnant patients. Local anesthetic or the DMSO solutions should *not* be used with pregnant patients. The DMSO solution should also be avoided in patients who are diabetic, have clotting disorders, or have other contraindications to steroid use.

The needle is directed at the most sensitive TP identified and is advanced until the TP is penetrated. Penetration of the TP elicits exquisite tenderness and pain, not only locally but also at the zone of reference. The depth of the injection depends on the region involved and on the site of the TP. Once the TP is penetrated, a total of 0.5 to 2 mL of solution is injected under some pressure. This process usually causes further exaggeration of the local or referred pain and tenderness and, not infrequently, local spasm.

The needle is then withdrawn slightly and redirected two or three times to cover the immediate area of the TP with a fanning technique depicted in Figure 29-8. Exaggeration of pain and tenderness and local spasms is presumptive evidence that the injection has been properly executed. Confirmation is obtained if the procedure effects relief of pain and muscle spasm, which is usually dramatic. If no relief is obtained, it is most likely that the TP was not injected, indicating another trial. It is essential to eliminate the TP or points completely by repeated infiltration because incomplete blockade is not only partially ineffective, but it is followed by increased pain after disappearance of the effects of the local anesthetic.

Although some physicians have reported injection of as much as 10 to 15 mL of solution at a given TP, we have found this amount to be unnecessarily excessive, and it carries the risk of systemic toxicity if multiple TPs are injected.

Treatment of the neck and head muscles can be done with a very short 27-gauge or 30-gauge needle. Use of a fine needle precludes most of the bleeding and subsequent discomfort associated with TP injections (4,5,16). When a fine needle is used in large muscle mass, however, there is always the possibility that it might break off.

Several TPs can be treated, provided the patient is monitored closely during and immediately after treatment. If the patient manifests signs of pallor, sweating, or faintness, treatment should be promptly discontinued. Immediately after the injection therapy, a warm, moist pack is applied to the area to relieve temporary discomfort. This also extends the time the patient is quiet after treatment, and patients report that they find this aspect of treatment soothing.

TPs in the extremities are slightly more difficult to locate precisely. When they have been identified, however, injection is generally safe and uncomplicated. If bleeding into tissue occurs, such as might be anticipated in the tight compartments of the forearm, the treatment is followed with applications of cold packs and compression rather than the warm, moist packs otherwise recommended.

The dominant role of the larger muscles of the lower torso requires that TPs identified in these areas be treated on the first visit. They are usually involved in a myofascial syndrome that has been well established. Failure to treat TPs in the lower trunk concurrent with or before treatment of points in other parts of the body is likely to result in greater discomfort for the patient. We have seen many patients in whom TPs in the neck and shoulder areas were treated by injection without a full clinical evaluation of TPs in other locations. The result for many of these patients was painful activation of TPs in the lumbar and gluteal muscles. In addition, treatment of the cervical and shoulder areas was not effective.

In patients who have severely limited ROM, it is recommended that muscles supplied by both anterior and posterior divisions of the nerve on ipsilateral and contralateral sides be examined for latent TPs. Obviously, if TPs are present they should be treated.

Relief of pain, tenderness, muscle spasm, and associated phenomena persists for several hours after treatment, and sometimes for a day or two. In patients with acute myofascial syndromes (i.e., the symptoms are of recent onset and caused by major trauma), two or three treatments are often sufficient to provide permanent relief. In general, young patients tend to respond more quickly and positively than older patients; however, a series of two to five treatments is usually sufficient either to provide prolonged relief or to establish that the patient is responding to the therapy. Patients with severe pain associated with activation of latent TPs might require 3 to 6 weeks of intensive therapy consisting of TP injections and physical therapy (4,5,7,16).

Patients who have had a history of severe pain for several years before treatment may not respond to treatments for many months. Persistence with the treatment is indicated in these cases, however, by the clear finding of numerous hyperactive TPs with either an ipsilateral tendency or general distribution throughout the body. Release of muscle tension for these patients has usually been dramatic, and it has been described as “tight armor suddenly falling off the whole body.”

Technique of Stretch and Spray

As previously mentioned, Travell and Simons (1,9) and Kraus (42), among others, prefer the technique of spraying the skin overlying the muscle of the trigger areas and subsequent stretch of the muscle to injection therapy. The advantages claimed for this technique are that it is simple, relatively painless, and a rapid way to relieve a single muscle syndrome. Moreover, they believe that it is more effective in deactivating all TPs in the affected muscles, some of which might be missed by palpation. They also believe that it is useful immediately after injection to ensure deactivation of any remaining active or latent TPs in a group of muscles. Although they claim that this technique provides a more rapid way to relieve myofascial syndromes, our extensive experience with both techniques suggests that beneficial results from the spray and stretch technique are slower in occurring.

Travell and Simons (1,9) emphasize that they use the term “stretch and spray,” not “spray and stretch” because they consider “stretch” the essential component, whereas the spray facilitates the stretch. Gentle, persistent stretch without spray is more likely to inactivate deep TPs than spray without stretch. They find the best results are obtained by spraying first and then stretching and spraying. They believe that the spraying reduces the painfulness of the stretch tension, helping the patient to achieve complete relaxation, and that it helps to block reflex muscle spasm initiated by autogenous stretch reflexes.

For this procedure, the patient is prepared as discussed above, but the position used for the technique differs depending on the target muscles to be sprayed and stretched. For myofascial syndromes in the head and neck, and for some in the upper limbs, the patient should be in a sitting position; for syndromes involving most of the muscles in the upper extremity, trunk, and lower extremity, the patient is placed recumbent either in the supine or lateral position, to permit the most appropriate spray and stretch.

Technique. The patient is made comfortable, and the part to be sprayed is well supported so that the involved muscles are relaxed. One end of the muscle must be anchored so that the pressure can be applied at the other end to passively stretch it. With the patient in the position for stretch, the bottle containing Flouri-Methane (Gebauer Chemical Company, Cleveland, OH) is held 18 inches away from the patient and the spray applied at an angle of 30 degree with the skin as illustrated in Figure 29-9. A jet or stream (not a diffuse mist) of the vapocoolant spray is applied to the skin overlying the trigger area and moved slowly in one direction, rather than to and fro. The direction is determined by the pain reference pattern of the specific TPs to be sprayed; the sweep should be started on the skin over the trigger area and made to travel toward the area of referred pain, and then over the referred pain pattern.

Figure 29-9. Stretch and spray technique.

The spray is applied in parallel sweeps to cover the entire muscle involved, as well as the area of reference, to achieve full muscle length. A given area of skin is sprayed only two or three times before rewarming. A moist hot pack is applied to rewarm the skin and help further relax the muscle. After the skin has rewarmed, stretch and spray can be repeated. Several cycles of full ROM and complete stretch and spray treatment of the muscle may be required. The patient is cautioned to avoid overloading the muscle after treatment.

Travell and Simons (1,9) believe that the stretch and spray technique inactivates myofascial TPs, with consequent release of the abnormal muscle tension and disappearance of the sensitive point and the referred pain and associated phenomena. We believe that the spray facilitates the stretching by inhibiting the pain and stretch reflexes, perhaps by provoking spinal inhibition, descending inhibition, and/or inhibition of TPs.

Adjunctive Therapies

For optimal results it is necessary to use other therapeutic measures in addition to deactivation of the TP. If severe autonomic (sympathetic) dysfunctions are prominent, a sympathetic block might be useful in addition to the infiltration or spray and stretch. Immediately after these procedures we frequently have the patient receive physical therapy in the form of massage (especially gentle deep friction) and, as previously mentioned, heat applied to the affected muscle. Passive and active motion of the part is an essential adjunct to treatment. The physician should impress on the patient the importance of his or her active participation in treatment and encourage the patient to undertake specific, appropriate forms of exercise. It is essential that the involved muscles not be activated too rapidly or moved to a painful degree, especially in the early phases of treatment, because severe pain itself is deleterious and provokes reflex muscle spasm.

Drugs should be used only as an adjunct to a comprehensive therapy program. In patients who are likely to have moderate to severe pain after the injection therapy, it is best to prescribe nonnarcotic analgesics such as aspirin or nonsteroidal antiinflammatory drugs to be taken between treatments. If muscle spasm is diffuse throughout the body, a short course of muscle relaxants may be prescribed during a trial therapy period. If the patient experiences severe intractable pain, small doses of a narcotic may be prescribed for 3 to 5 days, but not longer, lest the patient develop physical dependence. Patients with chronic, persistent pain often consult several physicians, with the consequent possibility of having had several prescriptions for medication.

In place of TP therapy, a number of clinicians have used other modalities, including massage (especially deep friction); electrical stimulation; ice massage; cervical or lumbar traction, or both; compression; ultrasound; and biofeedback (1). Because there is little conclusive research on how these various treatments act to modify myofascial pain syndromes, all can be considered on a case-by-case basis as either treatment or pain management adjuncts.

Pressure and Massage. Pressure over TPs and massage of muscles have been reported to be effective in treating myofascial syndromes. From a medical viewpoint, however, when these methods are used inappropriately they can exacerbate the conditions that perpetuate pain through the TP locus, resulting in more severe symptoms. Our observations led to the conclusion that pressure and massage must be used with caution when the small muscles of the head and neck have flared up with TP hyperactivity. When pressure, massage, or both are used in a controlled situation by a clinician who is prepared to follow through with alternate therapies, these noninvasive methods have the advantage of being an initial approach that does not increase the patient's anxiety.

Ice Massage. Report on the use of ice massage for pain relief shows that it might be comparable to transcutaneous electrical stimulation and acupuncture, mediating pain relief with similar neural mechanisms (beta afferent fibers). In a study by Melzack et al. (43), ice massage provided pain relief among patients with chronic low back pain, the majority of whom had undergone diskectomy, spinal fusion, or both or with radiologic evidence of degenerative disk disease. The efficacy of ice massage for TP desensitization has not been documented.

Electrical Stimulation. Transcutaneous electrical stimulation (TENS) as a therapeutic method is discussed in Chapter 98. This treatment has been demonstrated as a useful tool in reduction of myofascial pain as well as pain of nonmuscular etiology. Kaada (44), in a review of research on physiologic and biochemical mediators of pain, pointed out that neither the spinal gate mechanisms nor the analgesic effect of endorphins can explain the “widespread cutaneous vasodilation evoked by low frequency TENS and acupuncture.” He suggested that different mechanisms are working as pain mediators in response to these treatment methods. The three possibilities presented were reduction of vasoconstrictor tone, active vasodilation via sympathetic nerves by inhibiting the release of norepinephrine at the neuromuscular junction and vasoactive peptides, and an axon reflex. The axon reflex differs from the other mechanisms mediated over the sympathetic nerves in that it is local and “rather immediate.” Much of the confusion in the literature about the effectiveness of TENS is now being cleared; recent work illustrates the importance

of different stimulation parameters for specific painful conditions (see Chapter 98).

CONCLUSIONS

Myofascial syndromes affect virtually everyone at some time, either as a primary source of pain or in association with other painful conditions. The syndromes should be recognized by clinicians to prevent their attribution to normal aging or degenerative processes. They should be suspected in all chronic pain cases and in all cases in which pain exceeds expected duration or intensity. When myofascial pain is secondary to another painful condition, treatment of TPs can reduce the patient's pain level and aid in diagnosis of the underlying condition.

Creditable clinicians and investigators for the treatment of these conditions have recommended many treatment methods. At present, it is difficult to evaluate the relative efficacy of these methods or to determine the most appropriate applications. Much of the confusion can be attributed to differences in the patient populations that are served and in the wide range of pathology treated under the “myofascial pain syndromes” classification. The variations range from a single TP of recent activation to broadly generalized TP hypersensitivity of many years' duration accompanied by high levels of sympathetic nervous system involvement. All of these can be secondary to an underlying pathology, with or without neuropathy.

Myofascial syndromes are most effectively treated by penetration of the TPs and injection of a local anesthetic, low-dose steroids, or saline alone. The use of local anesthetics in conjunction with needling has the obvious advantage of eliminating patient discomfort during and after treatment. This highly effective therapy is sufficient to relieve pain without need for adjunct therapies when the patient is seen before the myofascial syndrome has been well established. Therefore, the optimal approach is for clinicians in all specialties to be alert to myofascial pain syndromes as primary and secondary sources of pain and to incorporate the basic techniques of TP desensitization into any comprehensive patient management program.

CHAPTER 30

Fibromyalgia Syndrome

I. J. Russell

Fibromyalgia syndrome (FMS) is a controversial disorder of unknown etiology. It is characterized by the history of chronic, bilateral, upper and lower body, “musculoskeletal” pain combined with typical examination findings of painful tenderness at 11 or more of 18 anatomically defined soft tissue tender points (TePs).

Even though the joints of FMS patients are apparently normal, the severity of the discomfort they experience and the extent to which they are limited physically are comparable to those reported by patients with rheumatoid arthritis (RA). Other clinical manifestations that are common but less consistently associated with FMS include lightheadedness, memory loss, insomnia, depression, fatigue, irritable bowel syndrome, and urodynia. The situation is further complicated by the apparent comorbidity of FMS with a variety of rheumatic, inflammatory, infectious, and endocrine disorders.

Despite many attempts to identify a histologic abnormality in the painful soft tissues, none has been confirmed. The widespread pain and low pain threshold of FMS patients has led to a suspicion that a neurochemical mechanism may be involved. Broad experimental support for that concept has led us to propose FMS as “chronic, widespread allodynia.”

In animal studies, a variety of manipulations of nerves and transmitters can induce allodynia. The findings from such studies may be relevant to humans with FMS. Serotonin is a recognized mediator in the regulation of deep sleep and of pain perception. Its production appears to be compromised in many tissues of FMS patients. One of the functions of serotonin is to regulate the release of substance P in the central nervous system (CNS) and thereby alter the perception of tissue damage. Substance P concentration appears to be elevated in the spinal fluid of most FMS patients. There also appear to be abnormalities in several neuroendocrine systems and in high-energy phosphate stores. The major challenges for the coming years will be to better characterize FMS with respect to its etiology (predisposing, initiating, and perpetuating factors). Such information should lead to the development of interventions that are more effective than those currently available.

This chapter first examines the basic considerations pertaining to FMS and then turns to clinical considerations. Under the basic considerations section, issues relating to diagnosis, epidemiology, natural history, and proposed pathogenesis of FMS are discussed. The section dealing with clinical considerations is intended to help the clinician deal compassionately with the many problems presented by individual FMS patients. A compendium of review articles contains up-to-date information about FMS (1).

BASIC CONSIDERATIONS

History

It seems unlikely that FMS is a new condition, but there is very little information available from antiquity to shed light on its history. Aches and pains are so common to the human condition that it is easy to argue that disorders like FMS have always been present.

An early use of the term *fibrositis* dates back to the turn of the century, when Sir Edward Gowers attempted to characterize lumbago (Table 30-1).

Dates	Persons	Events
1500s	Spa Balneotherapists	Rest and hydrotherapy for aches and pains prescribed
1900	Sir Edward Gowers	Published the term *fibrositis*
1950s	Philip Hench	Used fibrositis in clinical diagnosis
1970s	Smythe et al.	Fourteen tender points diagnosis criteria developed
1970s	Moldofsky et al.	Insomnia, alpha-delta sleep dysfunction noted
1980s	Yunus et al.	Two-stage criteria developed, *fibromyalgia* term first used
1988	Vaeroy et al.	Substance P concentration noted to be elevated in FMS spinal fluid
1990	Wolfe et al.	1990 ACR classification criteria developed
1992	Bennett et al.	Low concentration of growth hormone noted in FMS
1992	Russell et al.	Low concentration of serotonin noted in FMS
1993	Pillemer et al.	First NIH conference on FMS
1994	Crofford et al.	Abnormal HPA axis noted in FMS
1995	Mountz et al.	Low regional brain blood flow noted in FMS
1997	Buskila et al.	Increased rates of FMS after cervical spine trauma

TABLE 30-1. Key events in the history of fibromyalgia (FMS)

For many years, FMS was considered to be a subjective disorder of vague musculoskeletal pain that the physician could not objectively document on examination nor confirm by laboratory testing. The diagnosis was usually made by exclusion, but only after an extensive (and expensive) clinical evaluation had failed to disclose any other explanation for the patient's symptoms.

A dramatic milestone in the modern thinking about fibrositis was the insight provided by Smythe (2), who recognized that there was a group of patients whose widespread pain was accompanied by remarkably consistent tenderness to palpation at soft tissue body sites referred to as “tender points.” In a collaboration with Moldofsky (3), the concept of disrupted slow-wave sleep became associated with the fibrositis pattern of widespread pain and TePs. The diagnostic criteria developed by Smythe and Moldofsky were modified by Yunus and colleagues (4) to require less TePs but to include a variety of constitutional manifestations.

The prolonged morning stiffness reported by fibrositis patients resembled that of the inflammatory disorders, such as RA, but the erythrocyte sedimentation rate was usually normal in fibrositis and no other objective inflammatory features were found. For that reason, it was argued that the disorder was poorly named (the suffix *-itis*, inferring inflammation). The name was changed to *fibromyalgia syndrome*, but that name is similarly troublesome. It is not clear, for example, that either fibrous tissue (*fibro*) or muscle (*my*) is pathologically involved in this disorder. It seems wise to delay any further change in terminology until more information is known about the pathogenesis of this disorder.

In FMS, the clinical symptoms of widespread body pain, multiple TePs, long-duration morning stiffness, and inefficient sleep are characteristically and distinctly different from healthy normal controls. Despite clinical similarities of individuals with FMS, it is still possible that FMS is the ultimate manifestation of several distinct physiologic processes that involve genetic predispositions, age, chronic insomnia, neurochemical dysfunctions, endocrinopathies, spinal stenosis, and perhaps even physical trauma. It is possible that new findings from biochemical measures or genetic markers will allow identification of clinical or etiological subsets of FMS that should be viewed or managed differently. There may also be different modes of prevention.

From the early 1970s until approximately 1990, the numbers of publications about FMS (including those using the term *fibrositis*) numbered between 10 and 20 annually. After 1990, those numbers increased dramatically to more than 100 annually. A probable explanation for the dramatic change was a research study prospectively designed in collaboration with the American College of Rheumatology (ACR) (5). Investigators from approximately 20 clinical centers in the United States and Canada followed the same protocol to evaluate systematically the symptoms and signs found in people with the diagnosis of FMS. Healthy controls and disease control groups with early RA, systemic lupus erythematosus (SLE), and other painful conditions were assessed similarly. Analysis of these data led to classification criteria that have been endorsed by the ACR. The ACR criteria for the classification of FMS (Table 30-2) exhibited a moderately high sensitivity (88.4%) and specificity (81.1%), clarifying the clinical distinction between FMS and other painful conditions. Although these criteria have been criticized because they are subjective, they have facilitated research on FMS. They probably will not be effectively replaced until the pathogenesis of this condition is better understood and some form of laboratory test or histochemical lesion can objectively support the diagnosis and guide effective treatment.

From history: Widespread musculoskeletal pain.

Definition: For the past 3 months, pain has been experienced in four quadrants; the locations are counted as follows: both sides of the body, above and below the waist, in the trunk (e.g., cervical spine, anterior chest, thoracic spine, low back areas). Shoulder and buttock involvement count for either side of the body. "Low back" counts as lower segment.

From examination: Pain induced by palpation of tender points.

Definition: Pain must be inducible at 11 or more of the following 18 (9 bilateral) tender point sites:

Anatomic location of tender point sites:

1, 2. Occiput: at the suboccipital muscle insertion
3, 4. Low cervical: at the anterior aspects of the intertransverse spaces at C5–C7
5, 6. Trapezius: at the midpoint of the upper muscle border
7, 8. Supraspinatus: near the origins, above the spine of the scapula
9, 10. Second rib: upper surface just lateral to the second costochondral junction
11, 12. Lateral epicondyle: extensor muscle, 2 cm distal to the epicondyle
13, 14. Gluteal: in upper-outer quadrants of buttocks in anterior fold of muscle
15, 16. Greater trochanter: posterior to the trochanteric prominence
17, 18. Knees: at the medial fat pad proximal to the joint line and condyle

Adapted from Wolfe F, Smythe HA, Yunus MB, et al. The American College of Rheumatology 1990 criteria for the classification of fibromyalgia. Arthritis Rheum 1990;33:160–172.

TABLE 30-2. The 1990 American College of Rheumatology criteria for the classification of fibromyalgia syndrome

In the wake of successful diagnostic criteria, a number of important new findings regarding the epidemiology of FMS have been identified. FMS has been found to be common in most Western countries. It has been shown to be present in approximately 2% of the adult general population in the United States (6), with a similar distribution in other countries where valid epidemiologic studies had been conducted. Adult women were affected five to seven times more commonly than men. In children, the gender distribution was approximately equal for boys and girls (7).

In the absence of observable tissue pathology, some have thought of FMS as a psychosocial disorder. Dissatisfaction with this approach as an explanation for FMS led to an ongoing deliberation referred to as the “central versus peripheral” pathogenesis debate. In the absence of a histologic basis for peripheral disease, the focus shifted heavily toward involvement of the CNS. As a result, findings in the neurochemical mechanisms of nociception and in the neuroendocrine system have taken center stage. Abnormal levels of biochemicals such as tryptophan, serotonin, substance P, growth hormone, and abnormal diurnal regulation of cortisol production all have been reported. Exactly how CNS alterations lead to FMS remains unclear.

Debate continues as to whether FMS should be considered a psychosocial disorder or a disabling condition on a par with RA, osteoarthritis, compression myelopathies, myasthenia gravis, multiple sclerosis, and diabetic neuropathy. This controversy is important because of its impact on social welfare eligibility and the role of health care in the relief of symptoms (8,9).

Classification

FMS is not a form of arthritis. Joint range of motion usually remains normal throughout the course of FMS, although there may be some limitation of active range of motion due to the discomfort experienced. Joint swelling, inflammation, effusions, or heat are not expected components of FMS. Occasionally FMS may antedate or follow the onset of a rheumatic disease, but in the majority of cases, FMS is not simply the early stage of another medical condition.

Soft Tissue Pain Syndromes

FMS can be classified as a soft tissue pain syndrome characterized by widespread pain emanating from periarticular structures located outside the joint capsule and periosteum. The soft tissue pain syndromes differ from arthritic disorders in that the synovial joints are not directly involved. The anatomic structures that appear to be symptomatic can include ligaments, tendons, fascia, bursae, and muscles. All of these soft tissue structures are known to facilitate mechanical functions of the diarthrodial joints. Any of these structures can become painful and dysfunctional alone or in association with distinct inflammatory, autoimmune, arthritic, or endocrine disorders.

Table 30-3 shows a contemporary classification of soft tissue pain syndromes. The main subheadings divide the syndromes into localized, regionalized, and generalized categories. Most of the “localized” conditions are believed to result from repetitive mechanical injury to inadequately conditioned tissues. They are often named anatomically and are disclosed by a typical history plus the exquisite tenderness elicited by digital palpation of the affected structures.

Localized	Regionalized	Generalized
Entrapment syndrome (e.g., carpal tunnel syndrome)	Myofascial pain syndrome	Fibromyalgia syndrome
Tenosynovitis (e.g., biceps tendinitis)	Masticatory myofascial pain syndrome	Chronic fatigue syndrome
Bursitis (e.g., trochanteric bursitis)	Complex regional pain syndrome	Polymyalgia rheumatica
Enthesopathies (e.g., tennis elbow)	Referred visceral pain (e.g., left shoulder pain due to angina)	Hypermobility syndrome

Adapted from Russell IJ. A new journal [Editorial]. J Musculoske Pain 1993;1:1–7.

TABLE 30-3. Soft tissue pain disorders

The “regionalized” syndromes can also result from “overuse” and may involve more than one type of body structure but are still limited in anatomic scope to a region or body quadrant. The myofascial pain syndrome (MPS) is characterized by trigger points (TrPs) (contrasted with the TePs of FMS) and has traditionally been managed by physiatrists. The masticatory MPS involves the temporomandibular joint or TrPs, or both, in the muscles of mastication that are typically treated by dentists. Several types of visceral pain can be referred to a musculoskeletal structure (e.g., angina felt in the shoulder or jaw), and the recently renamed complex regional pain syndrome would be classified in this category.

The “generalized” category implies a systemic process that affects the musculoskeletal system in a more global manner. Chronic fatigue syndrome has been

characterized by persistent fatigue and a number of other constitutional symptoms. It initially presented in epidemics but more recent applications of that diagnosis have emphasized sporadic cases and current criteria no longer exclude FMS (10). An overlap between FMS and chronic fatigue syndrome has led to speculation that they are identical, but there are important historical and clinical differences, suggesting that they are separate family members of an overlapping soft tissue pain spectrum.

Symptoms and Signs

Widespread Pain

The most prominent symptom of FMS is chronic, widespread pain in soft tissue regions such as the muscles, ligaments, bursae, and tendons. The pain has been described as a persistent, diffuse, deep, aching, throbbing, sometimes stabbing, pain associated with distal extremity dysesthesias. Patients with FMS typically exhibit high pain severity scores on the *McGill Pain Questionnaire*. They choose dramatic words to describe their symptoms, and the veracity of the FMS patient has often been questioned, due to their dramatic verbal and facial portrayal of the pain they experience.

When patients were asked to indicate the locations of their pains on a body diagram they usually indicated bilateral body sites involving the upper and lower extremities, the neck posteriorly, the anterior chest, and the low back (Fig. 30-1). Monitoring of a patient's course with serial quantitative (percent-shaded) pain diagrams may provide a reliable method for research outcome studies (11).

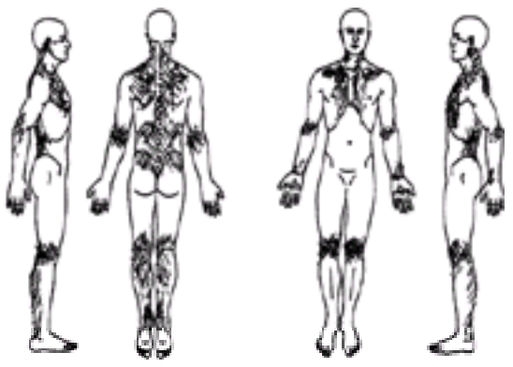

Figure 30-1. Fibromyalgia pain diagrams. The shaded areas on the set of four diagrams were marked by a patient with fibromyalgia to indicate the locations of her painful symptoms on the occasion of her entry into a clinical research study. The pattern of widespread pain is typical of pain diagrams by other fibromyalgia patients. Using the rule of nines, numeric values can be derived to indicate the proportion of the entire figure affected. That number provides an estimate of the pain severity.

Tender Points

The characteristic physical finding of multiple TePs in FMS can be elicited by pressing firmly (approximately 4 kg of pressure on an area of approximately 1 square cm) over each of 18 anatomically defined soft tissue sites called TePs. At least 11 of the 18 TePs must exhibit painful sensitivity from such pressure to meet the ACR TePs criteria for the diagnosis of FMS.

The tenderness in FMS is apparently located in the deep soft tissues because topical anesthesia has no effect on the severity of pain induced by deep-pressure stimuli (12). Despite this apparently unique sensitivity of the TePs to palpation pressure, there is no convincing evidence that the tissues that hurt are histologically or functionally abnormal.

Control Points

As investigators explored the application of the TeP examination to people with FMS, it was observed that there were body sites at which people with FMS exhibited very little tenderness to deep palpation pressure. These so-called control points (CPs) were at first expected to provide a resource for checking the specificity of tenderness at the TePs. According to the original theory, if a patient reported pain after deep palpation pressure at a CP, there must have been some psychological augmentation of the symptoms at the true TePs for the purpose of secondary gain. This concept was discounted when it was recognized that the consistently lower severity of tenderness at the CPs actually correlated quite closely with the severity of tenderness at the TePs (13). This provided substantial support for the hypothesis of a CNS rather than a peripheral muscle tissue pathogenesis of FMS.

Allodynia

Healthy individuals generally do not perceive a 4-kg digital pressure stimulus to be painful. Therefore, this finding in FMS seems to represent a lower-than-normal pain threshold and meets the clinical definition of allodynia. For that reason it was proposed that FMS could be viewed mechanistically as “chronic, widespread allodynia.” Allodynia is defined as a situation in which pain is perceived from a stimulus that is not normally painful (see Chapter 2).

Several methods have been explored to quantify pain and tenderness at TePs. These include

1. Counting the number of TeP sites (total TeP count) that are tender at a given time in a specific individual.
2. Documenting the relative severity of tenderness to digital palpation at 18 TePs [herein called the *tender point index* (TPI); some authors call it the *myalgic score*].
3. Reporting the average pain threshold (APT) from algometric (dolorimetric) examination of the 18 TePs. The TPI and APT correlate with each other, but the APT exhibits a higher reliability. The TPI bears some correlation to the patient's level of anxiety and depression that is not exhibited by the APT.
4. Documenting the extent of the pain distribution using a quantified pain diagram.

Epidemiology

Epidemiologic studies have provided valuable information about FMS. The frequency with which FMS is found in a number of subpopulations permits increasingly sophisticated estimates of the actual prevalence of the disorder. There is very little information about the incidence of FMS. Equally important is an improved understanding of the natural history of FMS.

Prevalence

FMS occurs in all ages, ethnic groups, and cultures studied to date. Its gender distribution is nearly equal in childhood but in adults, it is fourfold to sevenfold more common in females. Most of the epidemiologic studies conducted to determine the prevalence of FMS in the community have consisted of a screening questionnaire followed by confirmatory examination of those who reported widespread body pain. FMS does not seem to be a disorder limited to affluent peoples nor to the industrialized nations.

Two studies conducted in Canada and the United States found that approximately 65% of the general population are free of pain, 5% have transient pain, 20% have regional pain, and 10% have widespread pain (the group most likely to include people with FMS) (6,14). Examination of those with widespread pain has established that approximately 2% of the general population have FMS sufficient to meet ACR criteria. The overall adult population average of 2% was composed of approximately 0.5% males and 3.5% females. The gender distributions varied with age by decade, exhibiting the highest prevalence in women 50 to 60 years of age (6) (Fig. 30-2).

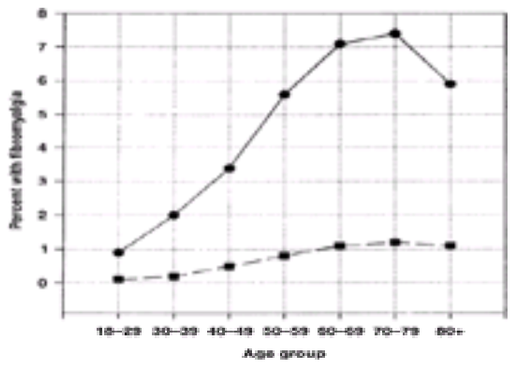

Figure 30-2. Age distribution of fibromyalgia syndrome by gender in the general population. Although the prevalence of fibromyalgia was consistently higher among females (*circles*) than males (*squares*), it increased with age in both sexes to approximately age 70. The explanation for the decline thereafter is elusive. (From Wolfe F, Ross K, Anderson J, et al. The prevalence and characteristics of fibromyalgia in the general population. *Arthritis Rheum* 1995;38:19–28, with permission.)

It has been observed that 6% to 10% of patients in a typical physician's waiting room (15) and 15% of those evaluated by a rheumatologist meet criteria for FMS. The implication is that for every 10 patients examined, at least one will have FMS.

Incidence

A group of Israeli investigators enrolled subjects who had recently suffered a whiplash injury in a rear-end automobile accident and a control group that had just suffered a lower extremity fracture in an industrial accident (16). At 18-month follow-up, more than 22% of the whiplash injury subjects had developed FMS, compared with less than 2% of the control group. In most cases, the diagnostic symptoms had developed within 3 months of the whiplash injury. From a separate magnetic resonance imaging study (17) comes the observation that the size of the cervical canal is an important risk factor for the development of chronic pain symptoms after a whiplash injury. Based on these independent observations, there is reason to believe that monitoring whiplash injury subjects, especially those with narrow cervical canals, will prospectively allow the development of FMS to be observed and characterized.

Natural History

Extended follow-up (7+ years) studies have shown that FMS is not a disorder in transition to another medical condition (8). Although FMS commonly accompanies RA, SLE, and Sjögren's syndrome, the associated condition is usually apparent at the time of diagnosis of FMS or shortly thereafter.

There is a growing awareness that the impact of FMS on an individual's quality of life and physical function is substantial and may be comparable to that of RA (18). Although there is considerable variation across the United States, it appears that approximately 30% of FMS patients accept shorter work hours or less physically taxing work to maintain employment and that approximately 15% currently receive disability funding because of their symptoms (9). The annual direct medical costs incurred by each FMS patient averaged $2,274 (8). As a result of this and other estimates, the calculated direct cost of FMS to the United States economy is in excess of $16 billion annually. There is currently no cure for FMS, so people who develop FMS will be affected for the rest of their lives. There is no information to suggest that FMS contributes to a shortening of life span, but longer follow-up studies will be needed to be certain that mild limitation is not present or even that drug therapy may have some effect on longevity.

Pathogenesis

The cause of FMS is still unknown. Theories regarding its etiology have undergone a transition from a psychiatric process, as some still view it, to a muscle disorder, as it is currently classified in the Medline Index, to a genetically determined CNS disorder of nociception and neuroendocrine dysfunction, as it probably should now be considered. In the following paragraphs, this historically relevant transition is briefly summarized.

Psychopathology

One of the most prevalent clinical myths about FMS has been that it is a somatic manifestation of an affective disorder. Some physicians have perceived it to be a sign of masked depression or merely an aberrant expression of anxiety in neurotic individuals. That concept has persisted, in part, because there has been no specific laboratory test for FMS. It is interesting to reflect on the history of RA by comparison. No one currently doubts that RA was an objective, painful disorder with inflammatory, destructive synovitis, but 20 to 30 years ago, before the roles of rheumatoid factors, inflammatory cells, and lymphokines were recognized as objective factors in the pathogenesis of RA, it was common for clinicians and investigators to view RA as an emotively driven disorder (19,20).

Payne et al. (21) studied 30 individuals in each of three groups: FMS, RA, and “other forms of chronic arthritis.” Responses by the FMS patients to questions on a *Minnesota Multiphasic Personality Inventory* (MMPI) resulted in variably higher scores on many of the scales (hypochondriasis, hysteria, psychosis, paranoia, schizophrenia) than were seen with either of the arthritic groups. These findings were echoed and expanded by another study reported in 1985 (22). The authors found a higher lifetime rate of major affective disorder among the FMS patients (70% versus 13%). In 64% of the FMS patients with major depression, the affective symptoms anteceded the onset of the FMS by at least 1 year. Only approximately 30% were depressed at the time of the study, which raised a question regarding the relevance of the depression to the patient's current somatic symptoms. Perhaps the most interesting observation was a higher prevalence (10% versus 3%) of major affective disorder in the first-degree relatives of the FMS patients.

Many of the psychological studies comparing FMS with RA involved interview methods in which the investigator was required to make subjective judgments. That is potentially critical because the interviewer in most of the studies was not blinded to the group designation. One study (23), which made a concerted point of blinding the evaluator to the prestudy diagnosis, found no difference in the prevalence of depression between FMS and RA.

In retrospect, the original study by Payne et al. (21) had several limitations. It is likely that there was some selection bias due to referral patterns, especially because their subjects were hospital inpatients. Moreover, the fact that the original MMPI had been developed and validated with psychiatric patients suggests that the questions used to identify somatization were not adequately validated against medical conditions in which people would be *expected to exhibit* a somatic symptom like pain. Thus, MMPI testing of patients with chronic pain was more likely to reflect the nature of the painful condition than to indicate a true psychological disturbance. Indeed, patients with RA have exhibited similarly elevated MMPI scores for hypochondriasis, depression, and hysteria (24).

Generalizations from a variety of sources would suggest that 30% to 40% of FMS patients are depressed. This frequency is higher than expected for healthy controls (less than 10%) and higher than expected for persons hospitalized with a variety of medical illness (20%) but is not consistently greater than observed with RA patients. Despite their continuing pain and morning stiffness, between 40% and 60% of FMS patients fail to meet criteria for any current affective disorder.

Another view has been that the pain and fatigue of FMS might be inappropriately amplified by the presence of depression or anxiety. A study described by Ward (25) was designed to evaluate the roles of mood or depression in modifying the perception of painful stimuli administered to RA patients. Depression explained less than 1% of the changes in pain and global arthritis status. It was concluded that depression was an unlikely cause for the pain of RA. It seems reasonable to extrapolate that conclusion to patients with FMS and suggest that depression in both conditions is reactive and is a consequence of daily chronic pain, insomnia, physical limitation, and compromised quality of life (26,27).

Muscle Physiology and Pathology

The perception of many FMS patients is that they experience deep muscle or even bone pain. An important minority of the TePs are located over muscle masses such as the lateral border of the trapezius, the supraspinatus, the lateral epicondyle, the upper gluteal, and the medial knee. Adding these observations to the perception of fatigue and exercise-induced pain in FMS logically led to the concept that there may be some form of energy deficit or anatomic abnormality in the skeletal muscles of people with FMS. However, a controlled, electron microscopic study has failed to identify any histologic abnormality specific for FMS (28). It has been convincingly

argued (29) that the abnormal findings in FMS skeletal muscle disclosed by nuclear magnetic resonance spectroscopy were actually due to chronic deconditioning, which is very prevalent among patients with FMS.

Central Nervous System Dysfunction

Having failed to find a histologic basis for FMS, the focus of research has shifted heavily toward a search for involvement of the CNS. As a result, abnormalities have now been found in the neurochemical process of nociception and in the neuroendocrine system. Abnormal levels of biochemicals, such as tryptophan, serotonin, substance P, and growth hormone, have been reported. The diurnal regulation of cortisol production appears to be distorted, potentially contributing to insomnia and to difficulty in managing physiologic stress.

Genetic Predisposition

It is quite common for a patient with FMS to report that a relative, usually a female, has had similar symptoms. There is growing evidence for an autosomal dominant mode of inheritance for FMS (30). In a study, Yunus et al. (31) found probable linkage of FMS with the histocompatibility locus examined by the sibship method. To date no abnormal genes have been identified, but several candidate genes have been proposed to explain metabolic abnormalities observed in the patients.

Neuroendocrine Model

Many of the symptoms of FMS resemble those observed in patients with hormone deficiencies. That observation has led to the study of neuroendocrine function in FMS (32). Subsets of people with FMS exhibit functional abnormalities in the hypothalamic-pituitary-adrenal axis, in the sympathoadrenal system, in the hypothalamic-pituitary-thyroid axis, or in the hypothalamic- pituitary-growth hormone axis. It appears that there may be diurnal rhythm abnormalities in cortisol production and that the epinephrine response to physiologic stress may be blunted.

Growth hormone was studied because it was known to be produced during delta-wave sleep that many FMS patients fail to achieve normally. Growth hormone is difficult to measure because its release is pulsatile and its plasma half-life is short. An alternative means of monitoring growth hormone production has been to measure the plasma levels of insulin-like growth factor-1 (IGF-1) (previously called *somatomedin C*), which has a long half-life. An age-adjusted deficiency of IGF-1 has been documented in a large number of FMS patients (33).

The reasons why these endocrinopathies would be associated with a chronic pain syndrome is not clear. It may be that CNS abnormalities in the availability of biogenic amines such as norepinephrine or serotonin are responsible for the abnormal regulation of the neuroendocrine system (34). These systems interact and are interdependent, so in susceptible individuals, a partial failure of one system may lead to subtle malfunction of others.

Administration of glucocorticosteroid medications to people with primary FMS does not seem to improve their symptoms (35). Conversely, substantial improvement of FMS symptoms may result from otherwise indicated corticosteroid treatment of patients with RA or SLE. FMS-like symptoms in such inflammatory disorders may be exacerbated by tapering the corticosteroid dose too rapidly. Whether that happens only when there is already an underlying predisposition to develop FMS is unknown. The administration of mineralocorticoids can reduce the severity of the neurally mediated hypotension that occurs in some FMS patients (36). Parenteral therapy with human growth hormone was effective in reducing the severity of FMS symptoms (37) but regular injection therapy with this hormone is not universally appealing to FMS patients and the cost of such therapy is prohibitive.

Gender Model

The much higher prevalence of FMS among females than among males has led to speculation regarding gender-specific causes. For example, in an epidemiologic study of a Midwest community (6), the curves representing pain thresholds (sensitivity to a pressure stimulus) in men and women consistently showed lower values for women. Because the examination component of the ACR criteria for FMS involves the response to a fixed pressure stimulus of 4 kg, it is not surprising that the ACR criteria have identified more women than men with FMS.

Understanding of the mechanisms responsible for this gender-related difference in pain thresholds is incomplete. Measurements of female hormones have not been very fruitful. A possible explanation for gender-related differences in pain perception has come from a positron emission tomography study of the brain that suggested that the metabolism of indoles was distinctly different in males and females (38). Gender-related differences in pain sensitivity and FMS prevalence could be explained by such differences.

Low-Energy Model

There is evidence (39) to suggest that adenosine triphosphate (ATP) levels may be lower than normal in FMS patients' red blood cells. The significance of that finding is still uncertain because the low levels do not correlate with the subject's perception of fatigue. If ATP is also low in FMS platelets, it could explain the low platelet serotonin level because energy is required for serotonin uptake and serotonin complexes with ATP would help to retain it internally. The role of peripheral platelet serotonin in central pain perception is still unclear.

Nociceptive Pain Model

The nociceptive pain model for FMS relates to central amplification of pain. It combines information available from animal systems and data collected from FMS studies to predict that central sensitization has resulted in an increase in the effects of afferent stimulae on pain perception. This model also predicts that chronic sensitization to pain might adversely alter the mechanisms involved in signal transmission.

Neurochemicals and Neurotransmitters

The roles of neurochemicals as neurotransmitters in the process of nociception and allodynia have been studied extensively in animals (40) and the findings are now at least theoretically relevant to human FMS (41). This line of reasoning has led to the measurement of neurotransmitter levels in biological fluids obtained from FMS patients. Two biochemical participants in the nociceptive process that appear to be important to FMS are serotonin and substance P.

Serotonin in Fibromyalgia Syndrome. Moldofsky and colleagues (42) were the first to suggest that serotonin might be involved in the pathogenesis of FMS, both in failing to attenuate persistent pain and to correct insomnia. They found a clinical correlate between FMS pain and the plasma concentration of tryptophan (TRP). More recently, the serum and cerebrospinal fluid (CSF) of FMS patients were found to exhibit low concentrations of TRP. Early findings of a low serum concentration of serotonin (43) have been supported by other investigators (44). It is now apparent that the low serum concentration of serotonin in FMS patients is due to low levels of serotonin in their peripheral platelets (45).

The levels of serotonin have not yet been reported in FMS CSF, but the levels of its immediate precursor, 5-hydroxy-TRP, and its metabolic product, 5-hydroxyindole acetic acid, have been. Both were found to exhibit lower-than-normal concentrations in FMS CSF relative to the CSF of healthy individuals (34,46). In addition, 5-hydroxyindole acetic acid was measured in the 24-hour samples of patients with FMS and compared with the results from normals (47). The rate of 5-hydroxyindole acetic acid excretion was significantly lower in FMS patients than in normals.

Klein et al. (48) proposed a novel and rather appealing hypothetical explanation for both the low serum TRP and serotonin concentrations in people with FMS. They reported finding high titers of antibodies (immunoglobulin G or immunoglobulin M classes of antiserotonin antibodies that cross-reacted with TRP) in the serum of FMS patients relative to normal controls and in controls with rheumatic conditions. Their data raised the possibility that an autoimmune process might be responsible for the low levels of serotonin in FMS sera and platelets.

Substance P in Fibromyalgia Syndrome. Substance P is a neuropeptide that has several important roles in the process of nociception (49). The concentration of substance P is normal in both the serum and the urine of people with FMS. Recent evidence (50) suggests, however, that substance P levels correlate inversely with TRP levels and 5-hydroxyindole acetic acid levels in FMS serum.

Vaeroy et al. (51) were the first to show that the concentration of substance P was elevated (approximately threefold) in the CSF of FMS patients compared with normal subjects. Their findings have now been reproduced in three other clinical studies (52,53 and 54). In each case, the average CSF substance P level in FMS was twofold to threefold higher than in the healthy controls.

In the author's first study of CSF substance P in FMS patients (Fig. 30-3), 87.5% of FMS exhibited CSF substance P concentrations greater than the highest normal value (52). Age and sex had no influence on the measured CSF SP levels, but minor differences were related to ethnicity. In an attempt to further characterize the nature of the CSF SP abnormality, a number of lumbar- level CSF samples were collected in three sequential numbered fractions. The CSF substance P concentrations in these samples failed to define a cranial to caudal gradient of CSF substance P concentration. Another experiment involved inducing noxious pressure on the lower-body TePs to see if it would have any effect on the lumbar-level CSF substance P concentration. There was no significant increase in the levels of CSF substance P as might have been expected if the substance P were coming primarily from local afferent dorsal horn neurons.

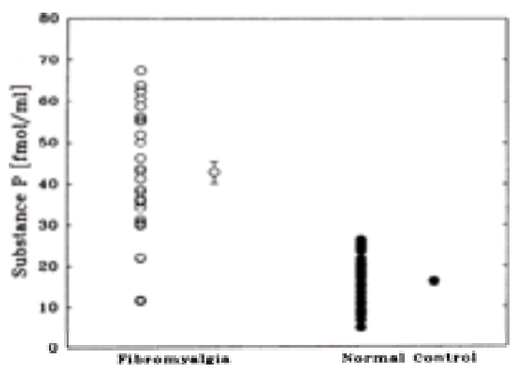

Figure 30-3. Substance P concentrations in cerebrospinal fluid samples. Fibromyalgia syndrome patients (*open dots*) exhibited significantly (p <.001) higher mean levels (*open dots with standard error bars*) than healthy normal controls (*closed dots*). Each dot represents an individual patient or a normal control. There was very little overlap of values between the two groups. Eighty-seven percent of fibromyalgia patients exhibited spinal fluid substance P levels higher than the highest normal control value. (From Russell IJ, Orr MD, Littman B, et al. Elevated cerebrospinal fluid levels of substance P in patients with the fibromyalgia syndrome. *Arthritis Rheum* 1994;37:1593–1601, with permission.)

Clinical Relevance of Elevated Cerebrospinal Fluid Substance P in Fibromyalgia Syndrome. In each of the four studies on CSF substance P discussed above, the conclusions were based on only a single sample of CSF from each subject. It was not possible from such data to know whether the abnormal CSF levels of substance P were stable or fluctuated with the patients' symptoms. To answer that question, lumbar level CSF samples were collected from the same 28 medication-free patients an average of 12 months after the first medication-free sample had been obtained (55). By medication-free it is meant that the FMS patients discontinued for 2 weeks all medications believed to be helpful in treatment of FMS symptoms. There was, on average, a slight increase in the concentration of CSF substance P over time that correlated directly with a small clinical change in pain and tenderness occurring over the same period of time. These findings imply that CSF substance P may be integrally related to changes in the severity of the symptomatic pain of FMS.

An important question that must eventually be settled is whether elevated CSF substance P concentration is unique to FMS. An earlier report (56) indicated that substance P was lower than normal in a variety of chronic painful conditions. Finally, both CSF substance P and CSF met-enkephalin have been reported to be normal in chronic pain patients. Patients with pain from herniated disks had normal CSF substance P levels, but CSF substance P levels were mildly elevated in patients with severely painful osteoarthritis of the hip and normalized in those subjects after most of the pain had been relieved by total hip arthroplasty (57).

Experience with spinal fluid neuropeptides includes analysis of substance P in CSF collected from more than 300 clinical subjects, including more than 150 primary FMS patients and more than 50 healthy controls (I.J. Russell, *unpublished data*, 1998). Disease control groups included more than 30 subjects with FMS associated with another painful condition (secondary FMS). A smaller group of 14 subjects had other painful conditions but lacked FMS. Only the healthy individuals' CSF substance P values were significantly different from those found in the primary FMS patients.

The FMS study group at the University of Alabama at Birmingham (54) has shown that the higher CSF substance P levels in FMS correlated with a decrease in regional cerebral blood flow within the caudate nucleus and thalamus of the same FMS patients. The reason for this relationship is not yet clear. It is possible that the decrease in blood flow could have been caused by neuropeptide Y (32) or dynorphin-A (58), as both are known to be potent vasoconstrictors and both are elevated in FMS. One could speculate, then, that the excess substance P is produced in response to tissue hypoxia, as an attempt on the part of the CNS to restore more normal blood flow. That explanation seems unlikely, however, because major brain hypoxic injury (ligation of an internal carotid artery in rats) causes a substantial decrease in brain tissue levels of substance P.

Nerve Growth Factor. An exciting development in the study of CSF substance P in FMS was the finding of elevated levels of nerve growth factor in the CSF of primary FMS patients, but not in FMS with an associated painful condition (secondary FMS) (59). This peptide neurotransmitter is believed to facilitate the growth of substance-containing neurons and to be involved in the process of neuroplasticity. For these reasons, nerve growth factor could be critical to the initiation or perpetuation of the painful symptoms of FMS (60,61).

Conclusions Regarding Pathogenesis

In contrast with the situation just a few years ago, when FMS patients were often viewed as healthy complainers without any examination findings, there are now classification criteria to aid in making the diagnosis. The purely psychiatric model appears to be inadequate in the face of widespread metabolic changes. Where the pathogenesis was once diligently sought in “painful muscles,” the symptoms now appear to better fit a CNS model. Abnormalities in neurochemical mediators of CNS nociceptive function (Fig. 30-4) have been demonstrated and may be relevant to FMS (62,63,64 and 65).

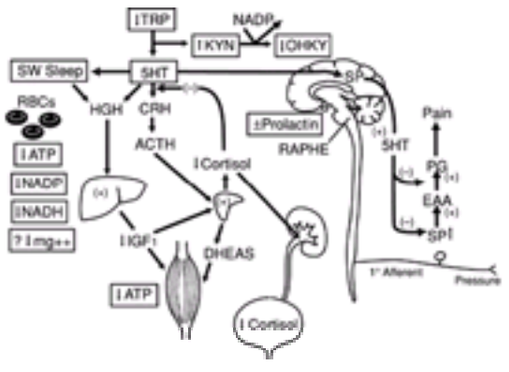

Figure 30-4. Laboratory abnormalities in fibromyalgia syndrome. They are reported to include lower-than-normal serum and cerebrospinal fluid (CSF) tryptophan (TRP) concentrations; increased CSF kynurenine (KYN) levels; decreased CSF 3- hydroxykynurenine (OHKY) levels; lower-than-normal red blood cell (RBC) adenine nucleotides such as adenosine triphosphate (ATP), and a functionally abnormal RBC transketolase enzyme that can be partially corrected by an increased concentration of thiamine pyrophosphate *in vitro*; decreased production of hypothalamic/ pituitary hormones such as human growth hormone (HGH), corticotropin-releasing hormone (CRH), and adrenal corticotropic hormone (ACTH); decreased production of liver insulinlike growth factor-1 (IGF-1); decreased production of dehydroepiandrosterone sulfate (DHEAS), and cortisol from the adrenal gland; decreased ATP levels in certain areas of skeletal muscle; and finally, increased levels of CSF substance P (SP). (5-HT, 5-hydroxytryptamine or serotonin; EAA, excitatory amino acids such as glutamine or asparagine; mg, magnesium; NADH, reduced form of nicotinamide adenine dinucleotide; NADP, nicotinamide-adenine dinucleotide phosphate; PG, prostaglandin synthesis step involving a cyclooxygenase type-2 enzyme; SW, delta slow wave, non–rapid eye movement, deep sleep.) (Adapted from Russell IJ. Neurochemical pathogenesis of fibromyalgia

syndrome. *J Musculoske Pain* 1996;1:61–92.)

The recognition of allodynia as a manifestation of abnormal central nociceptive processing has changed the perspective of FMS. It has led research in a new direction, toward the study of nociceptive neurotransmission in FMS. Some of the abnormalities found in FMS, namely low serotonin levels and the elevated substance P levels, are logically consistent with a pain-amplification syndrome. The extent to which these mechanisms are unique to FMS will be critical in determining the direction that future research should take. Certainly, a better understanding of the cause of FMS will be an important step toward the development of more effective therapy.

CLINICAL CONSIDERATIONS

Clinical Presentation

The typical patient with FMS is a middle-aged female who says to her physician, “Doctor, I hurt all over.” She may look fatigued, a little bewildered or even agitated, but usually does not appear chronically ill. The symptoms have usually been for more than 3 months. The pain is most pronounced in the regions of soft tissues such as the muscles, ligaments, bursae, and tendons, near the diarthrodial joints but not in them. Two graphic, actual, descriptions of the pain associated with FMS are as follows: “I feel as if I fell out of a car traveling at 30 miles per hour”; or “I feel just like the time I played volleyball in the hot sun all day at the beach. I had a terrible sunburn and every muscle was sore. No position was comfortable and I couldn't sleep.”

Some patients present quite differently. The initial complaint can mimic some other well-known medical condition, such as the substernal chest pain of angina pectoris, the throbbing occipital head pain of recurrent muscle contraction headache, the mechanical lumbar area pain of a degenerative disk syndrome, or even the radiating lower extremity pain of sciatica. Other common symptoms are listed in Table 30-4.

Depression, anxiety
Cognitive deficits, short-term memory loss
Throbbing occipital pain of muscle contraction headache
Lightheadedness, dizziness, syncope
Chronic insomnia, nocturnal myoclonus, nocturnal bruxism
Daytime tiredness resembling physical fatigue
Prolonged morning stiffness as in rheumatoid arthritis
Chest wall pain mimicking angina pectoris, breast area pain
Mechanical low back pain or sciaticalike radiation of pain
Bursitis, tendinitis, myalgias, arthralgias, piriformis syndrome
Numbness, tingling, dysesthesias in hands and feet
Irritable bowel, abdominal pain, diarrhea, constipation
Interstitial cystitis, frequency, urgency, sterile dysuria

These symptoms may be present at different times in a given patient, but none of them is required for classifying a patient as having fibromyalgia syndrome.

Adapted from Russell IJ. Fibromyalgia syndrome: approaches to management. Bull Rheum Dis 1994;43:1–4.

TABLE 30-4. Clinical symptoms associated with fibromyalgia syndrome

The patient's physical response to palpation of a TeP can be viewed as a semiobjective clinical sign similar to a deep tendon reflex. The designated sites do not appear to represent a single type of anatomic structure but can include skeletal muscles, ligaments, and bursae (see Table 30-2).

Testing for FMS TePs is not difficult, but it helps to learn the method from an experienced examiner and then to practice the examination with a patient known to have FMS. The procedure can be accomplished on a clinic patient in approximately 30 seconds. Three of the variables that can influence the reliability of this examination are the amount of digital palpation pressure applied, the rate at which it is applied, and whether it is applied singly or as a series of brief pulses of pressure. A clinical estimate of the correct amount of pressure can be achieved by pressing the examining thumb or finger against a soft tissue resistance (e.g., the mid-thigh) until the distal portion of the nail blanches. The more accurate means of standardizing the examining finger is to press it against a pediatric scale (4 kg is approximately 1.6 lb). Pressure gauges (dolorimeter or algometer, mechanical or electronic) are available to help standardize the amount of digital pressure to be applied. One type of electronic algometer is a pressure transducer that can be worn on the distal phalanx of the examiner. It will indicate the amount of pressure exerted by the examining digit at the time of withdrawal from the skin.

The pattern of the TeP distribution in a given FMS individual is not known to have any pathogenic significance. Approximately one-third of FMS patients will exhibit a preponderance of painful TeP sites on one side of the body. Some patients seem to be more affected in the upper half of the body than in the lower half. Early in the study of FMS, it was believed that “CPs” must fail to be tender in order to validate the presence of true TePs. Now, it is accepted that the pain thresholds at the control sites are similarly and diffusely lower than normal in FMS.

Sequential pressure on one TeP after another will often induce an involuntary writhing withdrawal on the part of the patient or even an unintended burst of tears. That should not be viewed as a hysterical response any more than would involuntary guarding of an acutely inflammed abdomen to deep palpation. After a patient has been examined at each of 18 TePs, he or she will often experience a residual deep ache described as bonelike pain that can continue to hurt for 1 to 3 days. A bruise may appear at some TeP sites after examination.

A TeP is defined differently than a TrP, so the two should not be used as synonyms (see Chapter 28 and Chapter 29). A TeP hurts locally when pressed but does not refer pain. In FMS, there are multiple, symmetric TePs. By contrast, a TrP is a regional phenomenon, which may be sensitive to pressure as a TeP is but also refers pain to a symptomatic zone of reference, which is usually more distal. The complex of symptoms and signs associated with a TrPs characterizes MPSs (as discussed in Chapter 29).

There is evidence of some overlap between MPS and FMS (66). At least one TrP may be found in 20% of healthy controls and in 68% of FMS patients in addition to a full complement of 11 or more TePs. If a typical TrP is present in an FMS patient, a concomitant diagnosis of MPS should be made. The two conditions should be treated separately, with the knowledge that TrPs in the setting of FMS are more resistant to treatment than when they present alone in isolated MPS (67).

The clinical recognition of FMS using the ACR criteria is not adequate to document the syndrome's severity in a given patient at a specific point in time. Although the TeP count is critical for diagnosis of FMS, it has not proven very useful as a measure of treatment efficacy. The TPI is easily determined clinically and provides an objective measure to follow. As shown in Table 30-5, a tenderness scale is applied to the tenderness at each site examined (nontender = 0; tender without physical response = 1; tender plus wince or withdrawal = 2; exaggerated withdrawal = 3; too painful to touch = 4). The sum of the tenderness severities at all 18 sites is the TPI. This value can be calculated and reported on clinical records as a measure of severity at time of the visit. The reliability and validity of TPI have not yet been established.

A.	Apply 4 kg of digital pressure at each tender point.	
B.	Observe body language, especially the face, for response.	
C.	Use the following scale to quantify each response:	
	Not painful:	0
	Feels painful, no physical response:	1+
	Feels painful, wince or withdrawal:	2+
	Feels painful, exaggerated withdrawal:	3+
	Area deemed too painful to allow pressure:	4+
D.	Add the individual tenderness severities for all 18 sites.	
E.	The sum is the tender point index.	
F.	The expected range for normal controls:	0–5
G.	The expected range for fibromyalgia:	11–72
H.	Typical finding in research study:	Tender point index of (mean ± SD) 35.7 ± 9.7

TABLE 30-5. Clinical determination of tenderness severity calculating the tender point index

Comorbidities

The clinical manifestations of FMS are often more complex than body pain alone. For example, patients experience great frustration with their inability to achieve normal, restorative sleep. They awaken feeling unrefreshed and are stiff for an extended period of time (often hours) each morning. During the day, they are tired but have difficulty napping. They have chronic muscle contraction–type headaches with pain in the occipital region extending over the scalp and leaving it sensitive to touch. Temporary relief can often be achieved by taking a hot bath, massaging the neck, and then sleeping with the neck supported by a small pillow. Depression is common, as seen in many chronic illnesses (23).

Considering the sleep loss and chronic headache associated with FMS, it is not surprising that patients complain of changes in cognitive functions. They have difficulty remembering events, patterns of behavior, task-related protocols, and numbers that had been second nature to them before the onset of FMS. This is a very inadequately studied aspect of FMS, so it is not known whether it results from loss of sleep, the distraction of head and body pain, or even from the myriad of medications taken in the hope of achieving relief.

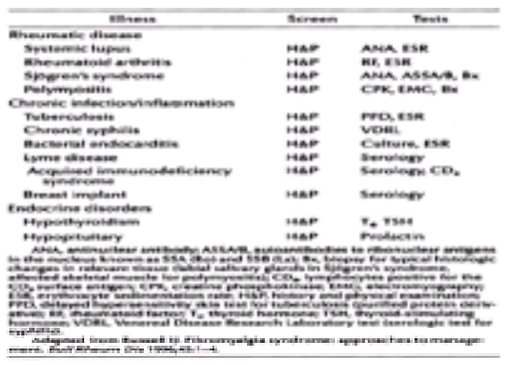
People with FMS often describe numbness or tingling of their hands or lips and a sense of hand or finger swelling. On questioning, however, they will usually acknowledge that the fingers do not really look swollen. This phenomenon sometimes resembles the symptoms of hyperventilation syndrome but the respiratory component is usually lacking.

Irritable bowel–like symptoms are seen in approximately 40% of patients with FMS. Patients may complain of troublesome constipation interspersed with painful cramping and diarrhea. Clinical examination often discloses tenderness to palpation in the left upper quadrant of the abdomen.

The bladder can also be involved, with complaints of urgency, frequency, a sense of incomplete voiding, and sometimes culture- negative dysuria. These symptoms mimic the syndrome of interstitial cystitis, but it is not yet clear whether the bladder is structurally involved.

Secondary Fibromyalgia Syndrome

A curious finding is that FMS may be associated with a number of other medical conditions. In the past, such an association was assumed to be governed by the other condition, so FMS was assumed to be somehow secondary to the other disorder (“secondary FMS”). Table 30-6 lists a classification of such associated conditions, divided into three headings: rheumatic diseases, infectious/inflammatory disorders, and endocrine disorders. The current belief is that these conditions have not developed from FMS and that FMS is not due to them. In fact, data suggest that the FMS that occurs in association with other conditions is clinically identical to “primary FMS” (5). It appears that CSF nerve growth factor concentrations are elevated only in persons with primary FMS; this may be a clue to the potential heterogenicity of factors leading to FMS.



Illness	Screen	Tests
Rheumatic disease		
Systemic lupus	H&P	ANA, ESR
Rheumatoid arthritis	H&P	RF, ESR
Sjögren's syndrome	H&P	ANA, ASSA/B, Bx
Polymyositis	H&P	CPK, EMG, Bx
Chronic infection/inflammation		
Tuberculosis	H&P	PPD, ESR
Chronic syphilis	H&P	VDRL
Bacterial endocarditis	H&P	Culture, ESR
Lyme disease	H&P	Serology
Acquired immunodeficiency syndrome	H&P	Serology, CD_4
Breast implant	H&P	Serology
Endocrine disorders		
Hypothyroidism	H&P	T_4, TSH
Hypopituitary	H&P	Prolactin

ANA, antinuclear antibody; ASSA/B, autoantibodies to ribonuclear antigens in the nucleus known as SSA (Ro) and SSB (La); Bx, biopsy for typical histologic changes in relevant tissue (labial salivary glands in Sjögren's syndrome, affected skeletal muscle for polymyositis); CD_4, lymphocytes positive for the CD_4 surface antigen; CPK, creatine phosphokinase; EMG, electromyography; ESR, erythrocyte sedimentation rate; H&P, history and physical examination; PPD, delayed hypersensitivity skin test to tuberculosis (purified protein derivative); RF, Rheumatoid factor; T_4, thyroid hormone; TSH, thyroid-stimulating hormone; VDRL, Venereal Disease Research Laboratory test (serologic test for syphilis).

TABLE 30-6. Clinical conditions that may accompany fibromyalgia and screening evaluation for them

Nearly one-third of patients with RA will be found to have FMS. A clinical observation is that the RA patients with concomitant FMS seem to have pain in and around their joints that is out of proportion to the amount of synovitis. This must be taken into account in treating the patient, because increasing the methotrexate dosage is not likely to reduce the pain severity amplified out of proportion by FMS. In fact, the best results are obtained by treating each of the conditions separately in the same patient.

The prevalence of FMS in people with SLE may approach 40%. Shin tenderness is thought to be more prevalent in SLE patients with concomitant FMS than in either condition alone. The SLE patients who met the criteria for FMS exhibited more severe symptoms and were more likely to be unable to perform daily activities. They were less likely to be employed, more likely to be divorced, and more likely to receive welfare or medical disability benefits (68,69). However, SLE patients with and those without FMS do not differ with respect to the severity of SLE activity, as evidenced by laboratory testing or progressive organ injury.

An important observation has been that the FMS symptoms may become more clearly apparent as the SLE symptoms resolve with treatment. The FMS symptoms seem particularly to emerge with too rapid a taper of the corticosteroid dosage. If not recognized as distinct from the SLE, the remaining or emerging FMS symptoms could prompt inappropriate immunosuppressive therapy. To reduce the severity of FMS symptoms with a steroid taper, it is best to decrease the dosage in graduated steps at approximately 2-week intervals. A suggested tapering protocol is based on the current dosage (from prednisone equivalent dose of 30 to 60 mg per day, each step would reduce the daily dose by 10 to 20 mg; between 15 and 30 mg per day, reduce by 2.5 to 5.0 mg per dose; between 1 and 15 mg per day, reduce by 1 to 2 mg per dose).

Approximately 50% of patients with Sjögren's syndrome also meet clinical criteria for FMS. Any association there might be between FMS and polymyositis, dermatomyositis, or polymyalgia rheumatica is less well defined.

Infectious and inflammatory conditions that seem to be associated with FMS include tuberculosis, syphilis, and Lyme disease. The prevalence of overlapping conditions depends on the community prevalence of the infectious disorder. There are no formal studies with tuberculosis and syphilis, but there may be more than a chance association between Lyme disease and FMS. A Lyme- endemic area monitored 287 patients with apparent infection for a mean of 2.5 years (range, 1 to 4 years). Eight percent met classification criteria for FMS, clearly more than would be expected by chance, based on a population prevalence of 2% for FMS. The symptoms of FMS tended to develop within 1 to 4 months after infection, often in association with Lyme arthritis. Most of the Lyme/FMS patients had typical serology, but a subset were seronegative, while exhibiting cellular immune responses to borrelial antigens, CSF pleocytosis, or even specific antibody formation in the CSF. The signs of Lyme disease generally resolved with antibiotic therapy (e.g., intravenous ceftriaxone, 2 g per day for 2 to 4 weeks), but the FMS symptoms persisted. Rheumatologists who practice in Lyme-endemic areas indicate that they diagnose many more patients with FMS alone than with concomitant Lyme/FMS. The extent of the clinical search for infection and whether or not to administer antibiotic therapy to a new FMS patient should depend on the regional prevalence of Lyme disease and clinical judgment.

An ongoing controversy has surrounded the issue of silicone breast implants. In one study (70), soft tissue pain was substantially more common among patients with implants than in persons who had reduction mammoplasty or breast cancer without implantation, but FMS was not specifically identified. When women with implants are troubled by musculoskeletal pain symptoms, consideration of FMS is warranted.

An association between subacute bacterial endocarditis and FMS has not really been proved using the current ACR criteria for classification of FMS, but the

description of the characteristic musculoskeletal symptoms (arthralgias, myalgias) associated with subacute bacterial endocarditis certainly suggests the possibility of an overlap of the two conditions. The most serious consequence of misdiagnosis would be a delay in antibiotic therapy for the endocarditis.

Mention was made earlier of the hypothalamic-pituitary-adrenal axis abnormalities in FMS. There is some evidence for abnormal production of cortisol, growth hormone, thyroid, and prolactin. The only generalization from this information at present is that careful clinical assessment of people with FMS is warranted, with intent to correct neuroendocrine abnormalities when they are important contributors to the clinical symptoms.

Disability

Pain is a troublesome symptom in many clinical settings; perhaps the most perplexing relates to decisions regarding certification for disability support. In the United States, FMS is not specifically listed as a disabling condition, whereas RA and osteoarthritis are included. Yet, it is clear that some people with FMS are physically or emotionally incapable of daily physical work. Not only does the constant pain nag at the affected person's attention but also morning stiffness can interfere with preparation for work and cognitive difficulties (probably due to insomnia and medication effects) can impair concentration. These are most likely problems of degree and probably are not incapacitatingly severe in most patients.

The problem for any society is to determine who is deserving of compensatory support and who should be expected to function in spite of his or her symptoms. This decision is particularly difficult when it is clear from research evidence that people with FMS should be involved in an active exercise program to maintain aerobic fitness and to increase their whole blood (platelet) serotonin levels (S.E. Geel, I.J. Russell, et al., *unpublished data*, 1998).

It is easy to believe that a person with a bleeding comminuted fracture is experiencing discomfort. On the other hand, there is natural skepticism when an apparently healthy individual dramatically complains of unbearable pain. Several sets of circumstances tend to support that measure of doubt. In FMS, routine laboratory tests have usually been normal, failing to implicate inflammation or dysfunction of a major organ system. Affective pathology, such as depression and anxiety, is present in a substantial proportion of FMS patients, raising the specter of psychic distortion of the perceived physical symptoms. Finally, some FMS patients have observed a temporal relationship between a physical injury and the onset of their symptoms. A common legal implication is that “someone should pay.” Naturally, the accused will mount a defense, which often takes the form of a counter offense. Disproportionate resources available to such a defender can prove formidable. Legal attempts to discredit both the person and the disorder reverberate widely, whether or not they bear scientific merit.

The task of the health care provider in the clinical setting is different from what is called for in the highly charged atmosphere of the courtroom. The objective should be to guide the patient on a path toward better health and function. No matter how obtuse the complaint, *illness is evidenced by virtue of presentation.* It is therefore incumbent on medicine to find solutions and to make them available to the patient. The search for solutions requires a knowledge base and an open mind on the part of both the clinician and the patient. Management of the condition must then proceed despite a substantial measure of remaining uncertainty.

On the other hand, it must be acknowledged that there is a rapidly growing, significant mass of information about the pathogenesis, natural history, and management of FMS. Objective measures of the FMS diagnosis will likely be available soon and severity measures may follow. Certainly, the best solution for any physical limitations of FMS would be a cure. Short of that, effective therapy should be offered to all who exhibit its symptoms. Because neither of those is now possible, clinicians in all fields who evaluate patients with pain must use their best judgment in relating to the issue of disability.

Therapeutic Approaches

There is no single treatment that is effective in controlling the symptoms of FMS, and no published management program has achieved universal acceptance. The management approach I recommend begins with an accepting attitude toward the disorder; progresses to a comprehensive clinical evaluation to establish accurate diagnoses; requires concerted education of affected individuals to involve them directly in the care process; and then enters the realm of psychological, physical, and pharmacologic interventions, whose benefits are maintained by close follow-up. Multidisciplinary pain management is useful in FMS patients (see Chapter 10, Chapter 18, and Chapter 109) (71).

Diagnosis

When a clinician evaluates an individual with a history of pain, the examination should include both a careful assessment of joints for evidence of arthritis and soft tissues around the joints for sites of painful tenderness. In most patients with FMS, nearly all of the TeP sites will be symptomatic and painful to palpation at the first clinical presentation. Occasionally, a patient will present with a single area of symptomatic pain (“chest pain” and “sciatica”) but on examination will be found to exhibit tenderness of which they were unaware at most of the other TePs. At times the generalized pain presentation can be so dramatic that it has been referred to as a “flair” or as “fibromyalgia storm.”

Tests

Despite the research recognition of reproducible biochemical abnormalities in FMS, none of those measures is yet indicated for routine use in clinical diagnosis. The diagnosis of FMS is adequately made by a typical history and TeP examination. The value of laboratory screening (e.g., blood cell counts; sedimentation rate; chemistry panel; creatine kinase; antinuclear antibody; rheumatoid factor; thyroid function tests; skin test for tuberculosis; and perhaps serologic tests for syphilis, the Lyme spirochete, or acquired immunodeficiency syndrome virus in individuals at risk) is to help screen for other clinical disorders that would require separate treatment (see Table 30-6). There is no diagnostic dependence of FMS on x-rays, electromyography, computerized tomography, magnetic resonance imaging, or radioisotope scans, so those tests should be used only if otherwise clinically indicated.

Education

Making a confident diagnosis of FMS usually has the effect of reducing the patient's use of medical resources such as emergency visits and expensive imaging tests. That benefit results principally from the patient's better understanding of his or her symptoms. Education may not reduce the severity of the pain experienced but can decrease the patient's concern that another condition such as cancer has been missed. Accurate reading materials, video programs, and support group interaction resources are increasingly available to assist the health care provider in this area (Table 30-7), but there is no substitute for quality physician time. The first visits should be used to instill confidence in the diagnosis and to directly involve the patient in responsibility for the outcome of the FMS care program. It is important to inform the patient up front that a cure is not available but that teamwork between clinician and patient can usually result in substantial and sustained benefit. Psychologists are helpful in the management of many patients with FMS.

TABLE 30-7. Materials available for patient education

For patients with very troublesome fatigue, especially toward the end of the day, an alternating work and rest program for daytime has been helpful. The actual details of the program are determined by trial and error. Patients begin by setting a timer in the morning for perhaps 1 hour of work. When the timer rings, they rest for a

period of time, perhaps 10 minutes. The timer would then be reset for the next cycle. No matter what is happening at the end of the work period, patients should stop and rest. At the end of the day, the results should be assessed and adjusted for the next day until a workable program has been found. Many women with FMS who do their work at home have found that 20 to 30 minutes of work followed by 10 minutes of rest is an effective schedule for them. Adapting this to a workplace setting is obviously more problematic but can sometimes be arranged.

Physical Modalities

Physical exercise is important to the maintenance of physical functions in patients with FMS. The problem is that unaccustomed physical exertion can induce severe body pain for an FMS patient, which will result in near incapacitation for several days thereafter. Gradual adaptation to a routine progressive exercise program such as alternate-day bicycle ergometry, walking, or water exercise will usually be well tolerated. Most patients report benefit from heat in the form of a hot bath or a professional modality. Use of the operant principles described in Chapter 89 can facilitate increases in physical activities.

Medications

Even though most patients with FMS regularly use one or more oral medications, none of those in common use can be said to be specific for FMS, and none is dramatically effective. The development of specific pharmacologic therapy requires a better understanding of the underlying biochemical abnormalities. Perhaps future medications will be found to increase platelet serotonin levels, increase serum IGF-1 concentrations, or decrease spinal fluid substance P concentrations, and in so doing, effect greater symptomatic benefit. Nevertheless, there is some biochemical logic to the medications that have proven beneficial to some patients with FMS.

The most commonly advocated medication programs involve the use of low-dose, tricyclic antidepressants, sedative-hypnotic medications, and analgesic dosages of nonsteroidal antiinflammatory drugs (NSAIDs) (Fig. 30-5). There has been anecdotal evidence of benefit from amitriptyline, cyclobenzaprine, tramadol, and alprazolam: All theoretically increase serotonin availability and have been studied in placebo-controlled trials. Marginal additional reduction in pain severity may be achieved by adding an NSAID, if well tolerated. A typical maintenance regimen might include amitriptyline (10 to 35 mg at bedtime) or cyclobenzaprine (2.5 to 10.0 mg at bedtime), along with ibuprofen (400 to 800 mg bid) or another NSAID. Our experience has suggested that the propionic acid NSAIDs are more useful than other classes of NSAIDs but that has not been proven by comparative study. Tricyclics have common side effects that limit their use (see Chapter 85). A drug holiday may be useful (Table 30-8).

Three to 4 months of serotonin reuptake inhibition:
Amitriptyline, 10–25 mg hs (cyclobenzaprine 5–10 mg hs)
Possibly fluoxetine, 10–20 mg, in the morning
Possibly ibuprofen, 800 mg bid, or nonnarcotic analgesic
Possibly tramadol, 50–300 mg, in divided dosages
One month of serotonin reuptake inhibitor holiday:
Alprazolam, 0.5–1.0 mg hs, or clonazepam, 1.0 mg hs
Resume serotonin reuptake inhibition for another cycle

Adapted from Russell IJ. Fibromyalgia syndrome: approaches to management. Bull Rheum Dis 1996;45:1–4.

TABLE 30-8. Drug holiday concept for use of low-dose serotonin reuptake inhibitors

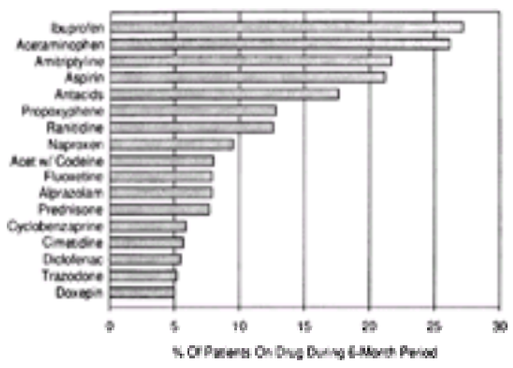

Figure 30-5. Drugs most commonly used by patients with fibromyalgia syndrome. According to a multicenter, 8-year follow-up study, which monitored medication usage, the nonsteroidal antiinflammatory drug most commonly used by fibromyalgia patients was ibuprofen, and the most commonly used psychoactive drug was amitriptyline. Note that "propoxyphene" includes various propoxyphene compounds. (Acet, acetaminophen.) (From Wolfe F, Anderson J, Harkness D, et al. A prospective, longitudinal, multicenter study of service utilization and costs in fibromyalgia. *Arthritis Rheum* 1997;40:1560–1570, with permission.)

In one study (72), tramadol was used in divided dose ranging from 50 mg to 400 mg per day. It was tolerated poorly by approximately 20% of FMS patients, who experienced nausea, somnolence, dizziness, pruritis, constipation, or headache. For those who tolerated at least 50 mg per day, relief from pain was quite uniform and persisted for at least 6 weeks. It is likely that this drug will find considerable use in the management of FMS. Many issues about its use in FMS remain to be resolved. Will it be subject to tachyphylaxis and thus benefit from periodic "holidays," as is seen with the more typical tricyclic drugs? Will it prove to be synergistic with other analgesic medications? Will concomitant sleep medications still be needed?

Because one of the theoretical goals with the tricyclic drugs was to increase the availability of serotonin, it seemed likely that the new, highly selective serotonin reuptake inhibitors might also be useful. To date, only the first approved in this class [fluoxetine (Prozac)] has been tested, but most have been tried clinically. Fluoxetine reduced the overall severity of depression in the treatment group but did not significantly alter the painful symptoms (73). One hypothetical explanation was that the muscarinic, histaminergic, or a_1-adrenergic receptors, which are more substantially influenced by the tricyclic drugs than by fluoxetine, may be important to the mechanism of benefit. When given to patients with FMS, fluoxetine should be given in the morning to avoid worsening the insomnia. There is evidence to suggest that a combination of fluoxetine (10 to 20 mg) in the morning followed by amitriptyline (10 to 35 mg) in the evening provides more relief from pain than either agent alone, while avoiding the nighttime insomnia or daytime grogginess that can characterize each separately.

In FMS patients, two glycolytic pathway enzymes that depend on thiamine pyrophosphate (vitamin B_1) as a cofactor appear to require higher than normal levels of the vitamin for optimal activity. It is not clear that administration of large doses of the vitamin will correct that problem but a trial (thiamine, 100 mg per day) might be reasonable, considering its safety profile.

A proprietary combination of malic acid and magnesium (Super Malic, 200/50 mg per tablet) was tested in FMS and was found useful in fairly high doses (600 to 1,200 mg bid). The dose-limiting factor may be loose stools due to the magnesium. Caution is also advised when administering magnesium to any patient with renal insufficiency because the levels of magnesium can rise and cause severe skeletal muscle (including diaphragmatic) weakness.

Topical capsaicin cream appears to be beneficial in FMS and can be used on locally painful areas in addition to a regimen of oral agents. The limiting factor may be the cutaneous burning sensation, which tends to decrease with use and may respond to topical lidocaine or a eutectic mixture of local anesthetic cream.

Opioid analgesics, including codeine admixtures with nonnarcotic analgesics, are currently not recommended in the treatment of FMS because of the perceived risk of

habituation in patients with chronic pain. Adequate assessment of the risks of efficacy of opioids has not yet been undertaken.

Follow-Up

It is difficult to extrapolate what may be optimal follow-up in a variety of physician-patient relationships and in other health care delivery settings. It is generally observed that FMS patients appreciate access to the physician at fairly frequent intervals (perhaps every 1 to 2 months for 3 visits) immediately after diagnosis and then do well with less frequent visits (perhaps every 3 to 4 months) thereafter. Visits can be used to document the severity of the TeP pain and to supportively monitor the patient's progress with the exercise program, the use of medications, the quality of sleep, and efforts toward self-education. The tone of the interaction should not be as follows: Patient: “I'm not better; what are you going to do about it?” Rather, it should be as follows: Physician: “You are still having quite a bit of trouble; let's see how we can work together more effectively to optimize the limited numbers of useful treatment options available.” The management of patients with FMS can be beneficial to the patient and satisfying for the physician.

CHAPTER 31

Treatment of Acute Musculoskeletal Pain

David R. Clawson

This chapter addresses acute musculoskeletal pain, defined as pain occurring from recent local tissue injury to ligament, joint capsule, fascia, tendon, muscle, or bone. The chapter does not address chronic musculoskeletal pain or musculoskeletal pain syndromes without clear local tissue damage. These are covered in Chapter 10, Chapter 28, Chapter 29, and Chapter 30. The chapter is subdivided into basic considerations, musculoskeletal system injuries and pain control, selected clinical examples, general management principles, and concluding remarks.

EPIDEMIOLOGY

The Centers for Disease Control and Prevention National Center for Health Statistics, Vital and Health Statistics Report for the year 1994 estimated in the U.S. general population approximately 8 million fractures and dislocations, 14 million sprains and strains, and 12 million contusions and other superficial injuries annually (1) (Table 31-1). These led annually to 137 million restricted activity days for fractures and dislocations, 115 million days for sprains and strains, and 48 million days for contusions and superficial injuries. There were 40 million bed-rest days for fractures and dislocations, 31 million bed-rest days for sprains and strains, and 12 million bed-rest days for contusions and superficial injuries annually. The number of lost workdays is approximately 40 million from fractures and dislocations, 39 million from sprains and strains, and 17 million from contusions and superficial injuries.

Type of injury	No. (millions)	Days of restricted activity (millions)	Days of bed disability (millions)	Days off lost work (millions)
Fractures and dislocations	7.8	137	40.6	65.3
Sprains and strains	14.3	115.1	31.5	38.3
Open wounds and lacerations	11.8	30.1	4.4	7.6
Contusions and superficial injuries	12.2	48.6	11.7	16.3
Other musculoskeletal injuries	16.5	122.4	31.5	40.3
All types	61.8	453.3	127.9	168.1

TABLE 31-1. Epidemiology and effect of musculoskeletal injuries; 1994 [a]

Only respiratory conditions rank higher than injuries in the incidence of acute conditions. It is estimated that approximately 92% of these injuries will be medically attended. Acute musculoskeletal injuries and their sequelae represent a substantial medical and social problem with enormous costs. Optimal outcomes are dependent on early medical, surgical, and rehabilitation efforts. Early activation can minimize the deleterious effects of inactivity and bed rest. These effects include contractures, muscle weakness and atrophy, immobilization osteoporosis, orthostatic hypotension, reduction in total plasma volume, reduction in cardiovascular performance, thromboembolic phenomena, cardiovascular deconditioning, skin atrophy and pressure sores, reduced respiratory efficiency, pneumonia, pulmonary embolism, urinary stasis and stones, negative nitrogen and mineral balance, decreased insulin sensitivity, constipation, anxiety and depression, impaired intellectual capacity, and impaired balance and coordination (2). Adequate pain management is essential for remobilization, prevention of these complications, and return to normal activities of daily living.

PHYSIOLOGY

Tissue injury results in stimulation of nociceptors and transmission of impulses along afferent nociceptive axons to the central nervous system (see Chapter 9). It is at the level of the supraspinal central nervous system that the nociceptive input is given meaning. The perception of the nociceptive input is modulated by past experiences, current emotional state, level of awareness, and other stimuli. Acute pain signals tissue damage and is identified by the organism as a form of stress. Acute pain is usually associated with an increase in autonomic activity such as hypertension, tachycardia, sweating, and vasoconstriction. In opposition, chronic pain conditions are not associated with ongoing tissue injury but are frequently described in terms of such damage. Tissue injury is a trigger for a complex cascade of events involving the inflammatory, immunologic, metabolic, neurologic, endocrinologic, and psychological systems. Nociception can be produced by a wide variety of stimuli including pressure, tension, heat, cold, chemical changes, and hydrogen ion concentration, histamine, serotonin, bradykinin, and other polypeptides, such as substance P.

These physiologic responses have evolved to prevent further tissue injury, maintain homeostasis, and prevent mortality. However, the evolution of the response to trauma and tissue injury may not have resulted in a system that is ideal for the modern person living in an industrial, cognitive society with the technologies of modern medicine. In some cases the immunologic, inflammatory, neurologic, endocrinologic, metabolic, and psychological responses to trauma and tissue injury may be excessive or maladaptive, and, in fact, increase morbidity and mortality. Human physiology, with respect to its response to trauma, is probably best designed to fight contaminated wounds and injuries inflicted by a predator, as evidenced by the intensity of the inflammatory cascade and the prolonged adrenergic and catabolic states after injury (Fig. 31-1).

Figure 31-1. Acute pain.

INFLAMMATORY RESPONSE

In 1888, Sir John Scott Burden-Sanderson wrote, “The process of inflammation is a succession of changes which occurs in the living tissue when it is injured, provided that the injury is not of such a degree as at once to destroy its structure and vitality” (3). This statement indicates that inflammation is a succession of events. The inflammatory response starts at a local level but is a multimodality, systemic process with events running both in sequence and also concurrently (see Chapter 3). At the time of tissue injury and the release of local chemical stimulants, the inflammatory pathway commences. Through local nociceptors and ascending afferent impulses, the inflammatory response perpetuates the pain response to the initial tissue trauma. Chemical mediators of inflammation can be exogenous mediators (i.e., venom, bacteria, and bacterial products), or endogenous mediators. Endogenous mediators come from plasma or from the local tissues. Injury to a cell changes the cellular membrane and membrane permeability, allowing the leakage of intracellular substances and exposing the phospholipids in the cell membrane. Hydrolysis occurs, and arachidonic acid is formed; it is then converted into prostaglandins and leukotrienes, the key mediators of the inflammatory cascade.

Stimulation of nociceptors results in an increase in the inflammatory response by reflex activation of the sympathetic nervous system, with local tissue release of axonal catecholamines, increased hypothalamic activity with release of pituitary hormones, and adrenomedullary release of circulating catecholamines. A change in blood vessel permeability and the activation of cells occurs, including leukocytes, fibroblasts, endothelial cells, and the production of cytokines. Lysosomal enzymes, vasoactive amines, and prostaglandins are released. Plasma leaks into the local tissues, either by direct vascular injury or through neural hormonal alterations in vascular permeability. In addition to the chemicals that directly stimulate nociceptors (bradykinin, serotonin, histamines, potassium, leukotrienes, and hydrogen ions), chemical mediators are released in the tissues that sensitize nociceptors or augment the response of local nociceptors (prostaglandins and thromboxanes) (see Chapter 3).

As a result of this cascade at the site of tissue injury, initially heavy edema, low oxygen tension, and aggressive immunologic response are seen. This environment may be advantageous for controlling bacterial contamination and preventing infection in a wound. However, it may also result in increased tissue damage, increased pain, and delayed tissue healing. Therefore, in aseptic tissue trauma (a clean wound) or in a world with multiple antibiotics, it may be beneficial to the organism to modulate this intense inflammatory response.

STRESS RESPONSE

Beyond the inflammatory pathway, tissue trauma and nociception interweave the immunologic, metabolic, endocrinologic, and psychological systems in the stress response. The pain response and the closely integrated stress response are part reflex and part learned behavior. The organism responds by a hard-wired reflex to noxious stimuli. This reflex response, however, may be variable from individual to individual. This system is modulated by the current physiologic state as well as conscious and subconscious learned behavior. From an evolutionary and survival standpoint, it is clearly advantageous for the organism to learn to avoid noxious stimuli and injury.

The stress response can be stimulated by decreasing circulating volume, changes in O_2, CO_2, or hydrogen ion concentrations, nociception, temperature, tissue injury, and adversive emotional states. These result in increased sympathetic activity with increased release of norepinephrine from postganglionic neural terminal axons as well as release (of epinephrine) from the adrenal medulla into the plasma. Peak concentration of circulating systemic catecholamines occurs 24 to 48 hours after tissue injury. The pain response begins with the stimulation of nociceptors with a signal traveling up the neural afferents to the central nervous system and then retrograde over the afferent pathways. Nociceptive primary afferents exist in the skin, subcutaneous tissue, periosteum, joint capsules, muscle, and viscera. The peripheral, spinal, and brain pathways for nociception and their transmitter substances are discussed in Chapter 3, Chapter 4 and Chapter 5.

In the management of musculoskeletal injury and pain, it is essential to keep the complexity of the nervous system in mind and to contemplate the emotional and cognitive aspects of pain and pain management. The psychological or emotional status of the organism, by affecting the outflow of the supraspinal centers, can affect the perception of pain and the total response to localized tissue injury. This may explain the phenomenon seen in athletic competition in which athletes may experience tremendous tissue impact and experience little pain and little fear (and may in fact experience rage). There may be relatively little residual tissue damage; edema and inflammation and the injury can heal relatively rapidly. However, for that same individual, tissue trauma in an entirely different setting, such as a motor vehicle accident, may evoke an entirely different emotional and physiologic response with excessive fear and anxiety that can, in the worst case scenario, lead to a chronic pain syndrome and chronic disability.

It must be remembered that the pain experience is in part reflex, an autonomic and automatic response, and also is part primitive or primal emotional and endocrinologic response, and is only in part a cognitive processing response. Emotional status and mental activities can influence the pain response through cortical and subcortical descending tracts. The outflow from these supraspinal centers in response to trauma, tissue injury, or stress results in increased cardiac output, increased peripheral vascular resistance, increased blood pressure, and increased oxygen consumption. From the pituitary there is release of adrenocorticotropic hormone and stimulation of the adrenal glands for the release of cortisol, increased release of glucagon, decreased insulin release, decreased insulin sensitivity, activation of plasma cyclic adenosine monophosphate, release of arginine vasopressin, and decreased free water excretion from the kidneys. This process results in mobilization of substrates or a catabolic state in an effort to sustain the organism. This catabolic state can last for hours to weeks.

The neuroendocrinologic response producing a catabolic state was probably at one point advantageous, in that it allowed the organism while incapable of hunting and gathering to mobilize substrates to nourish vital organ systems and the damaged tissues. It is interesting that the length of this catabolic state corresponds well with the level of tissue injury and theoretically the level of incapacitation. No clear benefit exists for a catabolic state when the organism has a safe harbor and adequate nutrition can be provided. Nutritional support and modulation of the catabolic state are beneficial to the patient.

The limbic system may also act disproportionately in certain circumstances (see Chapter 5). At a primitive level, it is advantageous for an organism to recognize threat from an instinctive standpoint as well as to be able to learn from previous experiences with threatening stimuli. It is important to be able to determine when to appropriately choose fight or choose flight and, if one survives, postinjury maintenance of a high level of arousal and vigilance for the likely return of a predator is beneficial. It is interesting that peak catecholamine levels do not occur until 24 to 48 hours after injury, sustaining the adrenergic state. However, in modern society with our current medical system, this level of sympathetic response is probably not beneficial and can be detrimental.

The patient may have an elevation in the pain response mediated by the somatomotor reflex system and muscle spasm, the sympathetic nervous system via vasoconstriction and release of norepinephrine and epinephrine, and by increased local ischemia or an enhanced inflammatory response. The central nervous system does exert a descending inhibition system, mediated by cortical diencephalic and mesencephalic tracts, periaqueductal gray matter and other opioid-receptor-rich tracts, and the dorsolateral funiculus from the locus ceruleus and the nucleus raphe magnus, sending noradrenergic and serotonergic transmission to the dorsal horn.

Gamma-aminobutyric acid (GABA) receptor–specific medications act presynaptically in the large primary afferents, 1-A afferents for muscle, to decrease somatomotor reflex activity, thus the rationale for the use of GABA-specific receptor medications such as the benzodiazepines for decreasing reflex muscle spasm in response to pain. Some a-adrenergic agonist receptors, when stimulated, inhibit pain transmission and possibly somatomotor reflex activity. This is the rationale for the use of medications such as clonidine and tizanidine in the management of pain, spasticity, and spasm. Endogenous opioids, enkephalins, and endorphins can inhibit

nociceptive transmission. The pituitary adrenal axis also exerts effects on stress, pain perception, and pain behaviors.

It is interesting to note that mood and emotional state are modulated by norepinephrine, serotonin, and GABA, as are the descending pain inhibitory pathways. Dopamine may have a small role in pain modulation, primarily through the arousal matrix.

Summary

The stress response appears to work best for preventing excessive morbidity or mortality in response to the physical assault of predators. However, hypercoagulability, catabolism, and hypervigilance are not adaptive when no physical threat exists, or the threat has been removed. The stress response can lead to multiple negative physical and psychological complications of trauma. Because the inflammatory and stress response systems can be exuberant and prolonged, medical modulation can be beneficial to the patient to relieve physical and emotional pain, promote healing, and prevent the development of chronic pain syndromes and the potential negative psychological sequelae of trauma.

TISSUE INJURIES

Connective tissue functions to support or contain other tissues or organs and to transmit mechanical forces. Components of connective tissue include collagen, ground substance (proteoglycans and water), and cells. The collagen fiber type and arrangement designate the classification of soft tissues. In general terms there are *loose* and *dense* connective tissues. Because of the high density and organization of the collagen in tendons and ligaments, these are referred to as dense connective tissue. The strength of connective tissue is a result of the triple helical structure protein, collagen. The ground substance is relatively amorphous. Proteoglycans and water are the main elements of the ground substance. Glycosaminoglycans, chondroitin sulfate, keratin sulfate, and hyaluronate make up the carbohydrate component of the proteoglycans. The main cellular component of connective tissue is fibroblasts. The collagen fibers give the tissue a high tensile strength. The ground substance allows diffusion of nutrients to the tissue. As well, it helps to minimize friction within the tissue and gives the tissue its compressive properties. Fibroblasts are responsible for the production of the collagen and the ground substance.

Tendons and ligaments have a high volume of type I collagen and a relatively low quantity of proteoglycan. They are particularly tolerant to tensile loads. Articular cartilage is composed of type II collagen and a large amount of proteoglycan-laden ground substance, making this a better tissue to handle compressive forces and associated frictional forces seen with weight-bearing activities. Also seen within connective tissue are circulating blood cells, including microphages acting as scavengers of dead cells, bacteria, and foreign particles and mediators of the inflammatory response; and mast cells (containing vasoactive substances) including histamine, serotonin, and possibly other kinins playing a key role in the control of blood flow and the inflammatory process. Lymphocytes and polymorphonuclear neutrophils can be seen within connective tissues.

The mechanical properties of soft tissues are not only determined by their structural components but also by temperature, activity, and age. Tendons and ligaments are stiffer when cold and become less viscous and more extensible with elevating temperature. Stretching results in creeping of the collagen fibers and change in the viscoelastic properties of that tissue, changes that can protect tissues from injury. In sports medicine, stretching has been recommended to prevent injury (4,5). In rehabilitation, stretching is used as a method to regain range of motion and improve function (6,7). Static stretching is the preferred technique for gaining sustained tissue elongation with minimal risk of injury. Ballistic stretching should be avoided. To get an adequate sustained elongation of soft tissues (i.e., stretch), it is helpful if the tissues are warm before stretching (8,9 and 10).

In sports medicine, active warming up with low-resistance, high-frequency exercise until a light perspiration has broken out on the skin (indicating an elevated body temperature and tissue temperature) should be performed before stretching. It may in fact be this warm-up procedure that is most responsible for injury prevention during the athletic activity that immediately follows. Stretching and resultant increased flexibility not only help prevent injury in the athletic activity immediately after, but if done on a consistent basis over time, also leads to a further reduction in soft tissue injuries and improved performance over time, as the athlete's baseline level of flexibility improves (11,12). An injury prevention program should include routine stretching five to seven times per week with warm- up and stretching before and stretching after any strenuous activity.

It should be noted that warming up not only improves the viscous properties of tissue, leading to increased flexibility and increased range of motion, but also leads to increased enzymatic activity, increased force production, perhaps secondary to increased enzymatic activity, an increase in the dissociation of oxygen from hemoglobin and myoglobin, increase in muscle blood flow, increase in the sensitivity of nerve receptors, and increase in the speed of nerve conduction velocities. The improvement in nerve conduction times leads to improved proprioception, coordination, and reaction times as well as pain response times. All of these can lead to further reduction in injury rates (13).

The changes in tissues discussed previously can also be achieved with passive warming of these tissues. These passive methods are used in the rehabilitation process and therapeutically use the multiple benefits of warming soft tissues to promote healing of injured tissue and reverse the tissue changes that may have resulted from immobilization (14,15).

The old adage that an ounce of prevention is worth a pound of cure holds for acute and chronic musculoskeletal injury and pain. In many cases it is as simple as warming up and stretching. These should be done in this temporal sequence: warming up and then stretching before any strenuous activity, whether that strain is cumulative, based on the volume of repetitive activity or from relatively low repetition activity but with high force production in the musculotendinous unit. Stronger muscles are also less likely to be injured than weaker muscles. This is an argument for strength training, not only to be used for performance enhancement but also for injury prevention (16).

The pathophysiology of tendon, ligament, and muscle injury and pain is similar. Soft tissue injuries can be classified in terms of etiology: (a) direct injuries, usually caused by blunt trauma; and (b) indirect injuries, which include the following types: Acute injuries occur with the sudden overloading of musculotendinous units. Chronic or overuse injuries are caused by repetitive overloading, frictional resistance, which occurs in highly repetitive activities, or both. Acute or chronic injuries are caused by sudden rupture of a persistent lesion (e.g., rupture of Achilles tendon with chronic tendinitis).

Collagen fibers are the major building blocks of the soft tissues. Normal physiologic loading may produce 2% to 5% strain in collagen fibers and still result in return to resting length after removal of the load. Strain equals the increase in length divided by the original length multiplied by 100. This is characterized as the elastic deformation property of the tissue. At 7% or 8% strain, collagen fiber failure begins. Beyond this one sees plastic deformation, or failure to resume original length after removal of the load. Microscopically collagen failure occurs. Healing of soft tissue injuries occurs by fibrous repair (scar tissue).

Okes and van der Muelen have described the phases of healing postinjury (17,18). An early phase is associated with the sympathetic response or early stress response to tissue injury, vasoconstriction, which may last up to 10 minutes. Beyond this early phase, there is phase 1, described as the acute inflammatory phase (Okes) or the reaction phase (van der Muelen). Phase 2 has been described as the repair phase by Okes, and the regeneration phase by van der Muelen. Phase 3 has been described by both as the remodeling phase.

Phase 1

This phase may last for up to 72 hours, depending on the severity of the injury. It has both cellular and humeral components. Disruption of the cells and surrounding connective tissue occurs. The injury to the small vessels and capillaries results in leaking or bleeding. The local cellular damage also leads to extravasation of intracellular substances. The inflammatory cascade is initiated with further edema formation. Within 24 hours macrophages are present in the tissue, releasing antibacterial and antiinflammatory substances and enzymes for the breakdown of damaged tissues and subsequently the phagocytosis of the residual debris. The complement system is also activated, resulting in antigen–antibody complexes, stimulating chemotaxis and phagocytosis. Degranulation of mast cells occurs with release of histamine and serotonin. Granulocytes release prostaglandin, further increasing vasodilatation and chemotaxis. Phase 1 is characterized by inflammation, swelling, redness, warmth, and acute pain.

Phase 2

Phase 2 may last from 48 hours to 6 weeks. As early as 24 hours postinjury, macrophages are present in the tissue, releasing antibacterial and antiinflammatory substances as well as enzymes for the breakdown of damaged tissue, and subsequently allowing phagocytosis of the residual debris. The repair of tissue only takes place when the site has become clean with the removal of cellular debris. Phagocytosis by the granulocytes of devitalized tissue and bacteria is the essential first step

in the healing process.

Early postinjury low oxygen tension occurs in the tissues because of blood vessel injury and poor perfusion, as well as the hypoxia created from the tissue edema. Aerobic bacteria do poorly in this environment; however, macrophages and granulocytes are able to perform their functions in a hypoxic environment, because of their capacity for anaerobic metabolism (i.e., glycolysis). The low oxygen tensions serve to stimulate vascular budding in the repair phase. There is usually relative immobilization and collagen contraction, which can help to protect the injured tissue, but also leads to a loss of flexibility and range of motion.

Phase 3

Phase 3, the remodeling phase, may last from 3 weeks to 12 months or possibly more, depending on the severity of the injury. This phase primarily involves the remodeling of collagen to increase the functional capabilities of the tendon or ligament to withstand the stresses of routine activities. The tensile strength of the collagen is related to the forces imposed on it during the remodeling phase. To fully rehabilitate the patient and prevent future injury, the rehabilitation program must incorporate highly specific but controlled exercises.

The collagen tissues in phase 2 are relatively disorganized. In phase 3 a higher level of organization occurs with appropriate orientation and improvement in the tensile strength of the tissues. Normal ligaments are composed of type I collagen. In a damaged, healing, or healed ligament a higher level of type III collagen is seen, having a fewer number of cross-linkages between and within the tropocollagen subunits. The quality of the tissue improves over time, but may never obtain the same tensile strength as an undamaged ligament (19).

Repair Processes

Phagocytosis by the granulocytes of devitalized tissue and bacteria is an essential first step in the healing process. Excessive edema can inhibit cellular migration to the devitalized tissues. Therefore, it makes sense to try to control this initial response to tissue damage, minimizing the extravasation of fluid and the amount of devitalized cellular material, both of which increase the workload for the phagocytes. In the early stage after injury it is important to control the exuberant inflammatory response and minimize bleeding and edema formation. This facilitates macrophage migration and expedites the removal of debris, enabling earlier pain relief and healing.

For the first 42 to 72 hours after injury, relative rest is important. Gentle nonpainful range of motion is useful. In lower extremity injuries, ambulating with assistive devices and limited weight bearing may be indicated. Complete immobilization and non– weight bearing are sometimes indicated. Ice and nonsteroidal antiinflammatory agents also help control inflammation and edema.

Connective tissue disruption is associated with stimulation of the pain pathways and inflammatory response. Vasodilatation, exudation of tissue fluids, extravasation of blood, and reactive edema are present. An exaggerated inflammatory response results in increased pain and delay in tissue healing. An excessive early inflammatory response associated with bleeding in the soft tissues and edema results in increased pain, prolonged pain, and delay in tissue healing. Ice, elevation, compression, nonsteroidal antiinflammatory drugs, and analgesics are indicated to reduce this response. With the removal of debris and resolution of edema, healing can take place. Initially, revascularization is followed by fibroblast proliferation and production of collagen. Early regeneration is characterized by disorganization and poor mechanical properties of the connective tissues. Remodeling is characterized by orientation and organization of the collagen fibers and stable bonds of the ground substance and takes place over many months after injury.

MUSCULOSKELETAL SYSTEM INJURIES

A general approach to acute musculoskeletal injuries is depicted in Figure 31-2.

Figure 31-2. An algorithm for the management of acute injuries.

Muscle Injury

Delayed Muscle Soreness

The most common form of muscle injury is delayed muscle soreness. High force eccentric loading of the muscle beyond its familiar capacity leads to injury of the muscle fibers and associated inflammatory response (20). Peak soreness is usually 24 to 48 hours after the stimulus and is usually substantially improved at 72 hours poststimulus. Icing after activity is helpful for prevention of symptoms. However, the patient is frequently unaware that symptoms are going to occur until 12 to 24 hours after exercise. Stretching has been shown to be effective in alleviating symptoms of delayed muscle soreness (21). Heat and a light workout when tolerable are beneficial and can hasten symptom resolution. In severe cases nonsteroidal antiinflammatory drugs may be indicated for inflammation and analgesia (22). Acetaminophen is also helpful for symptom management. Narcotics and antispasm medications are seldom indicated. Delayed muscle soreness has a benign course and is rarely associated with a long-term problem.

Compartmental Syndrome

Exercise-induced compartmental syndrome is a much more worrisome condition. Occasionally, with prolonged, repetitive exercise, excessive muscle damage can result in enough inflammation and edema within a muscle compartment to cause neurovascular compromise (23,24 and 25). The patient complains of pain with activation or stretch of the muscle; the most worrisome sign is the complaint of sensory changes within the extremity. The most commonly affected compartments include the anterior and deep posterior compartments of the leg (Fig. 31-3). On palpation, a compromised compartment is tense and painful. Immediate referral should be made to an orthopedic surgeon for compartment pressure measurements, sequential neurovascular examinations, and evaluation of the need for urgent surgical decompression.

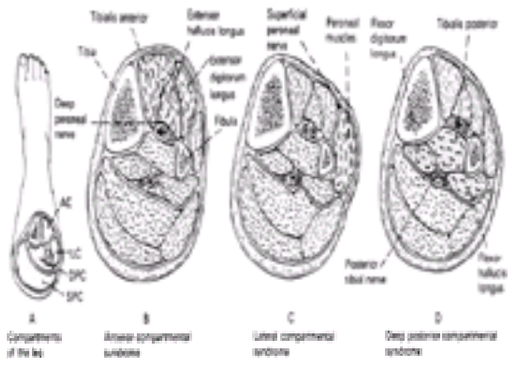

Figure 31-3. **A–D:** The leg contains four compartments bounded by bone and semirigid fascia. The anterior (AC), deep posterior (DPC), and lateral compartments (LC) each contain a major peripheral nerve having both sensory and motor components, as well as a group of muscles. (SPC, superficial posterior compartment.)

Muscle Strain

Muscle strains, as with ligament sprains, are categorized. First degree indicates a mild injury occurring at a microscopic level. Second degree indicates a moderate strain or partial tear, and third degree indicates severe complete tear of the muscle. These injuries occur when the tension elicited within the musculotendinous unit exceeds the biomechanical strength of a component part. Muscle strains can occur at the mid substance of the muscle or, more commonly, at the weak link in the chain, the musculotendinous junction (26). Typical sites for these injuries are depicted in Figure 31-4.

Figure 31-4. Gastrocnemius-Achilles junction separation. Medial head of the gastrocnemius tear occurring at the musculotendinous junction. Muscle strains most commonly occur at the musculotendinous junction during an eccentric contraction of the muscle.

Most of these injuries result from an eccentric muscle contraction that exceeds the capacity of the musculotendinous unit. Resistance to such forces is from both the intrinsic and the eccentric components of the musculotendinous unit. The system is designed for energy absorption. Contracted muscle is capable of storing more energy before failure than noncontracted muscle. Eccentric strength of a musculotendinous unit increases the tolerance for strain and lessens the risk for injury. As discussed earlier, warming of the tissue also has a protective effect (27). Histology after muscle strain initially shows hemorrhage. After 24 hours, distal fiber necrosis and infiltration of inflammatory cells occurs with an intense inflammatory reaction by 48 hours postinjury.

Early treatment consists of rest, ice, compression, and elevation. The goal is to minimize the inflammatory response, bleeding, and edema formation. Nonsteroidal antiinflammatory agents may be useful in this condition. Early intervention may result in a faster healing time as well as prevent the complications of prolific scarring, contracture, and loss of normal viscoelastic properties.

Muscle Contusion

Another form of muscle injury is the muscle contusion, which can result in a large distribution of muscle fiber damage (contusions are from direct injury; strains are from high-intensity contraction of the muscle against resistance). Complications of muscle contusion are bleeding and the formation of a hematoma. Hematomas can be intermuscular, spreading through the fascial planes, or more worrisome, intramuscular, occurring within the belly of the muscle. This can lead to increased local muscle cell injury, and because the blood cannot drain through the fascial planes, intramuscular hematomas take longer to resolve and have the potential of significant scar formation, muscle shortening, contracture, and, most worrisome, the development of myositis ossificans traumatica. Myositis ossificans traumatica is the formation of an osteoid matrix that goes on to mineralization within the substance of the muscle (28). This process can lead to prolonged and at times permanent impairment caused by pain and contracture.

Early intervention is key to preventing long-term morbidity. Rest, aggressive icing, compression, and elevation to minimize bleeding, inflammation, and edema formation are the cornerstones of early treatment. Nonsteroidal antiinflammatory medications may help control inflammation and provide analgesia. Acetaminophen may also be helpful for symptom control. In severe cases, oral narcotics and muscle relaxant medications may be indicated.

Ligament Injuries

Trauma to a ligament is classified as either first, second, or third degree, or grade I, II, or III. A grade I or first-degree sprain is considered mild, with microscopic stretching and minimal tearing of ligament fibers. There is mild pain at the time of injury or within 24 hours from injury. There is pain with stress of the ligaments. There may or may not be local tenderness. Recovery can be expected in 10 to 14 days. The pain response is typically mild and can be managed with ice, acetaminophen, or nonsteroidal antiinflammatory medications.

A grade II or second-degree ligament sprain is characterized by moderate tearing of the ligament fibers, loss of structural integrity, and instability. Pain occurs during activity, pain with stress, and local tenderness on palpation. One can expect adequate healing and rehabilitation to be complete within 4 to 6 weeks of injury. A slightly increased risk exists of developing chronic instability, altered joint mechanics, posttraumatic arthritis, and chronic pain. In addition to ice, acetaminophen, nonsteroidal antiinflammatory agents, or all three, early pain management may require low-dose narcotic analgesia and muscle relaxant medications.

A grade III or third-degree ligament sprain indicates complete disruption of the ligament on a macroscopic level (Fig. 31-5). Severe pain or loss of function occurs. Pain is felt with palpation, but paradoxically, at times there can be less pain with stress of the ligament than when the ligament is still partially intact.

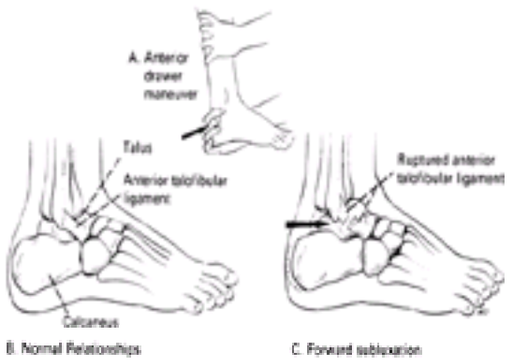

Figure 31-5. **A–C:** Positive anterior drawer sign: When the anterior talofibular ligament is ruptured, the talus can be subluxed forward in the ankle mortise.

Whole ligament strain levels can be as high as 20% to 40% before failure becomes apparent. After injury there may be the appearance of continuity of the ligaments macroscopically; however, microscopically there may be such failure that complete loss of the load- carrying capacity of the ligament occurs. Ligament failure occurs diffusely throughout the length of the ligament or at the site of ligament attachment to bone. Treatment varies from protected mobilization, modified immobilization to complete immobilization, to surgical correction. The period for healing, rehabilitation, and return to activities is variable, depending on the structure involved. Inadequate treatment carries the risk of developing chronic instability, posttraumatic arthritis and chronic pain, impairment, and disability. In addition to ice, acetaminophen, and nonsteroidal antiinflammatory medications, treatment may require small to moderate doses of narcotic analgesics and muscle relaxant medications.

Apophyseal Injuries

In the pubescent and adolescent population, because of hormonal changes, rapid growth, relative shortening of muscles, and increased strength (force production) of muscles, the apophyses can be at greater risk for injury than the musculotendinous units. What may appear as a tendinitis or muscle strain may in fact be an apophysitis or apophyseal avulsion. Common sites of apophyseal injury are the origin of the sartorius, at the anterior superior iliac spine, the origin of the rectus femoris at the anterior inferior iliac spine, the origin of the hamstrings at the ischial tuberosity, the insertion of the quadriceps mechanism through the patellar tendon at the tibial tuberosity, and the insertion of the gastroc-soleus mechanism at the calcaneus (Fig. 31-6). Treatment for apophyseal injuries is similar to the treatment for tendinitis or muscle strain. However, if gross displacement of the fragment occurs, referral to an orthopedic surgeon is recommended for consideration of surgical reduction and fixation.

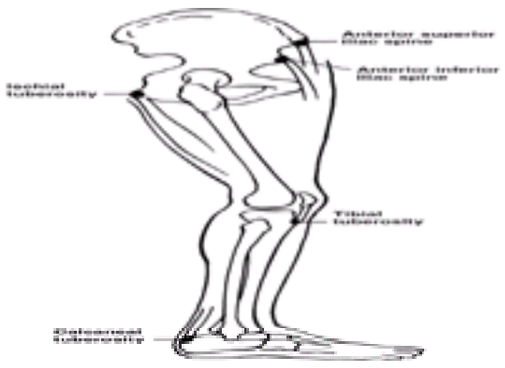

Figure 31-6. Apophyseal injuries. Common sites of apophyseal injuries. In the prepubescent and adolescent population, the apophyses can be the weakest link in the osseomusculotendinous unit, resulting in apophysitis or apophyseal avulsion.

Tendon Injury

The breaking point of human tendon is estimated at around several hundred kilograms per square centimeter. Tendon injury can be divided into three classifications: inflammatory (acute versus chronic), degenerative, or rupture, and these classifications can coexist (Fig. 31-7). Tendinitis or inflammation of the tendon is commonly an overuse injury. Repetitive loading leads to microinjury that results in an inflammatory cascade with increased permeability of cell membranes, leaking of intracellular substances into the extracellular spaces, edema, and pain. This can result from inadequate warm-up, insufficient flexibility, or insufficient strength (too much too soon).

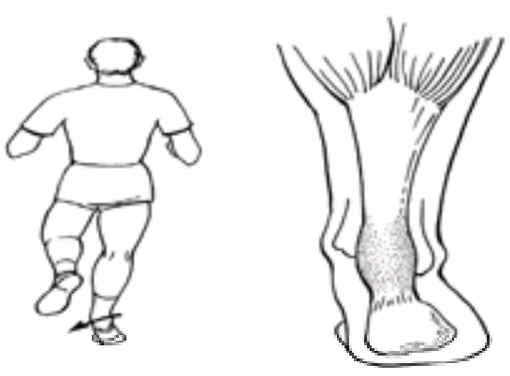

Figure 31-7. Achilles tendinitis. Overuse of a tendon can lead to inflammation and pain.

In the acute phase, relative rest, ice, and compression are indicated. Nonsteroidal antiinflammatory medications are frequently helpful, both to block the inflammatory response and for analgesia. Acetaminophen may also be helpful for pain relief. When the acute inflammatory phase resolves, ultrasound that provides deep heat to the tissues, gentle stretch to restore functional length, and gradual strengthening are indicated before returning to routine use of the tendon.

The term *tendinitis* indicates an acute or active inflammatory condition. Clinical examples are presented in Table 31-2. The term *tendinosis* should be used when the problem is predominantly degenerative. Some tendons become chronically painful, particularly the rotator cuff and the tendon of origin to the extensors of the wrist. Histologic examination of these chronically painful tendons are more consistent with tendinosis, revealing angiofibroblastic hyperplasia and fibrinoid necrosis with few or no inflammatory cells. In these cases the early response to antiinflammatory drugs may be based solely on their analgesic properties and may not constitute an actual antiinflammatory response (29). It is important to adequately treat acute tendinitis to prevent chronic changes within the tendon. Chronic edema leads to secondary changes in the peritendon tissue and the tendon itself. Fibrin deposits from chronic edema organize in the subperitendon space, forming thick nonelastic scarring and adhesions. Chronic changes of mucoid degeneration and calcification can also be seen. Complete rupture often requires surgical repair, and chronic changes also may benefit from debridement and surgical repair (Fig. 31-8).

Tendon	Site of pain	Associated findings
Extensor carpi radialis brevis/extensor carpi radialis longus/extensor digitorum communis	Lateral epicondyle of elbow	Pain/↓ in active wrist dorsiflexion
Extensor pollicis brevis/abductor pollicis longus (De Quervain's syndrome)	Snuffbox of wrist	Painful grip when thumb is inside fist and fist is deviated in palmar and medial directions
Iliotibial	Lateral condyle of knee	Pain increased by climbing stairs or running up a hill
Patellar (jumper's knee)	Patellar tendon distal to patella	Pain increased by jumping
Posterior tibial	Medial border of tibia or behind medial malleolus	Excessive pronation, pain increased by running or exercise
Flexor hallucis longus (trigger toe)	Behind medial malleolus	Found in dancers, pain increased by dancing

TABLE 31-2. Types of tendinitis

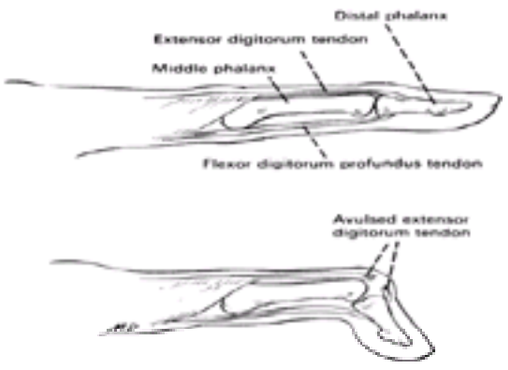

Figure 31-8. Normal and *mallet* finger: In mallet finger, the distal phalanx is flexed and the patient is unable to actively extend it.

Dislocations

Joint dislocations occur when a joint undergoes excessive range of motion with a force applied that results in tearing of the ligamentous, capsular, or both kinds of restraints of the joint. Fracture should be ruled out before attempts at relocating the joint. The patient also requires a complete assessment for neurovascular compromise. Initial treatment should include immobilization and ice. Relocation of the joint frequently results in dramatic pain relief. Effective analgesia is required to relocate the joint. Narcotics in combination with sedative-hypnotics or muscle relaxants frequently provide adequate analgesia and relaxation for reduction of the joint. The intravenous route for relaxants and opiates has distinct advantages in this setting. Regional anesthesia is sometimes required. Regional anesthesia has the benefit of not only providing pain relief but also relaxation of the musculature. Regional anesthesia may also provide early postreduction pain relief and block the endocrine and metabolic reflexes associated with trauma. After successful relocation, immobilization, ice, compression and elevation are indicated. For small joints, nonsteroidal antiinflammatory medications and acetaminophen may be adequate for pain management. In larger joints, oral narcotic and muscle relaxant medications are appropriate.

Bone Injury

Bone injury occurs when excessive loading occurs or energy is applied beyond what can be absorbed, followed by structural failure (Fig. 31-9). The greater the volume of bone, the more energy that can be absorbed before fracture. Also, the greater the elasticity of the bone, the more energy can be absorbed before frank fracture. The higher the rate of application of force, the lower the energy that can be absorbed before injury. Fracture and associated tissue injury are characterized by disruption of small vessels and capillary beds, bleeding, and the formation of a fracture hematoma. Local cell death occurs, with bone necrosis and tissue debris resulting in the release of lysosomal enzymes, thus the inflammatory cascade begins. As with all tissue healing, an inflammatory response is essential to this process. After macrophageal migration and removal of tissue debris, rapid vascular and cellular proliferation occurs. Increased periosteal capillary formation occurs. Despite the high capillary density, the high cellular volume results in relative low oxygen tension and low pH, which is a favorable environment for the growth of bone callus. Early callus formation begins when swelling has subsided and can take up to 3 weeks to form in fractures of major long bones. The callus results in fracture splinting and decreasing pain caused by immobilization. The bone now reorganizes to its normal or near normal architecture and healing is completed. Reduction and immobilization of the fracture is essential to promote adequate and early healing and pain management. Ice and elevation are indicated acutely. Adequate pain management frequently requires the use of oral, intramuscular, or intravenous narcotics as well as muscle relaxant medications. Acetaminophen and nonsteroidal antiinflammatory medications are helpful supplements.

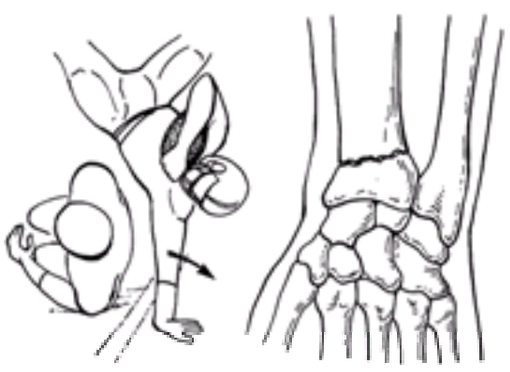

Figure 31-9. Colles' fracture of the radius. A common mechanism of wrist injuries is landing on an extended hand and wrist, in this case resulting in a distal radius fracture, or Colles' fracture.

Stress Fractures

Repetitive use injury can also occur to bones, in the form of stress reactions or stress fractures. Failure results from repetitive loading, which when applied as an individual instance of force would not cause the bone to fail. However, a cumulative fatigue results in failure. As with any tissue, bone is dynamic and constantly remodeling. Mechanical stress accelerates adaptive remodeling to strengthen the bone. However, a high volume of repetitive stress results in weakened trabeculae and, eventually, microfracture.

Common sites for stress fractures, in declining order of incidence, include tibia, tarsal bones, metatarsal bones, femoral neck, fibula, pelvis, hallux, sesamoids, and the spine. However, stress fractures can occur in other areas, particularly in athletes who may place excessive demands on other structures in their sport-specific training. Throwing athletes may present with clavicle fractures; tennis players with humeral fractures; wheelchair athletes, weight trainers, and gymnasts with radius and ulna fractures; rowers with rib fractures; football players, weight lifters, and gymnasts with vertebral or pars interarticularis fractures; and runners with pelvis fractures. Usually, relative rest is adequate treatment. Average times to recovery from common stress fractures are listed in Table 31-3. Occasionally, in a severe case, immobilization and non–weight-bearing status are indicated. With femoral neck stress fractures, open reduction and internal fixation may be indicated. Ice and nonsteroidal antiinflammatory medications are appropriate acutely. Pain management is usually adequate with acetaminophen or nonsteroidal antiinflammatory drugs.

Narcotics and muscle relaxant medications are seldom indicated for stress fractures.

Bone	Average recovery time (wk)
Femur	4–6
Tibia	4–6
Fibula	4
Metatarsals	3–4
Tarsals	8–12

TABLE 31-3. Average length of recovery from stress fracture

Clinical Examples

Rotator Cuff Tendinitis. Rotator cuff tendinitis is seen in upper extremity overhead athletes, such as swimmers, wrestlers, throwing athletes, and tennis players (30). It involves impingement of the rotator cuff musculature against the undersurface of the acromial arch (Fig. 31-10). As the arm moves overhead, the rotator cuff and subacromial bursa glide underneath the acromion and the coracoacromial ligament. This can cause impingement and chronic irritation resulting in inflammation of the tendon and the bursa and potentially tissue tearing. The shoulder capsule needs sufficient flexibility to allow normal humeral inferior gliding, and the rotator cuff needs adequate strength and control of the humeral head to prevent upward gliding and pinching of the soft tissues between the humeral head and acromion (see Chapter 58).

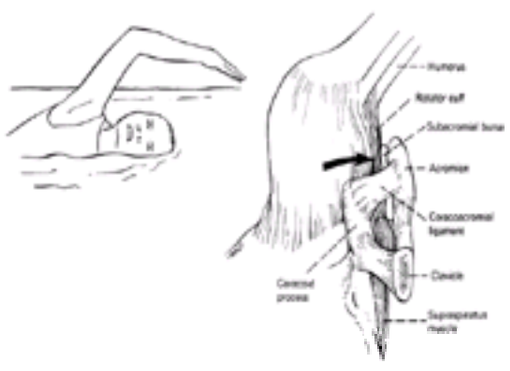

Figure 31-10. Rotator cuff impingement. As the arm moves overhead, the rotator cuff muscles and subacromial bursa slide underneath the acromion and the coracoacromial ligament. The arrow points to the area of impingement.

Patients present with complaints of aching in the shoulder region, frequently radiating down to the midlateral deltoid or even as far as the lateral elbow or forearm. Symptoms are aggravated by attempted forward flexion or abduction, particularly with the shoulder in internal rotation. The insertion of the supraspinatus into the humeral head area is frequently tender to palpation. The supraspinatus is the most commonly affected tendon in this process. Inflammation and degenerative tears usually occur approximately 1 cm from the insertion into the humeral head. Initial treatment requires eliminating or decreasing the frequency of the range of motion or activity that is aggravating the inflammatory condition. Nonsteroidal antiinflammatory medications and ice are indicated early in the course. These should be followed by ultrasound of the capsule, capsular stretching, strengthening of the rotator cuff and shoulder girdle musculature, restoration of normal movement, and gradual return to activity. If treatment fails, rotator cuff tear should be ruled out.

Acromioclavicular Dislocation. Acromioclavicular dislocation occurs when a high-velocity, high-force injury occurs to the tip of the shoulder (31). The acromion is forced downward, injuring the bridging ligaments between the acromion and the clavicle and between the clavicle and the coracoid process (Fig. 31-11). If only the acromioclavicular ligament is torn, an incomplete separation exists. The acromioclavicular ligament is tender to palpation, but no significant deformity is present. When both the acromioclavicular and the coracoclavicular ligaments have been torn, a complete acromioclavicular dislocation occurs and the untethered clavicle protrudes upward, giving the classic deformity of this injury. Both ligaments are tender on palpation. The patient has pain with attempted movement of the arm and chooses to support the arm. Initial treatment is with ice and analgesics. Oral narcotic medications frequently are needed, as well as support of the upper extremity in a sling for 7 to 10 days. If the clavicle has torn through overlying soft tissues it should be treated with open reduction and internal fixation.

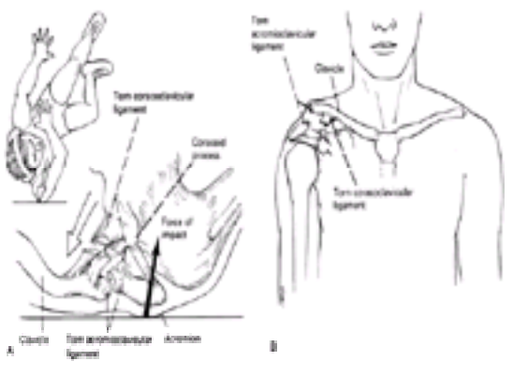

Figure 31-11. Acromioclavicular dislocation. **A:** A fall on the top of the shoulder forces the acromion downward, putting great tension on the ligaments joining the acromion to the clavicle and the clavicle to the coracoid process. The resulting tear of these ligaments produces an acromioclavicular separation or dislocation. **B:** When both the acromioclavicular and the coracoclavicular ligaments have torn, a complete acromioclavicular dislocation occurs, and the untethered clavicle rides up, giving a squared-off appearance to the shoulder.

Ankle Sprain

The most frequent form of ankle sprain is one of an inversion mechanism (32). The patient usually says that he or she rolled over the lateral side of the foot and had sudden onset of pain in the lateral anterior ankle. Swelling can be quite profound. The injured ligaments are tender to palpation. Most often the greatest tenderness starts at the anterolateral ankle. Usually the most severely injured ligament is the anterior talofibular ligament. Ecchymosis develops around the malleolus. On stress testing there may be some increased anterior subluxation of the talus or sideways shifting of the talus in the mortise. Radiography is useful to rule out bony injury.

Initial treatment is with a compressive and supportive dressing. Multiple types include elastic wraps, air orthoses, plastic and foam orthoses, and simple plaster splints. Usually reduction in weight bearing, elevation, and ice are adequate for pain management. In some cases acetaminophen, nonsteroidal antiinflammatory

medications, or mild narcotic analgesia are indicated. Clinical judgment determines the length of immobilization indicated, depending on the severity of the sprain.

Blood flow decreases proportionately as temperature decreases to a tissue temperature of 25°C. Therefore, the deeper the tissue injury, the longer the period of icing should be, as it takes longer to get cooling in the deeper tissues. Ice, ice chips, bags of frozen vegetables, ice baths, and whirlpools provide better cooling in terms of decreased intramuscular temperatures than products such as frozen gel packs, chemical ice, and freon-injected bladders (33). Studies have shown both physiologically and functionally the benefits of cryotherapy. Not only is there decreased inflammation and better pain management, but also the period of disability is substantially reduced with early cryotherapy after soft tissue injury (34,35). Cryotherapy is an effective form of analgesia and, in fact, anesthesia, but declines rapidly after removal of the modality (36). In many cases early mobilization can be initiated. This is best done in hot and cold bath contrast therapy. Immobilization may be indicated for up to 3 to 6 weeks. Surgical reconstruction is seldom required.

Metatarsal Stress Fracture

The most frequent stress fracture of the foot is to the second metatarsal (Fig. 31-12). Typically there has been a rapid increase in the patient's activity level, a change in footwear, or a change in activity surface before the onset of symptoms. A short first metatarsal is also a risk factor for this stress fracture. The patient complains of a dull ache in the foot that is present and worsens with activity. The site of the fracture is tender to palpation. Radiography may be unremarkable early on. Three to 4 weeks from onset of the symptoms a stress line may become visible and fracture callus may be present. Technetium dyphosphinate bone scans are more sensitive than radiography and may be helpful in the early diagnosis of stress fractures. Analgesia with nonsteroidal antiinflammatory drugs or acetaminophen may be indicated. Management of this injury is focused on the reduction or elimination of aggravating activities. It is infrequent that the patient needs to be made non–weight bearing. When the tenderness disappears, the patient can gradually return to previous activities.

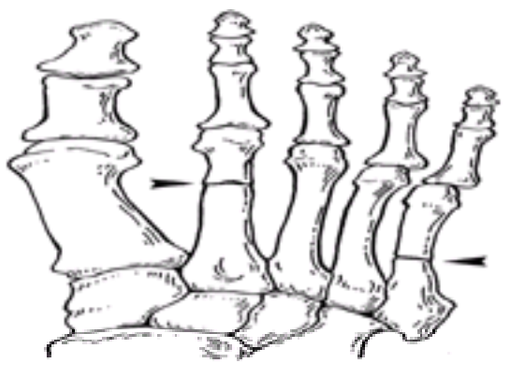

Figure 31-12. Metatarsal stress fracture. Second and fifth metatarsal stress fractures (*arrowheads*). High volume of repetitive stress results in weakening of the bone trabeculi; without adequate rest to remodel, a microfracture or stress fracture results.

Tibial Fracture

A tibial fracture frequently occurs when a sudden deceleration occurs across the midtibia, such as in athletic events when a player with his or her foot firmly planted on the ground falls into the leg of a competitor, or in the case of a skier in which the anterior aspect of the ski boot acts as a restraint against the distal to midtibia and the long lever arm of the ski produces sufficient force to fracture the tibia (Fig. 31-13). Examination shows the patient to have well-localized severe pain, inability to bear weight on the limb, and tenderness at the site with swelling. Deformity may or may not be present. Radiography is used to determine the severity of the injury and the need for surgical treatment. Immobilization is usually with a circumferential cast. The limb should be elevated for 48 to 72 hours. The patient is made non–weight bearing. Narcotic oral analgesia is usually adequate. These fractures typically heal within 12 weeks.

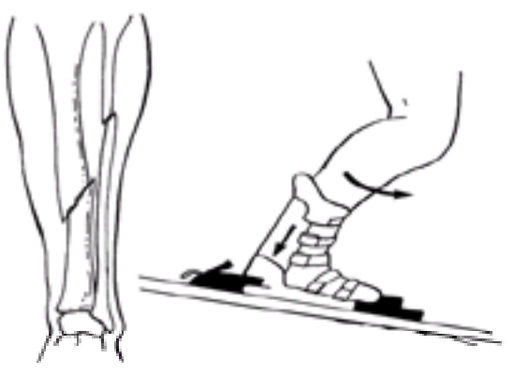

Figure 31-13. Rotational tibial fracture. Ski boot fracture of the tibia. Maximum force occurs as the tibia pivots across the superior margin of the ski boot (*arrows*), resulting in failure and fracture.

General Management Principles

A systematic approach can be developed for the management of an acute musculoskeletal pain problem. As discussed in the beginning of this chapter, musculoskeletal trauma and pain are associated with the stress response and release of stress hormones. The response results in breakdown of body tissue, increased metabolic rate, blood clotting, water retention, impaired immune function, increased sympathetic outflow, fight-or-flight response, and frequently an emotional change in the organism. Pain can be controlled peripherally by the elimination of the stimuli or by inhibition of chemical pain mediators including prostaglandins, a chief component of the inflammatory pathway, or more centrally by modulation of the analgesic pathways in the spinal cord and brain.

Tissue Level

At the tissue level the key to controlling pain is relieving abnormal forces on the injured tissues. With fractures and dislocations, reduction followed by a method of immobilization (sling, splint, cast, internal or external fixation) is indicated. With muscle, tendon, or ligament strains and sprains, a form of immobilization may be indicated as well. With all of these injuries it may be necessary to limit weight bearing through the extremity. The type of assistive device chosen depends on the severity of the injury; the patient's strength, balance, and neuromuscular coordination; and the patient's environmental needs.

Peripheral modification of pain can also be achieved by the use of locally injected anesthetic agents. Anesthetic agents are frequently required for the reduction of fractures and dislocations and provide the benefit of relaxing muscular activity including reflex spasm, blocking the reflex neuroendocrine and metabolic responses, and prompt pain relief. If the patient has severe pain lasting for days from extensive musculoskeletal injury that requires hospitalization, regional or local anesthetics may also be used for more prolonged pain management (see Chapter 102). In patients with rib fractures, local anesthetics may provide better pain relief than narcotics with no respiratory drive suppression, allowing better ventilation, oxygenation, and clearing of secretions (37).

The inflammatory response occurring at the site of the tissue injury is a primitive response, probably once necessary to fight contaminated wounds inflicted by a predator but now excessive in our world of modern medicine. Although the response is necessary for tissue healing, some modulation is appropriate to help minimize pain and minimize the excesses of this response, which can in fact slow tissue healing. Inflammation and edema increase nociception by the formation of chemical nociception stimulants and nociception sensitizers as well as increased tissue pressure. Edema interferes with tissue nutrition, oxygenation, and the cellular migration necessary for healing. Elevation and compression increase the hydrostatic gradient from the tissues to the lymphatic and venous circulation and help to prevent,

control, and dissipate edema.

Cryotherapy is also indicated in acute musculoskeletal trauma. Cold minimizes the inflammatory reaction to trauma, slows enzymatic activity, stimulates vasoconstriction and decreases blood flow (thus decreasing edema and hemorrhage), slows nerve conduction and nociceptive volleys, and decreases muscle spindle activity (inhibiting reflex muscle spasm) (38,39). The earlier the application of the cold, the better.

However, when bleeding and the acute phase of inflammation and edema production have passed, the benefits of ice decline. The vasoconstriction induced by ice may decrease the delivery of oxygen and nutrients to healing tissues. However, the analgesic and antispasm effect of ice without the potential toxicity of medications may warrant continued use of this modality. In acute injury ice should be used every 20 minutes for 20 to 30 minutes out of every hour for the first 4 hours, and then 20 to 30 minutes at least every 6 hours for 24 to 48 hours, depending on the severity of the injury. Rest, compression, and elevation are also part of therapy.

A risk exists of tissue damage with ice. Cloth can be placed on the skin before the application of ice. As well, petroleum jelly or a similar product can be placed on the skin for protection. Superficial nerves, such as the ulnar nerve as it crosses the elbow and the peroneal nerve as it crosses the fibular head, should be protected to prevent cold injury. Contraindications to the use of ice include Raynaud's disease, cold allergy, cryoglobulinemia, and paroxysmal cold hemoglobinuria. Relative contraindications are arterial insufficiency and impaired sensation.

After a musculoskeletal injury occurring in an athletic event, ice should be applied immediately for 10 to 20 minutes. Afterward the player may be reassessed for the ability to return to play. The evaluator needs to be aware that the cooling effect causes changes in the viscoelastic properties of the tissues, causing them to stiffen. As well, axonal cooling and slowing of nerve conduction velocity and potential blocking of nociceptive volleys may be beneficial for analgesia; but ice causes slowing of axons responsible for neuromuscular control and force production. Therefore, icing can lead to a decrease in performance and flexibility, potentially placing the athlete at risk for further injury (40).

The inflammatory response can also be controlled pharmacologically. The antiprostaglandins or nonsteroidal antiinflammatory drugs are the most commonly used drugs for the management of acute soft tissue injury.

The nonsteroidal antiinflammatory drugs not only have an antiinflammatory effect, but also have mild antipyretic and analgesic properties. In general, they are effective in the management of mild to moderate pain and can be used as adjuvant therapies for more severe pain. Nonsteroidal antiinflammatory drugs are discussed in Chapter 83. Current nonsteroidal antiinflammatory medications are known for causing gastrointestinal intolerance, gastrointestinal bleeding, and rarely bone marrow suppression. These medications are relatively nonspecific and inhibit the production of not only the prostaglandins that result in inflammation but also inhibit production of prostaglandins that appear to be more beneficial to overall homeostasis and health. The cyclooxygenase-2 inhibitors generation of nonsteroidal antiinflammatory drugs may minimize the unwanted effects of the nonsteroidal antiinflammatory drugs.

There have been numerous studies done to evaluate the efficacy of nonsteroidal antiinflammatory agents in reducing the severity and duration of pain as well as the disability after acute musculoskeletal injury. Efficacy has been mixed (41). If these medications are to be used, they should be used immediately, as antiprostaglandin pain relief is at maximum within the first 24 hours after injury (42). The use of these medications should be no longer than 5 to 7 days' duration. Beyond this point, their actions could be detrimental to the repair mechanism (43).

Corticosteroids are potent antiinflammatory medications. They are only briefly mentioned here, because they are not indicated in the management of acute musculoskeletal pain. However, they may be useful in the management of subacute musculoskeletal pain with a heavy inflammatory component, such as a bursitis or tendinitis. Side effects of the corticosteroids include induction of a catabolic state and reduction in the production of collagen and ground substance in connective tissues, thereby weakening the structures and potentially contributing to further tear, complete rupture, or tissue degeneration (44). Corticosteroid injections need to be used judiciously and may be ill-advised in and around major weight-bearing structures, as they lead to the decrease in synthesis of the matrix of articular cartilage and may result in destructive changes in the articular cartilaginous surface (45). The ability of corticosteroids to retard fibroblastic activity may also delay healing.

Corticosteroids should not be used as a sole form of treatment for these painful conditions. The biomechanical abnormality or irritant must be addressed before or in parallel with the use of a corticosteroid. Oral corticosteroid with tapering dose can also be used. Methylprednisolone or a Medrol Dosepak taper begins at 24 mg per day, tapering down to 4 mg over 6 days. A disadvantage of oral corticosteroids is systemic distribution of the corticosteroid and lower dosing delivered to the inflamed tissue. An advantage is a noninvasive method of administration. Adverse effects of injected corticosteroids include subcutaneous atrophy, depigmentation, and telangiectasias.

Opioids probably also work at the level of local tissue damage. There are opioid receptors on the peripheral nerve terminals, and stimulation of these results in inhibition of substance P release (46). Opioids also work both peripherally, at the level of the cord, and at the supraspinal level (47). Opioids are discussed in detail in Chapter 84. Tramadol (Ultram) has been demonstrated to be effective in the management of acute pain (48). However, in one study of postoperative orthopedic patients, tramadol was found no better than placebo (49).

Other muscle relaxant medications such as carisoprodol (Soma), hydroxyzine (Vistaril), metaxalone (Skelaxin), methocarbamol (Robaxin), and orphenadrine (Norflex) do not appear to act at the level of the spinal cord but more centrally and primarily work as sedatives, possibly depressing polysynaptic spinal reflexes (50). Carisoprodol (Soma) is a precursor of meprobamate and there is a risk of the development of dependency and substance abuse (51). This drug should be used with caution on a time-limited basis. Hydroxyzine is also thought to potentiate the effects of narcotic analgesia. Dantrolene sodium (Dantrium) is used in the management of spasticity, but is not indicated for use in reflex spasm associated with musculoskeletal injury. Dantrium probably interferes with the release of calcium from the sarcoplasm reticulum, thus decreasing the contractile response of skeletal muscle at the level of the muscle itself.

Tizanidine (Zanaflex) is an a_2-adrenergic agonist being used for treatment of spasticity. The effects of tizanidine appear to be on the polysynaptic reflex pathways; therefore, there may be a role for this medication in the management of muscle spasm and acute musculoskeletal injury. Hypotension and hepatotoxicity are the major concerns with this medication.

Other Treatments for Acute Musculoskeletal Pain

Acupuncture is widely used in musculoskeletal pain management (see Chapter 97). The mechanism of effectiveness of acupuncture is not known. However, reports exist of increased levels of endogenous opioids and other possible antinociceptive effects after treatment with acupuncture. Alternative medicine proponents have found acupuncture to be helpful in the management of acute pain, although controlled studies are sparse.

Ultrasound is capable of decreasing swelling by producing heat in the tissues, resulting in hyperemia and increased capillary permeability and promoting the absorption of inflammatory exudates (52). Ultrasound is contraindicated in the presence of growing bone and healing fractures, prosthetic implants, tumor, and viscous spaces. It should not be used in the first 48 hours after injury.

Transcutaneous electrical nerve stimulation has been shown to be effective postoperatively in decreasing immobilization time, decreasing dosages of narcotics, and decreasing hospital stay (53,54). Transcutaneous electrical nerve stimulation units have been proposed to provide analgesia by either stimulating light touch and proprioceptive axons and blocking or gating sensation at the spinal level, or increasing endorphins in the body.

Biofeedback, relaxation, and imagery can also be helpful in the management of muscle tension and anxiety (55,56). At the physiologic level, emotional arousal is accompanied by sympathetic excitation and increased muscle tone. This can establish a vicious cycle with increasing activation of the stress response and persistence or growth of the pain response. Benson first described the relaxation response, the antagonist of the fight-or-flight or stress response, in the 1970s (57). Focused attention, breathing, relaxation, repetitive motion, and visualization techniques are the cornerstones of this type of treatment (see Chapter 89, Chapter 90, Chapter 91 and Chapter 92).

Education of the patient also helps with acute pain management. Studies have shown that patients provided with information related to physiologic coping (i.e., instruction in coughing, deep breathing, and training in ambulation) reported less pain, required fewer medications, and had shorter lengths of stay (58,59 and 60). Also, patients provided with education on procedures and expected sensations complain of less pain and use less analgesic medication (61).

Other Sequelae of Trauma

Spasm

Spasm is defined as an involuntary and abnormal muscle contraction. It therefore encompasses multiple different subtypes of involuntary muscle activity. After acute musculoskeletal injury, the most common type of involuntary muscle activity found is spasm from segmental reflex activity resulting in increased muscle contraction in an effort to splint and protect injured tissues.

This activity needs to be differentiated from spasm caused by spasticity. *Spasticity* is defined as the presence of uncontrolled or disinhibited spinal and brainstem reflexes with hyperactive tendon jerks, clonus, increased muscle tone, and involuntary movements. Spasticity has been differentiated into gamma spasticity and alpha spasticity. The gamma motor neurons innervate small muscle fibers within the muscle spindles and set the sensitivity of the muscle spindles to stretch. Loss of gamma motor inhibition causes increased spindle sensitivity, resulting in increased activity of the stretch reflex. Afferent input traveling along the 1-A afferents synapse with the alpha motor neurons, resulting in muscle contraction.

Alpha spasticity is from long loop, multisegmental reflex activity. These loops lie within the brainstem and the spinal cord. Spasticity is an indication of an upper motor neuron lesion and must not be confused with muscle spasm from local tissue injury. In acute musculoskeletal injury the identification of hyperreflexia is a worrisome sign and an upper motor neuron lesion must be investigated and appropriately treated.

Treatment of spasticity includes range of motion and stretch, which results in a reduction in stretch reflex hyperactivity, and cryotherapy, which results in cooling of the muscle spindle as well as blocking or slowing of nerve conductions and dampening of the stretch reflex. Because this requires deep tissue heating, the ice must be left on for 20 to 30 minutes to see a significant effect. Warming the tissues is also effective. Increasing the temperature of the muscle spindles also decreases their activity and results in decreased reflex muscle spasm (62).

Medications such as baclofen and diazepam (GABA neurotransmitterlike medications), dantrolene sodium (which blocks calcium ion release from the sarcoplasm reticulum of the muscle fibers, thus inhibiting contraction), and tizanidine and clonidine (centrally acting a_2-agonists) are helpful in the management of spasticity.

Spasms from segmental reflex activity can be treated with principles similar to those applied to spasticity from upper motor neuron injury, as the final pathway is the segmental reflex arc. The benzodiazepines and Baclofen have an inhibitory effect at the level of the spinal cord, thus dampening this reflex activity. Sedation is the major side effect of concern. Dantrium works systemically throughout the muscle to decrease excitation contraction coupling muscle contraction and spasm. Hepatotoxicity is the major concern with this medication. Tizanidine and clonidine, with their a_2-agonist activity, probably enhance presynaptic inhibition or modulate polysynaptic reflex circuits. It seems that these medications would be less helpful in the management of peripheral injury and segmental muscle spasm. However, they may be able to decrease the segmental reflex activity through their action on descending supraspinal pathways. Hypotension is the greatest side effect with these medications. Tizanidine also has a history of inducing reversible elevation in liver enzymes. Epidural morphine and fentanyl have been effective in the management of muscle spasm but are not recommended as first-line interventions (63).

As in the spasms of spasticity, heat and cold therapy are efficacious for treating spasm from musculoskeletal injury. Ice is most effective and is recommended during the first 72 hours postinjury. Ice can be used after this 72-hour window; however, heat is preferred, as it helps to promote healing of the injured tissues.

Cramping is another form of involuntary muscle contraction. The precise etiology for muscle cramps is not known. Theoretic causes include electrolyte or mineral depletion, ischemia, acidosis, and fatigue with associated inability to completely relax a muscle. Near maximal or maximal contraction of a muscle while in a shortened position also induces a cramp (64). Treatment of cramps is with rest; restoration of normal fluid, electrolyte, and pH balance; stretching and avoiding placing the muscle in a shortened position; and ice. In cramping and spasticity, stretching is indicated. However, in acute musculoskeletal trauma, stretching for relief of spasm is contraindicated, as it may increase tissue damage. Immobilization of the injured tissues, joint, or limb with various wraps, orthotics, or simply bed rest may decrease segmental nociceptive input and reflex muscle spasm. Immobilization of the muscle in a shortened position should be avoided.

Unfortunately, muscle spasm appears to have at times a cyclical and self-propagating pattern. As muscles fatigue, they show a concomitant decreased ability to relax completely. Tonic muscle contraction can also lead to a degree of ischemia in the active muscle. Associated with this fatigue and ischemia are chemical and metabolic changes within the muscle. These changes result in muscle pain. Precisely what is responsible for this muscle pain is not clear. There are theories that the pain is due to one of the metabolic by- products or transfer of one of these by-products across the muscle cell membrane into the tissue fluid where it stimulates nociception. This was proposed by Lewis and described as factor P, also known as the substance P of Lewis (65). Psychological stress may also result in an increase in muscle pain and spasm, particularly along the axial skeleton. Biofeedback, relaxation, transcutaneous electrical nerve stimulation unit, anxiolytics, counseling, and education may be beneficial for these patients. In any case, early intervention in the treatment of spasm is prudent to prevent the sequelae of propagating the causes of local tissue pain and psychological stress response resulting in an exacerbation of pain and delayed healing.

Insomnia

Insomnia needs to be well managed. Lack of restorative sleep can lead to central nervous system neurochemical imbalance, increased nociceptor transmission, anxiety, and depression. In a patient who complains of acute insomnia, it is important to evaluate whether pain and anxiety management is adequate. For patients who have difficulty falling asleep, a short-acting sedative hypnotic such as triazolam, prazolam (Halcion), temazepam (Restoril), and zolpidem (Ambien), or an antihistamine such as diphenhydramine (Benadryl) or hydroxyzine (Vistaril) may be beneficial. For patients who have difficulty maintaining sleep, one needs to review that the patient has adequate pain management through the night. A long-acting narcotic or continuous infusion may allow the patient to sleep through the night. The tricylic antidepressant agents are also helpful for patients who have difficulty sleeping through the night.

Psychological Sequelae

After trauma it is important not only to assess the patient's level of nociception and pain but also the patient's emotional status and level of anxiety. It is critical that early management of both pain and anxiety is adequate. Ongoing assessment of pain and anxiety is imperative. Adequate control may necessitate the use of a combination of medications such as narcotics and benzodiazepines. Assessment can be facilitated by self-reporting pain and anxiety scales such as the Visual Analog scales. The emotional response to trauma can vary widely from patient to patient, and what would appear to be a relatively minor trauma may have a deep emotional significance with exaggerated stress response and suffering in some patients. It is essential to control all suffering associated with musculoskeletal trauma. It is important to remember that pain is dynamic. Studies have demonstrated long-lasting changes in cells within the spinal cord pathways after painful stimulus. It seems logical that such changes may also occur at supraspinal levels.

As well, it is important to remember that established pain is more difficult to suppress. Early intervention with medication, relaxation, and patient education can be the key to a successful outcome in preventing long-term morbidity and chronic pain conditions. Severe accidental injuries including musculoskeletal trauma can produce long-term psychological effects in the form of posttraumatic stress disorders (*Diagnostic and Statistical Manual*, third edition, of the American Psychiatric Association: 309.81). Muse has described a stress-related chronic pain syndrome (66). These patients are faced with not only functional restrictions but chronic pain and terrifying phobic reactions. When psychological conditions appear poorly controlled in both acute and chronic pain conditions, expert consultation should be sought expeditiously. Denying or ignoring the affective dimensions of acute pain and its concomitant stress is not acceptable in modern pain management.

CONCLUSIONS

Acute musculoskeletal pain is a complex, multisystem response involving the inflammatory and immunologic, neuroendocrinologic, and neuropsychological systems, as well as the stress response. The management of acute musculoskeletal pain must take an equally broad multisystem approach for optimal management and outcome. When developing the treatment plan for the management of acute pain, one needs to look both at the severity of the local tissue injury and the patient's psychological response to injury. The prudent physician looks at the appropriate level of intervention (i.e., local tissue, spinal cord, or supraspinal levels), modalities, and medications that best fit the needs of the patient and ensure an optimal outcome.

Options for acute musculoskeletal pain management include ice, intermittent or continuous local neural blockade, spinal analgesia via epidural opioid or anesthetic,

patient-controlled analgesia (usually with intravenous opioid), systemic administration of medications (including nonsteroidal antiinflammatory drugs, opioid agonists, serotonin, and norepinephrine reuptake inhibitors, GABA medications, and sedative hypnotics), and cognitive and behavioral interventions including biofeedback, relaxation, distraction, and imagery. In general, mild to moderate musculoskeletal pain can be managed with acetaminophen or a nonsteroidal antiinflammatory agent. Moderate to severe pain may require opioid therapy. Nonsteroidal agents and acetaminophen can have significant opioid dose–sparing effects and are useful in reducing the opioid side effects including sedation, respiratory depression, orthostasis, and bowel and bladder dysfunction. When additional symptoms are identified, such as muscle spasm, anxiety, and insomnia, additional medications may be indicated. To accurately determine a patient's pain management needs, it is important to consider the entire person's response to injury and to develop a holistic treatment plan that directly addresses the physical and psychological issues related to the patient's injury.

CHAPTER 32

Pain of Dermatologic Disorders

Joseph C. Langlois and John E. Olerud

Pain is not as distinctive a feature of dermatologic disorders as is the related disorder of pruritus, which is beyond the scope of this discussion. It is well known that pruritus appears to be so intolerable that the act of scratching inflicts a transient pain with attendant structural damage to the skin. It is generally considered that the induced pain is subjectively more tolerable than the itching. Nonetheless, pain is a distinctive feature of certain dermatologic disorders and merits attention simply because of the great prevalence of skin disorders. Dermatologic disease of sufficient significance that it should be seen by a physician is present in 30% of the population in the United States. Half of all problems related to skin present to primary care physicians other than dermatologists. Of the 12 most common disorders of skin disease, only herpes simplex is attended by pain symptoms. Herpes simplex has a prevalence rate of 4.2 to 1,000 in the United States (1). The effects of pain on the patient are best demonstrated by the impact of the persisting pain that sometimes follows herpes zoster, postherpetic neuralgia, which occasionally leads to suicide. This disease is discussed in Chapter 22, but this chapter focuses attention not only on the impact of pain but also on the need for appropriate recognition of the antecedent viral disease and on the value of immediate and appropriate treatment.

The diseases discussed in this chapter can be grouped into the categories of vasculitis, infections of viral and bacterial origin, inflammatory diseases of the subcutaneous space, and neoplasms. Some neoplasms, although benign, are specifically painful based on their neurovascular components. We discuss the causes and pathogenesis of the selected pain-related skin diseases, paying attention to symptoms and signs, methods of diagnosis, and preferred methods of treatment. For more comprehensive discussions of the individual diseases, refer to selected general textbooks of skin disease (2,3,4 and 5). Because of space limitations, vasculitides and tumors are described in Table 32-1 and Table 32-2.

TABLE 32-1. Characteristics of cutaneous vasculitides

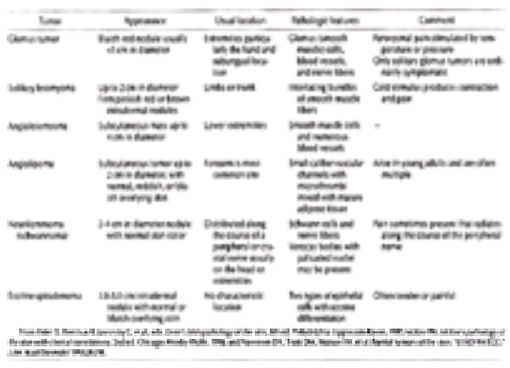

TABLE 32-2. Characteristics of benign painful cutaneous neoplasms

BASIC CONSIDERATIONS: ANATOMY AND PHYSIOLOGY OF THE SKIN

Human skin is a vast, sheetlike interface for the organism with its environment. It is adapted to the dryness of the atmosphere, resisting mechanical shearing and puncturing forces as well as the invasion of chemical and infective agents. This organ, which in aggregate covers an area of more than 2 m^2, has a mass greater than that of any other organ. It contains an extensive vascular and sweat gland system, essential for thermal regulation, and an even more extensive and finely attuned neuroreceptor network, including the varied transducers of pain and other sensations (Fig. 32-1).

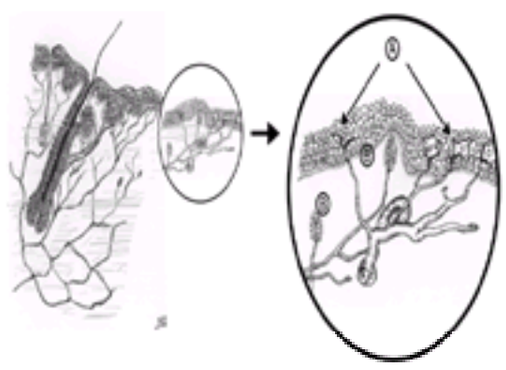

Figure 32-1. Schematic representations of sensory nerve formations (SNFs) for the cutaneous sensory nervous system. The SNFs depicted are the free nerve endings in the epidermis (*A*) and mechanosensors (*B*) in the dermis. Although nociception in the skin is mainly a function of free nerve endings composed of unmyelinated C fibers, more specialized SNFs for mechano- (baro-, preso-, osmo-) sensors, thermosensors, electrosensors, chemosensors, and nociosensors are also present. (Modified from Malinovsky L. Sensory nerve formations in the skin and their classification. *Microsc Res Tech* 1996;34:283–301.)

The skin is covered by a thin, stratified epithelium, the epidermis, which is only 75 to 100 micrometers thick except on the palms and soles, where it is four to five times thicker. The bulk of the skin is fibroelastic dense connective tissue known as the *dermis*, which supports the extensive network of vessels and nerves as well as the specialized glandular structure of the sweat apparatus and keratinizing appendages, such as hair and nail. The subcutaneous space is a variably fatty connective tissue perforated by collagenous septa, continuous on the outermost aspects with the fibers of the dermis and continuous beneath the skin with fascial or periosteal attachments to the skeleton.

It is generally believed that the peripheral pain receptors are the finely arborized (penicillate) free nerve endings that ramify in the superficial aspects of the dermis. This network of fine C fibers has been shown to innervate the epidermis as well (see Fig. 32-1) (6,7 and 8) and has been referred to as the *cutaneous sensory nervous system* (9). These fibers convey information from the skin to the central nervous system and thus have a sensory role. They also have an effector function in the skin, mediated by locally releasing neuropeptides. Sensory neurons express at least 17 different neuropeptides, including substance P and calcitonin generelated peptide (10). The cutaneous sensory nervous system appears to play an important role in the “communication” between the nervous system and the immune system, the vascular system, and the cells of the epidermis. Neuropeptides appear to participate in vital functions such as neuroinflammation and tissue repair (8,11). They have important biological effects on a variety of cells in the skin, including keratinocytes, endothelial cells, fibroblasts, Langerhans cells, mast cells, macrophages, and smooth muscle cells (9). It is easy to imagine how these effector functions may participate in the perpetuation of chronic skin conditions characterized by pain or itch.

The diagnosis of skin disease depends less on deductive logic than on direct observation. One should distinguish localized nodules resulting from small tumors of the skin from the large plaquelike swellings associated with acute edema and redness that mark inflammatory processes, and umbilicated small vesicles occurring in clusters on inflammatory bases that are characteristic of the herpetic viral infections. Subtle or marked defects in the integrity of the protective epidermal sheet should be noted, as manifested by denuded sites of bullae (erosions). Also to be noted are deeper defects in the integrity of the protective barrier that involve loss of the epidermis as well as of some dermis, leading to ulcer formation. Such lesions are inevitably attended by pain, unless associated with a neuropathy, that can best be explained by exposure of free nerve endings.

CLINICAL CONSIDERATIONS

Vasculitis

Characteristics of vasculitis are compared in Table 32-1.

Leukocytoclastic Vasculitis

Leukocytoclastic vasculitis is a common form of vasculitis affecting postcapillary venules (12,13,14 and 15). The clinical hallmarks of leukocytoclastic vasculitis are palpable purpuric lesions occurring in dependent areas such as the lower extremities in ambulatory patients or sacral area in bedridden patients. Other clinical lesions include purpuric macules, nodules, and bullous and ulcerative lesions. Less commonly, one may see urticaria, angioedema, pustules, vesicles, and livedo reticularis. Smaller lesions may be asymptomatic. Pruritus and burning may occur. Larger papules, nodules, or ulcerative lesions are frequently painful. The pain may be very debilitating in patients with chronic vasculitis.

Etiology and Pathophysiology

Leukocytoclastic vasculitis has a number of causes, including infectious agents (e.g., *Streptococcus*; tuberculosis; hepatitis A, B, and C; influenza), drugs (e.g., aspirin, phenacetin, sulfonamides, penicillin, iodides, phenothiazines), chemicals (e.g., insecticides, weed killers, petroleum products, fumes from heat-activated photocopy paper), foreign proteins (e.g., serum sickness, hyposensitization antigen), autoimmune disease (e.g., systemic lupus erythematosus, Sjögren's, ulcerative colitis, hemolytic anemia), and malignancies [e.g., Hodgkin's disease, acute and chronic leukemias, mycosis fungoides, immunoglobulin (Ig) A myeloma and carcinomas]. Leukocytoclastic vasculitis may also occur as a manifestation of C2 deficiency.

Evidence supports the concept that leukocytoclastic vasculitis is mediated by immune complexes being circulated in slight antigen excess and deposited in vessel walls, which leads to activation of the classic complement cascade, release of chemoattractants, infiltration of polymorphonuclear cells, and destruction of vessel walls by lysosomal enzymes. Lymphocytes and mast cells are also reported to play a role. Most recently, adhesion molecule expression and endothelial cell activation have been found to be involved in the pathogenesis (14). Direct immunofluorescence is typically positive for immunoglobulins and complement if the lesion is less than 24 hours old (preferably less than 4 hours).

Histologically there is infiltration of the vessel wall with polymorphonuclear cells, nuclear dust (leukocytoclasis), thickened vessel walls, fibrinoid necrosis, and hemorrhage. Extracutaneous involvement can occur with leukocytoclastic vasculitis, particularly in the kidney, but the joints, gastrointestinal tract, and pulmonary and nervous systems can be involved.

Variants of leukocytoclastic vasculitis include Henoch-Schönlein purpura, urticarial vasculitis, hypergammaglobulinemic purpura, and cryoglobulinemia. Hepatitis C has emerged as an important cause of cryoglobulinemic vasculitis (16). In addition, leukocytoclastic vasculitis can be a part of systemic lupus erythematosus and rheumatoid vasculitis.

Treatment

Suspected etiologic agents should be stopped and avoided in the future and infectious agents treated. Underlying diseases associated with antibody production should be treated and controlled. For some cases of leukocytoclastic vasculitis, no therapy is necessary. For mild cases, antihistamines or nonsteroidal antiinflammatory drugs can be used. Dapsone and colchicine sometimes are helpful. For severe cases involving other organs, cyclophosphamide and systemic prednisone should be considered. Pulse therapy for prednisone and cyclophosphamide has been reported to be successful, with fewer side effects for such inflammatory conditions. No good evidence exists that any form of therapy alters the course of the disease.

Polyarteritis Nodosa

Polyarteritis nodosa is an uncommon form of vasculitis affecting small- and medium-sized arteries. Two forms of cutaneous involvement can occur: benign cutaneous and systemic.

Symptoms and Signs

In benign cutaneous polyarteritis nodosa, tender nodules, livedo reticularis, and ulcers are characteristic. Systemic involvement rarely occurs (17).

In systemic polyarteritis nodosa, cutaneous involvement occurs in up to 50% of cases and consists of palpable purpura and ulcerations. Painful nodules occur only rarely. Small nodules might be palpable along the course of arteries. Histologically, both forms of polyarteritis nodosa show leukocytoclastic vasculitis in the small vessels of the skin. IgM, C3, and fibrin have been found in vessel walls on direct immunofluorescence, suggesting immune complex deposition in vessel walls. Hepatitis B infection, streptococcal infection, Crohn's disease, and relapsing polychondritis are reported associations.

Treatment

The benign cutaneous form of polyarteritis nodosa responds well to systemic steroids. Salicylates and other nonsteroidal antiinflammatory drugs can also be helpful in relieving pain. Sulfapyridine has been reported to induce remissions. Penicillin G is indicated in streptococcal-induced cases and prophylactic therapy may be needed. Low-dose methotrexate has also been reported to be effective (18).

Systemic polyarteritis nodosa is best treated with prednisone (1 mg per kg daily) plus cyclophosphamide (2 mg per kg daily) (19). Prednisone should be continued on a daily regimen for 1 month and then gradually converted to an alternate-day regimen, with the ultimate goal of discontinuation after approximately 6 months. Cyclophosphamide is then tapered if the disease is in remission, with the goal of ultimate discontinuation. Patients must be carefully monitored to keep the total leukocyte count above 3,000 per µL and the absolute neutrophil count at approximately 1,500 per µL. More recently, the use of monthly cyclophosphamide as a pulse dose has been shown to be effective (20). Patients who have hepatitis B–related polyarteritis nodosa respond to plasma exchange plus vidarabine or interferon-alpha-2b (21).

Wegener's Granulomatosis

Wegener's granulomatosis is an uncommon disease of unknown cause characterized by necrotizing vasculitis and granulomatous inflammation involving the upper and lower respiratory tracts, together with glomerulonephritis (22,23). It is thought to be the result of an allergic or hypersensitivity reaction to an as yet unknown antigen, with the tissue injury perhaps mediated by immune complexes. Approximately 90% of patients have antineutrophilic cytoplasmic antibodies (ANCA) usually of the cytoplasmic ANCA type (cANCA) directed at proteinase 3. Although this test may be useful diagnostically, it is uncertain whether this antibody plays a significant role in the pathogenesis of the disease.

Symptoms and Signs

In the limited form of Wegener's granulomatosis, renal involvement does not occur, but involvement of the joints and eyes may develop. Cutaneous lesions occur in approximately 45% of patients and include palpable purpura, papules, subcutaneous nodules, papulonecrotic lesions, nodules with ulceration, ulcers, vesicles, and pustules (23,24). Papules, nodules, and ulcerative lesions may be tender or painful. Most patients present with symptoms related to those of upper airway illness. Mucous membrane lesions are frequent and include oral ulcerations and friable gingival hyperplasia with petechiae. The latter is said to be pathognomonic of Wegener's granulomatosis (25). Saddle nose deformity may result from upper airway involvement. Histologically, there is necrotizing vasculitis involving small arteries and veins, necrotizing palisading granulomas, or granulomatous vasculitis.

Treatment

The treatment of choice for Wegener's granulomatosis is cyclophosphamide, 2 mg per kg daily, plus prednisone, 1 mg per kg daily. Patients with more severe disease may be given higher initial doses (22,23). The prednisone should be continued on a daily dosage for 2 to 4 weeks and then converted to an alternate-day regimen, 60 mg every other day, over 1 to 2 months. The patient is gradually tapered off the prednisone over a period of months until maintenance on cyclophosphamide alone is achieved. Cyclophosphamide is continued for 1 year after the patient is in remission and then tapered in 25-mg decrements every 2 to 3 months. If the patient is in remission and cannot tolerate further cyclophosphamide, an equal dose (in milligrams) of azathioprine can be substituted. Careful monitoring of leukocyte counts is essential to maintain the total leukocyte count above 3,000 to 3,500 per µL and the absolute neutrophil count above 1,000 to 1,500 per µL. Potential complications from cyclophosphamide include severe neutropenia, sepsis, hemorrhagic cystitis, hair loss, gonadal dysfunction, and neoplasia. The complications of prolonged corticosteroid use can also occur. Pulsed cyclophosphamide has been used in place of daily oral cyclophosphamide to lower the total dose and decrease complications but there is a higher frequency of relapses (26,27). Pulsed methotrexate has also been advocated in place of cyclophosphamide as a safer alternative (28). Trimethoprim-sulfamethoxazole has been used successfully for prevention of relapse in recent years (29).

Microscopic Polyangiitis

Microscopic polyangiitis is a systemic small-vessel vasculitis that affects the skin (40%) and typically is associated with necrotizing glomerulonephritis (90%) and pulmonary capillaritis (50%) (22,30). Histologically, a necrotizing vasculitis is seen that affects arterioles, capillaries, and venules, although small- and medium-sized arteries may be affected as well. Immune deposits are notably absent (pauciimmune) on direct immunofluorescence. More than 80% of patients have positive ANCA, usually of the perinuclear type (pANCA) directed at myeloperoxidase. Some patients have cANCA antibodies. It is unclear what role, if any, these antibodies play in the pathogenesis of the disease.

Microscopic polyangiitis has received more attention in the literature since it was newly redefined at the Chapel Hill Consensus Conference (31). Patients previously reported as having leukocytoclastic vasculitis or hypersensitivity vasculitis with systemic involvement were defined as having microscopic polyangiitis. As Braverman (32) points out in his discussion of this topic, the diagnosis of microscopic polyangiitis is based on the absence of immune deposits (pauciimmune) in the skin or visceral organs. Demonstration of the immune deposits can be difficult because they are greatly dependent on the age of the lesion. Whether microscopic polyangiitis proves to be a different disease with a different pathogenesis compared with hypersensitivity vasculitis and leukocytoclastic vasculitis remains to be seen.

Symptoms and Signs

The cutaneous lesions of microscopic polyangiitis are typical of those of a small-vessel vasculitis—that is, palpable purpura and ulcers, often painful.

Treatment

Serious internal organ involvement, such as pulmonary or renal disease, is treated aggressively with high-dose steroids and cyclophosphamide. Remission is achieved in 80% of patients.

Allergic Granulomatosis of Churg-Strauss

The rare syndrome allergic granulomatosis of Churg-Strauss is characterized by allergic rhinitis, asthma, eosinophilia, and systemic vasculitis. Other features include pulmonary infiltrates and cardiac involvement. In contrast to Wegener's granulomatosis, renal involvement is infrequent. Histologically, one sees a necrotizing vasculitis affecting small- to medium-sized vessels. Extravascular granulomas are the most common finding. Tissue infiltration with eosinophils is also a feature. Vascular immune deposits on direct immunofluorescence are typically absent. Approximately 70% of patients have positive ANCA, usually of the perinuclear type (pANCA), directed at myeloperoxidase (22,33,34).

Symptoms and Signs

Cutaneous lesions occur in approximately 70% of patients. Cutaneous nodules, usually tender, are the most frequent lesions and tend to occur on the scalp and extremities. Other types of cutaneous lesions include papules, vesicles, purpura or petechiae, infarctions, livedo reticularis, facial edema, urticaria, erythema, and ulcers. Pain can result from ischemia related to vasculitis or painful granulomas in the skin.

Treatment

The treatment of choice for allergic granulomatosis is systemic steroids, which has reduced the mortality rate from 100% to 38%. Prednisone in a dosage of 1 mg per kg daily is usually sufficient to control the disease. Occasionally 1.5 to 2.0 mg per kg daily might need to be used. Consideration should be given to adding cyclophosphamide, 2 mg per kg daily, for patients who do not respond to high-dose corticosteroids. Azathioprine, 1 to 2 mg per kg daily, can be useful for maintenance therapy in refractory disease (35). The number of patients treated to date with cytotoxic agents is too small to make any definitive conclusion about the cytotoxic agent of choice in patients refractory to corticosteroids. Cyclophosphamide might be preferable, based on successful experience with this agent in treating other serious forms of vasculitis, such as polyarteritis nodosa and Wegener's granulomatosis. Careful monitoring of these patients for complications of therapy is essential. Pulsed monthly cyclophosphamide was recommended by one study over daily oral cyclophosphamide to diminish adverse effects and lower the total amount of cyclophosphamide given (20).

Rheumatoid Vasculitis

Vasculitis associated with rheumatoid arthritis tends to occur in patients with more severe forms of arthritis. Vasculitis can affect vessels of varying size, including venules, capillaries, arterioles, and small- and medium-sized arteries.

Symptoms, Signs, and Pathophysiology

Clinically petechiae, palpable purpura, leg ulcerations, and nail fold, subungual, and digital infarcts are seen (36). These lesions can be painful on an ischemic basis. A variety of nonpainful skin manifestations of rheumatoid arthritis may be seen in these patients, including rheumatoid nodules, rheumatoid papules, rheumatoid neutrophilic dermatosis, and palmar erythema and livedo reticularis (37). Vasculitis can result in visceral infarction, coronary arteritis, cerebral vasculitis, and peripheral neuropathy. Mortality may be as high as 40%. Rarely, pyoderma gangrenosum and erythema elevatum diutinum have been reported with rheumatoid arthritis. Laboratory abnormalities with rheumatoid arthritis include positive rheumatoid factor, elevated sedimentation rate, leukocytosis, anemia, and hypergammaglobulinemia. High-titer IgG rheumatoid factor, anticomplementary activity, and low levels of complement, especially C4, are most indicative of rheumatoid vasculitis.

Treatment

Patients with rheumatoid vasculitis have been treated with various therapeutic agents. The only placebo-controlled study to date was conducted with azathioprine, in which no clinical benefit was demonstrated (38). Patients with asymptomatic cutaneous lesions of venulitis and no internal involvement may need no treatment.

Patients with severe disease may be treated with pulse cyclophosphamide every 2 weeks and steroids used only as supporting therapy (39). High-dose steroids combined with azathioprine are recommended by others (40). Patients must be monitored closely, particularly for severe neutropenia, sepsis, or both.

Livedoid Vasculitis

Livedoid vasculitis is an uncommon disease characterized by livedo reticularis and purpuric papules leading to exquisitely painful ulcerations on the lower extremities that heal with white atrophic scars referred to as *atrophy blanche* (41,42). Hyperpigmentation and telangiectasias are also characteristic. Some patients have associated disease such as systemic lupus erythematosus, polyarteritis nodosa, or Raynaud's phenomenon, but most do not. Other reported associations include hepatitis C infection, cryoglobulinemia, and gammopathies (42).

The histologic changes seen on biopsy have been referred to as a hyalinizing segmental vasculitis with endothelial proliferation, hyaline degeneration, and thrombosis of small vessels of the middle and lower levels of the dermis. Leukocytoclasis as seen in leukocytoclastic vasculitis is absent. Direct immunofluorescence commonly reveals fibrin, C3, and IgM in vessel walls, suggesting an immunologic basis for the disease.

Pathogenesis

Livedoid vasculitis has been referred to as livedoid vasculopathy rather than a vasculitis (43). The basis for this has been a number of observations suggesting an important role of the coagulation system. Patients have responded to fibrinolytic therapy, anticoagulants, antiplatelet drugs, pentoxifylline, and tissue plasminogen activator. Concentrations of fibrinopeptide A, a marker of thrombin generation, have been reported to be elevated in patients during exacerbations of their disease. Activated expression of platelet P-selectin and lymphocyte activation have been reported (44). A vasculopathy with hypercoagulable state and platelet activation may be the underlying pathogenic mechanism.

Treatment

Therapeutic agents of reported value for livedoid vasculitis include aspirin plus dipyridamole (46), phenformin plus ethylestrenol, nicotinamide, and low-dose heparin (47). Other reported treatments of benefit include tissue plasminogen activator, pentoxifylline (48), prostaglandin E1, ticlopidine (49), nifedipine, and low-dose danazol (45). Phenformin may be obtained through the Food and Drug Administration. Patients should avoid smoking. Antibiotics such as dicloxacillin or erythromycin for secondary infection, wet dressings (e.g., Burow's solution), and rest are important. Pain control is a significant problem and physical dependence on narcotics may occur. A methadone-containing pain cocktail can be helpful in selected cases.

OTHER VASCULAR DISORDERS

Antiphospholipid Syndrome

Antiphospholipid syndrome is characterized by a biologic false-positive test for syphilis; lupus anticoagulant or antiphospholipid antibodies associated with thrombosis of major arteries and veins, or both; fetal wastage in pregnant women; and sometimes thrombocytopenia (50,51,52 and 53). It may occur as an idiopathic disorder, associated with systemic lupus erythematosus, or as Sneddon's syndrome. The antiphospholipid antibodies are necessary but not sufficient for the syndrome because not all patients with antiphospholipid antibodies are symptomatic. Histologically one sees noninflammatory thrombosis of vessels in the skin. The pathogenesis of the disorder is poorly understood.

Symptoms and Signs

Patients suffer painful infarcts and ischemia from occlusion of major arteries and veins. Painful cutaneous lesions may occur as part of the syndrome, including painful skin ulcers (usually on the lower extremities), thrombophlebitis, cutaneous gangrene and necrosis (e.g., gangrene of digits or widespread cutaneous necrosis), painful

or tender skin nodules, livedoid vasculitis, and necrotizing vasculitis. Other cutaneous lesions include erythematous macules, purpura, ecchymosis, and subungual splinter hemorrhages. Livedo reticularis is the most common cutaneous manifestation of the syndrome. Sneddon's syndrome (livedo reticularis and recurrent strokes) may occur as part of the antiphospholipid syndrome but also may occur without antiphospholipid antibodies. Diagnosis requires correlation of clinical signs, with tests for antiphospholipid antibodies—enzyme-linked immunosorbent assay antiphospholipid antibody and lupus anticoagulant (partial thromboplastin time). Both tests should be ordered because individuals may have one test positive without the other being positive. Tests positive 6 to 8 weeks apart are useful in excluding transiently positive tests.

Treatment

Any associated risk factors for vascular events should be treated or eliminated, such as stopping smoking, treatment of hypertension or hyperlipidemia, and avoidance of oral contraceptives. Low-dose aspirin or low-dose heparin has been recommended for prevention of vascular events in patients who are at risk. Some patients have resistance to the usual doses of subcutaneous heparin (10,000 to 15,000 units daily) and may need higher doses of subcutaneous heparin (25,000 units daily) or intravenous heparin (40,000 units daily) to achieve the equivalent effect. In patients who have already had a vascular occlusive complication, warfarin is recommended. Low-dose warfarin plus low-dose aspirin has been recommended in patients with intracranial vascular thrombosis. Warfarin resistance may be encountered, and patients may need up to 20 mg per day. It is recommended that the international normalized ratio be maintained between 3 and 4 (54). Patients are maintained on anticoagulation for life.

Patients who have widespread vascular occlusive events or catastrophic antiphospholipid syndrome are candidates for treatment with immunosuppressive agents and immunotherapy with high-dose steroids, cyclophosphamide, plasmapheresis, and gammaglobulin therapy. There have been no prospective trials for any of the therapies for antiphospholipid syndrome.

Treatment of women to prevent fetal loss is indicated only in those women who have had a previous fetal loss. Depending on the level of risk, three regimens have been recommended—low-dose aspirin alone, aspirin plus prednisone, and a sequential regimen of aspirin followed by low-dose heparin and then a return to aspirin. If the patient is already taking warfarin for previous vascular occlusion, this should be changed to heparin (52,53).

Coumarin Necrosis

Coumarin necrosis is a rare reaction to coumarin congeners that typically occurs on the breast, thigh, abdomen, or buttocks of middle-aged and elderly obese women (55,56 and 57).

Pathophysiology

Histologically, one sees occlusion of vessels with fibrin thrombi and a paucity of inflammatory cells. Many patients are heterozygous for protein C deficiency (an autosomal dominant condition). Acquired protein C deficiency and an abnormally functioning protein C have also been reported. Protein C is a vitamin K–dependent factor, along with factors II, VII, IX, and X. Protein C acts as an inhibitor of coagulation through its inactivation of factors VIIIa and Va. Protein C and factor VII have relatively short half-lives compared with factors II, IX, and X. The relatively rapid fall in protein C levels with initiation of warfarin therapy leads to a transient hypercoagulable state.

Symptoms and Signs

Reaction occurs between the third and tenth days of therapy and is manifested by painful erythematous, indurated purpuric lesions that can progress to blistering, necrosis, and scarring. Pain is presumably present on an ischemic basis.

Treatment

Coumarin therapy should be discontinued. Patients are treated with heparin and vitamin K. Protein C concentrates may be helpful for the protein C deficiency. In patients who already have a history of warfarin-induced skin necrosis and need further anticoagulation, initiation of coumarin at low doses under the cover of full heparinization and administration of protein C has been suggested (57). Pentoxifylline, a tumor necrosis factor-alpha antagonist, was recommended after the study of one patient demonstrated upregulation of tumor necrosis factor-alpha on endothelial and infiltrating cells within an area of coumarin necrosis (58). The patient, however, did not receive the medication.

Calciphylaxis

Calciphylaxis is a rare, life-threatening disorder that causes painful ulcerations. It occurs most commonly in patients with chronic renal failure on dialysis with secondary hyperparathyroidism, although it has also been rarely reported in primary hyperparathyroidism and also in patients with normal parathyroid and calcium levels (59,60 and 61).

Pathophysiology

Based on an experimental model by Selye et al., calciphylaxis is believed to be a condition in which patients are “sensitized” by parathyroid hormone, and calcification subsequently occurs when patients are exposed to a “challenging” agent such as corticosteroids, albumin, and immunosuppressants (62,63). Most patients have secondary hyperparathyroidism with an elevated parathyroid hormone level and calcium X phosphate ion product of 70 or higher. Calcification occurs in small- and medium-sized arteries. The calcification can be seen on x-rays, which is helpful diagnostically. Histologically, one can see calcification of vessels and intimal proliferation. Intraluminal debris and fibrin thrombi are seen histologically and sometimes fat necrosis and a sparse lymphohistiocytic infiltrate are seen. Incisional biopsy is needed to obtain sufficient tissue for histologic examination.

Symptoms and Signs

Calciphylaxis begins as a painful mottling of the skin resembling livedo reticularis that evolves to ulceration and necrosis. It occurs most commonly on the distal extremities and lower legs, but it is also often seen on the pannus, thighs, and other areas of excess subcutaneous fat. Gangrene and amputation of digits may occur. Sepsis and amputation are serious complications that can occur and account for the high mortality of the disease.

Treatment

Lowering the calcium X phosphate product is initially indicated. This can be done with phosphate binders and low phosphate diet. Vitamin D_3 [1,25-(OH) 2-vitamin D_3] may be helpful in treating the secondary hyperparathyroidism, although vitamin D has also been reported to be a “sensitizer.”

Hyperparathyroidism is treated with parathyroidectomy (64). Often, one parathyroid gland is transplanted to the forearm and removed later only if necessary. Results are better if surgery is done early. Corticosteroids, immunosuppressants and other “challenging” agents should be avoided if possible.

Supportive care, wound care, and antibiotics for secondary infection are important as well. Amputation may be needed in some instances.

ULCERS

Ischemic Ulcers

Ischemic ulcers are painful ulcerations most commonly caused by arteriosclerosis and located on the distal lower extremities at sites of trauma and pressure, particularly on the toes, over bony prominences, the pretibial area, or the lateral malleolus (65,66). Atrophy of the skin and absence of hair may be associated skin findings. The pain is typically relieved by dependency and aggravated by elevation of the extremity. Ischemic ulcers may be preceded by intermittent claudication with

exercise. If the occlusion is severe patients may have rest pain.

In most instances, the pathology of the condition is an atherosclerotic plaque affecting large- and medium-sized vessels. Histologically, one sees accumulation of lipids, smooth muscle proliferation, collagen deposition, ulceration of the endothelial surface, and thrombosis of the surface. Diabetics may have small-vessel disease complicating their large-vessel disease. Diabetic peripheral neuropathy may diminish the pain and contribute to further injury by inadvertent trauma. Ischemic neuritis may occur as a complication as well. The differential diagnosis includes cholesterol and other arterial emboli, thromboangiitis obliterans (Buerger's disease), trauma to arteries, neurovascular compression, arteriovenous malformation, and hypertensive ischemic ulcer.

Evaluation of the patient should include examination of all pulses and auscultation for bruits. A Doppler flowmeter may be helpful in detecting pulses. Measurement of the ratio of systolic blood pressure in the ankle compared with the arm [ankle brachial index (ABI)] using a Doppler device is a sensitive indicator of disease. The ABI is normally greater than one. An ABI ratio of less than 0.5 indicates severe ischemia. The ABI may be falsely elevated in patients with noncompressible vessels because of significant calcification (e.g., seen in diabetes). The ABI ratio can also be measured after exercise and tends to fall immediately after exercise with occlusive disease. Arteriography is important if surgery is contemplated.

Treatment

General supportive measures include cessation of smoking, treatment of hyperlipidemia, control of blood pressure, and proper foot care to prevent trauma. Elevation of the extremity and compression stockings should be avoided. Patients with claudication benefit from exercise to promote collateral circulation. Sheepskins and foot cradles are helpful in local care to relieve pressure. Bypass surgery or transluminal dilation of arteries may be indicated in individual cases when conservative measures fail. Laser angioplasty, atherectomy, and stent placements are other nonoperative interventions that may be used besides percutaneous transluminal angioplasty.

Stasis Ulcers

Stasis ulcers are painful ulcerations that are usually located on the medial malleoli in patients with chronic venous insufficiency (67,68). Other clinical features include varicosities, hyperpigmentation secondary to hemosiderin deposition in tissues, induration of tissue secondary to fibrosis, and pitting edema. Complicating dermatitis can occur as a result of stasis or sensitization to topically applied medications, especially neomycin. Chronic venous insufficiency can arise from a familial tendency, on an idiopathic basis, or because of single or multiple bouts of thrombophlebitis, leading to destruction and incompetence of venous valves (postphlebitic limb). Obesity and medical conditions causing peripheral edema such as pulmonary, cardiac, renal, and liver disease may also be contributory. Pain and ulceration are presumably on an ischemic basis because of increased venous pressure, with resultant diminished capillary flow.

Treatment

Management should emphasize elevation of legs, when possible, to decrease hydrostatic pressure; wearing of support stockings; or optimal compression wraps. Measures to treat the ulcerations include wet dressings, synthetic dressings (e.g., hydrocolloids, hydrogels, calcium alginates, biological dressings), Unna boots, and antibiotics for secondary infection. Dermatitis related to stasis or sensitization to topical medication responds to topical steroids as well as to avoidance of the sensitizing agents. Weight reduction and diuretics may be helpful in individual cases. Stasis ulcers sometimes require skin grafting.

PAINFUL INFECTIONS

Many skin infections are painful; some are so rare that they are not covered in this chapter. Some of the more common painful infections of the skin are discussed.

Herpes Zoster

Herpes zoster is a painful eruption of varicella zoster virus in a dermatomal distribution (69). It is presented in detail in Chapter 22.

Symptoms and Signs

A prodrome of paresthesias, pain, or both in the involved dermatome is often experienced 1 to 2 days before onset of the skin eruption. Some patients may have pain without an eruption (zoster sine herpete). The individual lesions are clear vesicles on an erythematous base that are clustered within the involved dermatome. The vesicles become cloudy and often hemorrhagic over 3 to 4 days and then become dry and crusted. Healing takes place in 2 to 4 weeks.

Diagnosis

When necessary, the diagnosis can be confirmed by culture, although culture of this virus is somewhat difficult. At many centers, direct immunofluorescence on cells from the culture swab is used to rapidly identify herpes zoster. Pain usually subsides with healing of the lesions. Some patients, especially the elderly, have persistent pain in the involved dermatome. The pain is confined to the involved dermatome and is sharp, often burning, and ranges in intensity from mild to excruciating. Postherpetic neuralgia is discussed in Chapter 22.

Treatment

Local treatment of herpes zoster includes evaporative wet-to-wet Burow's compresses, as well as oral aspirin (0.6 g four times a day), with or without narcotic analgesics, depending on the severity of symptoms. In patients older than age 60 years or in those who are immunoincompetent, systemic corticosteroids and antiviral therapy are indicated. A course of famciclovir, 500 mg PO three times daily (70), with or without prednisone, 40 to 60 mg PO daily for 14 to 21 days, should be started within the first 3 days of the eruption. Chapter 22 is devoted to the description of herpes zoster and postherpetic neuralgia (71).

Herpes Simplex

Herpes simplex infection of the skin is often a painful eruption of clustered vesicular lesions on an erythematous base that may be preceded by burning or tingling 1 to 2 days before onset of the eruption (72,73 and 74).

Symptoms and Signs

The vesicles of herpes simplex can be mildly painful and are often described as sore when touched. The pain is rarely as severe or protracted as that experienced in herpes zoster infections and neither the vesicles nor the pain is in a dermatomal distribution. With primary infections, fever, malaise, and tender lymphadenopathy can also be present. The virus lies latent in sensory nerve ganglia and can periodically reactivate to produce recurrent episodes of herpes simplex infection, which tend to be milder and briefer than the primary infection. Herpes labialis and genital herpes infections are the most common clinical forms of the disease. Other clinical variants include gingivostomatitis, keratoconjunctivitis, herpetic whitlow, eczema herpeticum, and recurrent lumbosacral herpes simplex. Recurrent episodes of erythema multiforme can be triggered by recurrent episodes of herpes simplex. Immunosuppressed patients, such as those with human immunodeficiency virus, may have more frequent and severe infections that are slow in healing. Large, deep, painful ulcerations may develop and last for months if not treated.

Diagnosis

Finding multinucleated giant cells on a Tzanck preparation can permit a presumptive diagnosis of herpes simplex, although herpes zoster gives a similar positive result. Culturing the virus, which grows out readily within 72 hours, establishes a definitive diagnosis. Identification of herpes simplex virus (HSV) antigens or HSV-DNA in skin scrapings is a more rapid method of diagnosis.

Treatment

Treatment of herpes simplex infection includes wet compresses with Burow's solution and analgesics for pain if needed. Occasionally, herpes simplex infection is

complicated by bacterial infection with *Staphylococcus aureus* or group A streptococcus, and an antibacterial agent such as dicloxacillin or cephalexin is indicated.

Antiviral therapy with acyclovir (ACV) is effective for treatment and suppression of the virus, although it does not eliminate latent virus. First episodes of genital or oral-labial herpes simplex infection may be treated with oral ACV, 200 mg five times per day. Intravenous ACV (5 mg per kg every 8 hours for 5 days) is used for patients with severe disease or neurologic complications. Recurrent genital herpes is treated with ACV, 200 mg five times per day for 5 days. Suppression of recurrent disease is managed with ACV, 200 mg two to three times a day. Immunosuppressed patients may need intravenous ACV (5 mg per kg every 8 hours) for treatment of first or recurrent episodes as well as for suppression during high-risk periods. Patients with ACV-resistant HSV may be treated with intravenous foscarnet (40 mg per kg IV every 8 or 12 hours). Valacyclovir and famciclovir are alternative oral agents for HSV that have the advantage of less frequent oral dosing compared with ACV.

Erysipelas and Cellulitis

Erysipelas is a type of superficial skin infection caused by streptococcus pyogenes; it has a characteristic clinical appearance. Group A streptococci may also cause cellulitis (75). In erysipelas and cellulitis, the organism usually gains access by direct transcutaneous inoculation. Infection spreads within the superficial dermis as bacterial enzymes lyse mature proteoglycans.

Erysipelas usually appears on acral skin in adults as one or more painful, bright red, hot, edematous plaques within the skin that advance peripherally and are distinguishable by their sharply demarcated palpable edges. Lesions are painful and attended by high fever, malaise, and headache. Diagnosis depends on the recognition of this complex composed of sharply marginated painful red plaques with attendant systemic signs. Cellulitis is commonly a streptococcal infection of the skin and the subcutaneous tissue as well, with more marked and less clearly marginated redness than erysipelas. It is usually attended by fever. It is difficult to recover the organism for culture and recognition of the clinical syndrome.

Group A streptococcus is typically sensitive to and responds to treatment with oral penicillin VK (250 to 500 mg four times a day) for 10 days. However, it is often not possible to distinguish clinically cellulitis from *S. aureus* with certainty before culture results are known. For this reason, it is prudent to treat these patients with antibiotics effective for both group A streptococcus and *S. aureus*, such as dicloxacillin, 250 to 500 mg four times a day, or cephalexin, 250 to 500 mg four times a day, for 10 days or more depending on the clinical response. More seriously ill patients may need to be hospitalized and treated with intravenous antibiotics. Serious cutaneous infections with a similar clinical presentation have been reported with group B streptococcus, particularly in patients with diabetes (76).

Furunculosis and Carbuncle

Furuncles and carbuncles are painful staphylococcal abscesses of one or more hair follicles in any hair-bearing area of skin. The furuncle may commence as a superficial follicular centered pustule. The process extends down the hair follicle to produce a painful, red, swollen lesion surrounding a deeper abscess and surmounted by a central pustule. A carbuncle results from the dissection of a furuncle in the subcutaneous space to adjacent follicles and the ultimate development of abscesses in a number of adjacent follicles, leading to a more edematous, larger, much more painful, red lesion surmounted by numerous follicular pustules. Cultures should be made of the superficial pustules to determine the antibiotic sensitivities of the staphylococcal agent (77).

Deep abscesses should be surgically incised and drained, as well as cultured. Treatment should be given with an antibiotic effective for penicillin-resistant *S. aureus* such as dicloxacillin or cephalexin, 250 to 500 mg four times a day for 7 to 10 days. Patients with methicillin-resistant *S. aureus* may need intravenous vancomycin, 2.0 g per day in divided doses and adjusted for renal function. In patients with recurrent furunculosis, measures to reduce nasal carriage of *S. aureus* may be helpful. These include local application of mupirocin ointment and a combination of oral rifampin, 600 mg per day for 10 days, plus dicloxacillin, 250 to 500 mg four times a day for 10 days.

Erysipeloid

Erysipeloid is an acute infection with *Erysipelothrix rhusiopathiae*, the causal agent of swine erysipelas. It occurs most commonly as an occupational disease of butchers, fish handlers, and crab fisherman but may also occur in the domestic setting with handling of fish, poultry, and meat products.

The clinical lesion occurs after a prick or scratch when handling meats or fish and results in a hot, painful, swollen, violaceous red edema of the skin that spreads peripherally with central clearing of the rash. There is no scaling or desquamation. It may resemble erysipelas but constitutional symptoms are usually absent.

Erysipeloid responds to penicillin in doses of 2 to 3 million units daily, orally or intramuscularly, for 7 to 10 days. Higher doses are recommended if there is systemic involvement (78).

INFLAMMATIONS

Panniculitis

Erythema Nodosum

Erythema nodosum is a fairly common painful symptom complex characterized by erythematous, tender, slightly raised nodules typically located on the anterior tibial surfaces and sometimes associated with mild, constitutional symptoms of fever, malaise, myalgias, and arthralgias (79). The individual lesions can last for a few weeks, but new lesions can continue to appear.

The causes of erythema nodosum include infections (bacterial, viral, fungal, and protozoan), medications, malignant diseases, and a variety of other causes. Among the more common causes and causes important to keep in mind are streptococcal infections, tuberculosis, systemic fungal infections (e.g., coccidiomycosis, histoplasmosis, blastomycosis), drugs (e.g., sulfonamides, oral contraceptives, aspirin, iodides), sarcoidosis, and inflammatory bowel disease.

The pathogenesis of erythema nodosum is not understood but probably involves hypersensitive immunologic mechanisms. Histologically, an inflammatory process involves the septa between fat lobules.

Management includes treating any underlying disease as well as stopping any potential medications that might be the cause for erythema nodosum. Patients often respond to conservative measures, such as bed rest and salicylates (aspirin, 600 mg every 4 hours). It should be kept in mind that salicylates could also cause erythema nodosum. Iodides (potassium iodide, 300 to 900 mg daily) are also sometimes effective, as are short courses of systemic steroids.

Weber-Christian Disease

Weber-Christian disease typically occurs in middle-aged women and is characterized by recurrent episodes of fever in association with tender, at times aching, painful nodules on the trunk and extremities, particularly the thighs (80,81 and 82). The nodules may be erythematous, sometimes heal with atrophy, and, rarely, break down and discharge oily material. Visceral involvement can occur with involvement of omentum, bone, and joints. Histologically, the diagnosis depends on finding lipid-laden histiocytes or foam cells with lobular panniculitis. Weber-Christian disease bears similarities to cytophagic histiocytic panniculitis and some early reported cases of Weber-Christian disease were cases of alpha $_1$-antitrypsin deficiency. It remains a useful clinicopathologic diagnosis until methods that are more definitive are available to subdivide the panniculitides further.

Patients have been reported to respond to tetracycline, sulfapyridine, dapsone, antimalarials, corticosteroids, cyclophosphamide, and thalidomide. The more benign forms of therapy should be tried first, although corticosteroids are the most predictably effective. Antimalarials or corticosteroids appeared to be the most effective in studies by Panush and colleagues (82).

Dercum's Disease

Also known as *adiposis dolorosa*, Dercum's disease is a rare condition. It occurs most frequently in obese menopausal women and is characterized by painful, diffuse,

or nodular deposits of fat, most commonly on the trunk, arms, and periarticular soft tissue (83).

Histologically, the fatty deposits usually resemble those of ordinary lipomas. Angiolipomas, often painful tumors (Table 32-2), and granulomatous changes are reported (84).

Excision of individual tumors can sometimes be helpful, along with analgesics and weight reduction. Intravenous lidocaine has been reported to be of value.

Hidradenitis Suppurativa

Hidradenitis suppurativa is a chronic, painful, suppurative inflammatory disease of the apocrine glands in the axillae, genitocrural areas, and mammary region (85).

Etiology

The cause of hidradenitis suppurativa is thought to be occlusion of the apocrine duct, leading to an inflammatory foreign body-type reaction, leading to recurrent mixed secondary bacterial infection.

Symptoms and Signs

Hidradenitis suppurativa begins as one or more firm, subcutaneous nodules coalescing in weeks to become deep, painful abscesses surmounted by plaques of redness and heat. The deep abscesses dissect, with scarring and suppuration to adjacent follicles and apocrine glands, ultimately forming sinus tracts. The disease process waxes and wanes for years, causing scarring and gradually extending to involve larger and larger areas of skin in the regions noted.

Diagnosis

The important distinction of hidradenitis suppurativa from ordinary furuncles in the axillae or groin comes with the recognition of the chronic course, the formation of sinuses, and particularly the retracted scars and chronic intermittent suppuration.

Treatment

Oral antibiotics are often helpful in either short courses or long-term maintenance therapy if needed. Tetracycline in doses of 250 to 500 mg four times a day is usually prescribed. Equivalent full doses of erythromycin, cephalexin, and minocycline may be helpful. Individual lesions respond to intralesional steroids in concentrations of 2.5 to 5.0 mg per mL of triamcinolone acetonide solution. Short courses of systemic steroids (prednisone, 40 to 60 mg per day) for 1 to 2 weeks are useful if lesions are widespread and numerous.

Topical antibiotics and weight reduction, if needed, are helpful. Excision of the area with primary closure, a rotation flap, or grafting is the most definitive treatment available. Liposuction in early disease to remove the underlying apocrine glands and hair follicles has been reported to be helpful. This should be done before severe scarring has occurred.

Inflamed Epidermal Cyst

Epidermal cysts are very common, and most are asymptomatic. When traumatized or manipulated, the contents of the cyst may extrude into the surrounding dermis and incite an intense foreign body reaction. This produces a painful, warm, erythematous, and edematous lesion. Treatment consists of hot compresses, incision, and drainage, as well as antibiotics if secondary infection is suspected. When the inflammation subsides, the cyst is excised.

Bullous Dermatoses with Erosions

Pemphigus Vulgaris

Pemphigus refers to a rare group of blistering skin diseases that are painful when blisters rupture, leaving raw, denuded surfaces. Pemphigus vulgaris is the most common type (86). Other variants include pemphigus vegetans, pemphigus foliaceus, pemphigus erythematosus, and paraneoplastic pemphigus.

Pemphigus vulgaris typically begins with oral blisters that easily rupture and leave constantly painful oral erosions that, when extensive, preclude eating and swallowing. The disease inevitably progresses to involve the skin with flaccid blisters that easily rupture, leaving raw denuded surfaces. The scalp, chest, and intertriginous areas are commonly affected. Untreated, the disease progressively involves larger surfaces of the body and may be fatal. Histologically, the blistering is seen to occur in the lower part of the epidermis through a process known as *acantholysis*. Almost all patients with pemphigus vulgaris have deposits of IgG in the perilesional skin in the intercellular area of the epidermis, detected by direct immunofluorescence. Approximately 75% of patients have circulating antibodies to desmoplakin or desmoglein on indirect immunofluorescence.

Pemphigus vulgaris is an autoimmune disease mediated by antibodies directed against desmoplakin and desmoglein in the desmosome. The pemphigus vulgaris antigen is a member of the family of adhesion molecules called *cadherins* (calcium-dependent adhesion molecules). A 130-kd glycoprotein is complexed to an 85-kd plakoglobin. The gene for the 130-kd pemphigus antigen has been cloned.

Paraneoplastic pemphigus is a variant of pemphigus associated with benign and malignant tumors. It is characterized by painful oral erosions and a polymorphous, blistering skin eruption that can leave painful raw denuded surfaces. Histologically, one sees acantholysis as in pemphigus vulgaris but also necrotic keratinocytes and interface dermatitis. Direct immunofluorescence demonstrates intercellular IgG and complement and often linear or granular deposition along the basement membrane. The circulating autoantibodies recognize a high-molecular-weight complex of polypeptides: 250, 230, 210, 190, and 170 kd. These have been characterized as desmoplakin I (250 kd), bullous pemphigoid antigen (230 kd), desmoplakin II (210 kd), and not fully characterized 190- and 170-kd polypeptides. The associated tumors are usually malignant and typically one of the following: non- Hodgkin's lymphoma (42%), chronic lymphocytic leukemia (29%), Castleman's tumor (10%), thymoma (6%), spindle cell neoplasms (6%), or Waldenström's macroglobulinemia (6%) (87,88).

Treatment of pemphigus vulgaris is primarily high-dose corticosteroids (80 to 120 mg daily of prednisone), or pulse doses of prednisone are used initially to bring the disease under control. Later, steroid-sparing agents, such as azathioprine, methotrexate, cyclophosphamide, or gold, are added to enable tapering of the corticosteroids. Cyclosporine A has had limited effectiveness. The mortality rate remains at approximately 5%, related primarily to complications of treatment.

In paraneoplastic pemphigus, search for the underlying tumor is essential. Treatment of paraneoplastic pemphigus is most straightforward if the tumor is benign. Excision of the tumor usually results in resolution or marked improvement in the rash. If the patient has an underlying malignancy, the paraneoplastic pemphigus is often refractory to treatment, especially the stomatitis, and it does not parallel the activity of the underlying malignancy. A subset of patients has responded to a combination of prednisone (1 to 2 mg per kg per day) and cyclosporine (5 mg per kg per day).

Bullous Pemphigoid

Bullous pemphigoid is an uncommon subepidermal blistering disease that usually affects elderly patients (89). Pruritus is sometimes present. When blisters rupture, they leave raw, painful surfaces that can be exquisitely sensitive for several days until healed. Lesions typically occur on the thighs, abdomen, forearms, and axillae. Oral lesions occur in approximately one-third of cases.

The blister occurs between the epidermis and dermis, producing tense bullae as opposed to the flaccid bullae and early erosions of pemphigus vulgaris. Although the condition tends to be chronic with exacerbations and remissions, the disease is self-limited, and with treatment, the overall prognosis is good.

Deposits of IgG, C3, or both are found on direct immunofluorescence at the basement membrane zone of the epidermis in almost all patients. Approximately two-thirds of patients have circulating antibodies to the basement membrane zone on indirect immunofluorescence. Bullous pemphigoid is an autoimmune disease

with autoantibodies directed against the bullous pemphigoid antigen. The bullous pemphigoid antigen is associated with the lamina lucida portion of the basement membrane zone and the hemidesmosomes. The antigen has two components: a 230-kd polypeptide reactive with most patients' sera and a 180-kd polypeptide reactive with a smaller percentage of patients' sera.

Potent topical steroids such as fluocinonide 0.05% cream or clobetasol 0.05% cream and wet dressings are usually sufficient for limited disease. Systemic steroids, such as prednisone in daily dosages of 60 to 80 mg, are indicated for widespread disease. Tapering the prednisone and using steroid-sparing agents such as azathioprine, methotrexate, or cyclophosphamide are recommended if difficulty is encountered. In those patients who receive azathioprine, measurement of thiopurine methyltransferase has been recommended to provide a guideline in dosing because thiopurine methyltransferase metabolizes the drug (90). Dapsone is helpful in approximately 15% of cases, especially in cases with a neutrophil-rich infiltrate histologically. Erythromycin alone or tetracycline (500 mg four times a day) plus niacinamide (1.5 to 2.5 g per day) have been effective in some patients and may be particularly helpful in patients unable to tolerate systemic steroids.

Epidermolysis Bullosa

Epidermolysis bullosa refers to a group of uncommon diseases in which minor trauma results in detachment of the epidermis from the dermis, causing painful blistering of the skin. Hereditary and acquired forms exist that are both scarring and nonscarring (91,92). Mucous membranes and skin can be involved. Milia formation and dystrophic nails are helpful clinical clues that indicate the scarring type.

Blisters lie within or beneath the epidermis, depending on the type of epidermolysis bullosa. Little, if any, inflammatory infiltrate is usually present, but dense infiltrates may be seen in the acquired form of the disease. Electron microscopy and immunohistochemical mapping with antibodies to type VII collagen, laminin, or bullous pemphigoid antibodies are often necessary in classifying the hereditary forms of the disease. Immunofluorescence on 1 molar sodium chloride (1 M NaCl) split skin is needed to confirm the diagnosis of acquired epidermolysis bullosa. Acquired epidermolysis bullosa has been reported in association with various systemic diseases, including diabetes mellitus, inflammatory bowel disease, systemic lupus erythematosus, lung carcinoma, chronic lymphocytic leukemia, multiple myeloma, and amyloidosis. In acquired epidermolysis bullosa, search for an underlying systemic illness is indicated.

Pathogenesis. Molecular biological techniques have been extremely helpful in understanding the specific gene defects that occur in the hereditary forms of the disease. Point mutations in keratin genes have been found in epidermolysis bullosa simplex and the type VII collagen gene in recessive dystrophic epidermolysis bullosa (88). Molecular biological and monoclonal antibody techniques suggest mutations in the anchoring filament–associated proteins in junctional epidermolysis bullosa. Acquired epidermolysis bullosa is an immune-mediated subepidermal bullous disease with autoantibodies to type VII collagen. Four different regions within the noncollagenous portion of amino-terminus of the alpha chain of type VII collagen have been found to be antigenic sites.

Treatment. Measures should be taken to avoid trauma, friction, and heat to skin and mucous membranes. Nutritional support and topical antibiotics and dressings are useful. Skin grafts may be needed in some instances. Esophageal dilation and surgical correction of scarring may also be needed at times. Acquired epidermolysis bullosa is treated with prednisone (1 to 2 mg per kg). Dapsone, colchicine, and plasmapheresis have been reported to be helpful. Cyclosporine in doses of 6 mg per kg may also be helpful.

Cutaneous Endometriosis

In cutaneous endometriosis, endometrial tissue deposits in skin are often tender and painful, especially at the time of menstruation (93). The lesion is usually solitary, varying from 0.5 to 6.0 cm in diameter, and appears usually as a brownish or bluish nodule. This rare condition most often arises in surgical scars, such as those from cesarean sections or episiotomies. The disease can also arise spontaneously, especially in the umbilicus. Treatment is either with hormones (estrogen, progesterone, or androgen) or excision.

DISORDERS OF CONNECTIVE TISSUE STRUCTURE (CARTILAGE DISORDERS)

Relapsing Polychondritis

Relapsing polychondritis is a systemic inflammatory disease characterized by inflammation and often pain in cartilaginous structures (94). The cause of the disease is unknown. An autoimmune basis is suggested by a variety of autoimmune phenomena associated with the disorder.

Recurrent bouts of pain, erythema, and edema of the external ears are the most constant features of the disease. The earlobes are spared. The ears ultimately may become “cauliflower” or “floppy” in appearance due to loss of cartilaginous support. Painful skin lesions (palpable purpura) related to a systemic vasculitis may also occur. Other reported cutaneous manifestations include urticaria, angioedema, livedo reticularis, panniculitis, erythema multiforme and erythema nodosumlike lesions. The other major features of the disease include nasal involvement with saddle nose deformity, ocular involvement (scleritis, episcleritis, and uveitis), oligo- or polyarthritis, vestibular damage, respiratory tract involvement, and involvement of cardiac valves and the aorta. Serious complications may occur from respiratory tract involvement producing respiratory obstruction. Cardiac involvement leads to valvular dysfunction; aortic aneurysms may also occur.

Detection of autoantibodies to type II collagen, circulating immune complexes, deposition of immunoglobulins, and complement at the chondrofibrous junction support an autoimmune pathogenesis. The association with other preceding or coexistent autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, and Behçet's disease has been reported.

Milder features of the disease may be controlled with nonsteroidal antiinflammatory drugs and dapsone. Dapsone is typically started at a dosage of 50 mg per day and increased if needed, with careful monitoring for side effects. Hemolysis occurs in a dose- dependent fashion. Systemic steroids are needed for any serious internal organ involvement. Immunosuppressive agents such as azathioprine and cyclophosphamide may be needed in some instances. Methotrexate was found to be the most effective immunosuppressive agent in one reported series of patients (95). Anti-CO_4 monoclonal antibody as well as oral minocycline have also been reported to be effective.

Chondrodermatitis Nodularis Chronica Helicis

Chondrodermatitis nodularis chronica helicis is a chronic, painful condition of the ear characterized by 2 to 4 mm of erythematous, very tender papules on the rim of the outer helix of the external ear. The lesions often have a slight scale, crust, or erosion (96). Although there is no tendency to malignant change, squamous cell cancer and basal cell cancer are in the differential diagnosis, and biopsy may be needed to exclude these possibilities.

Histologically, one sees degenerative changes in the dermis and cartilage; chronic inflammatory changes at the periphery and epidermal ulceration with an edematous and thickened epidermis are observed. Vascular insufficiency may be the underlying cause, whether induced by trauma, pressure, cold, or chronic actinic damage (97).

Treatment with intralesional steroids (0.1 mL of triamcinolone, 2.5 mg per mL) may be helpful, but repeated injections at monthly intervals may be needed. Excision of the entire lesion is also helpful. A pillow with a hole in it for the ear is commercially available and helps some patients by relieving pressure on the lesion.

NEUROVASCULAR CUTANEOUS DISEASE

Sensory Mononeuropathies

A variety of sensory mononeuropathies affect the skin (98). They may involve cranial nerves, the extremities, or the trunk (see Chapter 19). Patients may experience numbness, burning, tingling, pruritus, or other paresthesias in the distribution of the affected nerve. Most commonly this is related to trauma or mechanical irritation of the affected nerve, but diabetes, vasculitis, and benign and malignant tumors are in the differential diagnosis. Electrodiagnostic studies can be confirmatory. Among the more common sensory neuropathies are meralgia paresthetica (lateral femoral cutaneous nerve), cheiralgia paresthetica (superficial branch of the radial nerve), gonyalgia paresthetica (infrapatellar branch of saphenous nerve), digitalgia paresthetica (digital nerve), notalgia paresthetica (posterior rami to T-2 to T-6), intercostal neuropathy, and mental nerve neuropathy. The mental nerve neuropathy with numbness on the side of the chin is the most ominous because it is more likely to be associated with malignancy than the extremity lesions. The malignancy may be a solid tumor or reticuloendothelial malignancy and usually is proximal to the mental

foramen. Thorough evaluation is indicated (see Chapter 47).

Notalgia paresthetica is the variant most commonly seen by dermatologists, probably because pruritus is the predominant symptom; however, tingling, pain, and other paresthesias may be present. It has been postulated that spinal nerves emerging at right angles through the multifidus spinae muscles are subjected to trauma or entrapment. A hereditary form has been reported and also association with multiple endocrine neoplasia type 2a (99).

Clinically, one sees a hyperpigmented patch in the affected area. Histologically, there may be hyperpigmentation of the basal layer, melanophages, and macular amyloidosis. These changes are believed to be secondary to scratching.

Treatment usually consists of topical and intralesional steroids, which afford only partial relief. Treatment with a topical local anesthetic lidocaine/prilocaine or topical capsaicin may be helpful for some patients. A paravertebral nerve block with bupivacaine plus methylprednisolone was helpful for one patient (100) and an epidural steroid injection (101) was helpful for another.

Fabry's Disease

Fabry's disease is a rare X-linked genodermatosis with deficiency of the enzyme alpha-galactosidase A, which produces accumulation of neutral glycosphingolipids in tissues. These glycosphingolipids accumulate in vascular endothelium, resulting in vascular occlusion, ischemia, and pain (102,103 and 104).

Symptoms and Signs

The characteristic cutaneous lesions of Fabry's are dark reddish macules and papules (angiokeratomas) that are 3 to 4 mm in diameter. They may or may not have epidermal changes with hyperkeratosis and scaling. They occur most commonly between the umbilicus and the knees but may be widespread, sparing only the face, scalp, and ears. They typically occur between 7 and 13 years of age and are nonpainful. Hypohidrosis and peripheral edema are other cutaneous features of the disease.

A painful and incapacitating peripheral neuropathy occurs in Fabry's disease (see Chapter 19). The pain typically occurs in crises affecting the fingers and toes and occasionally radiating proximally. Attacks of abdominal and flank pain may occur, simulating an acute abdomen and renal stones. The attacks of pain may last from minutes to several days and be associated with low-grade fever and elevated erythrocyte sedimentation rate. The attacks may be brought on by exertion, fatigue, fever, heat, and cold. Between attacks, patients may be left with burning, tingling paresthesias in the hands and feet.

Characteristic eye findings include corneal opacities, tortuous conjunctival and retinal vessels, and a unique posterior capsular cataract termed the *Fabry cataract*.

The cardiac, renal, and central nervous system manifestations account for the major morbidity and mortality of the disease, with death usually by age 41 before hemodialysis and renal transplantation became available. Other manifestations include bronchitis, arthropathy, diarrhea, and hypogonadism.

The glycosphingolipid is demonstrable in the skin with Sudan black-B and periodic acid-Schiff stains and appears under the electron microscope as inclusions with a concentric, lamellar, and myelinlike appearance. The glycolipid is demonstrable in cells in the urine as birefringent inclusions, with the appearance of a Maltese cross under polarized light. The diagnosis is biochemically confirmed by finding deficient alpha-galactosidase activity in plasma or serum, leukocytes, tears, biopsied tissues, or cultured skin fibroblasts. Alternatively, trihexosyl ceramide levels can be demonstrated to be increased in urinary sediment, plasma, or cultured skin fibroblasts.

The differential diagnosis of Fabry's disease includes other unusual lysosomal storage diseases in which angiokeratomas have been reported. These include fucosidosis, aspartylglycosaminuria, adult-onset GM1-gangliosidosis, sialidosis, galactosialidosis, alpha- *N*-acetylgalactosaminidase deficiency, and Schindler's disease (infantile and adult forms). There have been a few cases in which diffuse angiokeratomas similar to Fabry's have occurred with no detectable underlying enzyme abnormality and no detectable cellular inclusions on electron microscopy.

Treatment

Treatment consists of supportive therapy for renal and cardiac disease. Paresthesias may respond to conventional doses of anticonvulsant medications (see Chapter 86). The role of organ transplantation and administration of alpha-galactosidase A in restoring normal enzyme levels is being explored. Genetic counseling is also indicated.

NEOPLASMS

A number of benign cutaneous neoplasms of the skin have pain as a characteristic feature, which may be a helpful clue as to their diagnosis at the time of their initial presentation. The diagnosis may be suspected beforehand but needs to be confirmed histologically. Because the lesions are symptomatic, most patients will want the entire lesion excised, which is usually curative. Table 32-2 lists characteristic features of these tumors. Other benign or malignant tumors of the skin may on occasion be painful, especially if ulcerated, if expanding in closed spaces, or if occurring on weight-bearing surfaces.

ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of Dr. George F. Odland to this chapter. He was the original primary author, and many of his touches and words remain part of the fabric of the chapter.

CHAPTER 33

Pain Due to Vascular Disease

Kaj H. Johansen

Pain is a common and, frequently, diagnostic feature of many vascular diseases (1). Although the precise etiology of these diseases is multifactorial, it is probable that pain caused primarily by vascular disease may afflict up to 10% of all Americans at some time. This group includes patients with coronary artery disease, aortic disease, disease of the major vessels to the viscera and to the head and neck, and disease of the vessels to the limbs (see Chapter 61 for additional information on coronary and aortic disease).

This chapter contains a general discussion of most important vascular diseases that produce pain. Because the management of vascular disease is a vast subject, the focus is on the mechanisms and pathophysiology of vascular pain and its control. Because pain of cardiac and aortic origin is discussed in Chapter 61 and pain associated with other visceral vascular disease is considered in various chapters of Part IV, this chapter is devoted to peripheral vascular disease (PVD). The material is presented in three major sections: (a) basic considerations, including a brief review of the anatomy and nerve supply of the peripheral vessels, the general characteristics of pain and its mechanisms and other symptomatology of vascular diseases, and diagnosis of these disorders; (b) diseases of the arteries; and (c) diseases of the veins and the lymphatic system. Detailed discussion of all aspects of vascular disease can be found in comprehensive textbooks on this subject (2,3,4 and 5).

BASIC CONSIDERATIONS

Anatomic Aspects

In discussing vascular disease, some authorities classify the vessels as follows: (a) large arteries, restricted to the aorta and to the major arteries of the thorax, abdomen, and neck; (b) medium-sized arteries (i.e., those with proper names that arise as the first branches of the large arteries or are located outside of the thorax or abdomen); (c) “small arteries” (those unnamed vessels of macroscopic size that are branches of the medium-sized arteries); and (d) the microcirculation, used for the array of vessels from the level of arterioles to and including the venules (6). On the venous side of the circulation, there are large veins, again within the confines of the thorax, chest, and neck. Other veins are classified as deep or superficial, depending on whether they are inside or outside of the fascial envelopes that encase the deeper structures of the extremities and neck. The extensive intercommunications between the superficial and deep venous systems, which are functionally very important, are called the *perforating veins*.

The innervation of these blood vessels includes afferent (sensory) fibers, some of which transmit nociceptive impulses and are components of spinal nerves for the body below the head and of cranial nerves in the head. These fibers have their cell bodies in sensory ganglia; their proximal axonal branches that contact the second-order neurons are in the neuraxis, and their distal axonal branches are part of the somatic nerves that supply these structures. The efferent fibers are sympathetic nerves with a predominance of vasoconstrictors, but also some vasodilator fibers and fibers that supply sweat glands and erector pili muscles. The origin, course, and distribution of these nerves to the blood vessels of the upper limb are discussed in detail in Chapter 54 and depicted in Figure 54-22; those that supply the lower limb are considered in Chapter 75. The sensory and sympathetic supply to the aorta and the large arteries and veins in the thoracic and abdominal cavity is discussed in Chapter 60 and Chapter 65, and the nerve supply to the vessels of the head is discussed in Chapter 46.

Mechanisms of Pain of Vascular Disease

Pain resulting from vascular disease is produced by one or more of the following pathophysiologic factors: (a) inadequate perfusion of tissues, with consequent transient or continuous ischemia such as occurs in the muscles of the limb during exercise, ischemia of the skin that produces rest pain, and ischemia of an organ such as the heart or gastrointestinal tract; (b) secondary changes, such as ulcerations or gangrene in the skin or abdominal viscera; (c) sudden or accelerated changes in the vascular dimension of large vessels, such as occurs with expanding aneurysm; (d) rupture of the aorta or other intracavitary arteries, with consequent spillage of blood that stimulates nociceptive fibers in the parietal peritoneum or parietal pleura; (e) intense spasm consequent to the intraarterial injection of materials that irritate the endothelium of the artery; and (f) impairment of venous return, with consequent massive edema that rapidly stretches fascial compartments. The location, distribution, intensity, quality, duration, and temporal characteristics of the pain that results are determined by the pathology of the disease, its location, the rapidity with which tissue ischemia develops, and most important, the extent of the involvement of the pathologic process.

Classification of Peripheral Vascular Disease

The most important painful diseases of the peripheral vessels are listed in Table 33-1. The order of the listing is according to the aforementioned classification of arteries and veins and in the order of frequency and general importance of each disease.

TABLE 33-1. Classification of peripheral vascular diseases

Evaluation of the Patient

The diagnosis of peripheral vascular disorders that cause pain always starts with a detailed history and complete physical examination. With regard to the history, background data such as occupation, family and social history, prior illness, and surgery can provide insight into what otherwise appears to be a complex or confusing type of problem. For example, machine operators, mechanics, farmers, and others who work with their hands a great deal can develop occupational occlusive arterial disease or Raynaud's phenomenon from vibrating tools. Handling of cold products or entering walk-in freezers can aggravate any type of occlusive arterial disease. A strong family history of arterial disease (cerebral, coronary, or peripheral) can signify a familial lipid disorder and indicate that other poorly understood factors related to inheritance are at play. It is important to find out if previous illness or operations were of vascular nature or if they were accompanied or complicated by vascular problems such as thrombophlebitis, pulmonary embolism, or acute arterial occlusion. Smoking and diabetes are two crucial comorbidities contributing to arterial disease.

The physical examination consists of inspection, palpation, and Doppler interrogation of the vessels of the involved limb and other extremities. The physician should note the quality of the arterial pulsations and the color and temperature of the skin. Using the Doppler ultrasonic flow detector, the blood pressure should be compared with that in the arm: A value of less than 0.9 signifies the presence of arterial occlusive disease in the lower extremities (7). In the diabetic, ankle Doppler pressures may be falsely elevated because of those patients' lower extremity arterial medial calcification. Other tests such as transcutaneous oximetry must be used to quantitate blood supply.

Because PVD is frequently only a part of a more widespread problem, the patient's general vascular status should be determined, including a general physical and neurologic examination to search for lesions of the central and peripheral nervous system. In addition, a radiologic study of the chest and an electrocardiogram may aid diagnosis (see below).

The most prominent symptoms and signs of PVD are (a) pain; (b) decreased or absent pulses, indicating a decrease in or total obstruction of the arterial supply to the limb; (c) prominent veins that develop with venous obstruction; (d) abnormal skin color; (e) diminished (rarely elevated) skin temperature; (f) swelling; and (g) trophic changes of the skin and its appendages.

Pain

Although pain is the most common symptom in PVD, its nature varies with the disease. Therefore, a fairly accurate assessment of the disease can usually be made by a careful evaluation of the pain. It is important to ascertain the history of onset, the localization and distribution, the intensity, the duration and other temporal characteristics, the circumstances that precipitate or aggravate it, and the factors that ameliorate or relieve the pain (see Chapter 12). It is particularly important to know where the pain occurs in its distribution (e.g., the calf, thigh, hip or back, toes or foot), whether the pain is continuous or intermittent, and the duration of the painful experience.

Continuous pain is produced by sudden arterial occlusion; by ulceration and gangrene; by ischemic neuropathy caused by arterial insufficiency; by inflammation of arteries, veins, or lymphatics; and by venous or (occasionally) lymphatic congestion of a limb. *Intermittent pain* (intermittent claudication, from Latin *claudicare*, to limp) is precipitated or aggravated by exercise of contracting muscles and occurs solely in the anatomic distribution of chronic occlusive arterial disease such as arteriosclerosis obliterans (ASO), thromboangiitis obliterans (TAO) (Buerger's disease) and other types of vasculitis, and entrapment syndromes.

The *intensity* of the pain varies according to the etiology and degree of circulatory imbalance and whether the imbalance occurs gradually or suddenly. The *quality* of the pain also varies with the disease process and mechanism of the pain. The pain of intermittent claudication is usually sharp and often burning in character and is promptly relieved by cessation of the activity that precipitates the pain. The pain of ischemic neuropathy is usually aching in character, often associated with paresthesia, but at times the patient complains of a pulling, tearing, or agonizing sensation. The pain of sudden arterial occlusion is usually sharp when the lesion involves the limbs and is dull and sickening in character when the occlusion involves the aorta or vessels to the abdominal viscera. The pain of erythromelalgia is usually burning and is aggravated by heat and relieved by cold.

Associated Phenomena (Signs of Peripheral Vascular Disease)

Table 33-2 summarizes the signs of PVD. Careful observation of changes in skin color, palpation of the pulses, and skin temperature and trophic changes correlated with the characteristics of the pain usually permit the physician to make an accurate diagnosis of the specific type of PVD present.

TABLE 33-2. Signs of peripheral vascular disease

Laboratory Studies

Laboratory studies that should be included as part of the evaluation of patients with PVD include a complete blood count; urinalysis; blood urea nitrogen, and creatinine evaluations; multiphasic screening biochemical profile; and a glucose tolerance test to eliminate overt or subclinical diabetes. Patients with arteriosclerosis should have plasma lipids measured, including fasting cholesterol, triglycerides, and lipoprotein levels. Homocysteine levels may be valuable. In thromboembolic disorders, a coagulation profile should be obtained.

Special Diagnostic Studies

To confirm and document the arterial insufficiency found or suspected by clinical evaluation and to determine the degree of functional impairment, a variety of noninvasive instruments, primarily based on pioneering work in medical ultrasound by Strandness and colleagues (6,7), are now available in peripheral vascular laboratories. Because these instruments are capable of producing objective information on hard copy, they are useful for following the progress of the patient during the course of conservative treatment and for evaluation before, during, and after surgical therapy. Even more sophisticated instruments are used by the vascular surgeon to select the site of amputation and to predict healing of ischemic lesions or the success of an operation.

Pressure Measurements

As noted above, the simplest pressure measurement method available is to determine the ankle systolic pressure with a handheld Doppler ultrasound instrument and compare it with the brachial systolic pressure (2,3,4,5,6,7,8 and 9). These instruments are accurate, simple to use, relatively inexpensive, and ideal to use in the office or at the bedside to confirm the diagnosis of arterial insufficiency or to follow the course of the disease. Normally, the ankle systolic pressure should be equal to or greater than the brachial systolic pressure [ankle brachial index (ABI) of more than 0.9] (7). With arterial insufficiency in the lower limb, however, the ABI is less than 0.9, depending on the degree of insufficiency. With mild insufficiency the ABI is between 0.7 and 0.9, with moderate disease it is between 0.5 and 0.7, and with severe disease it is less than 0.5 (8). Ischemic skin lesions would not be expected to heal with an ABI of less than 0.4.

The sensitivity of tests using pressure measurements can be increased by augmenting blood flow through the stenotic segment. This can be accomplished by exercise on a treadmill or on an exercise bicycle to the point of claudication. Postexercise ankle blood pressure falls, often to unrecognizable levels, requiring several minutes to return to the preexercise level (Fig. 33-1). The explanation of this phenomenon is that with exercise there is a marked fall in arterial resistance in the muscles; blood flow is fixed through the arterial stenosis, and the amount of inflow available through the collateral arteries is inadequate because of their high resistance to flow. As a consequence, distal arterial pressure falls, explaining the pallor in the foot observed during and immediately after exercise. This test is most useful in following the progress of the disease with or without therapy.

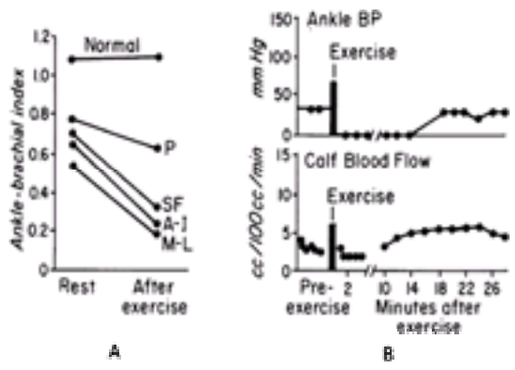

Figure 33-1. **A:** Mean ankle-brachial indexes (ankle systolic blood pressure divided by brachial systolic blood pressure) at rest and after exercise in normal subjects and patients with arteriosclerosis obliterans. Location of occlusion is indicated by letters: P, popliteal below the knee; SF, superficial femoral; AI, aortal iliac; ML, multilevel. **B:** Ankle pressure and calf blood flow before and after exercise in a patient with occlusion of the iliac, common femoral, and superficial femoral arteries. This patient had severe claudication and moderate rest pain. (BP, blood pressure.) (Modified from Sumner DS. Practical approach to vascular laboratory testing in occlusive arterial disease. In: Rutherford RB, ed. *Vascular surgery*, 2nd ed. Philadelphia: WB Saunders, 1984:45–56.)

If more detailed information is desired, the patient can be studied in the vascular laboratory using duplex ultrasound techniques. The specific capabilities of duplex ultrasound relate to its ability not only to localize arterial (and venous) obstructions, but also to make detailed hemodynamic assessments of flow within the normal and affected vessels. Arteriography is rarely indicated unless the patient is to be considered for revascularization. Arteriography documents the exact location of arterial occlusion, length of the occlusion, condition of the vessels above and below the occlusion, the location of other occlusions, and extent of the collateral circulation.

PERIPHERAL DISEASE OF LARGE AND MEDIUM ARTERIES

Arteriosclerosis Obliterans

ASO, also known as obliterative arteriosclerosis, atherosclerotic occlusive disease, and chronic occlusive arterial disease, is the peripheral arterial manifestation of generalized atherosclerosis. Most commonly it affects the lower abdominal aorta; the iliac arteries and the arteries supplying the lower limbs; and the femoral, popliteal, and tibial arteries (Fig. 33-2). Although much less commonly symptomatic, ASO of the upper limbs is not rare and can cause disabling ischemic symptoms or even loss of digits, most commonly in diabetics.

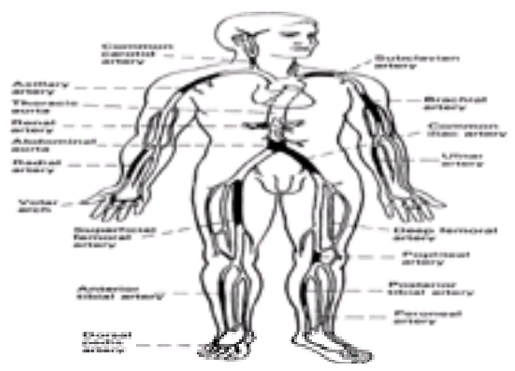

Figure 33-2. The most common sites of arteriosclerosis obliterans in the peripheral arteries. The extent, degree, and pattern of the obstructive lesion vary considerably in each site.

ASO is responsible for 95% of the cases of chronic occlusive arterial disease (3,8). It is a degenerative disease of the peripheral arteries that usually develops slowly and insidiously, most commonly in persons older than age 50 years, although it may occur sporadically in younger persons. Men are affected more often than women, in ratios varying between 5 to 1 and 10 to 1 (8,10). In approximately one-third of patients, ASO is associated with coronary artery disease, and in some 20% to 30% it is associated with diabetes mellitus (8,11).

Etiology

No single factor has been identified as the specific cause of ASO. In addition to age, sex, and its association with diabetes, important risk factors include smoking, hyperlipidemia, and hypertension, and these clearly accelerate the progression of ASO. Ninety percent of patients have a current or past smoking history when first examined, and progression of the disease and failure of arterial bypass grafts are much higher in patients who continue to smoke (11,12). Limb circulation is further compromised by the increase in viscosity of blood in patients with the secondary polycythemia of smoking and the reduced cardiac output associated with heart disease. Alterations in fibrinogen, fibrinolytic activity, and platelet adhesiveness and aggregation due to smoking may also contribute to the progression of

arteriosclerosis or promote thrombosis of already diseased vessels (13). Although diet, focal infections, occupation, heredity, genetic factors, and endocrine imbalance have been implicated in arteriosclerosis in general, their roles as etiologic agents for peripheral ASO remain uncertain (2,8,13).

Pathophysiology

Lesions of arteriosclerosis have three components: atheromas, medial changes, and thrombosis. Usually all three are present in the same area, but one component may be most prominent. The earliest lesion is an atheromatous plaque that develops in the intima. Progression is manifested by enlargement and confluence of atheromatous lesions, which can contain large amounts of lipids, and fibrous tissue. Calcification of the base of the atheroma may occur. The media is thin, and the arterial smooth muscle and elastic tissue are replaced by fibrous tissue. Hemorrhage can also occur via the vasa vasorum. The intimal surface degenerates and liquefies, leaving a rugged irregular ulcer as a starting point for a thrombus to develop. Thrombosis can occur several times with partial organization and recanalization.

The basic pathophysiologic defect produced by ASO is ischemia of the tissue supplied by the obstructed artery or arteries. The disease develops slowly and insidiously and is probably present for 5 to 10 years before symptoms develop (8,13). As the artery becomes progressively stenotic and finally occludes, a collateral circulation develops, probably in response to ischemia in muscles during exercise (Fig. 33-3). The severity of the ischemia depends on the site and extent of the arterial lesion and on the adequacy of the collateral circulation. During the early course of the disease, the flow through the collateral vessels is usually adequate to maintain the viability of the affected extremity but is not sufficient to prevent symptoms, especially during exercise, and the patient experiences the pathophysiologic symptom of intermittent claudication. If the disease progresses, flow through the collateral vessels might become inadequate, causing more ischemia, and the patient might experience pain at rest (8). Further progression can result in skin ulceration and gangrene.

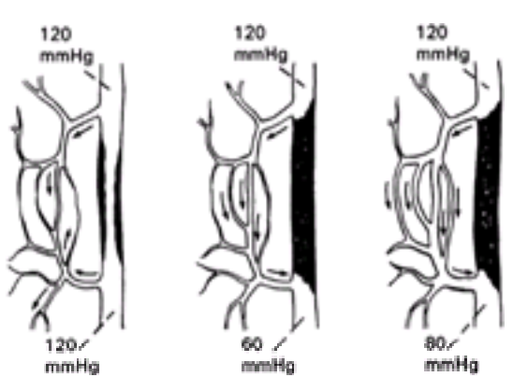

Figure 33-3. Hemodynamic theory of collateral formation. **A:** A developing stenosis in the main artery without a drop in pressure across it. The arrows indicate direction and volume of blood flow in the side branches. **B:** The lesion has progressed to acute thrombosis with a consequent pressure drop of 60 mm Hg and reversal of blood flow in the reentry artery below the obstruction. **C:** Over the course of several weeks the blood flow through the collateral increases in response to the pressure differential, and the gradient across the lesion decreases. (Modified from Kempczinski RF, Bernhard VM. Introduction and general considerations of management of chronic ischemia of the lower extremities. In: Rutherford RB, ed. *Vascular surgery*, 2nd ed. Philadelphia: WB Saunders, 1984:547–558.)

Symptoms and Signs

The earliest symptom is *intermittent claudication*, as noted previously, characterized by extreme fatigue, cramping, and tightening of calf or thigh muscle that progresses to a sharp pain (and occasionally numbness) brought on by walking and relieved within a few minutes by rest. It is not necessary to sit down to obtain relief, but merely to stop walking (8). The distance the patient can walk varies with the degree and extent of arterial occlusion but remains constant for a given time. With mild degrees of occlusion the patient can walk several blocks, but as the disease progresses there is a decrease in the claudication distance. The pain is more severe and occurs earlier when the patient walks rapidly or uphill or upstairs (13).

The location of intermittent claudication depends on the muscle group most severely affected by the arterial insufficiency. Because the femoral-popliteal artery segment is most often involved in ASO, intermittent claudication occurs most often in the calf muscles. The close correlation between the site of intermittent claudication and location of the occlusive disease is characteristic of ASO. Thus, aortoiliac disease causes intermittent claudication in the buttocks, hips, thighs, as well as the calf (Leriche syndrome) (Fig. 33-4). Tandem areas of occlusion such as the iliac and superficial femoral or superficial femoral and tibial artery produce severe, incapacitating intermittent claudication that often is associated with or progresses to rest pain and tissue necrosis. Patients who have involvement of the popliteal-tibial segment, such as in TAO (see below) develop intermittent claudication involving the muscles in the foot (13). Occlusive disease confined only to the tibial arteries or the peroneal artery often does not produce claudication.

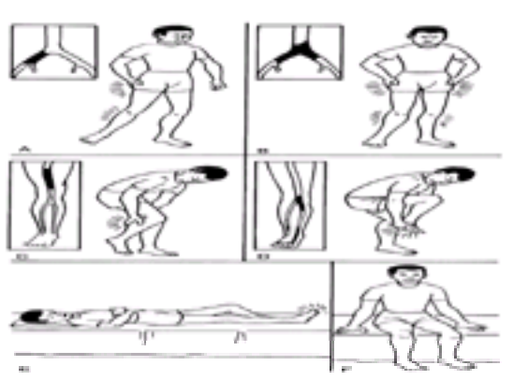

Figure 33-4. Sites of pain (*radiating lines*) caused by arteriosclerosis obliterans in different parts of the arteries of the lower limb. **A:** Obstruction in the right common iliac artery. **B:** Obstruction in both common iliacs and lower aorta, which produces pain in the buttocks, hips, thighs, and calf—the so-called Leriche syndrome. **C:** Obstruction of the superficial femoral artery, which produces severe incapacitating intermittent claudication in the calf. **D:** Obstruction of the popliteal and tibial arteries (and dorsal pedis arterial arch), with pain in the foot. **E:** Rest pain in the digits and distal part of the foot (when the patient lies in bed), as indicated by the facial expression. **F:** Relief of rest pain when the limb is dependent.

Rest pain develops if the disease progresses to multiple levels of occlusion of arteries, including those supplying the collateral vessels. The condition becomes so extensive that arterial flow to the distal limb and foot is insufficient even at rest. Rest pain has the following distinguishing characteristic features (6): (a) It always involves the toes and distal foot and occasionally the heel; (b) the pain is burning in quality, constant and severe, and always worse at night when the patient is in bed because of the loss of beneficial effects of gravity in carrying the blood distally; (c) pain can be partially or completely relieved by dependency and is aggravated by elevating the foot; (d) it is frequently associated with trophic changes in the foot and toes and with ulceration or gangrene; and (e) it rarely improves unless perfusion to the ischemic area can be increased. Occasional patients may note numbness, rather than pain, in the toes or heel; such “rest numbness” has the same morbid implications regarding limb salvage as does rest pain.

At this stage of severe ischemia, ischemic neuropathy can develop and produce severe lancinating shooting or sharp pain in the leg and foot. This pain, similar to diabetic neuropathy, may not completely be mitigated by revascularization but is usually relieved by amputation.

Diminished or *absent pulses* in the affected extremity are the most important physical sign of ASO. Just as the anatomic site of the intermittent claudication is a clue as to which artery is obstructed, so too is the location of the diminished or absent pulses an accurate guideline as to the site of the occlusion (12). When the

aortic-iliac vessels are involved, the femoral pulse is diminished or absent. In superficial femoral artery disease, the femoral pulse is present in the groin, but the popliteal and foot pulses are diminished or absent. In popliteal-tibial disease (common in diabetic patients), the femoral and popliteal pulses are present but the foot pulses are absent. Although the dorsalis pedis pulse is developmentally absent in approximately 6% of persons with otherwise normal pulses, absence of the posterior tibial pulse always indicates occlusive disease (8).

Color changes that occur when the foot is elevated or dependent are a confirmatory physical sign of severe arterial insufficiency. Elevation of the legs causes pallor of the skin of the affected foot because pressure and flow in the collateral circulation are inadequate to overcome the effect of gravity. When the legs are placed in dependency after the period of elevation, a reddish-purple color (rubor) slowly appears. If the venous filling time is delayed beyond 15 seconds, arterial insufficiency is present (8).

Trophic changes do not occur with mild to moderate ASO, and the foot maintains normal color, temperature, and skin nutrition. When ischemia becomes severe, however, trophic changes occur and the foot becomes cool with loss of hair, thickened nails, and dry scaly skin. During this stage, the skin is chronically ruborous due to maximal small vessel dilatation and retention of desaturated blood—the body's attempt to nourish the severely ischemic tissue. Ischemic ulcers in the toes and other parts of the foot can appear spontaneously, but more often they are the result of trauma with nonhealing because of inadequate arterial perfusion to effect healing of otherwise trivial skin lesions.

Arteriosclerosis Obliterans in the Upper Extremity. Although ASO most frequently involves the arteries of the lower limbs, the presence of this condition in the upper limb can cause disabling ischemic symptoms or even loss of digits (2,3 and 4,14). As with ASO in the lower limbs, the symptoms vary according to the degree of ischemia, ranging from no symptoms to fatigue and pain with active use of the muscles of the limb (“arm claudication”). With more severe occlusion the patient has dysesthesia or coldness and eventually develops severe pain of ischemic ulceration. In addition, chronic occlusive arterial disease in the upper extremity can cause intermittent color changes of the fingers on exposure to cold or with emotional unrest, which may be considered as a secondary Raynaud's phenomenon.

Examination of the arterial circulation of the upper extremity should include measurement of blood pressure in both arms, and the pulsation of the subclavian, axillary, brachial, radial, and ulnar arteries should be evaluated and graded. Simultaneous palpation of both radial arteries at the wrist may be a valuable addition to the examination because delay of one radial artery pulse is a useful sign of unilateral subclavian artery occlusion proximal to the origin of the vertebral artery with resultant rerouting of the arterial circulation to the involved arm via retrograde flow in the vertebral artery (commonly although incorrectly known as the “subclavian steal syndrome”) (15). As for the lower extremities the handheld Doppler probe can be used to quantitate limb or digit blood pressures. In addition, Allen's test (Fig. 33-5) provides a method for evaluating the patency of the radial and ulnar arteries and of the superficial palmar arch by observing not only the rate of color return, but also its distribution to the palm of the hand and fingers.

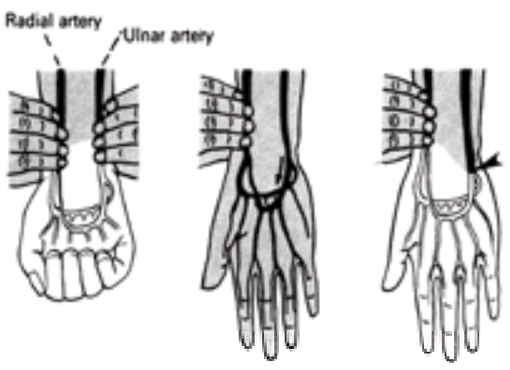

Figure 33-5. Allen's test for determination of patency or occlusion of the vessels to the hand. **A:** Compression of both ulnar and radial arteries produces ischemia and paleness of the closed hand; the hand remains pale when it is opened. **B:** If the ulnar artery is patent, color promptly returns to the palm while the radial artery is still compressed by the examiner. **C:** If the artery is occluded, the skin remains pale as long as the radial artery inflow is blocked by the examiner. The patency of the radial artery is tested by maintaining pressure on the ulnar artery. (Modified from Spittell JA Jr. Occlusive arterial disease in the upper extremities. In: Spittell JA Jr, ed. *Clinical vascular disease*. Philadelphia: FA Davis, 1983:61.)

Arteriosclerosis Obliterans in Patients with Diabetes Mellitus. Patients with ASO associated with diabetes mellitus pre–sent certain differences in the site, pattern, and location of their arterial obstructive lesions, and they often develop a peripheral neuropathy that not only modifies the pain pattern, but also greatly influences available therapy and its outcome (16,17 and 18). With regard to location and extent of the pathology, the following differences are noted: (a) The diabetic patient with ASO has more occlusions involving the tibial and peroneal arteries than the nondiabetic with ASO; (b) the incidence of occlusion in the femoral-popliteal segment is essentially the same between the two groups; and (c) diabetic patients with ASO have a lower incidence of aortoiliac involvement.

A peripheral neuropathy that frequently develops in patients with diabetes produces a bilateral symmetric hypesthesia, with loss of pain sensation, proprioception, and sympathetic tone (16,17). Decrease or loss of pain sensation prevents the patient from recognizing minor trauma and frequently results in the development of painless, nonhealing ulcers at sites of injury or over pressure points such as the metatarsal heads. Because the neuropathy involves the sympathetic fibers, which are, of course, component parts of the peripheral nerves, loss of vasoconstrictor tone results in dry skin, which may crack or fissure, thereby permitting invasion of skin bacteria. Neurologic examination may reveal absent ankle reflexes, loss of proprioception, and a diminished vibratory sense.

When ulcers or areas of necrosis develop they are often deep, extending along tissue planes to involve the underlying tendons, joints, or phalangeal and metatarsal bones. Osteomyelitis is a common sequel and greatly complicates management (19). The fact that the ulcers are painless confirms the diagnosis of diabetic peripheral neuropathy because few other conditions can produce the same picture (6,18).

Diagnosis

Presence of the characteristic symptoms and physical findings mentioned above should be sufficient to diagnose ASO in all but the mildest cases. Special diagnostic studies mentioned in the preceding section are useful for confirming and quantitating the degree of the arterial insufficiency, but the physician often can select the appropriate treatment or refer the patient to a vascular surgeon based solely on a careful history and physical examination.

ASO must be differentiated from other arterial obstructive diseases, including thromboangiitis obliterans, arterial embolism or thrombosis, arterial entrapment syndromes certain neurospinal disorders that produce pseudoclaudication, and myofascial pain syndromes of the limb. The differential diagnosis between ASO and Raynaud's disease, Raynaud's phenomenon, and other vasospastic disorders should not be difficult because the arterial pulses are usually present in these latter conditions. The most important diagnostic features of chronic obstructive arterial occlusive disease are summarized in Table 33-3.

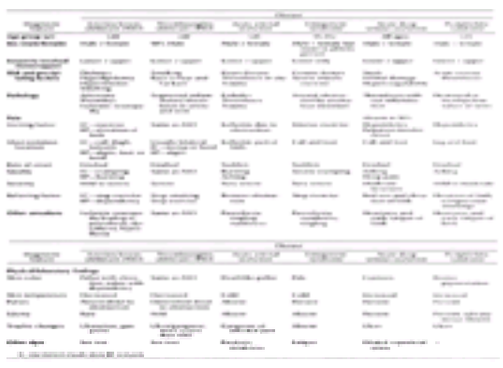

TABLE 33-3. Differential diagnostic features of occlusive peripheral vascular diseases

Treatment

Treatment for patients with ASO is determined by the severity of the disease and the patient's general condition, occupation, and lifestyle. The development of mild to moderate intermittent claudication poses no threat of limb loss. Generally speaking, most patients remain symptomatically stable or may occasionally show some improvement (20). Only 5% become worse, and only 5% to 7% ultimately require extremity amputation (21,22). This is in striking contrast to patients who present with ischemic ulceration or rest pain, virtually all of whom face amputation unless successful limb revascularization is accomplished (23).

Progression of ASO occurs more frequently and rapidly in patients who have diabetes mellitus, who smoke, and who have other risk factors. Unfortunately, these risk factors are additive—for example, the prognosis is geometrically worse in diabetics who smoke (24). Progression of ASO is also more likely to occur when the lesion involves the femoral-popliteal-tibial arterial segments than when it involves the aortoiliac segment (8). The life expectancy of patients with ASO is compromised because of the high incidence of concomitant atherosclerotic complications in other areas, particularly in the coronary arteries.

In view of these considerations, it is obvious that the type of therapy for patients with ASO is determined primarily by the degree and severity of their symptoms and physical findings. Mild to moderate disease is treated conservatively and its course followed closely, whereas incapacitated patients who are unable to work or to function normally in retirement require intervention when possible. Conservative therapy consists of prompt cessation of cigarette smoking, control of hypertension, elimination of hyperlipoproteinemia, changes of patterns of activity and stress, weight loss, a structured exercise program, and, importantly, the regulation of diabetes mellitus if present. These produce major changes in lifestyle and require close and extensive follow-up for successful application (25).

General Measures. General measures include thorough discussion with patients, emphasizing to them that intermittent claudication *per se* is not life-threatening and reassurance that the disease is usually not progressive; however, if worsening of symptoms should occur, intervention might be considered (12,13). Factors that decrease walking time to onset of claudication, such as walking uphill, climbing stairs, and carrying excess body weight or bundles, should be avoided. Obese patients should be placed on a weight-reduction diet. Tobacco smoking has been shown to be highly correlated with intermittent claudication in many epidemiologic studies, and in the Framingham study cigarette smoking was second to no other risk factor as a cause of intermittent claudication (26). The rate of occurrence of intermittent claudication was twice as great among smokers than nonsmokers, and the risk tended to increase with the intensity of the habit. Other clinical studies provide impressive evidence that patients must stop smoking to decrease the risk of amputation and that unless patients stop smoking the results of surgical therapy will be markedly compromised (8,27). Studies have shown that there are more occlusions of bypass grafts or of endoarterectomies if patients continue smoking compared with patients who stopped smoking after surgery.

There is also general agreement in the literature that exercise regimens increase walking distance in patients with intermittent claudication. Successful exercise regimens should include a supervised program done daily, every other day, or weekly, but it is important that the patient exercise daily for periods of 30 to 60 minutes (8,28,29).

The diabetic patient offers special challenges. The patient should be instructed to take protective and prophylactic measures aimed primarily at elimination of foot or toe trauma, which is the chief cause of gangrene. Of paramount importance is the establishment and maintenance of good foot hygiene, including keeping the feet clean, warm, and dry at all times; wearing only correctly fitting shoes; and taking other measures to prevent skin abrasion, contusion, pressure points, corns, calluses, and fungus infection. Toenails should be cut straight across to avoid ingrown nails and infections. Exposure to cold should be avoided. A change of occupation to one of a sedentary nature or one in which the possibility of trauma to the feet is minimal might be advisable. A randomized trial has demonstrated that a simple, repetitive educational program directed at diabetic patients and their families can significantly reduce hospitalizations, amputations, and mortality associated with diabetic foot infection.

Other Medical Measures. Fibrinolytic, anticoagulant, and antiplatelet therapy; vasodilator drugs; and hemorrheologic agents have been used as medical therapy for ASO. Lytic or anticoagulant agents have not been shown to delay or prevent the progression of ASO. Vasodilator drugs that have been subjected to experimental trials include tolazoline (an alpha-receptor blocker), nylidrin (a beta-receptor stimulant), isoxsuprine, papaverine and its derivatives, and niacin and its derivatives. There is no substantive evidence that vasodilator drugs are effective in treatment of obstructive arterial disease, either for intermittent claudication or for ischemic rest symptoms.

Various agents that alter blood viscosity or other flow characteristics have been demonstrated in prospective randomized trials to improve walking distance in patients with intermittent claudication. These include pentoxifylline, which exerts its influence on the red cell cytoskeleton, and cilastozol, which appears to be both a vasodilator as well as a platelet antiaggregant. Experience has suggested that patient compliance and absence of smoking predict beneficial therapeutic results with these agents.

Pain Control. In patients with mild to moderate rest pain, discomfort can sometimes be controlled with nonsteroidal antiinflammatory drugs, such as aspirin or acetaminophen, combined with codeine. The dose of the nonsteroidal antiinflammatory drug can be gradually increased to 1 g every 4 hours, and codeine can be increased to 128 mg every 4 hours. This combination can be used for long periods of time with insignificant risk of physical dependence and little risk of addiction or tolerance. Side effects of both drugs should be treated (see Chapter 83 and Chapter 84). For severe rest pain, narcotics can be used for several weeks, but such patients require surgical intervention—either revascularization or amputation.

Surgery. In the event that the vascular patient remains miserable despite maximal medical therapy or the underlying condition progresses to limb-threatening ischemia (characterized by rest pain, ulcers, or gangrene), surgical therapy is indicated either in the form of transcatheter angioplasty (balloon dilatation or stenting) or operative revascularization (Fig. 33-6). In some settings, amputation may be the most rational option. Selection of the patient for revascularization of the lower extremity should be based on a realistic assessment of risk, expected long-term patency of the reconstruction, likelihood of complications, and the relative risk of limb loss without surgery (8,30). In carefully selected patients, relief of symptoms and salvage of the lower extremities are readily accomplished by adequate revascularization. Satisfactory results require careful delineation of the scope of the occlusive process and meticulous attention to procedural technical details.

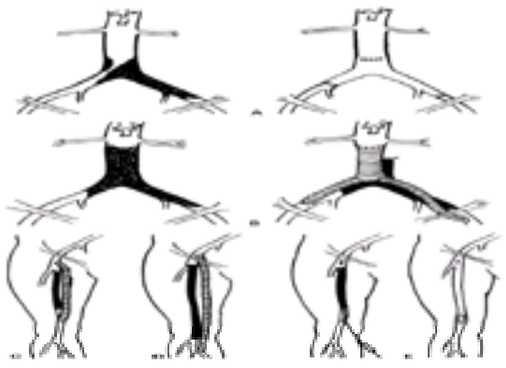

Figure 33-6. Various types of surgical procedures to achieve arterial revascularization. **A:** Aortoiliac endarterectomy, which is especially useful in younger individuals with minimal deterioration of the arterial wall. This is accomplished through transverse incision in the aortic and iliac arteries, removing the atheromatous and thrombotic cast, with subsequent reanastomosis of the iliac arteries and closure of the transverse incision in the aorta. **B:** Endarterectomy of the proximal aorta, end-to-end aorta-graft anastomosis with oversewing of the distal aorta and bypass graft to right external iliac artery and to the left common femoral artery. **C:** A prosthetic bypass connecting the external iliac with the lower portion of the femoral artery. **D:** The lower end of the prosthesis in **C** is grafted to the posterior tibial artery. **E:** Endoluminal endarterectomy with vein patch arterioplasty. (Modified from Hollier LH. Principles and techniques of surgical treatment of occlusive arterial disease of the lower extremities. In: Spittell JA Jr, ed. *Clinical vascular disease*. Philadelphia: FA Davis, 1983:37–48.)

In general arterial stents have been found to be more effective and more durable than balloon dilatation. Iliac artery stents have a primary patency rate of 70% to 80% at 5 years, whereas stents placed in the superficial femoral artery fare much less well, with a patency rate of approximately 40% to 50% at 1 year. Early patency rates for aortofemoral bypass grafts are greater than 98%, and 5- and 10-year patency rates in excess of 90% have been reported (see Fig. 33-6). Femoral-popliteal bypass using the greater saphenous vein (for which patency is far better than with prosthetic materials) provides a 5-year patency rate of 70% to 80%, whereas femoral-tibial vein bypass can provide a 5-year patency rate of 50% in situations with good runoff. In some patients who have superficial femoral artery occlusive disease and profunda stenosis with good collateral circulation between the profunda femoris tributaries and the popliteal-tibial system, a simple profundoplasty may be sufficient to relieve mild to moderate rest pain. Femoral-femoral bypass to treat unilateral iliac occlusive disease has a 5-year patency of only about 50%, which can be improved with donor iliac artery stenting. Axillofemoral bypass grafting may approach the 5-year patency rate of aortofemoral bypass.

Interventional or surgical revascularization is required less often for patients with ASO in the upper limb, partly because ASO occurs less frequently in the upper extremity and also because the collateral arterial supply around the shoulder and elbow, usually robust, tends to minimize the more distal ischemic effects of any occlusive disease located proximal to these collateral beds. Obviously, if segmental occlusive disease is found, stenting or bypass is indicated and should produce excellent results.

Lumbar Sympathectomy. Previous to the advent of vascular surgery, sympathetic denervation of the affected extremity, achieved either surgically or chemically, was used widely for the treatment of various PVDs, including ASO.

Recently acquired information has brought into question the efficacy of sympathectomy in the treatment of most types of peripheral arterial occlusive disease. Sympathectomy does not improve muscular blood flow, and some have even questioned whether it improves nutritive skin blood flow. The clinical improvement in many well-documented cases of intermittent claudication and ischemic pain following sympathectomy reported might be attributable in part to afferent denervation, reduction of vasomotor tone, and perhaps change in the threshold of sensory receptors. In current practice, although the technique remains valuable diagnostically and as treatment for certain nonvascular conditions such as hyperhidrosis or complex regional pain syndrome, little credible evidence supports the use of surgical or chemical sympathectomy for the treatment of ASO.

Thromboangiitis Obliterans

In 1908, Buerger (31) first described a disease entity that caused a specific nonatherosclerotic lesion involving arteries, veins, and nerves of the extremity that frequently led to the development of gangrene. The existence of this disease remained unchallenged for approximately 50 years until Wessler and associates (32) published a provocative article that was critical of the original publication and seriously questioned the existence of this disease. Since 1960, the problem has been reexamined in several excellent clinical reviews and reports, and practically without exception the conclusion has been reached that the disease does exist and can be recognized if rigid diagnostic criteria are followed (33,34).

TAO is an occlusive disease of medium-sized and small arteries and veins affecting chiefly the distal parts of the lower and upper limbs of young adult male smokers. The arterial lesions are often associated with recurrent episodes of segmental superficial thrombophlebitis. Originally thought to occur exclusively in Jews, it is now known to affect all races, and reports in recent decades have indicated its prevalence in the Orient and the Middle East; it is an uncommon PVD in the United States (8,34).

Etiology

The cause of TAO is not known. It occurs nearly exclusively in young male smokers, and striking relationships have been noted between exacerbations and continued use of tobacco and between remissions and cessations of smoking. A slight increase in the proportion of women in TAO populations has been noted—perhaps reflecting women's increasing incidence of smoking (35).

Pathophysiology

The acute pathologic lesions in TAO consist of segmental inflammation of all layers of the walls of medium-sized and small arteries and veins, although the architecture of the wall is preserved. The distal arteries of the lower extremity are more commonly involved, and the lesions are usually more severe here than in the upper extremity (36). The vessels commonly involved are the tibial, radial and ulnar plantar, palmar, and digital arteries. Larger arteries such as the femoral and brachial are affected later and only when the disease is severe and progressive. Thrombosis occurs in the inflamed segment, producing occlusion of the lumen. Fibroblastic proliferation occurs early, with rapid organization of overlying thrombosis. Later there is prominent fibrous tissue throughout the artery and vein, frequently including nearby nerves and binding them together in a dense mass. Recanalization is common, but the multiple new lumina do not approach the original size of the vessel. The lesions are not diffuse but are distinctly focal or segmental, with relatively normal segments of vessels situated between them and distinct lines of demarcation between adjacent normal and pathologic segments. Occlusion of the arteries is followed by development of collateral and anastomotic vessels that are demonstrable by arteriography. The secondary pathologic effects of the disease are the result of severe distal ischemia and inadequate collateral vessel development.

Symptoms and Signs

In addition to the fact that TAO occurs in primarily young male cigarette smokers, the following are other distinguishing clinical features of TAO: (a) There is usually bilateral symmetrical involvement; (b) the distal location of the occlusion in the leg leads to development of instep claudication, a unique feature of the disease; (c) involvement of the distal arteries of the arm, palm, and digit can lead to hand claudication; and (d) cold sensitivity of the Raynaud's type is often present (6,35).

The most common and most bothersome problem in TAO is ischemic rest pain, usually in the toes or distal feet. When intermittent claudication occurs it might be an ache, a sense of fatigue or a persistent cramp, or a severe aching, squeezing pain that is typical in its relationship to the usual walk-pain-rest-relief cycle. If the disease involves the upper extremities, the patient develops intermittent claudication in both hands or forearms when these parts are used actively in doing certain tasks. The ischemic rest pain usually involves the toes and feet or hands and fingers, is often very severe, has a burning quality, is unrelenting, is aggravated by elevation of the extremity, and in late stages may not be relieved by dependency.

Late in the course of progressive TAO, the patient might experience pain of ischemic neuropathy, which is severe and widespread in the extremity. It is usually paroxysmal, often associated with paresthesia and dysesthesia, and may be characterized by bouts of lancinating pain. If ulceration and gangrene develop, the patient experiences pain that is localized to the region adjacent to the ulcers or gangrenous tissue and has the characteristics of rest pain. The pain is severe, persistent, and usually worse at night.

The clinical course of TAO is markedly influenced by whether the patient stops smoking. If smoking continues, episodic progression of occlusive lesions occurs and there is progressively worsening arterial insufficiency. However, after smoking cessation new occlusions do not occur and collateral anastomotic channels develop with time, providing slow improvement in circulation (8,35,36). If the disease has progressed to such an extent that severe digital ischemia has occurred, gangrene is likely to develop after even minor trauma, even if the patient has stopped smoking. The risks of digit or limb loss are vastly greater in TAO than in ASO; patients with TAO can expect a near-normal life span, however, in contrast to patients with ASO, in whom there is decreased survival because of concomitant coronary and/or cerebral arterial disease.

Diagnosis

The diagnosis of TAO is readily made on the history and physical examination, particularly palpation of pulses in distal parts of the limbs. The posterior tibial or dorsalis pedis pulsations, or both, will be greatly diminished or absent. When the disease involves the upper limbs, a positive (unfavorable) Allen test indicates occlusion of the radial and/or ulnar artery distal to the wrist (35,36). A Doppler flow detector is useful in confirming the clinical assessment of the occlusive arterial process. Although not pathognomonic, arteriographic findings showing multiple segmental occlusions in the forearm, hand, or lower leg and foot are typical enough to be confirmative evidence of the diagnosis. Collateral arteries, when present, are usually tortuous and have a “corkscrew” appearance (8) (Fig. 33-7). TAO must be differentiated from other occlusive diseases, including ASO, scleroderma associated with secondary Raynaud's phenomenon, and occlusive arterial disease due to

chronic occupational trauma.

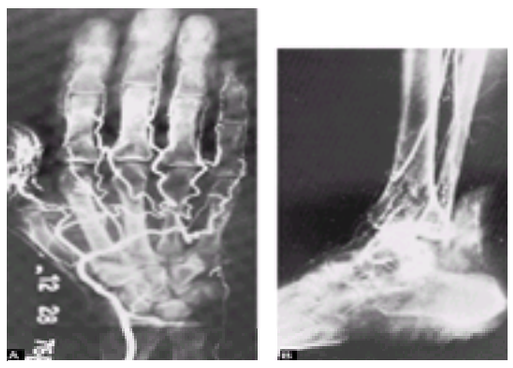

Figure 33-7. Angiograms of patients with thromboangiitis obliterans. **A:** Angiogram of a hand of a patient with disease, showing lack of filling of the ulnar artery, the tortuous corkscrewlike arteries in the hand, and the “skipped” areas of nonfilling in the digital arteries. **B:** Angiogram of the distal part of the leg of a patient with thromboangiitis obliterans. The anterior tibial and posterior tibial arteries appear normal until their abrupt occlusion at the ankle. (From deWolfe VG. Chronic occlusive arterial disease of the lower extremities. In: Spittell JA Jr, ed. *Clinical vascular disease*. Philadelphia: FA Davis, 1983:15–135, with permission.)

Treatment

The cornerstone of therapy of TAO is complete and permanent cessation of tobacco use in any form. The patient must be provided a thorough description of the disease and it should be impressed in the strongest possible terms that there is no option to stopping smoking promptly and permanently if disease progression and amputation are to be avoided.

Mild to moderate pain should be controlled with systemic nonnarcotic analgesics, used alone or combined with codeine. Potent narcotics can be used for short periods of time to control severe pain; in certain cases they may be used for prolonged periods, provided the patient can be monitored closely. Because the arteries involved are small and in most instances located distal to the knee or elbow, often with the involvement of the digital arteries, and because of the multiplicity of the involved segments, interventional radiologic techniques or bypass surgery is rarely feasible in patients with TAO (8,36). Amputation is generally curative, and wound-healing problems are rare because arterial inflow is good.

Acute Arterial Occlusion

The medium-sized arteries of the upper and lower limbs are the most frequently acutely occluded vessels from a variety of causes, but the three most important etiologic factors are embolism, acute thrombosis, and direct injury to the vessel (37,38,39,40 and 41). The clinical picture that results is variable, depending on such factors as the location of the obstruction, the functional capability of the existing collateral circulation, and the general condition of the patient, particularly with regard to cardiac function.

Etiology

An aortic dissection can cause acute arterial occlusion by mechanical blockage of the arterial channel (or of branch vessels) with subsequent thrombosis. Aneurysm of the popliteal or subclavian artery can result in limb-threatening acute arterial occlusion, either by acute thrombosis or by distant embolization.

The incidence of arterial embolism appears to be increasing as a result of an aging population, longer survival of cardiac patients, and the common use of invasive techniques and prosthetic devices. The heart is the chief source of emboli (Fig. 33-8). A thrombus in a fibrillating atrium remained until recently the most common source of emboli, but now has been supplanted by mural clot associated with recent myocardial infarction (40). Recent cardioversion, known valvular disease, history of prior cardiac surgery, or a normal rhythm in a patient with known previous arrhythmia should make the examining physician suspicious about the diagnosis of cardiogenic embolism (40).

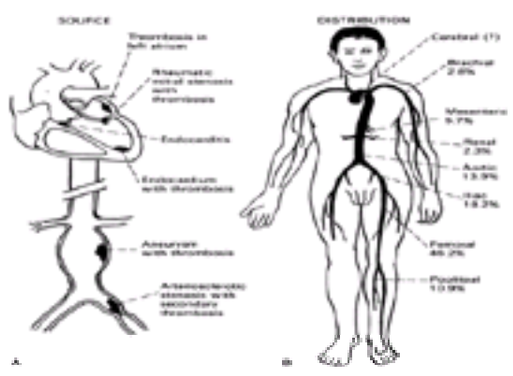

Figure 33-8. The source and distribution of arterial emboli in a series of 338 patients. **A:** More than 90% of the emboli originated in the left atrium or left ventricle; the rest originated from thrombi associated with arteriosclerosis or aneurysm. **B:** More than 90% of the emboli impacted in the distal aorta or in the lower extremities. (From Gordon RD, Fogarty TJ. Peripheral arterial embolism. In: Rutherford RB, ed. *Vascular surgery*, 2nd ed. Philadelphia: WB Saunders, 1984: 449–459, with permission.)

Although arterial thrombosis is less frequent than embolism as a cause of acute ischemia, it remains as an important etiologic factor. Acute arterial thrombosis almost invariably occurs in the area of preexisting atherosclerotic intimal lesion (38). Popliteal aneurysms are frequently complicated by *in situ* thrombosis *or* embolization, which can often result in severe ischemia. The role of vascular trauma in producing acute arterial occlusion is discussed in the next subsection.

Pathophysiology

The severity of the ischemia is partly related to the site and degree of the occlusion. The abrupt cessation of blood to an extremity initiates a chain of events that affects not only the limb but also the entire body. Occlusion of a major artery usually results in propagation of the thrombus proximally and distally, with progressive obliteration of collateral pathways (Fig. 33-9). As the degree and extent of ischemia worsen and tissue destruction ensues, metabolic waste products accumulate and their release into the central circulation produces deleterious systemic effects. Moreover, severe ischemia of a limb may result in massive ischemic myopathy, with consequent cellular disintegration and release of high concentrations of potassium and myoglobin. The systemic effects include acidosis, hyperkalemia, and myoglobinemia. As the myoglobin is filtered through the kidney, crystallization can occur in the tubules, resulting in the “metabolic-myonephropathic” syndrome, myoglobinuric nephrosis and rapidly progressive renal failure.

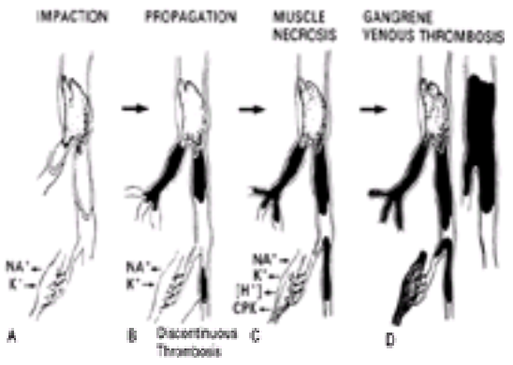

Figure 33-9. Pathophysiology of embolism. **A:** Impaction of the embolus at bifurcation of the artery. **B:** Propagation of the embolus distally with obliteration of the collaterals. **C:** Myopathy and cellular disintegration consequent to severe ischemia, with release of potassium and myoglobin. **D:** Progression to gangrene and venous thrombosis. The interval from impaction to necrosis is variable, but some necrosis is usually present after 6 hours. (CPK, creatine phosphokinase; H^+, hydrogen; K^+, potassium; NA^+, sodium.) (From Gordon RD, Fogarty TJ. Peripheral arterial embolism. In: Rutherford RB, ed. *Vascular surgery*, 2nd ed. Philadelphia: WB Saunders, 1984:449–459.)

Symptoms and Signs

The site and degree of occlusion, the extent of collateral blood flow, and the duration of ischemia all affect the severity and extent of the symptoms and the outcome of therapy. With mild occlusion there may be few or no symptoms, whereas with moderate degrees of obstruction there may be gradual development of symptoms over several hours or merely a change in the distance a patient can walk before claudication occurs. Major (severe) obstruction of blood flow to an extremity is generally heralded by the well-recognized syndrome of the six Ps: pain, pallor, loss of pulses, polar or poikilothermia (coolness), paresthesia, and paralysis (37). In more than half of such patients, the pain is rapid in onset and with a swift progression in severity that reaches a peak in minutes to hours (38,40). If the collateral circulation is able to provide sufficient blood flow to the ischemic area, the pain gradually decreases in severity after a period of initial vasospasm. Unless the collaterals are unusually abundant, however, some degree of pain persists.

The pallor that occurs in acute arterial occlusion is often a deathlike paleness that persists despite attempts by the patient to improve circulation by walking or massage of the limb (40). The extremity might stay pale for hours or even days or rapidly change to a bluish, mottled discoloration due to arterial flow stagnation that extends to the capillaries and venous circulation. Fixed staining of the skin is ominous, signifying progressive tissue ischemia and cellular necrosis.

The loss of a pulse in an extremity in which it was previously present is the hallmark of acute arterial occlusion (40). As the ischemia worsens, nerve function becomes compromised and paresthesia develops, followed by the loss of fine touch and proprioception. These changes are rapidly followed by loss of motor function and complete loss of all sensation, with irrevocable loss of tissue. If the circulation is not restored within 6 to 8 hours of the onset of symptoms, the chance of salvage of the extremity is greatly diminished (40).

Diagnosis

Assessment of acute arterial occlusion and its critical precipitating factors is accomplished by a competent history recording, physical examination, and vascular laboratory studies. Arteriography, if performed, will demonstrate the characteristic sudden interruption in dye flow in the embolized artery, perhaps with a “meniscus sign,” and the feeble collateral development that has resulted in the patient's severe acute ischemia.

Treatment

Treatment, of course, aims to restore normal blood flow. In the case of arterial embolism, treatment consists of thrombolytic disobliteration by the use of urokinase or similar agents or surgical embolectomy. Anticoagulant administration is crucial and should be started as soon as the diagnosis is made. Patients who develop arterial thrombosis usually can be treated by transcatheter thrombolysis (Fig. 33-10). Because the pathogenesis of this lesion is usually a roughened or lacerated intima, reocclusion is common and systemic heparinization at the time of removal, then warfarin administration, can help prevent further clot formation. Heparin is given in full doses (75 to 100 units per kg body weight) even though the patient is to undergo arteriography or surgery. Administration of a vasodilating agent such as papaverine or tolazoline at the time of embolectomy or thrombectomy may interrupt reflex vasospasm of the distal circulation.

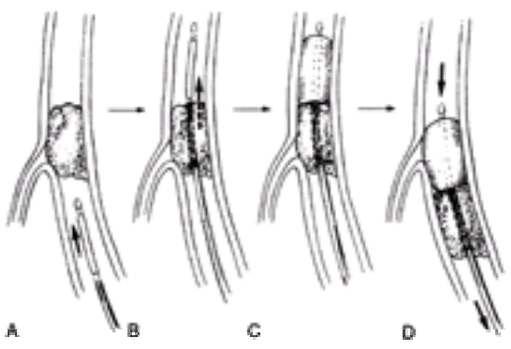

Figure 33-10. Extraction of an embolus lodged at the iliac artery bifurcation with a Fogarty catheter. The catheter is introduced through a transverse arteriotomy **(A)** and very gently passed through the embolus to prevent intimal damage **(B)**. The balloon is then inflated **(C)**, and the catheter (with the embolus) is withdrawn **(D)**. After removal of the thrombotic material, irrigation of the distal arterial system is carried out with heparinized saline solution. (From Gordon RD, Fogarty TJ. Peripheral arterial embolism. In: Rutherford RB, ed. *Vascular surgery*, 2nd ed. Philadelphia: WB Saunders, 1984:449–459, with permission.)

Vascular Trauma

The treatment of vascular injuries improved markedly during the Korean War, when therapy changed from ligation to attempts at repair and amputation risk fell from 50% to 13% (42). More recent surgical advances, both in diagnosis and in treatment, can be considered among the most important encouraging trends in the care of peripheral vascular disorders. Nevertheless, vascular trauma remains a challenge for the physician and the vascular surgeon because of the increasing frequency of these cases (43).

Etiology

The most common cause of peripheral vascular injuries is penetrating trauma, which includes the spectrum between simple puncture wounds to wounds from high-velocity missiles. Penetrating trauma also includes iatrogenic injuries such as those following percutaneous catheterization of peripheral arteries for diagnostic procedures or access for monitoring. Blunt trauma—contusion or crush injuries—can produce transmural or partial destruction of the arterial wall, resulting in elevation of the intima and formation of intramural hematoma. The frequency of chemical injury to blood vessels has increased with inadvertent iatrogenic intraarterial injection of drugs and with the widespread drug-abuse problem.

Pathophysiology

Primary pathology of acute vascular injury includes hemorrhage, arterial disruption, and ischemia. Arterial injury can be obvious when there is pulsatile external hemorrhage, but bleeding can occur also in body cavities and in deeper tissue contained by fascial compartments. Until proved otherwise, ischemia of an extremity must be treated as though it were primarily due to vascular injury. Although extremity ischemia can be tolerated for 6 to 8 hours, occlusion of the carotid artery may result in brain damage within minutes of the injury in approximately 20% of patients (42). Delay in restoring perfusion to an extremity causes a vicious cycle, called the *ischemia-reperfusion syndrome* and characterized by the generation of oxygen radicals, damage to vascular endothelium, activation of platelets and leukocytes, microvascular occlusion, and cellular damage. The primary pathophysiologic changes associated with acute venous injuries include venous hypertension and consequent edema and compression of tissue in closed compartments. Other changes associated with major vascular injuries include false aneurysms and traumatic arteriovenous fistulae.

Symptoms and Signs

Symptoms and signs of arterial injury are similar to those of acute arterial occlusion. The commonly described sudden excruciating pain occurs only in approximately half of the patients with sudden arterial catastrophes. Numbness, marked coldness, tingling, pallor, weakness, and pain are associated in various combinations. Variations in symptoms probably depend on the suddenness of the organic lesion and the degree of vasospasm. Signs of vascular injury include an expanding or pulsatile hematoma, a false aneurysm, continuous murmurs of an arteriovenous fistula, loss of pulses, progressive swelling of an extremity, unexplained ischemic dysfunction, and a unilateral cool, pulseless extremity.

Diagnosis

Vascular injury must be assumed with any wound in the vicinity of a major blood vessel. Unless markedly unstable, all trauma patients should have a complete vascular examination, including palpation of the carotids and all peripheral pulses. It is important to note that normal pulses do not rule out vascular injuries; indeed, 10% of significant major vascular injuries result in no physical findings (44). Neurologic function must also be assessed, and auscultation must be carried out over the area of the obvious or suspected injury. The Doppler flow probe can be useful in detecting diminished pulse and determining whether there is flow in an artery in which injury is suspected. Because a significant percent of these patients have no physical findings suggesting vascular trauma, routine use of duplex sonography or arteriography is necessary (42). For example, posterior dislocation of the knee causes injury to the popliteal artery in 50% of the cases; arteriography or duplex scanning is mandatory in all such instances (45).

Treatment

Treatment of serious vascular injury requires prompt direct repair or bypass surgery. Success is based on timeliness and completeness of therapy, including balloon catheter removal of distal thrombus, appropriate soft tissue coverage of the reconstruction, and a low threshold for performing fasciotomy to prevent a postreperfusion compartment syndrome.

Aneurysm

Saccular or fusiform aneurysm of medium-sized vessels of the extremities can occur, but much less commonly than abdominal aortic or iliac aneurysm. When it occurs, aneurysm can involve the common femoral, superficial femoral, or popliteal arteries (46). Aneurysms of the arteries of the upper extremity are less frequent than those in the lower extremity and usually involve the subclavian, axillary, or brachial arteries. Femoral and popliteal aneurysms are often bilateral and are associated with aneurysm in the aorta or its primary branches in a majority of cases (6,46).

Etiology

The cause of aneurysm in the lower limb is usually degenerative processes, although mycotic arteritis and trauma also play a role in a small percentage of patients. Pseudoaneurysms due to prior diagnostic or therapeutic interventions are increasingly common. The most common cause of aneurysm in the upper limb is arterial trauma; less common causes include mycotic arteritis.

Pathophysiology

The sequelae and pathophysiology of aneurysm of peripheral vessels are quite different from those of aortic aneurysm in that, at these levels of the circulation, the vessels are prone to thrombosis or peripheral embolization, or both. Rupture can occur, but it is much less frequent than with aneurysm of the large arteries.

Symptoms and Signs

The symptoms depend on the site and size of the aneurysm and its sequelae. Femoral artery aneurysms are usually symptomless except for local mass or distal limb swelling. However, a majority of patients with popliteal aneurysm ultimately present with claudication, rest pain, and even gangrene. Limb loss occurs in 10% to 20% of patients (46). Some patients will present because of a painful swollen calf and demonstrate a prominent superficial venous pattern, suggesting deep venous thrombosis (DVT). In most cases the latter is caused by compression of the popliteal vein by the adjacent aneurysmal mass and clears with aneurysm repair, although a few patients are left with secondary venous thromboses.

When thrombosis of the aneurysm occurs gradually, the collateral circulation might have time to develop sufficiently so that the patient experiences pain only with exercise or rest pain. When the thrombosis occurs quickly, however, severe ischemia often develops, leading to tissue necrosis and limb loss. Surgical intervention is not always successful even if timely.

Therapy

Treatment consists of resection and replacement with either prosthesis or vein graft. Before surgery, arteriography is deemed advisable to demonstrate the arterial circulation bilaterally plus the runoff on the involved side. In some instances, particularly with popliteal aneurysm, the sac is isolated by proximal and distal ligation and distal blood flow is maintained by a bypass graft (6).

Popliteal Entrapment Syndrome

Etiology

Muscular entrapment of the popliteal artery can occur as the vessel courses medial to an anomalous head of the gastrocnemius muscle at the knee or beneath an enlarged plantaris or popliteal muscle (Fig. 33-11) (47,48). This entity characteristically affects young adults, usually males in the third or fourth decade of life, and occurs more frequently than previously thought.

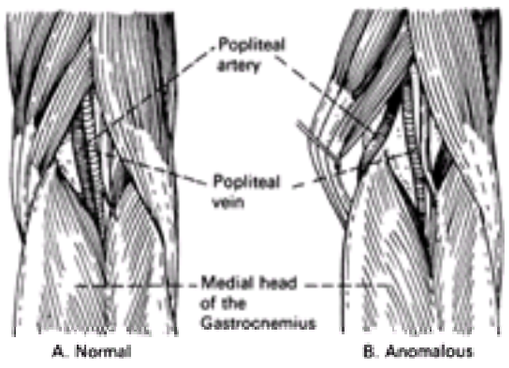

Figure 33-11. **A:** The normal relationship of the popliteal artery and the two heads of the gastrocnemius muscle. **B:** The most common (type 1) anomaly, which causes entrapment syndrome. The popliteal artery is looped medially around and then under the normally arising medial head of the gastrocnemius. Medial hamstring muscles have been retracted for clarity. During strenuous exercise of the leg, the muscle compresses the artery, with consequent ischemia and intermittent claudication. (Modified from Haimovici H. *Vascular surgery*. New York: McGraw-Hill, 1976:498.)

Symptoms and Signs

Onset of symptoms is often sudden, occurring during an episode of intense lower extremity activity. The symptoms are described as cramping in the calf or foot and coldness, blanching, paresthesia, and numbness of the foot associated with walking and relieved by resting the leg. Symptoms are usually unilateral despite subsequent demonstration of bilateral involvement (48). The symptoms may be correlated with the development of thrombosis and segmental occlusion of the mid-portion of the popliteal artery. If the popliteal artery becomes occluded acute ischemia can occur, but limb loss is rare because of the collateral circulation, which usually develops in response to the chronic compression and narrowing.

Diagnosis

Diagnosis is usually made from the patient's history and confirmed by physical findings, especially the presence of normal pulses at rest and in a position of relaxation of calf muscles. In patients with an occluding thrombus of recent origin, popliteal and pedal pulses are absent. In cases of partial chronic occlusion of the popliteal artery by thrombus, the popliteal artery pulse is absent but pedal pulses may be present, although they are diminutive and disappear with exercise. Approximately one-third of the patients have characteristic symptoms but palpable popliteal and pedal pulses (48). Passive dorsiflexion of the foot with active plantar flexion against resistance, which causes the contracted gastrocnemius to compress the abnormally positioned artery, causes loss of the pedal pulse. Auscultation of the popliteal artery can reveal a systolic bruit if the artery is sufficiently suppressed. Duplex scanning of the popliteal artery, demonstrating normalcy at rest but partial or complete extrinsic compression with calf muscle contraction, is diagnostic. Bilateral femoral arteriography is a critical part of the examination to rule out contralateral entrapment.

Treatment

All cases of popliteal artery entrapment, whether the artery is occluded or not, should be treated surgically (48). This applies not only to symptomatic limbs but also to asymptomatic limbs in which the anomaly is incidentally identified by routine bilateral arteriography. To temporize and risk ischemic changes in such young, healthy individuals is inappropriate (48). The procedure is myotomy, complete transection of the compressing muscle or fascial band. In addition, thrombectomy is required when the popliteal artery is occluded by fresh thrombus. If organized thrombus with a poor line of cleavage between thrombus and vessel wall is present or if the vessel is narrowed owing to fibrosis, arterial resection and vein bypass are indicated (48). Results are generally good because of those patients' youth and otherwise normal vasculature.

Compartmental Syndromes

Swelling within a compartment of the arm or leg can lead to severe acute pain and irreversible neuromuscular damage, with loss of function related to the contents of the involved space (49). The most frequent, and indeed the classic, form of this problem is the anterior tibial compartmental syndrome (49). Compartmental syndrome can be a chronic recurrent problem, associated with lower extremity exercise, often in young athletes. Acute compartmental syndrome usually follows extremity trauma or acute ischemia exercise and is manifested by the following symptoms: (a) Within a few hours excruciating pain occurs in the compartment; (b) the muscle within the compartment becomes tense and diffusely tender; (c) there is weakness of dorsiflexion; and (d) sensation is diminished in the distribution of the deep peroneal nerve, particularly in the first web space of the foot. Unless the compartment is promptly decompressed by fasciotomy, there is extensive muscle necrosis and permanent damage to the deep peroneal nerve. This condition is discussed in more detail in Chapter 79.

An equivalent course of events can involve the other three compartments in the leg or the three compartments of the forearm; the etiology might differ, but the outcome is the same unless the problem is promptly recognized and treatment is instituted immediately. Other causes of swelling within compartments bounded by fascial envelopes and bone include trauma, acute arterial obstruction, and restoration of normal perfusion to an extremity that has been ischemic for prolonged periods of time. The association between severe pain in a tight, very tender compartment, and the possibility of subsequent development of myoneural ischemia and necrosis must be kept in mind and readily recognized and treated. The same urgency must be applied to the compartmental syndrome as to any other acute vascular problem because time is of the essence. This urgency is best exemplified by the high incidence of extensive muscle necrosis in the involved compartment when fasciotomy is delayed for more than a few hours (49).

DISEASES OF THE SMALL ARTERIES

The most important diseases of the small arteries that produce pain include embolism, collagen vascular disease, and local cold injuries. Although the latter also involve the microcirculation, they are discussed in this section.

Embolism

Etiology and Pathophysiology

The complicated plaque of arteriosclerosis converts the normal arterial intima from a smooth surface to one with an irregular surface with areas of ulceration. These areas can harbor small thrombi interspersed with cholesterol crystals that can be released and produce occlusion of small arteries of the foot (or occasionally the hand), leading to the development of severe ischemia that can ultimately result in digital, foot, or limb amputation (50). Alternatively the mural thrombus lining an arterial aneurysm may be shed into the distal circulation with similar results. The phenomenon has been given the descriptive terms of “blue toe” or “trash foot” syndrome.

Symptoms and Signs

The clinical picture is dramatic, and the patient usually notes the sudden onset of pain is confined to the digits, often of both feet. The pain is of the ischemic type and is relieved to varying degrees by dependency. The toes are cold, with interspersed areas of erythema and cyanosis. Livedo reticularis of the foot is common and is a clue to the underlying pathology.

Treatment

Treatment is expectant, with attention directed at keeping the patient comfortable. Pain should be controlled with nonnarcotic analgesics; potent narcotics may be used for a short period if the pain is severe. The ultimate outcome depends entirely on the extent of the occlusion and collateral circulation and the degree of reflex

spasm. In the event that conservative measures are not effective and there is obvious gangrene of the toes, amputation at the digital or transmetatarsal level will be required. In some cases it is necessary to bypass or endarterectomize the proximal arterial site responsible for the emboli to prevent recurrences (6).

Vasculitis

Inflammatory and proliferative changes of the small arteries and arterioles occur in diverse diseases, the most important of which are periarteritis nodosa, systemic lupus erythematosus, scleroderma, dermatomyositis, rheumatoid arthritis, rheumatic fever, and systemic giant cell arteritis (temporal arteritis). TAO (Buerger's disease) is classified by some as a vasculitis and is discussed earlier in this chapter. Histologic changes with the vasculitides vary in both extent and severity and range from acute necrotizing arteritis to a proliferative endarteritis. These changes in themselves are often nonspecific and can be seen in varying degrees in all of these diseases. Most of these conditions are discussed in Chapter 27.

Disorders Due to Cold Injuries

Exposure to cold can alter both cells and extravascular fluid (direct effects) and can disrupt the integrity of peripheral circulation and the function of organized tissues (indirect effects) (51). The mildest form of cold injury is called *frostnip* and tends to occur in organs farthest away from the core of the body, such as the fingers, toes, hands and feet, ear lobes, nose, and cheeks. More severe cold injury can be divided into freezing injuries (e.g., frostbite) and nonfreezing injuries (e.g., immersion foot, trench foot, pernio).

Pernio (Chilblain)

Pernio, or chilblain, is the mildest form of disorders due to local cold injuries. This condition occurs most frequently in patients who live in moist, cool, or temperate climates and is seen more frequently in England than in the United States (52). Pernio was long considered a purely dermatologic lesion, but recent work has emphasized the vascular nature of the disease. Acute pernio, or chilblain, has been experienced by many children who go out in the snow or in cold, wet weather without adequate protection for their feet and by women who wear short skirts in cold weather. A chronic form develops after repeated exposure to cold by susceptible individuals.

Symptoms and Signs. In the acute phase the skin is reddish, cyanotic, and slightly edematous. Occasionally small blebs appear that can become hemorrhagic, or small purpuric spots develop that can persist for a long time (52). The patient experiences itching and burning sensations after exposure to cold. When the condition occurs in the legs it is almost always bilateral and symmetric.

In the chronic stage, which develops from persistent exposure to cold and dampness, the blisters break down and produce superficial ulcers with a hemorrhagic, pigmented base. These ulcers persist throughout the exposure or even for the entire winter. Severe pain can accompany the ulcer, and the skin can be cold and cyanotic. Healing produces a pigmented scar, which can break down on further exposure. Pigmentation persists after healing.

Treatment. Pernio can be minimized by avoiding exposure to cold and providing adequate protection from cold when it cannot be avoided completely. When the condition occurs, the limb should be warmed gradually, but the affected region should be kept away from extremely elevated temperatures because excessive heat can easily produce a burn. The lesion should not be rubbed with snow or placed in excessive cold water, because these measures can further damage the skin and add to the vasoconstriction already present. The blisters should be debrided and sterile dressing applied without any salves or antiseptic. Further exposure to cold should be avoided. A recent prospective randomized trial has demonstrated substantial benefit from administration of calcium channel blocker drugs, thus underscoring the vasospastic nature of the condition (53).

Trench Foot and Immersion Foot

Immersion foot and trench foot are similar entities, observed originally during wartime in personnel whose feet have been wet for prolonged periods but not frozen, but now seen in urban destitute or homeless populations as well. Most authorities consider both of these conditions similar entities, and, indeed, some believe that they represent a form of the pernio syndrome (52).

Pathophysiology. The pathophysiology can be divided into three phases: (a) an initial vasospastic ischemic phase characterized by cold-induced vasoconstriction, increased blood viscosity, and impaired oxygen transport; (b) an intermediate hyperemic phase characterized by a bounding pulse, pulsatile circulation, and red, swollen, and painful feet; and (c) a late ischemic vasospastic phase.

Symptoms and Signs. In the initial vasospastic ischemic phase, the extremities are pale or cyanotic and cold; arterial pulsations are reduced; edema appears; and if the exposure is prolonged there are petechial lesions, shallow ulcerations, and patchy areas of anesthesia.

The intermediate hyperemic phase begins when the patient is removed from the cold and is placed in a warm environment, and it usually lasts approximately 2 weeks. During this phase the feet become red and hot, arterial pulsations are full and bounding, and edema supervenes. The edema increases rapidly unless the extremities are placed in a cool environment. Frequently blebs appear and become filled with hemorrhagic fluid. After several days the numbness disappears and the patient experiences burning paresthesia and pain, which can be intense and of a shooting character. Lymphangitis, phlebitis, and cellulitis can complicate the condition.

The late vasospastic ischemic phase does not occur if the initial lesion is of a mild degree and proper treatment is instituted early. In severe cases recovery is slow, and coldness, pain, hyperhidrosis, paresthesia, and stiffness persist for weeks, months, or even years. The sensitivity to cold, manifested by a typical Raynaud's syndrome, can persist for a long period of time.

Treatment. The problem of rewarming is critical in these patients during the stage of ischemia, when overheating of tissue can lead to thermal injury (51). Avoidance of trauma and maintenance of asepsis are extremely important. In patients who have persistence of sensitivity to cold and develop pain on weight bearing (which can cause discomfort for many years), sympathectomy may be considered if prognostic sympathetic blockade produces effective relief.

Frostbite

The degree of cold necessary to produce frostbite is influenced by a number of factors, but primarily the environmental temperature. Exposure to a temperature of –30°C will shortly result in freezing of the extremities of most normal individuals. In the presence of a strong wind, frostbite can occur up to a temperature of –4°C, due to rapid evaporation of sweat and dissipation of the layer of radiant heat around the skin (54). Frostbite can occur at temperatures above 4°C in individuals who have occlusive arterial diseases. Severe hypoxia, anemia, malnutrition, and hypoproteinia with edema are definite contributing factors in the development of frostbite. Wetting of the extremity, such as occurs with perspiration or immersion in water, greatly increases the tendency to freezing because water dissipates heat much more rapidly than air (55). The metabolic effects of physical activity reduce the hazard from thermal cold injuries, but enforced immobility predisposes to development of lesions. Smoking, through its peripheral vasoconstricting action, can be a contributing factor.

Pathophysiology. The pathophysiology of frostbite involves two major mechanisms: (a) vasoconstriction with subsequent stasis and thrombus formation and (b) formation of ice crystals in the tissues and extracellular fluid (56,57 and 58). Exposure to freezing temperatures produces local and reflex arterial and venous constriction that results in increased venous pressure and decreased capillary perfusion (Fig. 33-12). At the same time, ice crystals form in the extravascular space and solutes in the residual nonfrozen interstitial fluid become concentrated and thus produce a localized hypertonic area. As extracellular water passes along this induced osmotic gradient into the extracellular solution, it too is incorporated into ice crystals (51,52). Eventually all intracellular water not directly bound to cellular constituents can be appropriated into this gradient and the cell converted into a shrunken mass of solute surrounded by ice crystals. Final crystallization of the plasma volume completely arrests blood flow, and cells themselves can freeze as lower temperatures are approached. With prolonged exposure to cold and with reduced or absent circulation, there develop swelling; vacuolization; and other inflammatory reactions of the intima of small arteries, arterioles, and capillaries, together with low-grade inflammation of all affected tissue.

Figure 33-12. Pathophysiology of frostbite. See text for details. (Modified from MacLean D, Emslie-Smith D. *Accidental hypothermia.* Boston: Blackwell Scientific, 1977:237–246, with permission.)

With thawing, an initial hyperemic vascular phase intervenes that results from prior capillary and arteriolar damage followed by microcirculatory sludging and subsequent thrombus formation (52,57,58 and 59). Arteriovenous shunting then aggravates the overall insult and converts a hypoperfused area into a nearly avascular one. Moreover, on resumption of the circulation, the damaged endothelium allows pathologic permeability, extravasation, and further intravascular clumping so that the vascular bed of the frozen tissue is occluded by thrombi. Early on, the intravascular clumping is reversible, but with the passage of time, clumped red blood cells within vessels in injured tissue lose their morphologic identity and take on the appearance of a homogeneous hyaline plug (51) (see Fig. 33-12).

The course of most cases of frostbite and other injuries from cold is usually of three phases: (a) the acute phase, characterized by freezing, which produces vasoconstriction and ice-crystal formation, followed by thawing with consequent vasodilation, blistering, and beginning necrosis; (b) the subacute phase, during which necrosis is resolved and vasospasm starts; and (c) the chronic phase, during which the vasospasm continues and pain and recurrent ulceration can occur.

Symptoms and Signs. Frostbite is conventionally classified into degrees according to severity of tissue changes (60). In *first- degree frostbite* the outer layer of the skin is involved, appearing waxy and firm. The patient experiences aching pain, numbness, and paresthesia, but there is no blistering or peeling. Prompt return to a normal environment results in complete recovery, with no demonstrable damage to the tissues.

Second-degree frostbite occurs when exposure is sufficient to produce damage to the superficial layers of the skin. The skin is waxy white and firm, and the involved digits become stiff. As the extremity is thawed, reactive hyperemia develops around the frozen area and gradually spreads to include the entire involved area. The skin is now red and tender, and the patient might complain of burning pain. Edema and blisters develop, and portions of the superficial skin can become necrotic and peel off. In 2 to 3 weeks the superficial layers of the skin peel off, leaving a complete layer of healed skin.

Third-degree frostbite occurs with more severe or prolonged exposure, resulting in damage involving the full thickness of the skin and subcutaneous tissue. The symptoms are the same as with second-degree frostbite, but the pain is more severe and the healing phase is more prolonged. In the deeper necrotic areas the skin becomes darker and adherent to form a hard, dry eschar over the necrotic area. Secondary infection around and under this eschar is common.

Fourth-degree frostbite is caused by very severe and prolonged cold exposure resulting in gangrene of the deep tissue, including bone, with consequent loss of an extremity or portion thereof. Early symptoms are the same except that with rewarming the pain after thawing is severe. The hyperemia does not extend over the dead area, however, and blisters do not occur. The tissues, generally the distal portions of the digits, become gradually darker and shriveled. Spontaneous amputation eventually ensues.

The late sequelae of moderate to severe frostbite include (a) persistent hypersensitivity to cold; (b) pain at rest and in phantom limb fashion if spontaneous amputation has occurred; (c) hypesthesia and subjective numbness alone or in combination with hyperesthesia and allodynia; (d) hyperhidrosis and decrease in hair; (e) persistent skin changes; and (f) such signs of sympathetically mediated pain syndromes as osteoporosis and rigid nails. These late symptoms are generally worse in the winter and after exposure to cold (51).

Diagnosis. The diagnosis of cold injuries is easily made with the history of exposure to cold and the signs of freezing of tissues. The presence of underlying organic vascular disease should always be considered and sought for, especially in circumstances in which others are exposed equally with the patient but developed milder or no frostbite.

Treatment. Most instances of frostbite can be prevented by adequate prophylactic measures. Particular care should be taken to prevent exposure to cold by those known to have occlusive or vasospastic arterial disease. Warm, loose-fitting clothing should be worn during necessary exposure (52,57,58 and 59). Every effort should be made to keep the body and extremities dry. Special foot care is important in those necessarily exposed to cold. This includes daily washing, careful drying, gentle rubbing with oil, and careful attention to the nails, avoiding even minor trauma.

Frostbite should be considered a medical emergency (52). In first-degree frostbite, restoring the normal temperature of the skin is all that is required. The best source of heat for this is the warm skin of the patient's own body. Great care should be taken to avoid trauma, especially from extrinsic heat sources or from vigorous rubbing of the part. Measures to raise core temperature are important. At high altitudes the administration of oxygen is definitely indicated. Persons whose feet are frozen should not be allowed to walk even short distances if it is possible to arrange for other means of transportation, because walking can severely injure the frostbitten foot (52,57). The long controversy of whether rapid or slow thawing should be carried out has been resolved in favor of rapid thawing, achieved by exposing the involved tissue to a warm bath of no more than 40°C to 42°C (104°F to 107.6°F) for 15 to 20 minutes (52,57,58 and 59). If the local damage is extensive, an antibiotic should be administered. Although heparin, fibrinolytic agents, steroids, vasodilators, antiplatelet agents, and other materials have been found useful in experimental models, similar data in humans are less convincing—a fact that might be related to the long interval from the time of injury until treatment. Sympathectomy may be considered but data supporting its human use are unconvincing. In patients with severe injury seen later in the disease and in whom symptoms persist, sympathetic blocks are used for diagnostic purposes. If the results are positive, the patients may have a sympathetically mediated pain syndrome and surgical or chemical sympathectomy should be entertained. Amputation is obligatory in severe cases with extensive gangrene or unremitting pain.

DISEASES OF THE MICROCIRCULATION

The most important painful diseases that involve the microvasculature can be divided into two major categories: (a) vasospastic diseases, which include Raynaud's disease, Raynaud's phenomenon, acrocyanosis, and livedo reticularis and (b) vasodilating disorders, of which erythromelalgia is the most important.

Raynaud's Disease

In 1862, Maurice Raynaud described a disease entity characterized by symmetric impairment of the circulation in the digits of the extremities manifested by pain and phasic color changes, sometimes progressing to ulceration of the fingertips and even gangrene (61). The larger arteries seemed uninvolved. Subsequently it was pointed out that Raynaud had not discovered a separate disease entity but had described a symptom complex that could be either primary or secondary. Consequently, writers have labeled these conditions as *Raynaud's disease*, *Raynaud's phenomenon*, *Raynaud's syndrome*, and other names (see 62 for references). Although controversy remains about terminology, many authorities agree that the term *Raynaud's disease* should be reserved for the relatively common circumstance of benign episodic digital vasospasm in response to cold or emotional stimuli and that the term *Raynaud's phenomenon* should be used for cases in which an underlying pathologic process is responsible for the symptoms.

Raynaud's disease is the benign form of cold sensitivity, and the criteria for establishing this diagnosis have not changed since the original description by Allen and Brown in 1932 (63). These are as follows: (a) The attacks can be precipitated either by exposure to cold or by emotional stimuli; (b) involvement is bilateral and symmetric; (c) there is no evidence of occlusive disease involving the digital arteries; (d) trophic change or gangrene is rare; (e) the disease must have been present for a minimal period of 2 years; and (f) there must be no evidence of an underlying disease that could cause the symptoms. All other cases that exhibit episodic digital

ischemia but do not meet the above criteria and for which an organic basis can be found should be labeled Raynaud's phenomenon.

Etiology and Pathophysiology

The exact cause of Raynaud's disease is unknown, although gender, age, and constitutional factors probably play a role in its development (62,64). Up to 90% of cases are in women and onset of the disease occurs before the age of 30 in approximately 60% of the cases, before 40 years in 80%, and before 55 years in all cases (see 62 for references).

Exposure of the extremity to cold is the most important factor that initiates either Raynaud's disease or Raynaud's phenomenon (65). The threshold for the abnormal vascular response appears to be lowered by anything that activates the sympathetic outflow or release of catecholamines. Patients note that on exposure to cold the fingers turn white, then blue, and finally red during the attack (the so-called tricolor changes).

The color changes in the skin depend on the tone of the capillaries and blood flow through them, whereas temperature changes are related to the condition of the arterioles. The pallor is due to arteriolar spasm and during this stage the capillary microscope will reveal that blood is not entering the capillaries (62). The subsequent hypoxia causes loss of tone, first in the capillary walls, resulting in capillary vasodilation. Stagnant capillary blood becomes increasingly deoxygenated and the fingers become both cold and cyanotic. Increasing anoxia ultimately produces paralysis of the arteriolar walls, which relax; then flush appears, first producing a reddish-blue color and finally a profound hyperemia with fingers that are red and slightly swollen.

Symptoms and Signs

The patient, often a young woman of asthenic build, complains of typical attacks of numb fingers (occasionally the toes as well) on exposure to cold. Usually such color changes begin gradually, although occasionally there is a severe sudden attack (62). Onset of symptoms is precipitated by cold, but as the patient becomes anxious about the condition emotional stress may contribute significantly. At first only the tips of the fingers of both hands are involved, but later more proximal parts of the fingers are also involved, and in the late stages the color changes can extend back to the rest of the hands. Complaints of various paresthesias can accompany the color changes, including numbness, tingling, a feeling of tightness, “pins and needles,” stiffness, aching, and burning. During the attack the fingers are cold and sensory acuity is often diminished. Slight swelling of the involved fingers can occur, but only during and after the attacks. During the initial phase of the disease, pain occurs but is not a prominent symptom. In the advanced stages of Raynaud's disease the attacks become so severe and so frequent as to be disabling. Exposure to a slightly cool environment and almost any emotional stress can precipitate a bout; consequently, the warmer weather of the summer season might afford little relief.

Diagnosis

The diagnosis of Raynaud's disease is relatively easy in cases in which the aforementioned criteria are met. In addition to taking a detailed history and carrying out a complete physical examination, it is essential to exclude the possibility of occlusive arterial disease, which can be done if both the radial and ulnar pulses are present. It is essential to differentiate Raynaud's disease from Raynaud's phenomenon by searching for possible causes of the latter disease. The information that the patients are usually young at time of onset, are predominantly female, and have bilateral symmetric involvement of the upper extremities points to the diagnosis of Raynaud's disease. The differential diagnostic features of the most important vasospastic diseases of the extremities are summarized in Table 33-4. These features can be compared with those in Table 33-3, pertaining to occlusive disease. Importantly, the development of digital trophic changes such as ulceration or frank gangrene generally signifies the presence of Raynaud's phenomenon, resulting from an underlying rheumatologic or other disease.

TABLE 33-4. Differential diagnosis of various vasospastic disorders

The diagnosis of Raynaud's disease and differentiation from Raynaud's phenomenon can be accomplished by the performance of digital arteriography, which will show vasoconstriction of otherwise normal arteries in the former, but segmental digital arterial occlusions and arterial collateral formation in the latter.

Treatment

The type of therapy selected for managing patients with Raynaud's disease depends on the severity of signs and symptoms. In milder cases, certain basic general measures are sufficient. First, it is important to offer reassurance because many patients have considerable anxiety about the development of gangrene, amputation of digits, and other complications as a result of misinformation from relatives, friends, and lay literature (62,64). Patients can be reassured that the condition generally remains stable and ultimately regresses. Second, patients should be carefully instructed to avoid exposure to cold and to protect the extremities by wearing fur-lined gloves and, in some instances, lined boots, and also to keep the body as well as the extremities warm.

In mild to moderate cases, vasodilators such as calcium channel–blocking medications given by mouth have beneficial effects (62). Other agents that have been reported to be useful include (a) prazosin (Minipress) in doses of 1 mg once or twice a day, (b) tolazoline hydrochloride given orally in doses of 25 to 50 mg three or four times daily, (c) griseofulvin in oral doses of 500 to 1,000 mg daily, and (d) phenoxybenzamine hydrochloride (Dibenzyline) in oral doses of 10 to 20 mg 4 times a day (see 62 for references). In moderate to advanced stages of the disease, patients should be advised to move to a warm climate because this in itself can be sufficient to avoid progression of the disease.

In patients who are disabled by severe disease, regional sympathetic denervation should be given serious consideration, especially for lower extremity digital vasospasm. Although it is less effective for the upper limb, it can provide satisfactory results. Palmar digital sympathectomy is probably more effective than cervical sympathectomy, which can have excellent initial results but is unpredictably durable.

Raynaud's Phenomenon

Raynaud's phenomenon by definition is digital ischemia secondary to other pathologic processes. The most important conditions that can cause secondary Raynaud's phenomenon are listed in Table 33-5 (62,64).

TABLE 33-5. Raynaud's phenomenon

Etiology

Microtrauma to the small vessels of the hand and fingers caused by the continued use of a pneumatic hammer or other vibrating tools, such as a chain saw, are frequent causes of Raynaud's phenomenon in both hands. Similarly, the frequent use of tools that require squeezing action of the hand, as seen among farmers, creamery workers, and laborers whose hands are subjected to repeated blunt trauma can also result in bilateral Raynaud's phenomenon. These patients will complain of cold, discoloration, and pain in one or more fingers. Pianists, typists, and other keyboard workers who use their hands for long periods every day may develop vasospastic disease of one or two digits, and the vasospasm is evoked only on exposure to cold (62).

Patients who have thoracic outlet compression syndrome, caused by a cervical rib or hypertrophic scalene muscles or other anatomic abnormality, may develop Raynaud's phenomenon in the affected limb. Patients also may develop Raynaud's phenomenon consequent to carpal tunnel syndrome. In patients with Raynaud's phenomenon the symptoms are frequently more severe and are often associated with areas of digital gangrene and necrosis. The prognosis for loss of digits for those with many of the diseases listed under “miscellaneous conditions” of Table 33-5 is poor.

Symptoms and Signs

The symptoms are similar to those described for Raynaud's disease but more severe, and more constant and ultimately associated with digital trophic changes. The extent of pain experienced by patients is extremely variable. Fingertip ulcers or areas of gangrene are extremely painful, sometimes refractory even to narcotic analgesics. Patients with intact skin will note pain only during the attack, when the digits are profoundly ischemic.

Diagnosis

Raynaud's phenomenon is readily diagnosed on the basis of the age and sex of the patient, on the history of the underlying connective tissue or other disease, and occasionally on information of the occupation of the individual. Whereas Raynaud's disease occurs predominantly in females younger than age 40 years, secondary Raynaud's phenomenon occurs in a more equal gender distribution: Young women more commonly suffer from collagen vascular diseases, whereas young and middle-aged men more often demonstrate occupational Raynaud's phenomenon. Details about the digits involved at onset and subsequently can be useful points in differentiating primary from secondary Raynaud's symptoms. Limitation of the disease to one limb, particularly an upper limb, suggests Raynaud's phenomenon (Table 33-6).

TABLE 33-6. Differential diagnosis of Raynaud's disease and Raynaud's phenomenon

Some diagnostic features	Raynaud's disease	Raynaud's phenomenon
Sex	Female	Male = female
Age at onset (yr)	<40	>40
Bilateral involvement	Usually	Not usually
Ischemic changes	–	+
Underlying systemic disorder	–	+

The physical examination should include complete examination of pulses and elevation and dependency tests of the hands to determine any digital ischemia caused by occlusive arterial disease. Use of the handheld Doppler flow detector can be used to identify palmar and digital arterial occlusion as well as ulnar or radial occlusion. Tests for thoracic outlet compression are particularly indicated in the examination of patients with unilateral upper extremity Raynaud's phenomenon. Skin temperature measurements of the digits before and 30 seconds after immersion of the hands in ice (cold immersion test) is a useful procedure in diagnosing both Raynaud's disease and Raynaud's phenomenon. Whereas the normal response to cold immersion is recovery of digital skin temperature to preimmersion values in 10 minutes or less, it might take 20 minutes or longer for the digital temperature of patients with Raynaud's disease or phenomenon to return to preimmersion levels. Digital strain-gauge plethysmography will display wave forms of digital arteries blunted by vasoconstriction associated with cold immersion: Digital vessels with obstruction will be abnormal in the control setting before cold immersion.

Treatment

Management of patients with Raynaud's phenomenon is the same as for Raynaud's disease regarding protection from cold and trauma, avoidance of tobacco, and the use of vasodilators. In patients with secondary Raynaud's phenomenon, therapy directed toward the underlying condition such as carpal tunnel syndrome or thoracic outlet syndrome, ergotism, and myxedema may relieve the Raynaud's phenomenon. In the patient in whom the condition is caused by repeated trauma, cessation of the causative factor not only stops the progression of any occlusive arterial disease but can ameliorate the Raynaud's phenomenon as well. With recurrent or refractory digital ulceration, local therapy with soaks, protection of the limb, administration of antibiotics, and, occasionally, topical nitroglycerin administration may be successful. Debridement of ulcerations often helps, but healing is commonly slow.

Regional sympathetic denervation may be considered in intractable cases of secondary Raynaud's phenomenon if the underlying cause cannot be eliminated and the disease progresses. Before considering surgery, at least three or four prognostic sympathetic blocks should be carried out with long-acting local anesthetics. As noted previously, palmar periarterial sympathectomy may be more effective than cervical sympathectomy. Fingertip or digital amputation may be required.

Acrocyanosis

Acrocyanosis is a peripheral vasospastic disorder manifested by coldness, intense diffuse cyanosis, and occasionally edema and hyperhidrosis. Although it is frequently confused with Raynaud's disease, the symptoms are sufficiently different to make it a separate entity (6,62,64).

Etiology

The cause of acrocyanosis is obscure, but it is apparent that those with this disorder have an underlying susceptibility to cold. Some authorities attribute it to a dysfunction (hyperactivity) of the sympathetic vasomotor nerves, and others are of the opinion that the fault lies in the smaller vessels of the affected extremity (62,64). The condition occurs predominantly in young women.

Pathophysiology

The mechanism of acrocyanosis has not been clearly defined. The evidence suggests that there is arteriolar spasm followed by secondary dilatation of the capillaries and venules. In chronic cases there can be hypertrophy of the media layer of the affected arterioles (62).

Symptoms and Signs

The clinical picture of acrocyanosis is that of a constant coldness and bluish-purple discoloration of the extremities, particularly the hands and fingers, and, to a lesser degree, the feet and toes, which are aggravated by exposure to cold temperatures. Edema and hyperhidrosis are sometimes present. The symptoms are most marked during the winter, but they can be present (although to a lesser extent) in warmer weather (64). During the summer the extremities are warmer and the color of the skin changes from deep purple, when the skin is extremely cold, to red, when it is warmer. There are no episodes of blanching. In contrast to Raynaud's disease and Raynaud's phenomenon, trophic changes, ulceration, and gangrene do not occur. Examination of the peripheral arteries does not reveal any evidence of occlusive arterial disease.

Diagnosis

Diagnosis is made by the history and clinical manifestations, and the condition is differentiated from Raynaud's disease by the fact that cutaneous discoloration in acrocyanosis is constant without periods of pallor or hyperemia. Acrocyanosis can be differentiated from the cyanosis that occurs with occlusive diseases by the fact that pulses are present. The presence of pulmonary or cardiac diseases that might produce cyanosis should be ruled out.

Treatment

The patient should be reassured about the benign nature of the disease and instructed to avoid exposure to cold. In patients who are disabled, a trial of vasodilators such as calcium channel blockers may be given.

Livedo Reticularis

Livedo reticularis is characterized by a local prominent mottling, or reticular (“fishnet”) reddish-blue discoloration of the skin of the extremities (6,62,64). Although the condition was long considered a primary dermatologic disorder, in recent years the underlying vascular nature of the condition has become recognized (62).

Etiology

The cause of idiopathic livedo reticularis is unknown, although there is unquestionably some inherent vasomotor instability in these patients, most of whom are women. Secondary livedo reticularis can be the initial manifestation of one of the conditions listed below and can affect both men and women (64):

- Connective tissue diseases
- Vasculitis
- Myeloproliferative disorders
- Dysproteinemias
- Atheroembolism (cholesterol embolization)
- After cold injury
- Use of amantadine hydrochloride
- Complex regional pain syndrome

Pathophysiology

The changes occurring with livedo reticularis are similar to those of acrocyanosis—a narrowing, either organic or functional, of arterioles, with dilatation of the capillaries and venules (62,64). The obstruction of the arterioles, which can be either spastic or organic, occurs principally in the peripheral portion and therefore affects only the peripheral subdermal capillary arborization, thus accounting for the peculiar reticular nature of the discoloration. Histologic studies reveal proliferation of the intima in isolated arterioles and small arteries in advanced cases. Although some of these arteries are occluded completely, in most instances no changes are noted in the arterioles of the skin underlying the discolored parts.

Symptoms and Signs

Idiopathic livedo reticularis begins early, typically in the late teens or early 20s, and the patient complains of persistent bluish to bluish-red mottling of the skin of both legs and feet that can extend to the thighs. It can also involve the hands and arms and occasionally the trunk (62,64). Some patients complain of coldness, numbness, dull aching pain, and paresthesia of the affected limb. In most patients the condition is mild and causes no other symptoms or signs. Some patients, primarily women, develop recurrent ulcerations (usually during the winter) about the ankles and feet that have the appearance of typical ischemic ulcers. These ulcers are painful, slow to heal, and located in the distal lateral or posterior leg or dorsum of the foot. The large arteries such as dorsalis pedis, posterior tibial, and popliteal are not involved, although thrombosis of the digital arteries may occur.

Diagnosis

Diagnosis of livedo reticularis can be made readily from the appearance of the extremity. The condition can be confused with acrocyanosis, Raynaud's disease, pernio, scleroderma, and even with some of the chronic arterial occlusive diseases.

Treatment

Patients with idiopathic livedo reticularis should be thoroughly informed about the condition and given reassurance as well as instructions on protecting the involved parts and the body as a whole from exposure to cold. When patients are distressed by the cosmetic effects, a trial of vasodilators, such as prazosin (Minipress) in a dosage of 1 mg twice daily, is given. If ulceration is present, local care, rest in bed and elevation of the extremity, and elastic supportive bandage are used. In secondary livedo reticularis, treatment of the underlying condition is indicated (62,64).

For patients in whom these conservative measures fail and have marked disability from the condition, sympathectomy should be considered because it may make the livedo pattern less prominent and helps to heal the ulcers.

Erythromelalgia (Erythmelalgia)

Erythromelalgia is a term first used by Weir Mitchell to describe a condition manifested by hot, red, and painful extremities due to abnormal arteriolar vasodilatation (66). The more descriptive term “erythmelalgia” is more appropriate for the condition, because it emphasizes the fact that the painful, red skin on the extremity also exhibits an increase in temperature (67).

Etiology

Weir Mitchell divided the condition into a primary (idiopathic) form and a secondary form (66). The cause of the primary form is unknown and the condition occurs in

persons who do not have any demonstrable organic disease of the nervous or vascular systems. Secondary erythmelalgia is usually a symptom of myeloproliferative disorders, but it can also occur with hypertension, venous insufficiency, diabetes, systemic lupus erythematosus, and rheumatoid arthritis (62).

Pathophysiology

The basic mechanism of the vasodilation and the cause of the burning pain are unknown. The temperature at which distress can be produced varies with different persons and in different parts of the extremity of the same person. It usually lies within the range of 32° to 36°C; the temperature at which it occurs in a specific patient was designated by Lewis as the “critical point” (68). If the temperature is higher than this critical point the distress persists, and with temperature lower than this critical point the distress disappears. In the past, vasodilatation was considered the direct cause of this attack of burning pain, but studies in which the blood flow to the limb was terminated by inflation of a cuff and plethysmographic studies have demonstrated that the condition is not due to increased blood flow.

Symptoms and Signs

The primary form of erythromelalgia is relatively rare. It is often bilateral, and middle-aged men are more often affected, although women and children can also be affected. The condition is characterized by severe burning pain and red discoloration. The skin temperature is often raised, the skin is flushed, and venous engorgement is present. The skin is also hyperalgesic and hyperesthetic. The attacks of severe burning pain last from a few minutes to many hours. The distress can be noticeably greater during the summer months and when the patient has fever. Relief often will have been obtained by exposing the affected extremity or extremities to cool air or by immersing them in cool or iced water.

Trophic changes, ulceration, and gangrene are not seen in primary erythromelalgia but may be encountered in the secondary type. Some swelling and puffiness might be present in the localized burning region, or the whole extremity might be slightly swollen. Examination of the peripheral arteries does not reveal evidence of occlusive disease in the primary type, whereas in the secondary type, particularly that associated with polycythemia vera, there might be evidence of occlusive arterial disease.

Diagnosis

A diagnosis of primary erythromelalgia is justified when the patient complains of severe burning pain associated with increased temperature of the skin and no secondary cause for the syndrome is found. To make the diagnosis, it is essential to demonstrate that the skin temperature and the burning pain are related, and this can be achieved by production of reflex vasodilatation, or more commonly, by direct application of heat. Relief of the burning pain by exposure of the limb to cold or ice water confirms the diagnosis.

It is important to differentiate true erythromelalgia from the painful, red, but cold extremities noted in patients with TAO or ASO by measuring the skin temperature and assessing the pulses.

Treatment

Medical treatment consists of making the patient comfortable by avoiding heat and any other conditions that produce vasodilatation in the extremities. When erythromelalgia is secondary to other conditions, treatment of the syndrome would encompass the treatment of the underlying condition. As little as 650 mg of acetylsalicylic acid (aspirin) produces striking and persistent relief, sometimes for days (62). Although the mechanism by which aspirin works is not known, the response is so common that erythromelalgia should be suspected when a patient mentions that substantial and prolonged relief of burning pain in the extremities is experienced with this drug. Others have reported phenoxybenzamine (Dibenzyline) as effective, and still others have used methysergide, a serotonin-blocking agent, providing some dramatic relief with primary erythromelalgia (62). Because the continued use of methysergide can cause vascular complications and retroperitoneal fibrosis, it should be used as a last resort.

DISEASES OF THE PERIPHERAL VEINS AND LYMPHATICS

The most important painful disorders of the peripheral veins are (a) acute venous occlusion, which can present as thrombophlebitis or as acute DVT; (b) chronic venous occlusion, often referred to as *postphlebitic* or *postthrombotic syndrome*; and (c) varicose veins. Disorders of the lymphatics rarely produce pain; lymphedema is briefly mentioned at the end of this section for the sake of completeness in considering all PVD.

Acute Venous Occlusion

As already implied, obstruction of superficial or deep veins occurs in two forms: One is associated with an intense inflammatory component, as usually observed with involvement of superficial veins, and the other, which is more common and potentially lethal, is thrombosis of the deep veins, in which inflammation as the inciting event or clinical manifestation is less common. Although some authorities discuss these two types together, others believe it is appropriate to discuss them separately because the clinical courses, treatments, and prognoses of each are different (6,69,70).

Thrombophlebitis

Thrombophlebitis consists of partial or complete occlusion of a vein by thrombus, associated with inflammatory changes in the vein and adjacent structures. The inflammatory reaction promotes adherence of the thrombus to the venous walls, so thromboembolism occurs infrequently.

Etiology and Pathophysiology. Despite numerous studies, the cause of thrombophlebitis (other than chemical phlebitis secondary to direct intimal injury) remains unclear. In most patients, the following are considered to be contributing factors: (a) slowing or stasis of the venous blood flow, which allows cellular constituents to adhere to the vessel wall, with consequent clotting and subsequent inflammation; (b) alteration of blood constituents and activation of coagulation factors that enhance platelet aggregation, with consequent thrombus formation; and (c) development of venous endothelial damage, which further promotes adherence of blood constituents, development of a thrombus, and an inflammatory reaction. The last factor is particularly important in thrombophlebitis that follows injection of drugs or substances that irritate and produce microscopic lesions of the intima of the vein. A significant percentage of cases of thrombophlebitis occur as perioperative or postpartum complications—a subject discussed in the next subsection (Acute Deep Venous Thrombosis).

Symptoms and Signs. The symptoms and signs of superficial thrombophlebitis include pain and exquisite tenderness along the course of the involved vein, perivenous erythema and edema, and, in some instances, edema involving the limb. Patients with deep thrombophlebitis may manifest moderate to severe calf or thigh pain, exquisite tenderness, Homans' sign (calf pain on dorsiflexion of the foot), dilated superficial veins, and diffuse edema and pallor of the involved extremity. Such symptoms and signs are inconstant, however, and the diagnosis rarely can be made on clinical grounds. Patients with severe superficial thrombophlebitis manifest systemic symptoms including fever, tachycardia, tachypnea, and general malaise: This may be particularly evident when bacterial infection and actual venous suppuration take place—so-called septic phlebitis.

Diagnosis. The diagnosis is readily made by the history and presenting symptoms and signs. This condition must be differentiated from bacterial cellulitis and lymphangitis. The Doppler velocity detector helps to distinguish these, as thrombophlebitis is always associated with thrombosis of the involved segments, whereas the others are not (6).

Therapy. The therapy for superficial thrombophlebitis is largely supportive, with application of heat, elevation of the foot, administration of antiinflammatory drugs such as ibuprofen, administration of antibiotics, and elastic compression (6). The pain is controlled with various types of nonsteroidal antiinflammatory agents, but if these prove ineffective, opioids are given by mouth. Therapy is discussed in more detail in the section that follows.

Acute Deep Venous Thrombosis

Deep venous thrombosis (DVT) is one of the more common painful vascular disorders. Together with its sequelae, DVT is often associated with significant morbidity, prolonged hospitalization, decreased productivity, and lifelong disability (71). As a result of increased interest in venous disorders and because of increased availability of diagnostic procedures such as duplex sonography and photo- or impedance plethysmography scans to establish diagnosis, increased numbers of cases

are being diagnosed and treated. Recent estimates suggest that there are 200,000 deaths annually in the United States from pulmonary embolism (71).

Etiology and Pathophysiology. Most authorities agree that components of Virchow's classic triads of stasis, intimal damage, and hypercoagulability continue to be responsible for most cases of DVT (71). Because these contributing factors have already been mentioned in connection with thrombophlebitis, only a few additional comments are made here. Stasis of venous blood in the extremities, caused by prolonged immobilization or inactivity consequent to a medical or surgical illness, contributes to local accumulation of thrombogenic factors by preventing flow-induced dilution and by decreasing the flow of naturally circulating anticoagulants such as antithrombin III (71). These cause prolonged contact of the platelets and activate coagulation factors such as serotonin, catecholamines, and other catalysts that enhance platelet aggregation. After intimal damage, subintimal collagen and base membranes are exposed, and this promotes platelet adherence and activation of factor XII. Factor XIIa can initiate the intrinsic coagulation cascade: Platelet adherence leads to platelet aggregation, which leads to release of platelet granule contents resulting in thrombus formation. It has been demonstrated that once a venous thrombus is formed, one-third of such thromboses undergo spontaneous lysis, one-third persist, and the remaining thromboses propagate into more proximal veins, with associated increased risk of embolization (71). Such a sequence is much more common for the large veins of the thighs and pelvis.

Stasis and the consequent hypercoagulability undoubtedly play a critical role in postoperative thromboembolism. Because no antecedent disease or injury of the veins of the lower limb (where most of the lesions occur) is present in most cases of postoperative thromboembolism, the causes of the pathophysiology must relate to the anesthetic method, the operative procedure, and postoperative immobilization. As discussed in Chapter 102, the incidence of postoperative thromboembolism in the lower limbs is greater with general anesthesia than with regional anesthesia. The risk of postoperative DVT is particularly elevated after reconstructive orthopedic procedures of the knee and hip (69).

Other risk factors that play an important role in DVT include advanced age, congestive heart failure, atrial fibrillation, estrogen therapy, previous DVT, and the presence of malignancy (69,70 and 71). In pregnant patients, the incidence of venous thromboembolism after delivery is several times higher than before delivery, and the incidence is increased in those who have had obstetric complications (69).

Symptoms and Signs. The presence or absence of symptoms and signs with DVT depends on the location and extent of the thrombus, the degree of occlusion induced, the presence of collaterals, and the effect of gravity (69). The usual signs and symptoms of DVT of the lower extremity include pain and exquisite tenderness of the calf, increased tissue turgor (or resistance, particularly in the calf), edema, and increased skin temperature of the affected limb (due to diversion of blood to superficial veins). Features of limited diagnostic value include Homans' sign, dilated superficial veins, suffusion and cyanosis of the skin, and the presence of fever and tachycardia. Unfortunately, DVT is clinically “silent” in up to half of all patients; pulmonary embolism may be the first indication of the disease.

Acute thrombosis involving the axillary or the subclavian vein produces edema that includes the entire upper limb, prominent venous collaterals over the shoulder and chest, pain and discomfort, and tenderness over the axillary vein. Complicating pulmonary embolism is uncommon in acute upper extremity DVT, although it does occur (69).

A special type of massive venous thrombosis of the leg that produces a painful, edematous, cool, cyanotic lower limb is called *phlegmasia cerulea dolens.* The massive edema causes the skin to be taut and shiny (69). Cutaneous blebs and superficial gangrene, followed by more extensive necrosis of tissue, are part of the clinical picture. The disorder results from severe (not infrequently global) obstruction of all the venous channels draining the extremity, producing an extremely high venous pressure. This may be associated both with inadequate lymphatic flow, edema, and compartmental hypertension, and ultimately cessation of arterial inflow and the onset of tissue necrosis.

Diagnosis. DVT should be differentiated from a number of other conditions that produce similar symptoms and signs, including congestive heart failure, cellulitis, chronic venous insufficiency, lymphedema, edema of pregnancy, hepatic and renal insufficiency, and rupture of the plantaris tendon (71). A complete history and comprehensive physical examination, together with confirmative vascular laboratory studies, are essential to make a correct diagnosis and to develop the most appropriate therapeutic strategy. Objective techniques to diagnose DVT include both noninvasive tests such as duplex ultrasound examination of the peripheral veins and venous plethysmography. Invasive tests such as phlebography are now rarely used, although when noninvasive diagnostic techniques are negative or equivocal and clinical suspicion remains high, ascending phlebography should be used to settle the issue. This test, done with the patient in a semi-upright position, involves injection of a contrast medium through a small needle placed in a dorsal vein of the foot and permits visualization of both the superficial and deep systems.

Treatment. The goals of therapy of DVT are to (a) abort ongoing thrombotic process, (b) restore venous patency, (c) prevent pulmonary embolism, and (d) minimize the sequelae of peripheral venous hypertension. All patients should be hospitalized and placed on bed rest with elevation of the involved extremity above the level of the right atrium. Because extensive thrombosis can cause sequestration of large amounts of fluids, patients with phlegmasia syndromes should be carefully monitored and effective fluid replacement therapy should be given to maintain satisfactory cardiac output and peripheral perfusion.

Pain should be controlled with systemic analgesics. Usually nonsteroidal antiinflammatory agents in effective analgesic doses are sufficient. Patients who experience severe pain should be given opioids, preferably by mouth, at fixed intervals (see Chapter 84). The initial dose depends on the severity of pain, but a dose of 30 mg of morphine by mouth should be tried; if insufficient, it should be increased to 60 mg every 4 hours by the clock. If available, patient-controlled analgesia is preferable because it permits the patient to self-administer the drug to produce more sustained and even pain relief and usually requires lesser amounts of the opioids per 24 hours than when they are given intermittently (see Chapter 84).

Anticoagulant therapy should be started immediately to initiate inhibition of coagulation and permit thrombolysis to occur unopposed. Heparin remains the agent of choice, starting with a “priming dose” of 5,000 to 10,000 units, and this dose is immediately followed by a heparin infusion, usually 1,000 to 1,500 units per hour (6,70). After approximately 18 hours the infusion is regulated to maintain the activated partial thromboplastin time at two to three times the initial level control value. Warfarin is started orally after 2 to 3 days, and heparin infusion is continued until the international normalized ratio is more than 2.5. Edema, inflammation, and pain should have subsided by this point, and ambulation is started with the extremities wrapped in elastic bandages. The duration of oral anticoagulation depends on the severity of the problem: For femoral, popliteal, or iliofemoral thrombosis with or without pulmonary embolism, anticoagulation should be continued for 3 to 6 months (6). Anticoagulation should be maintained indefinitely in those with a chronic underlying risk factor for DVT (e.g., cancer, paraplegia, congestive heart failure). Obviously, the patient should be monitored carefully to promptly diagnose any complication associated with anticoagulant therapy such as hemorrhage, allergic manifestation, osteoporosis, and other adverse conditions.

Fibrinolytic agents such as streptokinase, urokinase, and tissue activator plasminogen have been extensively evaluated in the treatment of DVT in an attempt to preserve patency and normal valve function (71). These agents' benefits, although real, are present only when therapy can be initiated soon (less than 48 to 72 hours) after onset of clotting and must be balanced against an increased risk of hemorrhagic complications.

After the acute phase of therapy, most patients are managed by the use of elastic support, which has been demonstrated to reduce the incidence and severity of later postphlebitic syndrome.

Surgical treatment is rarely indicated in venous thrombosis (2,6,69,71). Patients with an acute iliofemoral thrombosis with compromised arterial perfusion of the limbs who fail to respond to elevation and heparin and who have not had a previous episode of DVT can be considered for iliofemoral thrombectomy and postoperative heparin therapy (71). When thrombolysis and anticoagulation are contraindicated, as in cases of trauma, recent surgery, or bleeding diatheses, vena cava filter placement may be lifesaving.

Postphlebitic (Postthrombotic) Syndrome

Second to pulmonary embolism, the most serious complication of DVT is the postthrombotic (postphlebitic) syndrome, which is characterized by chronic swelling, pain, hyperpigmentation, secondary varicose veins, and cutaneous perimalleolar ulcers (71,72). Although other conditions produce edema of the lower extremity (inferior vena cava obstruction, arteriovenous fistula, lymphedema, congestive heart failure, hepatic failure, and renal failure), postthrombotic syndrome is the most frequent cause of lower limb edema (71). Moreover, postphlebitic syndrome is the most common cause of ulceration of the lower limb (71).

Pathophysiology

Normally, direction of blood in the leg is from the superficial veins to the deep veins by means of the communicating or perforating veins, and the valves situated in these three systems of veins ensures this directional flow pattern. When the patient is erect, the venous pressure at the ankle can exceed 120 mm Hg, but during

walking or other forms of exercise, the normal ankle venous pressure is reduced by the pumping action of the calf muscles (71). When the valves are destroyed or become incompetent secondary to venous thrombosis, the directional flow pattern is altered, and with each contraction of the calf muscles blood flows antegrade, retrograde, and out through the perforating veins so that the venous pressure at the ankle actually increases (6). Increased venous and capillary pressure results in edema, and as the blood is forced outward through the perforators, a high-pressure “leak” develops from rupture of the small veins in the vicinity of the perforators and consequent microscopic hemorrhages. Repeated microhemorrhages lead to deposition of hemosiderin (pigment), producing a tannish-bronze pigmentation, subcutaneous fibrosis, and lymphatic obstruction. The venous hypertension, edema, and fibrosis reduce the cutaneous perfusion sufficiently so that the skin's response to even minor trauma or infection is impaired and nonhealing ulcerations occur.

Symptoms and Signs

Most patients complain of pain, heaviness, and early fatigability of the legs and manifest edema, the aforementioned pigmentation, and nonhealing ulcers that develop secondary to trauma. The pain is always relieved by elevation of the limb, and the edema decreases. If an ulcer is present there may be local pain and tenderness of varying severity.

Diagnosis

In addition to a thorough history and physical examination, including circumferential measurement of the two calves, a duplex ultrasound examination is used to determine the patency and valvular competence of the deep, perforating, and superficial venous systems (6,71).

Treatment

Nonoperative management suffices in the vast majority of patients with postphlebitic syndrome. Such therapy includes reduction or elimination of edema, correction of any associated medical problems, and continued patient education to ensure long-term compliance with management principles (71,72). The edema generally resolves quickly when the venous hypertension is reduced or eliminated by bed rest, with the extremity elevated above the level of the heart, and calf exercise (repetitive dorsiflexion of the ankle) is continued while at bed rest. When the edema has subsided or has become substantially reduced, the patient is fitted for elastic compression stockings, which tend to minimize the edema and keep the superficial veins collapsed (6). The stockings are applied before arising in the morning and are removed in the evening when the patient retires. The patient is encouraged to remain active when erect and to elevate the legs when sitting and to avoid sitting with the knees flexed.

When ulcers are present, they should be cleansed by frequent dressing changes; a zinc oxide–impregnated dressing may be used but is effective only when an elastic bandage holds it in place (6). If the ulcers persist after 6 to 8 weeks of nonoperative management, split-thickness skin grafts may be carried out with or without concomitant ligation and removal of the nearby incompetent superficial and perforating veins (73). Cross-femoral transposition of the saphenous vein has also been found useful in selected individuals with unilateral obstruction of the iliofemoral venous system. This procedure, which entails transposition of the competent greater saphenous vein from the uninvolved extremity across the pubis and anastomosing it end to side to the drainage system of the involved extremity, may be effective in approximately 70% of *selected* patients (74). Ipsilateral saphenous vein bypass of an obstructed superficial femoral vein is also occasionally effective. Other procedures include repair of incompetent femoral valves and vein segment transposition, which entails anastomosing a vein containing competent valves to an adjacent vein in which the proximal valves are incompetent (74).

Varicose Veins

Varicose veins are the most common disorder of the venous system of the lower extremity; they are said to afflict up to 10% of all Americans (75). The greater and lesser saphenous systems are most commonly the cause, but it is the secondary branches of these veins that become varicose. Varicosity usually appears after the age of 20 years, but it can develop in women in relation to puberty and during pregnancy (6). In men the onset of the disorder is evenly distributed by decades up to age 70 years.

Pathophysiology

It is important to classify varicose veins as either primary or secondary (6,73). Primary varicose veins occur in the absence of deep venous disease and generally have a benign course: They often appear in a familial pattern. Varicosities that occur secondary to obstruction and valvular incompetence of the deep venous system are a much more serious problem.

Symptoms and Signs

The disability that occurs with primary varicose veins is usually minimal, but with prolonged dependency, patients complain of heaviness and mild, dull, aching pain that is occasionally associated with minimal swelling. The symptoms and the swelling are promptly relieved by elevation or elastic support. When the varicose veins are secondary to prior DVT, loss of valves, and incompetent perforating veins, the symptoms are much more serious and are accompanied by swelling, stasis pigmentation, and cutaneous ulceration, as discussed in connection with the postphlebitic syndrome.

Diagnosis

The diagnosis of primary varicose veins is easily established by inspection of the legs in the upright position, which causes the dilated tortuous veins to become readily apparent. When isolated clusters are observed in atypical locations, the possibility of an underlying incompetent perforating vein should be considered (6). Duplex scanning can be used to assess whether incompetent perforating veins are contributing factors.

Therapy

Most patients with symptomatic primary varicose veins should be reassured and treated initially with compression stockings (6). If the deep veins and perforating veins are patent and competent (primary varicose veins), it is unusual to see stasis, pigmentation, or ulceration. In those unusual instances in which treatment with compression stockings is inadequate, high ligation and selective stripping of the long and short saphenous system will likely be successful (6).

Lymphedema

Lymphedema, an abnormal accumulation of lymph in the extremity, occurs from multiple causes, including infection, trauma, allergy, and malignancy (76). It is most commonly idiopathic. Painless swelling of the involved extremity is the earliest and most common symptom and sign with most types of lymphedema. Initially, the swelling tends to subside somewhat at night, but as the process progresses, the swelling becomes permanent, due to fibrosis of both the skin and subcutaneous tissues. Pain is rarely a problem in these patients, except for those who develop cellulitis or ulceration. In such instances, pain is relieved when antibiotic therapy results in resolution of cellulitis, or local ulcer therapy produces skin healing.

CHAPTER 34

Pain in Spinal Cord Injury Patients

John D. Loeser

HISTORICAL OVERVIEW

A particularly difficult group of chronic pain patients to manage are those who have sustained an injury to the spinal cord or cauda equina. These patients usually have devastating neurologic deficits such as paraplegia or quadriplegia. A significant fraction of such individuals also are plagued by refractory chronic pain; estimates of the prevalence of pain have varied from 7% to 75% (1). Some of this variation is caused by the lack of an agreed-on classification scheme for the pains that occur in patients with spinal cord injury; some of it may be because of the vigor with which questions about pain were pursued or answered. These pain syndromes, which are described in detail in this chapter, are clearly directly related to the spinal cord injury. The type of pain associated with the spinal cord injury itself has been considered in detail in Chapter 23 as one of the central pain syndromes.

Severe pain is likely to interfere with the rehabilitation potential of patients who have sustained a spinal cord injury (2,3). Attempts to alleviate pain after spinal cord injury consume significant amounts of health care but have often been unsuccessful. In the past two decades, there has been increased interest in the physiologic mechanisms underlying pain after spinal cord injury and in the development of useful classification schemes. Some types of pain in spinal cord injury patients can be treated with widely accepted standardized forms of therapy when their etiology has been carefully identified. New treatments may offer the promise of pain relief in specific types of pain after spinal cord injury.

Most patients who sustain an injury to the spinal cord have also received massive trauma to the vertebral column and its supporting structures. This typically leads to acute pain similar to that seen with musculoskeletal trauma anywhere in the body. The principles of posttraumatic pain management as discussed in Chapter 43 are applicable to patients with spinal trauma; this chapter does not discuss the management of acute pain seen in such injuries.

The problem of pain after spinal cord injury was addressed by Riddoch (4) in his 1917 paper. I cannot find an earlier paper that focused on this problem. Munro's classic paper on spinal cord injuries in 1943 did not even mention the issue of chronic pain (5). After World War II, Botterell and colleagues described chronic pain in 12 of 103 spinal cord injury patients; 11 of these 12 had cauda equina injuries (6). Kuhn reported that 0.234% of the injuries in World War II involved the spinal cord and that 22.5% of 113 patients with spinal cord injury had chronic pain (7). Davis reported an incidence of 27% in 471 spinal cord injury patients (8). In 1962, Kaplan and colleagues attempted to classify spinal cord injury pains and stated that 37% of 52 spinal cord injury patients had chronic pain 1 year after injury; this increased to 50% by 5 years later (9). Richards and colleagues claimed that 77% of 88 spinal cord injury patients had chronic pain and that psychosocial variables predicted approximately one-half of the variance (10). Waisbrod and colleagues believed that there were three types of pain after spinal cord injury on the basis of their study of 27 patients (11). Woolsey identified less than a 20% incidence of chronic pain in a group of 100 spinal cord injury patients (12). Stormer and colleagues reported on a multicenter study of 901 spinal cord injury patients, 66% of whom had chronic pain (13). Lamid and colleagues, Levi and colleagues, New and colleagues, Beric, Demirel and colleagues, and Rose and colleagues have all contributed data on the incidence of pain after spinal cord injury (14,15,16,17,18 and 19). The methodology and the patient population being studied appear to greatly influence the incidence of spinal cord injury pain. Collating these reports leads me to guess that more than one-half of patients who sustain a spinal cord injury suffer from chronic pain severe enough to interfere with rehabilitation and the activities of daily living and therefore reduce quality of life.

Burke and Woodward constructed a simple classification of pains seen after spinal cord injury and discussed their relationship to phantom phenomena (20). Donovan and colleagues designed a classification scheme for spinal cord injury pain in 1982, but subsequent case series either have used parochial classifications without the attempt to integrate concepts or did not even attempt to classify types of pain (21). Frisbie, Beric, and Siddall and colleagues have published classification schemes for pain after spinal cord injury (22,23 and 24). No attempts have been made to validate any classification system either on the basis of clinical findings, response to treatments, or putative mechanisms. We do not yet have animal models of spinal cord injury that replicate the varied pain phenomena seen in humans.

BASIC CONSIDERATIONS

Experimental Models

Developing animal models for the pain after spinal cord injury is important for the development of successful treatment strategies. Valid models would appear to be those that mimic the histologic effects of human spinal cord injury. Three are currently used: the spinal cord contusion model, the ischemic model, and the excitotoxic model. The spinal contusion model, usually evoked by dropping a weight on the exposed spinal cord, has not been directly used in the study of pain. However, it produces changes in the excitability of neurons that could be relevant to the development of pain after spinal cord injury (25). The ischemic model developed by Wiesenfeld-Hallin and her colleagues uses a photochemical method to produce graduated ischemia in the spinal cord (26). This group of studies has shown that neurochemical changes occur after spinal cord injury that may be responsible for both an acute allodynia syndrome that is not seen in humans and a chronic pain syndrome that may replicate some of the features of central pain after human spinal cord injury. Interactions between opiate and cholecystokinin segmental modulatory systems may play a role in the development of pain, but this model has not ruled out the effects of altered downstream modulation on damaged spinal cord segments.

The excitotoxic model has been described by Yezierski, who has also been one of the more active scientists in this area (27). Substantial evidence has accrued that glutamate was responsible for much of the damage seen after spinal cord injury. This has led to a series of studies using agonists and antagonists of glutamate and *N*-methyl-d-aspartate receptors injected directly into the spinal cord in the absence of trauma. Cavitation within the cord is noted, and the animals manifest allodynia and other signs of chronic pain. It is believed that the effects of excitotoxic substances may lead to cell death and altered synaptic connectivity as well as imbalances between different functional systems. Exactly how this produces pain that persists even when the involved cord segments are removed (as in distal cordectomy in humans) is not clear. The abnormal behaviors seen in animals whose spinal cords had been injected with quisqualic acid (an

alpha-amino-3-hydroxyl-5-methyl-4-isoxazole propionic acid metabotropic receptor agonist) were reversed by intrathecal adrenal medullary transplants (28).

Eide has proposed that upregulation of neuronal activity is the cause of both spontaneous and evoked pain after spinal cord injury (29). He stated that increased glutaminergic excitatory activity involving *N*-methyl-d-aspartate receptor activation is the primary cause. This can lead to changes in voltage-sensitive Na^+ channels. Other mechanisms may be the loss of endogenous inhibition contributed by opioids, monoamines, and gamma-aminobutyric acid. In short, so many changes occur in the spinal cord after injury that it is difficult to ascertain which ones are specifically relevant to the development of pain.

Plasticity

It is now well established that the central nervous system undergoes dramatic changes in response to either peripheral nerve or spinal cord injury. Existing axons sprout and develop connections to new populations of neurons. Second-order neurons lose their synaptic input and enter into new structural relations with glia. Trophic substances play a large role in modulating this type of plasticity, which could underlie some of the pain syndromes that follow spinal cord injury. Damage to neurons from excitatory amino acids has also been proposed as a mechanism for the development of pain (27).

Research studies have generally focused on the effects of deafferentation via dorsal rhizotomy or direct spinal cord injury by cordotomy or trauma to the spinal cord. They are, therefore, relevant only to transitional zone or spinal cord injury pain and do not have much relevance to the other types of pain described in the following sections. Indeed, those models that lead to alterations in, but not the compete loss of, sensation are really suitable only for transitional zone pain or partial spinal cord injury.

A large body of literature exists on the effects of spinal cord lesions on the development of behaviors that suggest chronic pain (30). Among the early studies of the effects of spinal cord lesions on neuronal activity were those of Loeser (31). Although all animals who have sustained a spinal cord injury manifest neuronal hyperactivity in the dorsal horn, only a small fraction develop any detectable pain behaviors. A species effect occurs on the genesis of pain behaviors after spinal cord injury; in addition, within the human species only a fraction of patients report chronic pain. Of course, the ambiguity of what an animal feels that causes it to chew on or to withdraw an extremity is always present. It remains fairly well demonstrated, however, that lesions of the peripheral nerves and spinal cord can lead to behaviors that suggest both spontaneous and evoked pains such as thermal and mechanical allodynia.

Christensen and Hulsebosch have described a model for either transitional zone pains (see Classification of Pain Syndromes, later in this chapter) or pains seen after partial spinal cord injury (32, 33). Their rats developed mechanical and thermal allodynia after a cord hemisection. Dorsal horn neurons were shown to be hyperexcitable in this preparation, suggesting that central sensitization played a role in the development of a pain state after spinal cord injury. The same authors also demonstrated that calcitonin gene-related peptide, which is normally confined to lamina I and II of the dorsal horn, can be found in lamina III and IV after spinal cord hemisection. This suggests ingrowth of fine primary afferent fibers into nuclear regions where they do not normally occur. The intensity of this response to injury was modulated by levels of nerve growth factor; this suggested a potential strategy for prevention of spinal cord changes after injury that could be related to the genesis of pain. This research suggests that plasticity in the spinal cord is responsible for the development of pain.

Central Pattern Generation

Another concept for spinal cord injury pain was proposed by Melzack and Loeser (34). Based on the clinical evidence that cordotomy and cordectomy were usually not effective for the relief of spinal cord injury pain (see Classification of Pain Syndromes, later in this chapter), they proposed that structures rostral to the level of injury were essential for the genesis of this type of pain. Melzack has carried this theme forward to develop the concept of the neuromatrix: The brain contains widely distributed parallel processing neural networks that create an image of self through genetic programs and memories of past experience (35). Afferent inputs act on this neuromatrix and produce output patterns that lead to the report of pain. This concept points to an unresolved issue about pain after spinal cord injury: Is the apparatus essential to produce the report of pain located at or near the site of injury, or does it lie in more rostral structures? The presence of spinal cord injury pain in patients who have high cervical spinal cord lesions seems to indicate that suprasegmental structures may play a critical role. There have been few, if any, experimental studies that address this issue. This concept does not negate the role of neural changes at the level of injury, but it does state that the genesis of the pain is from suprasegmental structures, not the injury site.

PATIENT EVALUATION

The assessment of every patient with spinal cord injury and chronic pain requires a detailed history that describes the onset of the pain and its quality, distribution, and the factors that make it better or worse. It is also important to ascertain how intervening surgeries and treatments have influenced the pain. The physical examination must precisely describe the patient's neurologic status; if this is changing, the relationship to the pain complaint must also be determined. The stability of the traumatized spine must be ascertained through history, physical examination, and imaging studies. Electrodiagnostic studies may be useful in determining the exact levels of injury to the nervous system and specific peripheral nerve function when indicated (see Chapter 13). Diagnostic nerve blocks can also help delineate the level of a painful lesion (see Chapter 102). On the basis of the history, physical examination, and appropriate imaging and electrical studies, it should be possible to classify the pain syndrome as described in the following sections and illustrated in Figure 34-1. The assignment of the patient to one of these pain classes permits optimal treatment planning and implementation. More than one type of pain can be present in the spinal cord injury patient.

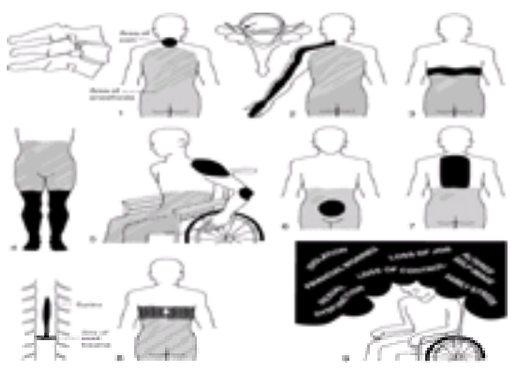

Figure 34-1. Types of pain observed in patients after spinal cord injury. See Table 34-1 and text for explanation.

1. Mechanical instability of the spine
2. Nerve root entrapment
3. Segmental deafferentation
4. Spinal cord injury pain
5. Secondary overuse or pressure syndromes
6. Visceral pain
7. Muscle spasm pain
8. Syringomyelia pain

TABLE 34-1. Classification of spinal cord injury pains

CLASSIFICATION OF PAIN SYNDROMES

Mechanical Instability of the Spine

This type of pain is most common after cervical spine injury and is rarer after thoracic or lumbar injury (Table 34-1). It may be present from the time of injury or, rarely, it may develop later. This is a type of musculoskeletal pain that is caused by the disruption of ligaments or fracture of bones with resultant instability of adjacent structures. It is characterized by the movement of osseous structures in abnormal planes or in abnormal amounts.

Pain usually commences soon after injury and is related to activity or position. The pain is in the region of the spine, although it may radiate around the trunk or toward an extremity; but it is not radicular. This type of pain can be seen after spine injury without an associated spinal cord injury. Radiography, computed tomographic scan, or magnetic resonance imaging (MRI) show instability by manifesting abnormal movement.

This type of pain is relieved by immobilization; it is also usually sensitive to opiate and nonsteroidal antiinflammatory drugs. Immobilization until spontaneous healing has occurred and surgical fusion are both effective treatments in almost all patients. The pain secondary to mechanical instability is almost always alleviated by surgical fusion across a region of instability. Sved and colleagues found that early surgery to stabilize the spine did not lead to any alteration in the incidence of chronic pain after spinal cord injury (36).

Nerve Root Entrapment

Nerve root entrapment leads to radicular pain in the distribution of a single nerve root. It may, rarely, be bilateral. This type of pain occurs at the level of spinal trauma, and the pain usually is present from the time of injury. Nerve root entrapment may be associated with mechanical instability, but this is not a necessary concomitant. This pain is usually described as lancinating, burning, or stabbing. If the involved root contributes to the brachial or lumbosacral plexus, there may be electromyographic or somatosensory-evoked potential abnormalities. Radiographic, computed tomographic or MRI evidence of compression of the nerve root in the foramen by bone or disk is correlated with the location of the pain.

This radiculopathic pain may be relieved by opiates or by neuropathic pain-relieving drugs such as anticonvulsants or tricyclic antidepressants (see Chapter 85 and Chapter 86). If it is associated with instability, stabilization provides relief. If it is associated with bone or disk in the neural foramen, surgical decompression is usually effective.

An important variant of this type of pain is seen after injury to the cauda equina. Several potential etiologies exist for pain after such an injury. First, the spinal cord may be significantly deafferented, leading to changes in central connectivity and neuronal activity that could cause pain. Second, the damaged roots of the cauda equina could be spontaneously active and generate signals that are interpreted as pain. The arachnoiditis that follows major injury to the cauda equina may limit the normal movement of the nerve roots and lead to mechanical irritation of the roots with slight movements (37). Third, peripheral stimuli could lead to abnormal activity at the site of axonal injury.

The pain is reported in the lower lumbar and sacral dermatomes; it is constant but may fluctuate with activity or autonomic activation. It is usually described as burning, stabbing, and hot. Most authors have commented on the refractory nature of pain after cauda equina injury. Spinal cord stimulation has sometimes been successful (see Chapter 100).

Segmental Deafferentation

Segmental deafferentation pain has also been labeled *girdle zone* or *transitional zone* pain. It occurs at the border of normal sensation and anesthetic skin. Transitional zone pain is described as burning and aching and is often associated with allodynia and hyperpathia in the painful region. The pain is located in a two- to four-segment band that is bilateral and circumferential. As many as one- third of spinal cord injury patients who have pain have the segmental deafferentation type, although Beric lumped together radicular pains and transitional zone pains in his report (23). This type of pain usually develops in the first few months after injury.

Transitional zone pain does not usually respond to opiates, but it may respond to neuropathic pain-relieving medications such as anticonvulsants and antidepressants (see Chapter 85 and Chapter 86). Epidural or somatic nerve root blocks that make the painful area anesthetic may relieve the pain. Dorsal root entry zone lesions usually relieve this pain, perhaps by their dorsal rhizotomy effect or perhaps by being an analogue of distal cordectomy that raises the sensory level above the painful region (see Chapter 106). Some have reported pain relief by spinal cord stimulation (see Chapter 100). If the type of pain was not delineated in a clinical report, it is highly likely that this was the type of pain relieved by whatever treatment is being advocated.

Spinal Cord Injury Pain

Spinal cord injury pain is the most difficult to manage of the spinal cord injury pain syndromes. It is perceived in anesthetic regions below the level of injury, although it has also been reported by some patients who do not have a complete cord transection and have some preserved functions. It may be visceral, dysesthetic, superficial, or chronic regional pain syndrome–like. Patients use various descriptors such as tingling, numbness, aching, throbbing, squeezing, and sickening. Sometimes a lancinating component also exists. The pain is always ascribed to specific body regions and is usually bilateral. Patients often provide bizarre descriptions. It is constant, but may fluctuate with mood or activity. It is not related to position or activity. The pain usually starts soon after injury and is found in approximately one-third of spinal cord injury patients who complain of chronic pain. Other terms used for this type of pain include *central pain*, *phantom pain*, *central dysesthesia syndrome*, and *dysesthetic pain* (38,39 and 40). Beric and colleagues described a double lesion phenomenon occurring in patients with cervical or thoracic cord injuries who developed lower motor neuron signs in the lumbosacral segments (41).

Concurrent infections or other illnesses may aggravate this central pain state. It responds poorly to oral opioids or any other medications. It may respond to intrathecal opioids, or to a combination of bupivacaine, clonidine, and opioid when systemic routes are ineffective. Surgical procedures such as cordectomy or any other ablative procedure are rarely successful (see Chapter 106), and it is unlikely to respond to spinal cord or brain stimulation (see Chapter 100 and Chapter 101). Most patients with this type of pain do not get significant relief from any of the currently available therapies.

Beric and colleagues found that 13 of 102 consecutive traumatic spinal cord injury patients with pain had this type of pain (23). Beric and colleagues suggested that this type of pain was caused by loss of spinothalamic systems with the relative preservation of dorsal column function (38).

Secondary Overuse or Pressure Syndromes

Secondary overuse or pressure syndromes are common in paraplegics and much less common in quadriplegics. The pain occurs in normally innervated regions rostral to the level of the spinal cord injury. The onset is delayed months or even years after the cord injury. The pain is described as aching in the area of pressure or overuse and is worse with use of involved joints or pressure on the part. It is typically seen in the shoulders and carpal tunnels of those who propel themselves in wheelchairs and therefore use their shoulders as hips (42). Lal in 1998 reported on shoulder joint degenerative changes in 72% of a sample of paraplegics (43). If the pain is caused by nerve compression, abnormal electrophysiologic studies as well as MRI neurography can aid in diagnosis.

Resting the painful part or protecting it from trauma can alleviate this type of pain. Nonsteroidal antiinflammatory drugs or, when needed, opioids are also helpful. This is not a neuropathic pain and it is not alleviated by anticonvulsants or antidepressants. Peripheral nerve compression can, when necessary, be alleviated by surgical decompression.

Visceral Pain

It is not at all clear that this is a distinct category of chronic pain in patients with spinal cord injury. The patient describes burning, cramping, bloating, and constant but often fluctuating pain. Some patients seem to have intermittent attacks of this type of pain. The onset is usually delayed for months or years after the spinal cord trauma. Visceral pain may be caused by normal afferent input via the sympathetic and vagus nerves in paraplegics and the vagus nerves alone in those who are quadriplegic. This pain could be stimulus driven from abdominal myoneural dysfunction, it could result from imbalance of afferent input, or it could be a form of spinal

cord injury pain as described previously. Davis and Martin believed that this was a pain associated with autonomic phenomena (40). It was described by Kuhn in 1950 in patients with visually inspected cord transections who had preserved recognition of noxious genital stimulation (44). Komisaruk and colleagues reported that women with high spinal cord transections could still perceive genital stimulation (45).

Virtually no information exists on the treatment of this type of pain after spinal cord injury.

Muscle Spasm Pain

Muscle spasm pain is found only in patients with partial spinal cord injuries in whom some sensation is preserved but severe muscle spasm develops. The patient reports pain associated with visible and palpable muscle spasm at or below the level of spinal cord injury. The pain usually starts well after the spinal cord injury. This pain is best relieved by alleviating the muscle spasms; analgesics may be helpful but rarely are adequate. Hence, oral or intrathecal antispasticity medications are the primary treatment for this type of pain.

Syringomyelia

Chronic pain may occur in association with the development of a posttraumatic syrinx in the spinal cord (46). This pain always has a delayed onset, perhaps even years after the spinal cord injury. The development of a syrinx is characterized by new neurologic deficits at a higher level than the original injury. The loss of pain and temperature sensation is typical, but all sensory and motor functions can be affected. Patients describe a constant, burning pain that may be associated with allodynia.

Diagnosis is established by MRI scan (Fig. 34-2). The most effective treatment for the syrinx is surgical decompression of the arachnoid scar at the level of injury so that there is free flow of spinal fluid around the spinal cord. Treating the syrinx by inserting a drainage tube that goes either to the subarachnoid space or the peritoneal cavity does not provide as good long-term results. Even though the syrinx may collapse, it is not always the case that pain relief will be obtained. The medications used for neuropathic pain (see following discussion) may be helpful when syringomyelic pain persists after collapse of the syrinx.

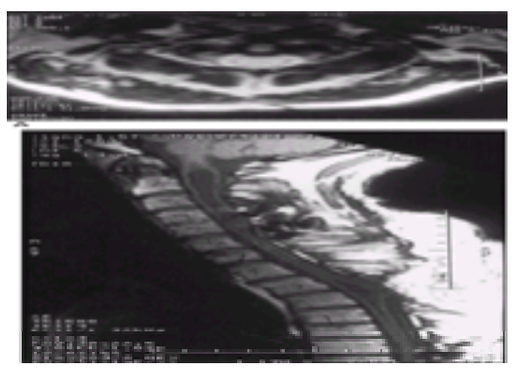

Figure 34-2. **A:** Sagittal magnetic resonance scan of cervical spinal cord demonstrating posttraumatic syringomyelia. **B:** Axial magnetic resonance scan through cervical syringomyelia. Note thin rim of spinal cord tissue surrounding the central cavity.

Cognitive, Affective, and Environmental Pain Syndromes

Any pain syndrome can be modified by cognitive and affective factors as well as environmental influences on the patient. The eight types of pain described are certainly no exceptions to this general rule. Indeed, the disability ascribed to chronic pain is highly likely to be primarily related to these three confounders. It is also possible that the entirety of a patient's pain behaviors can be related to affective or environmental factors, but this is certainly not common. All pain syndromes related to spinal cord injury can benefit from the application of psychological management strategies (47).

Patients who have sustained a spinal cord injury are often physically and psychologically devastated. Suffering may be caused by pain; alternatively, it can be engendered by other effects of spinal cord injury. Lundqvist and colleagues found that pain was the only complication of spinal cord injury that lowered quality of life scores (48). Westgren and Levi reported that pain had more effect on quality of life scores than the extent of spinal cord injury (49). Biomedically focused physicians tend to ignore the psychological factors that may be leading to pain behaviors. The literature contains repeated references to the role of factors other than spinal cord injury itself in the genesis of pain behaviors and disability ascribed to pain (50).

TREATMENT

Pharmacologic

Few properly conducted clinical trials adequately describe the nature of the patients' pains and use effective clinical study techniques. Drewes and colleagues in a double-blind, placebo-controlled study found that valproate was not effective for spinal cord injury pain (51). Small sample size, uncontrolled, unblinded studies characterize the literature in this area. Extrapolation from other types of pain related to central or peripheral nervous system injury has led to the widespread use of anticonvulsant and antidepressant medications with some successes (52,53) (see Chapter 85 and Chapter 86). Some patients may respond to systemic opioids, but this appears to be the exception rather than the rule. All of the medications used for any type of chronic pain have been tried in uncontrolled fashions for the variety of pain syndromes that occur after spinal cord injury (54). Overuse and pressure syndromes may respond to nonsteroidal antiinflammatory drugs.

The advent of intrathecal drug administration systems has led to the delivery of opioids and other pain-relieving drugs directly to the spinal cord (see Chapter 103). Some patients with pain after spinal cord injury have been reported to respond to a variety of drugs delivered by this route. My own experience with opioids for central pain states is not favorable; the addition of local anesthetics or clonidine to opioids may prove to be more effective (55).

Psychological

Patients with a major spinal cord injury usually have significant psychological distress (56,57). The superimposition of chronic pain is a major factor that prevents expected rehabilitation and return to employment and function in domestic life. Psychological assessment should be part of the evaluation of every spinal cord injury patient with chronic pain of any type (see Chapter 16) (58). Use of the strategies described in Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92, Chapter 93 and Chapter 94 can facilitate both pain management and return to maximal functional status (59). Association with groups of spinal cord injury patients is also a positive step for most patients.

Physical

Those pain syndromes that are associated with overuse or pressure can often be managed by physical measures alone. Physicians who specialize in the management of spinal cord injury patients are familiar with the problems engendered by paraplegia and quadriplegia and can design prosthetic devices, orthotics, and exercise routines that aid in the management of these problems. Physical therapies are not useful for the pains related to spinal cord injury itself. Transcutaneous nerve stimulation has not been very effective (60). Stimulating anesthetic skin never provides pain relief; some patients with transitional zone pain may get some relief from stimulation in the area of pain and partial sensation.

Surgical

Orthopedic and neurosurgical procedures designed to stabilize the spine immediately after trauma and to decompress impinged nerve roots can be effective at

eliminating the pains of instability or nerve root compression (61). On the other hand, Burke reported that patients who had spinal surgery were more likely to have chronic pain than those who were treated conservatively; this was not congruent with the observations made by Sved (36,62). Decompressive surgery with lysis of adhesions at the site of spinal cord injury is also effective in the treatment of syringomyelia, although the pain associated with this condition may not remit even though the syrinx is collapsed.

Ablative neurosurgical procedures need to be tailored to the type of pain syndrome if they are to be successful (see Chapter 105 and Chapter 106). When it is impossible to decompress a mechanically compromised nerve root, dorsal rhizotomy may be useful. For transitional zone pains, dorsal root entry zone lesions are often effective (63). The transition zone pains may also be alleviated in some patients by transecting the spinal cord at a higher level (64). For spinal cord injury pain, ablative surgery, including cordotomy, distal cordectomy, and thalamotomy, has a low chance of success.

Electrical stimulation of the spinal cord may be effective for transitional zone or radicular pains, but it does not help spinal cord injury pain (65) (see Chapter 100). Deep brain stimulation has some utility when all else has failed (1,66) (see Chapter 23 and Chapter 101).

CHAPTER 35

Cancer Pain: Assessment and Diagnosis

Dermot R. Fitzgibbon and C. Richard Chapman

Cancer currently afflicts an estimated 1,382,400 new patients annually and causes 560,000 deaths per year, making it the second leading cause of death in the United States (1).* Among women, the three most commonly diagnosed cancers, breast, lung and bronchus, and colon and rectum, account for over one-half of all cancer deaths. Lung is the leading cancer site, accounting for 25% of all cancer deaths. Breast cancer alone accounts for 30% of new cancer cases, and estimates predict approximately 180,200 new cases for 1997. Breast cancer accounted for 17% of female cancer deaths in 1997. Among men, the most common cancers are prostate, lung and bronchus, and colon and rectum. Prostate is the leading cancer site, accounting for 43% of new cancer cases. Men are more likely to die of lung cancer than from cancer at any other site. Data for 1995 suggest that overall cancer mortality has begun to decline (2). Figure 35-1 and Figure 35-2 show estimated new cancer cases for the 10 leading sites and estimated cancer deaths by sex in the United States for 1997.

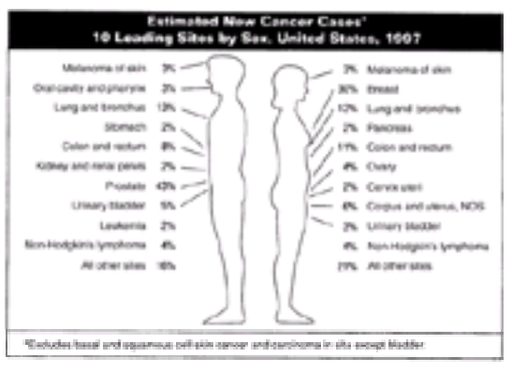

Figure 35-1. Estimated new cancer cases. (NOS, not otherwise specified.) (From Parker SL, Tong T, Bolden S, Wingo PA. Cancer statistics, 1997. *CA Cancer J Clin* 1997;47:5–27, with permission.)

Cancer is one of the medical conditions patients fear most (3). In addition to anxiety about cancer as a potentially lethal disease, patient and family expectancies that pain is an inevitable and untreatable consequence are major sources of distress (3). Cancer pain elevates psychological distress (4,5 and 6), alters social life (7), disturbs sleep (8), and compromises enjoyment of life (9).

End-of-life considerations and palliative care are rarely major issues for acute and chronic nonmalignant pain conditions, but these concerns become extremely important for the cancer pain patient with advanced disease (see Chapter 40). The complexities that emerge from the medical and psychosocial aspects of the situation necessitate a multidisciplinary or interdisciplinary approach to care. The changing nature of cancer pain, either in response to treatments directed at the tumor or progression of the tumor, mandates vigilance and potential frequent alteration of treatment strategies for pain. Many health care professionals may become involved with the cancer pain patient at any one time (Fig. 35-3). Successful pain management requires that the person or persons responsible for pain management adopt, or at least become familiar with, an interdisciplinary approach. In addition, the humanitarian nature of cancer pain management, the focus on suffering and comfort, and the associated effects on patients' relatives all contribute to the uniqueness of this form of pain control.

Figure 35-3. Interdisciplinary care teams of the cancer patient with pain.

Controlling pain associated with cancer is a major health care problem (10,11). Thirty percent of patients with cancer have pain at the time of diagnosis, and 65% to 85% have pain when their disease is advanced (10,11,12,13 and 14). The interaction of pain and its treatment with other common cancer symptoms such as fatigue, weakness, dyspnea, nausea, constipation, and impaired cognition magnifies the negative effect of cancer pain (12,14). Cancer patients treated on an outpatient basis frequently have pain that is inadequately controlled (11,15,16). Cleeland and colleagues (11) reported that 67% of outpatients (871 of 1,308 patients) indicated that they had pain or had taken analgesic drugs daily during the preceding week, whereas 36% had pain severe enough to impair their ability to function. Patients seen at centers that treated predominantly minorities were three times more likely than those treated elsewhere to have inadequate pain management. A discrepancy between patient and physician in judging the severity of the patient's pain was predictive of inadequate pain management (odds ratio, 2.3). Other factors in this study that predicted inadequate pain management included pain that physicians did not attribute to cancer (odds ratio, 1.9), better performance status (odds ratio, 1.8), age of 70 years or older (odds ratio, 2.4), and female sex (odds ratio, 1.5).

DEFICIENCIES IN ASSESSMENT AND DIAGNOSIS OF CANCER PAIN

Experienced physicians now recognize a need for significant improvement in cancer pain assessment and treatment in their practice (17). Lack of expertise by clinicians in assessing and managing cancer pain has been listed as an important cause of poor pain control (18). Interviews of practicing physicians demonstrate knowledge deficits in the basic principles of cancer pain management (19). Similar findings are demonstrated in nurses and nursing students (20,21 and 22).

Assessment of resident physician clinical performance has traditionally comprised limited subjective faculty evaluations and multiple choice tests appropriate only for measuring knowledge. Performance-based testing is a form of evaluation that objectively measures clinical ability (23). It tests what a trainee does in a simulated or real clinical situation. Sloan and colleagues (24) used a standardized assessment protocol called an *objective structured clinical examination*, designed to use performance-based testing to evaluate the skills of 33 resident physicians in assessing and managing severe chronic pain of a cancer patient. The case evolves in a standard manner and students must reassess the patient, formulate treatment, and justify their choices, in a manner similar to an oral board examination. The investigators found many fundamental deficiencies in both assessment and treatment of cancer pain. Only 45% of physicians correctly assessed pain intensity and only 33% adequately assessed the pain description. In addition, most residents assessed pain-relieving factors, previous pain history, and psychosocial history poorly or not at all. In all, only 58% of the trainees were judged to be competent in cancer pain assessment and treatment. These deficiencies were equally evident at both junior and senior levels.

Pain management requires a variety of assessment skills and the integration of knowledge about pharmacology, pharmacokinetics and pharmacodynamics, patient characteristics such as individual variability and compliance with medications, side effects and quality of life determinants, and disease specifics. These skills must contribute to clinical judgment and decision making, often requiring substantial individual experience. Computer simulation software may create a tool that embraces the principles and ideals of cancer pain assessment and management as outlined at professional society meetings, and in clinical guidelines, journal articles, and editorials. Such tools, which are currently in development, may provide convenient platforms to move that learning into the working environment of the student, health care provider, and institution. Although the potential of such tools is still under development, the software may provide the ability to efficiently assist in the identification of specific errors in knowledge, judgment, and practice patterns of the individual.

PAIN AND THE CANCER PATIENT

Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage (25). The sensory features and subjective qualities of pain vary, depending on its origin. Its emotional features depend in part on the social and physical context in which pain occurs, associated cognition, and the meaning of tissue trauma for the individual, but they are almost always negative.

Sensory Component of Cancer Pain

From a sensory perspective, tumor-associated pain may be classified as nociceptive (somatic or visceral) and neuropathic. Somatic nociceptive pain may be grouped into superficial (cutaneous) and deep. Most cutaneous pain is well localized, sharp, pricking, or burning. Deep tissue pain usually seems diffuse and dull or aching in quality. Visceral pain is diffuse, often referred to the body surface, perseverating, and frequently associated with a queasy quality that patients describe as *sickening*.

Compression and invasion of nerves by tumor result in the destruction of myelinated and unmyelinated fibers and of supporting tissue.

The process of tumor compression and invasion of nerves entails several degenerative, regenerative, and other pathophysiologic processes. The whole afferent neuron is affected and goes through reactive, presumably reparative, biochemical changes. The neuron loses its neuropeptides (26), atrophies, and may finally degenerate. This applies particularly to unmyelinated afferent neurons. The conditions in a nerve, when invaded or compressed by cancerous tissue, are probably similar to those after lesions of nerves induced by mechanical or other events. The process induces changes in the discharge properties of neurons (resting activity, response to mechanical and chemical stimulation).

Affective Processing and Suffering

The emotional mechanisms of cancer pain, and not its sensory features, are the reasons that it generates suffering. Of course, most cancer patients suffer from a complex array of problems and not only pain. Nonetheless, sustained nociception in and of itself can produce suffering because of its ability to create negative emotional arousal and elicit associated stress responses (see Chapter 6).

Suffering is a complex negative emotional and cognitive state characterized by perceived threat to the integrity of the self, perceived helplessness in the face of that threat, and exhaustion of psychosocial and personal resources for coping with that threat (27). The perceived threat to the self may encompass the body, the psychosocial self, or both. Suffering related to cancer is inherently emotional, unpleasant, complex, and enduring. The physician should recognize that, although suffering may be a consequence of pain, it is separate from pain and not a synonym for it. It differs from pain in that it entails additional cognitive affective states. For example, perceived helplessness (inability to cope, bankruptcy of physical, psychological, or social resources) is a key element in the suffering of most patients with incurable disease. Similarly, grief can ensue when a cancer patient perceives the loss of a psychological or social resource, a body part or desired personal appearance, a prized employment status, or a physical capability for a treasured activity. Loss often equates with perceived threat to self. In addition, suffering in the cancer patient sometimes involves a sense of separation from social support or alienation. These factors, combined with the emotional distress, fatigue, and stress associated with prolonged pain produce a complex state that differs from pain itself.

Psychological Factors and the Complexities of Cancer Pain

Health care providers frequently view pain reported by cancer patients as primarily somatogenic, whereas they regard pain of chronic nonmalignant pain patients, who lack adequate objective physical pathology, as psychogenic (28). Consequently, providers tend to treat cancer pain with pharmacologic, medical, or surgical modalities. Psychological factors are considered to be of secondary importance (29).

As stated previously, pain is a complex experience entailing physiologic, sensory, affective, cognitive, and behavioral components. The final individual perception of pain is dependent on nociceptive input and psychological modifiers such as fear, anxiety, anger, and depression (Fig. 35-4).

Figure 35-4. Individual perception of pain. Noxious stimuli are modified at the supraspinal level by emotions such as anxiety, fear, and anger.

Turk and colleagues (28) classified the multidimensional nature of cancer pain. They compared the adaptation of cancer patients and chronic noncancer patients to persisting pain. The majority of the cancer patients, both with (81%) and without (84%) metastatic disease, as well as the noncancer chronic pain patients (85%), fit one of three psychosocial subgroups: dysfunctional (high levels of pain, perceived interference, affective distress, and low levels of perceived control and activity), interpersonally distressed (high levels of affective distress, negative responses from significant others, and low levels of perceived support), and adaptive copers (low levels of interference and affective distress, high levels of perceived control and activity).

Substantial evidence suggests that psychological factors play an important role in exacerbating pain with clear origins of disease (see Chapter 24, Chapter 25 and Chapter 26). For example, the belief that pain signifies disease, a commonly held belief among cancer patients (4), is associated with elevated pain intensity (9,30). Spiegel and Bloom (30) also reported that the affective states of cancer patients, the belief that pain is an indicator for disease progression, and medication use all predict pain severity. Patients who attribute their pain to a warning of underlying disease report greater pain than patients with more benign interpretations, despite comparable levels of disease progression.

Because of psychological factors, the relationship between pain severity and the extent of disease is rarely as linear as one might assume (31). Research investigating the relationships between physical pathology and pain in cancer has shown conflicting results. First, not all patients with advanced cancer report pain. Twycross and Fairfield (32) reported that only 41 of 100 terminal- stage cancer patients reported pain caused by disease. Front and colleagues (33) demonstrated that for many cancer patients, pain reports did not correspond to the presence or location of bone metastases. Turk and colleagues (28) found that patients with cancer-related pain reported a significantly higher level of perceived disability and inactivity caused by pain than did those with pain of nonmalignant origin. Because the level of pain severity was comparable for the two patient groups, elevated disability may have been a consequence of the meanings patients attributed to their pain. The progression of disease means further deterioration of health and impending death. Indeed, the patients with cancer-related pain appeared to be more fearful of pain and reported significantly higher levels of cognitive and behavioral fear responses than did the patients with chronic pain not associated with cancer. These patients appeared to think and worry more about pain and avoid activities to prevent initiation of pain, and they generally felt more hopeless than the patients with noncancer-related pain.

DEPRESSION IN CANCER PATIENTS

Broadly speaking, depressed persons complain of a pervasive dysphoric mood, anhedonia, apathy and disinterest in normal activities, sleep problems, low energy, and in severe cases suicidal ideation (see Chapter 26). Approximately 25% of cancer patients meet criteria for major depressive syndrome at some point during their illness (34), whereas the prevalence of depression in the patient population at large approximates 6% for outpatients and 11% for inpatients (35,36). Craig and Abeloff (37) estimated an overall prevalence of depression at 53% for hospitalized cancer patients with varying primary sites and stages. Passik and Breitbart (36) noted that depression is more often comorbid with certain tumor types, such as pancreas and lung, than with others.

Depression is a complex family of mood disorders, as the evolving *Diagnostic and Statistical Manual* classifications of the American Psychiatric Association indicate, and any global statement about it risks provoking contention (see Chapter 26). To address this complexity, much of the classical thinking on depression attempted to force depressive syndromes (and patients) onto one or another continuum characterized by extremes at the poles (38,39). Two common continua are reactive versus endogenous and neurotic versus psychotic depression. The various continua differ less than one might expect in basic characterizations of depression, and for our purposes, they are almost equivalent. For simplicity, and because its language fits the cancer patient more readily, we describe the reactive-endogenous continuum.

Patients at the reactive pole tend to link their depression to an event, a stressful situation, or a loss. In the cancer patient, the cancer diagnosis itself can serve as the precipitating event, as can the failure of an antineoplastic intervention, the loss of ability to work, or a mutilating or debilitating surgery. When asked, depressed cancer patients may admit anxiety, restlessness, irritability, problems falling asleep, and sometimes obsessional thinking or other obsessional problems. Often, they do not present depressive symptoms to the physician because they assume that the physician is concerned only with the cancer itself. Those patients at the

endogenous pole seemingly develop depression without a precipitating cause. They tend to show marked slowing in motor responses, early morning wakening with the most severe mood disturbance in the morning, weight loss, and feelings of hopelessness. One form of endogenous depression is bipolar mood disorder, in which patients shift between the extremes of depression and mania. A genetic predisposition for unipolar and bipolar depression clearly exists (40). In these patients, a history of depressive disorder is the best indicator of current endogenous depression. Of course, many and perhaps most patients fall between the extremes of reactive and endogenous depression.

Detecting and Assessing Depression in the Cancer Patient

It is important for the physician treating cancer pain to recognize and address depression (Table 35-1). All too often, depression goes unnoticed or unaddressed in the cancer patient (41). Most physicians focus on somatic rather than psychological problems in patients with life-threatening illness, and some erroneously regard reactive depression in a patient who has received a diagnosis of cancer to be a normal response. Few oncologists or supporting consultants feel qualified to address depression, and for those who do, time limits on patient contact time make it difficult to engage in extensive questioning about psychological well-being. Patients and family members may add to the problem by assuming that care providers concern themselves solely with controlling the disease and wish to avoid the distractions that psychological management entails.

Effect	Comment
Suffering	Significant contribution, particularly when major organic disease is present.
Medical evaluation and decision making	Depressive symptoms can complicate.
Outcome and survival	Depressive disorders can adversely affect.
Recovery and compliance	Depressed medically ill patients tend to have slower recovery and poorer compliance.
Suicide	Undetected and untreated depression can lead to suicide.
Pain	Poorly managed pain is a common cause of reactive depression in patients with severe, life-threatening disease.

TABLE 35-1. Consequences of pain and depression in cancer patients

Diagnosing depression in the cancer patient is not straightforward because symptom overlap exists between the psychiatric disorder, the toxicities of treatment, and the effects of the primary disease. Chemotherapeutic agents (e.g., vincristine, vinblastine, l- asparaginase, procarbazine, or cytoxin), biological interventions such as interferon or interleukin, the antifungal agent amphotericin B, the toxic sequelae of whole-brain irradiation, and paraneoplastic syndromes can all produce symptoms that resemble depression. Consequently, many of the physical symptoms of depression such as fatigue, diminished appetite, and weight loss also occur in emotionally healthy cancer patients (42).

Screening for depression should focus primarily on the cognitive and affective features of depression, because these are not confounded with treatment-associated toxicities. Cognitive and behavioral signs of depression include observable sadness; statements of pervasive despair, hopelessness, or despondency; comments about being an unfair burden to others; expression of guilt or low self-esteem; and statements that life is and has been devoid of worth. Depressed patients also resist reassurances; for example, they tend to reject statements that a pain problem may not signal the progression of the disease.

SOURCES OF PAIN IN THE CANCER PATIENT

Most cancer pain results from one or more of three fundamental causes (Table 35-2):

Cause	Example
As a direct consequence of tumor	Involvement of bones; obstruction of hollow organs; compression of nerves
As an indirect consequence of tumors	By infections; by metabolic imbalances; by venous/lymphatic occlusion
As a consequence of tumor therapy	After surgical intervention; after chemotherapy; after radiation therapy
Without relation to cancer	Migraine; diabetic neuropathy; myofascial pain problems

TABLE 35-2. Causes of pain in patients with cancer

- direct tumor involvement,
- cancer-directed therapy, and
- mechanisms unrelated to cancer or its treatment.

Patients may present with complex patterns of pain that result from combinations of these categories, thus complicating the diagnosis. Factors influencing the pain complaint include the primary tumor type, stage of disease, tumor site, and mood factors (anxiety and depression) (6,43,44). Vainio and colleagues (44) estimated the prevalence of pain in 1,840 patients with advanced cancer from seven hospices in Europe, the United States, and Australia. Twenty-four percent of the patients surveyed had no pain, 24% had mild pain, 30% moderate pain, and 21% severe pain. In addition, the prevalence of moderate or severe pain was highest in gynecologic cancer and in head and neck cancer. Severe pain was most common in prostate cancer (Table 35-3).

Primary site	None	Mild	Moderate	Severe	No.
Prostate	17	22	30	41	41
Esophagus	29	21	13	38	24
Gynecologic	10	10	47	33	30
Colorectal	21	21	27	32	63
Lymphohematologic	13	29	26	32	38
Head and neck	17	11	43	29	35
Lung	26	23	30	21	241
Breast	22	25	31	21	118
Stomach	26	30	26	17	53
Other or unknown	26	27	32	15	417
Total	24	24	30	21	1,060

TABLE 35-3. Prevalence of pain (percentage of patients) by primary site among palliative care cancer patients

Many patients with advanced disease frequently have multiple pains at different sites. Multiple pain complaints were more common in patients with breast, lung, and prostate cancer compared with gastrointestinal cancers (43). In a prospective study of 2,266 cancer patients, Grond and colleagues (45) assessed localization, etiology, and pathophysiologic mechanisms of pain syndromes associated with cancer. Thirty percent of the patients presented with one, 39% with two, and 31% with three or more distinct pain syndromes. The majority of patients had pain caused by cancer (85%) or antineoplastic treatment (17%); 9% had pain related to cancer disease and 9% caused by etiologies unrelated to cancer. These investigations classified pain as originating from nociceptors in bone (35%), soft tissue (45%), or visceral structures (33%), or of neuropathic origin (34%). Patients localized pain syndromes in the lower back (36%), abdominal region (27%), thoracic region (23%), lower limbs (21%), head (17%), and pelvic region (15%). Regions and systems affected by the main pain syndrome varied widely depending on the site of cancer origin, whereas the cancer site did not markedly influence the pain's temporal characteristics, intensity, or etiology.

Although a significant association exists between most cancer pain and the presence of metastases, certain tumor types are exceptions, notably breast and prostate cancers. Neither the prevalence nor the severity of pain among breast cancer patients varies directly as a function of metastatic sites of disease (30,33). Palmer and colleagues (46) evaluated the sensitivity of pain as an indicator of bone metastases in patients with breast or prostate cancer. Pain was a common finding, whether or not metastatic disease was present, and it occurred in over one-half of the patients. Although most patients with bone metastases reported bone pain, significant numbers (21% of breast and 22% of prostate patients) were asymptomatic.

These findings indicate that cancer pain poses a substantial management challenge for the physician. Pain can change over time, involve multiple sites, stem from several origins, involve several causes simultaneously, and may correspond loosely or not at all to the tumor.

CLASSIFICATION OF CANCER PAIN BY FEATURE

Several schemata exist for classifying pain in the cancer patient and are potentially useful for diagnosis and management. One such scheme is presented in Table 35-4.

Chronicity
Intensity and severity
Pathophysiology and mechanism
Individual type and stage of disease
Pattern of pain
Syndrome

TABLE 35-4. Methods used for classifying pain in the cancer patient

Chronicity

Acute pain can occur during and after certain diagnostic procedures and various anticancer therapies, particularly postoperative pain after surgical intervention (47) and pain during chemotherapy (48) or radiation therapy (49) (Table 35-5). The course of acute pain is usually predictable and self-limiting, and the pain does not represent a difficult diagnostic problem. In contrast, assessment of patients with chronic pain tends to be much more difficult and complex.

Procedure	Problem
Diagnostic procedures	Blood samples
	Lumbar puncture
	Angiography
	Endoscopy
	Biopsy
Chemotherapy	Mucositis
	Myalgia
	Arthralgia
	Pancreatitis
	Gastrointestinal distress
	Cardiomyopathy
	Extravasation of drug into tissues
Radiation treatment	Skin burns
	Mucositis
	Pharyngitis
	Esophagitis
	Proctitis
	Itching
	Painful fractures
Surgical therapy	Postoperative pain
	Ileus, colitis
	Urinary retention distress

TABLE 35-5. Acute pain associated with cancer management

Intensity and Severity

Health care workers commonly underestimate the severity of a patient's pain (50,51), particularly when relying on their own observations. This tendency is problematic because pain is often undertreated when patients and physicians differ in their judgment of the pain's severity (11). Although both severity and the degree of interference with function are crucial to the adequate assessment of pain, severity is the primary factor determining the effect of pain on the patient, and it drives the urgency and energy of the treatment process (52). Thus, the consistent measurement of pain intensity helps assess patients' progress, provides outcome measures for research purposes, and may guide therapy (53) (see Chapter 15).

Patient self-report is always the primary source of information for the measurement of symptoms. Observer ratings of symptom severity correlate poorly with patient ratings and are generally inadequate substitutes for patient reporting. Grossman and colleagues (50) found a low correlation between patients' visual analog scores for pain and those of health care providers. The discrepancies were most pronounced in those patients reporting severe pain. Although one can monitor some objective signs to clarify the manifestations and effect of certain symptoms, these signs only complement subjective assessment. An assessment of pain intensity should include an evaluation of not only the present pain intensity but also pain at its least and worst.

The three most commonly used instruments for assessing cancer pain intensity are mentioned here:

- Visual Analog Scale (VAS): A slash mark corresponding to intensity of pain is placed on a 100-mm line ranging at one end from “no pain,” to the other end, “pain as bad as it could possibly be.”
- Numeric Rating Scale: A number is assigned to the intensity of pain on a scale of 0 to 10; 0 reflecting “no pain” and 10 reflecting the “worst pain possible.”
- Verbal Descriptor Scale: The patient chooses one of the following selections that best describes pain: no pain, mild pain, moderate pain, severe pain, or worst possible pain.

All three measures correlate highly with one another. For pain assessment in clinical settings, the VAS, Verbal Descriptor Scale, and Numeric Rating Scale approach equivalency (54) so that clarity, ease of administration, and simplicity of scoring become justifiable criteria in response scale selection. In clinical trials, the Numeric Rating Scale has proven more reliable than the VAS, especially with less educated patients (55). Numeric scales work well as cancer clinical trial instruments because

they are easier to understand and easier to score (56).

Several studies have shown that differences between categorical pain severity items are not linear (57,58). For instance, when pain severity is rated at the midpoint or higher on numeric rating scales, patients report disproportionately more interference with daily function (59). Many people, both with and without cancer, function quite effectively with a background level of mild pain that does not seriously impair or distract them. As pain severity increases to moderate intensity, pain passes a threshold beyond which it is hard for the patient to ignore. At this point, it disrupts many aspects of the patient's life. When pain is severe, it becomes a primary focus of attention and prohibits most activities. Pain severity and the degree to which the patient's function is impaired are highly associated. As a way of delineating different levels of cancer pain severity, Serlin and colleagues (31) explored the relationship between numeric ratings of pain severity and ratings of pain's interference with such functions as activity, mood, and sleep. Based on the degree of interference with function, ratings of 1 to 4 correspond to mild pain, 5 to 6 to moderate pain, and 7 to 10 to severe pain.

Pathophysiology and Mechanisms

A general classification by pathophysiology distinguishes nociceptive (somatic and visceral) from neuropathic pain. This distinction is fundamental in assessment because it determines therapy. In principle, pain results from stimulation of nociceptors or by lesions of afferent nerve fibers. Pain is nociceptive if the sustaining mechanisms are related to ongoing tissue pathology. Pain is neuropathic when evidence suggests that the pain stems from injury to neural tissues and aberrant somatosensory processing in the periphery or in the central nervous system (CNS). Physical influences such as pressure, traction, compression, and tumor infiltration, as well as metabolic or chemical disturbances, produce pain. Obviously, classification by a physiologic mechanism would be an improvement, but sufficient information to do this is not available.

Tumor Involvement of Encapsulated Organs

Primary or secondary tumors of the liver are the most frequent examples of tumors of encapsulated organs. These can enlarge the organ to several times the normal size. Because the organ capsule of connective tissue grows less rapidly than the tumor, the intracapsular pressure increases as capsular distension develops. In addition, tumor infiltrates the capsule locally, producing dull and, rarely, also stabbing pains. The massive growth of the organ not only stimulates intracapsular nociceptors, but it also irritates larger nerves by pressure or traction on the tissue suspending the organ. Similar organ-enlarging processes in the spleen and kidneys do not lead to pain to the same extent as in the liver, perhaps because of the more stable suspension or embedding of these organs, which are farther away from the midline with its abundant nerve pathways. Kidney tumors produce pain only when the kidney has been almost completely destroyed and the tumor has invaded the pararenal tissue, or when it destroys the renal pelvis.

The brain is also an encapsulated organ. Its special feature is that the bony skull capsule prevents any enlargement. Pain arises here, not by destruction of parenchyma, but by the increase of intracranial pressure with stimulation of the meningeal nociceptors. Such an increase of intracranial pressure occurs in space-occupying tumor growth or in focal or generalized brain edema. Focally, edema can develop around isolated tumors. Generalized edema develops in diffuse metastatic invasion of the meninges caused by disturbance of the circulation of cerebrospinal fluid (CSF). Such a tumor invasion of the leptomeninges is frequent in malignant lymphomas. However, metastatic invasion of the leptomeninges occurs in patients with solid tumors (e.g., bronchial carcinoma and malignant melanoma), with the predominant symptom being headache. In such cases, tumor infiltration of cranial nerves may also occur.

Tumor Infiltration of Peripheral Nerves

Because peripheral nerves can usually evade pressure from a tumor on one side, infiltration by tumor tissue is the quintessential tissue trauma stimulus. In addition, indirect damage of unknown pathogenesis might also occur to peripheral nerves in the context of tumor conditions (e.g., paraneoplastic syndromes). Tumor tissue often infiltrates the perineural cleft, but this does not regularly cause pain. A massive and then painful entrapment of the nerve plexus or individual nerves sometimes occurs, especially in extensive breast carcinomas and their recurrences or in chest wall metastases of bronchial carcinomas. The perineural cleft widens with tumor infiltration, and infiltration of the tumor into the nerve itself is common. Degenerative changes of the axis cylinders are sometimes visible with conventional screening methods. Primary tumors of the peripheral nerves themselves lead to painful destruction. Tumor compression regularly elicits pain when the affected nerve cannot give way (e.g., a spinal nerve).

Tumor Infiltration of Soft Tissues

On the one hand, tumor infiltration of soft tissues causes pain via the mechanisms described previously, as with massive infiltrations of the retroperitoneum. On the other hand, infiltration and destruction of mobile structures (e.g., of the skeletal musculature) can lead to pain via disturbance of function. Here, the tumor spreads in the interstitium and destroys blood vessels, lymphatics, and nerves.

Tumor Infiltration of Bone

The most frequent cause of pain in tumor patients is infiltration of bone. This applies to primary and secondary neoplasias originating from the bone marrow as well as to neoplasias of the bone itself. Such tumors always cause pain when they lead to an elevation of the intraosseous pressure, to loss of stability, or to a lesion of the periosteum resulting in periosteal elevation, or with the release of chemical mediators of nociception. The neural structures that generate nociception reside in the bone marrow, in the bone, and in the periosteum.

In metastatic processes, the degree of bone destruction is often extensive. Vertebral spread of tumor may involve intervertebral foramina, where it can compress nerve roots (Fig. 35-5). Further spread posteriorly leads to encroachment of the spinal cord and the spinal nerves. In bone, the metastases primarily localized in the bone marrow result in osteolysis or osteosclerosis. Necroses and hemorrhages occur frequently in bone metastases and doubtless play a role in the etiology of pain. The hemorrhages probably result from microfractures. Metastatic bone disease is discussed in detail later in this chapter.

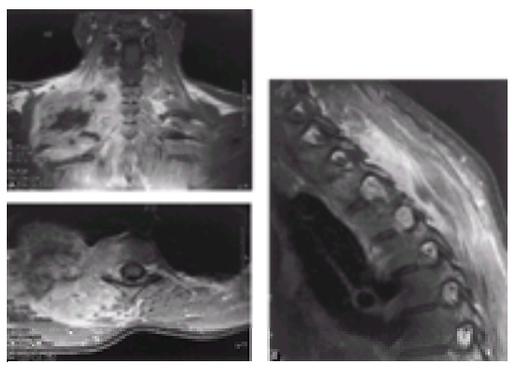

Figure 35-5. **A:** Coronal T1-weighted magnetic resonance imaging scan showing a right apical lung mass with invasion into the spinal canal. **B:** Sagittal T1-weighted magnetic resonance imaging scan (postgadolinium) showing tumor spread into right T-2 and T-3 vertebral foramina with mass infiltration of posterior spinal elements. **C:** Axial T1-weighted magnetic resonance imaging scan showing mass in apex of right lung and right paravertebral muscles extending into T-2 vertebral body and foramen.

Tumor Infiltration of Abdominal Hollow Organs

In general, tumors and their sequelae in the bronchial tree are indolent, whereas those in abdominal hollow organs cause pain. This applies to all primary and secondary intestinal tumors. However, their pain-eliciting potency differs widely from individual to individual. The pain results from ulcerations, motility disorders, dilatations, and disorders of blood flow. In accordance with the extent of the lymphatic tissue, large tumors with extensive ulceration and hemorrhage occur in malignant lymphomas of the gastrointestinal tract. Perineural tumor infiltration, arteritis, or perineural inflammatory reactions are common in tumors of the abdominal

and urogenital hollow organs.

Tumor Infiltration and Inflammation of Serous Mucosa

Normally, pleural carcinosis does not cause pain, probably because of the development of pleural effusion, which prevents the pleurae from rubbing together. In peritoneal carcinosis, pain occurs more frequently, and it may be the first symptom of tumor disease. It stems from either direct contact of the metastases with peripheral nerves or an inflammatory reaction elicited by the carcinosis with disorders of visceral motility. Acute inflammatory reactions of the peritoneum with the clinical picture of *acute abdomen* and possibly with empyema appear after tumor-induced perforation or penetration of hollow viscera.

Tumor-Induced Necroses in Solid Organs

Specific necroses produce typical pain symptoms in the pancreas. Such necroses, with the clinical picture of autodigestive pancreatitis, can occur with pancreatic metastases of a bronchial carcinoma. The autodigestion probably results from tumorous destruction of the parenchyma together with tumor infiltration and stenoses of the excretory ducts.

Tumor-Induced Occlusions of Blood Vessels

Invasion of the lymphatics and blood vessels is part of the biology of malignant neoplasias and is the precondition for metastasis. Generally, small and peripheral vessels are involved, obstruction of which does not result in any appreciable disorder of the circulation. Larger veins occasionally become infiltrated and occluded. Infiltration of larger arteries is rare.

Tumor Type and Stage of Disease

Factors influencing the pain complaint include the primary tumor type, stage of disease, tumor site, and mood factors such as anxiety and depression (6,43,44). When metastatic disease appears, approximately one in three patients reports significant pain. As discussed previously, although pain tends to reflect the presence of metastases, this may not always be the case for certain tumor types, particularly for patients with breast or prostate cancers. The prevalence and severity of pain among breast cancer patients do not appear to vary directly as a function of metastatic sites of disease (30,33).

Pain caused by tumor may occur at the onset of disease or at an advanced stage. Although rarely one of the early indicators of the onset of disease, pain is not a significant problem for the majority of patients in the early stages of disease, with 5% to 10% of patients with solid tumors reporting pain at a level that interferes with mood and activity. However, pain is obviously a major concern that often prompts the patient to seek medical consultation. Vuorinen and colleagues (60) found that 28% of newly diagnosed unselected cancer patients reported pain. Cleeland and colleagues (61) reported that the majority of patients with end-stage disease have pain of a severity that interferes with several aspects of the patient's quality of life. Daut and Cleeland (9) found that pain was an early symptom of cancer in 40% to 50% of patients with cancer of the breast, ovary, prostate, colon, and rectum, and in approximately 20% of patients with cancer of the uterus and cervix.

Knowledge of the natural history of the disease facilitates an understanding of the pain process and is important in determining the nature and timing of treatment. Examples of the more common disease processes follow.

Pancreatic Cancer Pain Syndromes

Over the past 20 years, the incidence of pancreatic carcinoma in Europe and North America has remained unchanged, with an estimated 9 to 10 cases per 100,000 and slightly increased male to female and black to white ratios. Pancreatic cancer currently ranks as the fifth most common cause of cancer-related deaths in Western countries (62). Approximately 90% of pancreatic tumors are adenocarcinomas with a ductal phenotype. Neuroendocrine tumors and acinar cell carcinomas represent approximately 2% to 5% of all pancreatic tumors. Local tumor extension almost invariably involves the peripancreatic fat tissue through direct invasion of lymphatic channels and perineural spaces. Duodenum, stomach, gallbladder, and peritoneum are infiltrated by tumors located in the pancreatic head; body and tail tumors can invade liver, spleen, and left adrenal gland. Lymphatic spread to adjacent and distant lymph nodes seems to precede hematogenous spread, which affects, in descending order, liver, peritoneum, lungs, adrenals, kidneys, bones, and brain. Thirty percent to 60% of patients experience pain with early, relatively limited disease, and over 80% of those with advanced disease have pain (63,64).

Singh and colleagues (65) reported that 60% of patients undergoing pancreatic resections and 84% of those not resected have moderate to severe pain. Pain caused by pancreatic cancer is usually abdominal, typically referred to the epigastric region or the upper abdominal quadrants, but it can also involve the lower quadrants or be diffuse (64). Back pain is associated with abdominal pain in 50% to 65% of cases, but only 5% to 10% of patients report it as their only complaint (66). In one series, 67% of patients could not describe their pain location better than as over their “diffuse abdomen” (66). Direct infiltration of pancreatic afferent nerves, pancreatic duct obstruction with retention pancreatitis, biliary obstruction, or duodenal infiltration resulting in bowel obstruction can generate pain. Eating often aggravates the pain. Tumors of the head of the pancreas may cause epigastric pain with right flank radiation more often, whereas pain from tumors in the tail has left-sided radiation (67). Back pain in the region of T-10– L-2 is common and is the first symptom in 10% to 30% of cases. Lying flat typically exacerbates it and sitting relieves it. This pain probably comes from retroperitoneal tumor involvement, and it may not respond to celiac plexus block. It often merges with similar syndromes caused by nodal or other soft tissue tumor involvement in the retroperitoneal region (Table 35-6). The effect of pancreatic pain can be profound. It is commonly associated with depressed mood, and contributes to the rapid decline in function that characterizes this disease (36,66).

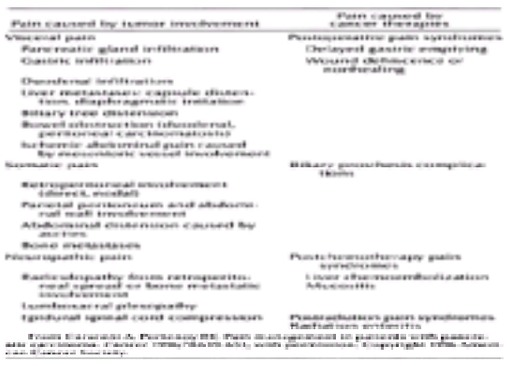

TABLE 35-6. Pancreatic cancer pain syndromes

Ovarian Cancer

The prevalence of pain associated with ovarian cancer resembles the prevalence rates in populations with other solid tumors (68). Ovarian cancer spreads by intraperitoneal, lymphatic, and locally invasive pathways. Lymphatic pathways may extend from the abdominal retroperitoneum to the groin via the inguinal and femoral canals or across the diaphragm to the pleural space. Intraperitoneal spread of tumor begins with extension of tumor through the ovarian capsule, allowing implantation of tumor throughout the abdomen. Intraperitoneal metastases show a predilection for the omentum and diaphragm, but no organ is spared, and concomitant ascites is frequent. Portenoy and colleagues (68) noted that pain, fatigue, and psychological distress were the most prevalent symptoms in patients with advanced (stage III or IV) ovarian cancer. Patients generally describe pain as occurring in the abdominopelvic or lower back region, as being frequent or almost constant, and moderate to severe in intensity. Patients with advanced disease may experience pain in the lower extremities either from invasion of the lumbosacral plexus by tumor or by lymphedema secondary to iliac vessel occlusion.

Cervical Cancer

Cancer of the cervix is a frequent cancer in women worldwide. There are several histologic subtypes of cervical carcinoma. Squamous cell carcinoma is the most

frequently seen and accounts for 80% to 90% of invasive cervical cancers. The next most frequent subtype is adenocarcinoma. The cervix drains by preureteral, postureteral, and uterosacral routes into the following regional lymph nodes: parametrial, paracervical, hypogastric (obturator), common iliac, external iliac, internal iliac, sacral, and presacral. The common sites of distant spread include the aortic (paraaortic, periaortic), lateral aortic and mediastinal nodes, lungs, and skeleton. In patients with locally advanced disease (stages IIB to IVA), 24% have paraaortic disease (69). Identification of paraaortic nodal status allows modification of therapy (usually extended field radiation therapy) with improved survival (70,71). Detection of paraaortic lymph node metastases may be difficult using standard imaging techniques such as abdominopelvic computed tomography (CT) scanning. The sensitivity of CT scanning for identifying paraaortic nodal metastasis may be only 34% (69). Rose and colleagues (72) demonstrated that positron emission tomography (PET) scanning accurately predicts both the presence and absence of pelvic and paraaortic nodal metastatic disease. Identification of sensitive and specific imaging modalities is a useful adjunct in this disease.

Prostate Cancer

These cancers are generally adenocarcinomas. The two most frequent staging systems used for prostate cancer are the American Urologic Association Cancer Staging (A through D) and the TNM classification (0 through IV) of the International Union against Cancer. Approximately 40% of patients with prostate cancer have stage D (IV) disease on presentation, and most of these have bone metastases, with a median survival of 2.4 years. Because of the predilection of prostate cancer to spread to bony sites, a significant proportion of patients with metastatic disease have bone pain. Prostate cancer rarely spreads to vital organs, and the disease tends to progress slowly. The only exceptions are spinal cord compression or ureteral obstruction secondary to retroperitoneal lymph node metastases.

Tumors of the prostate gland may produce local rectal, urethral, suprapubic, and penile pain as a result of expansion and inflammation of the prostate; pain referred to the back, lower extremities, and abdominal area resulting from tumor growth within the pelvis; and distant bone pain with associated neurologic dysfunction associated with long bone, vertebral, and skull metastases (Table 35-7). The regional lymph nodes of the prostate are the nodes of the true pelvis, which are the pelvic nodes below the bifurcation of the common iliac arteries. Distant lymph nodes are outside the confines of the true pelvis. They are the aortic (paraaortic, periaortic, lumbar), common iliac, inguinal, superficial inguinal (femoral), supraclavicular, cervical, scalene, and retroperitoneal nodes. Ultrasound, CT, magnetic resonance imaging (MRI), or lymphangiography can image them. In prostate cancer, preliminary studies using 2-[F-18] fluoro-2-deoxy-d-glucose (FDG) tracer demonstrated that PET cannot reliably differentiate between primary prostate cancer and benign prostatic hyperplasia, and that PET is not as sensitive as bone scintigraphy for the detection of osseous metastases. However, PET may have a role in the detection of lymph node metastases in patients with prostate-specific antigen relapse after primary local therapy (73).

Causes of pain	Examples and clinical syndromes
Bone metastasis	Single metastasis of pelvis or long bone
	Vertebral body metastasis, spinal cord compression
	Base of skull metastasis, cranial nerve palsies
	Perineal pain syndromes
Soft tissue metastasis	Lumbosacral plexopathy
	Pelvic tension "myalgia"
Pelvic visceral pain	"Prostatitis" pain

From Payne R. Pain management in the patient with prostate cancer. Cancer 1993;71:1131-1137, with permission. Copyright 1996 American Cancer Society.

TABLE 35-7. Causes of pain in prostate cancer

One can identify clinical syndromes by the site of bony involvement, the coexistence of mechanical instability secondary to fractures, and the neurologic dysfunction caused by tumor infiltration of contiguous neurologic structures. Bone metastases to the hip and pelvis often produce local pain that is exacerbated by movement, especially during weight bearing. Local invasion of tumor from the pelvis into the sacrum may produce the syndrome of perineal pain. Patients with this syndrome complain of local and perirectal pain that is accentuated by pressure on the perineal region, such as that caused by sitting or lying prone. In its most extreme form, the patient cannot sit or lie flat. Dysfunction of the parasympathetic sacral innervation to bladder and bowel impairs continence early in the course of this syndrome. Local spread of tumor from the prostate into other pelvic and abdominal structures often produces visceral and neuropathic pain. Tumor invasion of the lumbosacral plexus may occur.

Prostate-specific antigen (PSA) is useful in the diagnosis and staging of men with prostate cancer and in monitoring men after all forms of treatment for prostate cancer (74). Serial measurements may more closely reflect actual disease status than single measurements. For example, changes in PSA after radiation therapy or androgen ablation therapy for prostate cancer reflect progression of disease, and add additional information with respect to disease status over that obtained with a single PSA measurement (75,76). In untreated patients, PSA correlates with clinical stage, increasing with increasing tumor stage (77).

Breast Cancer

Breast cancer consists of the following histologic types: carcinoma, ductal, lobular, nipple, and other (undifferentiated). Therapeutic strategies for individual patients with breast cancer frequently depend on the following prognostic variables: size of the primary neoplasm, the presence and extent of axillary lymph node metastases, pathologic stage of disease after primary therapy, and the presence or absence of receptor (estrogen, progesterone) activity. The breast lymphatics drain via three major routes: axillary, transpectoral, and internal mammary. Intramammary lymph nodes are considered with, and coded as, axillary lymph nodes for staging purposes. Metastasis to any other lymph node is distant.

PET scanning can be used to evaluate primary lesions, regionally metastatic, and systemic metastases of breast cancer. Combined FDG-PET and MRI provide useful treatment-planning data for patients clinically suspected of having recurrent axillary or supraclavicular breast cancer. FDG-PET help confirm metastases in patients with indeterminate MRI findings and depicted unsuspected metastases outside the axilla (78). FDG-PET is also superior to bone scintigraphy in the detection of osteolytic breast cancer metastases (79).

Breast cancer can metastasize to any organ in the body: Bone, lung, liver, and brain are frequent sites. Metastases usually appear within a few years, but recurrence may occur, particularly in bone, many years later. Although metastatic disease may be asymptomatic, the most common site of metastases, bone, typically hurts. Between 40% and 60% of patients with metastatic breast cancer have bone disease, and in many of these patients, the involved bones (vertebrae, femoral and humoral shafts, the acetabular area) are those that are involved with motion. Moreover, patients with metastatic breast cancer and bone involvement as their only site of metastatic disease may have median survival expectations of 27 to 29 months, during which time pain may be the chief manifestation of disease. Even patients with pulmonary metastases have median survivals of the order of 18 to 23 months (80), and patients with only unilateral pleural involvement on the order of 44 months (81).

The clinician most likely will have a long relationship with the patient with metastatic breast cancer, and will have the opportunity to follow the course and progression of disease. The course of disease in patients with metastatic breast cancer fits one of two patterns: an indolent course or disease not immediately life-threatening, and that which is rapidly progressing or with extensive vital organ disease. Knowledge of the natural history of the disease is important in determining the nature and timing of treatment.

Table 35-8 lists some of the common causes of pain in patients with breast cancer.

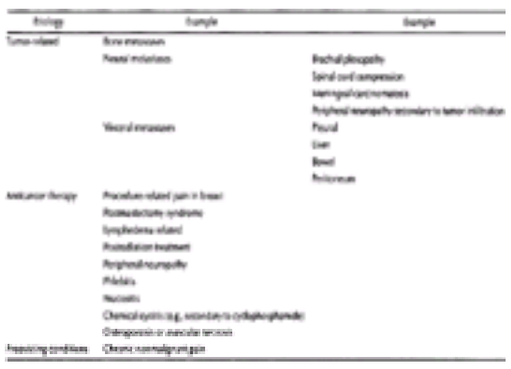

TABLE 35-8. Causes of pain in patients with breast cancer

Lung Cancer

Bronchogenic cancers comprise two groups that reflect their biology and management: small cell lung cancers (SCLC) and non–small cell lung cancers. Each of these further divides into subtypes, but these categories often blend into each other or coexist. SCLCs are relatively sensitive to cytotoxic chemotherapy and radiation therapy. They account for approximately 25% of lung tumors and although usually centrally located, these can arise peripherally. Clinically, these tumors demonstrate a rapid growth rate and early metastatic dissemination.

Before the advent of systemic therapy, local surgical or radiation therapy alone produced poor median survivals, ranging from 8 to 17 weeks and 5-year survivals of less than 1% (82). Effective chemotherapy has allowed the control of disseminated disease and improved the median survival of patients to 1 year or more, increasing the number of long-term disease-free survivors to between 5% and 10% (83).

SCLC tumors express many neuroendocrine markers. Individual tumors may secrete up to 10 discrete hormones (84). Histologically, SCLCs include small cell anaplastic carcinoma, which includes the oat cell type. Small cell anaplastic carcinoma is an aggressive and rapidly growing neoplasm and is limited to the thorax at presentation in only 25% of patients. Metastases occur in regional lymph nodes, lung, abdominal lymph nodes, liver, adrenal gland, bone, CNS, and also bone marrow.

Non–small cell lung cancers are a morphologically diverse group that includes squamous cell carcinoma, adenocarcinoma, and large cell anaplastic carcinoma. Squamous cell carcinoma is less likely to metastasize early. Adenocarcinomas have become the most frequent form of lung cancer in the United States (85). Adenocarcinoma metastasizes widely and frequently to the other lung, liver, bone, kidney, and the CNS. Large cell anaplastic carcinoma metastasizes in a pattern similar to adenocarcinoma, with a predilection for mediastinal lymph nodes, pleura, adrenals, CNS, and bone.

For the purposes of prognosis and for analyzing data from clinical studies, we divide small cell lung cancer into limited and extensive disease categories. Limited disease is characterized by tumor that is clinically confined to the chest, mediastinum, and ipsilateral supraclavicular lymph nodes. Ipsilateral pleural effusion represents limited disease. All other sites of metastases are defined as extensive disease (86). The median survival for patients with limited disease is approximately 12 to 18 months; for extensive disease it approximates 9 months (87).

Lung cancers, particularly SCLC, often entail clinical paraneoplastic syndromes. Malignancy-associated hyponatremia is commonly associated with excessive production of arginine vasopressin by tumor cells, and a large fraction of new cases of the syndrome of inappropriate antidiuretic hormone secretion in elderly smokers are caused by SCLC. Approximately 10% of all lung cancer patients have hypercalcemia, and of these 10% to 15% do not have evident bone metastases. Humoral hypercalcemia of malignancy is more common in non–small cell lung cancer, and especially squamous cell carcinoma. The neurologic syndromes associated with lung cancer are rare disorders such as subacute cerebellar degeneration, optic neuritis and retinopathy, subacute necrotizing myelopathy, and peripheral neuropathy.

Pain is a major symptom in patients with all types of advanced lung cancer (88,89). Chest pain is the most common site of pain in patients with small cell cancer. The pain is often poorly localized, dull in character, may radiate to the neck or back, and exacerbates with coughing. Mercadante and colleagues (89) reported that patients with advanced lung cancer commonly reported chest wall (including ribs and shoulder blade) pain, followed by pain in the lower extremities and lumbar regions, then abdomen and upper extremities, and the head area.

Renal Cell Cancers

Renal cell carcinoma accounts for 2% of all cancers (1). Twenty-five percent to 30% of patients have overt metastases at presentation. Frequent sites include the lung (50% to 60% of patients with metastases), bone (30% to 40%), liver (30% to 40%), and brain (5%). Unusual sites of metastases characterize renal cancer, however, and may involve virtually any organ site, including the thyroid, pancreas, skeletal muscle, and skin or underlying soft tissue. Common metastatic sites include bone, liver, lung, brain, and distant lymph nodes. The regional lymph nodes of the kidney are renal hilar, paracaval, aortic (paraaortic, periaortic, lateral aortic), and retroperitoneal.

Surgical resection remains the cornerstone of treatment for renal cell carcinomas. Radical nephrectomy involves resection of kidney, perirenal fat, and ipsilateral adrenal gland. The extent and benefit of lymphadenectomy is controversial. In 10% to 20% of patients, nodal involvement is found at surgery without clinically evident distant metastases (90,91). Virtually all such patients later relapse with distant metastases despite lymphadenectomy (91). Although an occasional patient may be cured by resection of a lymph node metastasis, in most patients the benefit of lymphadenectomy is limited to the prognostic information it provides.

The most important determinant of survival is the anatomic extent of the tumor (i.e., the pathologic stage). Patients with organ- confined disease that is resected completely generally have better outcomes than those with nodal involvement or distant metastases. Twenty percent to 30% of patients with localized tumors relapse after radical nephrectomy. Less than 5% have local recurrences, whereas lung metastases are the most common sites of distant relapse, occurring in 50% to 60% of patients (92,93). The median time before a relapse after nephrectomy is 15 to 18 months, and 85% of relapses occur within 3 years (92,93).

Colorectal Cancer

The vast majority of these tumors are adenocarcinoma (more than 90%) and, to a lesser degree, carcinoid tumors, leiomyosarcomas, and lymphoma. Spread to regional lymph nodes generally correlates to depth of invasion by the primary tumor and the grade of differentiation. Nodal spread occurs in 10% to 20% of tumors confined to the bowel wall. Hematogenous spread is usually to the liver via portal venous transmission.

The liver is the prime organ for metastatic spread (65%); extraabdominal metastases in lung (25%) and brain and bone (10%) are much less common. Most recurrences appear within 2 years (approximately 70%) and almost all (90%) within 5 years.

Surgery is the primary modality of treatment. There is no well-defined role for radiation treatment in colon cancer. The response rates to chemotherapy (usually 5-fluorouracil) in recurrent and metastatic cancer remain poor and of limited duration. Ulander and colleagues (94) reported on the quality of life in 86 patients who underwent surgery for colorectal cancer. Patients with colon cancer (n = 39) had significantly less pain and less constipation at follow-up compared with preoperatively than did patients with rectal cancer (n = 47). Patients with rectal cancer, having undergone preoperative radiotherapy treatment, had significantly lower confidence intervals for means (95%) on the physical functioning and role functioning scales at follow-up versus preoperatively.

In addition to staging systems, independent prognostic factors include histologic type, histologic grade, serum carcinoembryonic antigen level, and extramural venous invasion.

Patterns of Cancer Pain

Cancer patients may have constant or intermittent pain, as discussed previously. *Breakthrough pain* refers to sudden increases in the base level of pain or different but recurring pains (95).

The majority of breakthrough pains are usually associated with tumor, but Portenoy and colleagues (95) reported that tumor therapy was the cause in 14% of cases and 4% were unrelated to either the cancer or its treatment. There are three types of breakthrough pain:

- *Incident pain* is pain directly related to an event or activity, such as turning in bed, weight bearing, a bowel movement, swallowing meals, and so forth. Often, incident pain is well defined and predictable, so that physicians can anticipate and treat the problem prophylactically.
- *End of dose failure* is pain that emerges because of too much time between doses of medication. One can predict this pattern for the individual patient and readily prevent it by using time-contingent dosing at an appropriate interval. The key is monitoring symptoms in relation to the dosing schedule.
- *Spontaneous pain* occurs spontaneously without relationship to particular events or procedures. These pains are more difficult because of their unpredictable nature and their often fleeting character. In some cases adjunctive analgesics effectively provide relief. Longer lasting pains require rapid-onset analgesics. Increasing the dose of the time-contingent opioids often increases the overall side effects of these medications.

Cancer Pain Syndromes

Table 35-9, Table 35-10, Table 35-11 and Table 35-12 list the common pain syndromes in the patient with cancer. Table 35-13 lists the prevalence of painful manifestations of cancer and their common etiologies. Bone, viscera, and nerve are the most common sites of metastases associated with chronic cancer pain. Each of these sites is discussed separately.

BONE METASTASES

Skeletal involvement, a frequent and troublesome complication affecting many patients with neoplastic disease, is the third most common metastatic site after the lung and liver (96). Metastatic cancer may invade bone in 30% to 70% of patients (97). Up to 85% of patients dying from breast, prostate, or lung cancer demonstrate bone involvement at autopsy (98). Bone pain is the most common kind of pain caused by cancer (32,99,100). Pain from bone metastases affects 28% of hospice inpatients, 34% of patients in a cancer pain clinic (101), and 45% of advanced cancer patients at home. Bone disease frequently gives rise to complications that have a significant effect on a patient's quality of life because osteolytic bone disease is a major source of pain and causes problems such as difficulty in ambulation, neurologic deficits, and pathologic fractures. Fractures are common in patients with myeloma and breast cancer, and long bones are more frequently involved (102).

Bone metastases from carcinomas of the breast, lung, prostate, kidney, and thyroid are the most frequent (Table 35-14). The prevalence of skeletal disease is greatest in breast and prostate carcinoma, reflecting both the high incidence and the relatively long clinical course of these tumors. These two cancers alone probably account for more than 80% of cases of metastatic bone disease. In breast carcinoma, the incidence of bone metastases is significantly higher for tumors that produce parathyroid hormone-related peptide (PTHrP) (103) and are either steroid-receptor positive (104) or well differentiated (105), whereas in prostate carcinoma, bone metastases are more often associated with poorly differentiated tumors (106).

Primary site	Bone metastases (%)
Breast	50-85
Prostate	50-75
Lung	30-50
Kidney	30-50
Thyroid	39
Pancreas	5-10
Colon and rectum	5-10
Stomach	5-10
Liver	8
Ovary	2-6

TABLE 35-14. Frequency of bone metastases in cancer

Bone metastases most commonly affect the axial skeleton, where the red marrow is located in adults. Bone metastases are typically termed *lytic*, *sclerotic*, or *mixed*, according to the radiographic appearances of the lesions. Where bone resorption predominates, with little new bone formation, focal bone destruction occurs and the metastases have a lytic appearance. Lytic lesions are most common in multiple myeloma, melanoma, breast, lung, thyroid, renal, and gastrointestinal malignancies. Conversely, in bone metastases characterized by increased osteoblastic activity, the lesions appear sclerotic. Metastases from prostate carcinoma especially, but also those of breast, lung, carcinoid, and medullablastoma tumors, produce sclerotic lesions. Some tumors characteristically demonstrate a purely lytic radiographic appearance, such as multiple myeloma, lung cancer, and renal carcinoma, and these are more prone to pathologic fracture. Other tumors have a blastic radiographic appearance. Prostate cancer cells produce osteoblast stimulatory factors, probably specific growth factors or acid phosphatase (107). In this case, new bone forms directly on trabecular bone surface before osteoclastic resorption (108). The resulting sclerotic metastases are less prone to fracture because of locally increased bony mass. Breast cancer cells metastatic to bone promote osteoclastic activity. However, this upsets the normal balance of bone resorption and new formation. Breast metastases exhibit a mixed picture of both lytic and sclerotic areas (109). These different mechanisms correspond to typical radiologic features showing mixed lytic and sclerotic metastases, osteolytic metastases, or sclerotic metastases, respectively.

Metastases may reach the skeleton by direct invasion from the primary tumor or by extension from a secondary site, such as a lymph node. True lymphatic spread to the skeleton is rare. Direct invasion is usually accompanied by a detectable soft tissue mass, an unusual feature of metastases that occur by hematogenous spread. The left sides of the vertebral bodies are more frequently affected by direct invasion from local lymph nodes because the left-sided lymph nodes are closer to bone than the right-sided ones (110). Hematogenous spread is far more frequent than lymphatic spread or direct invasion. The venous route, especially Batson's paravertebral plexus, appears to be more important for hematogenous spread than the arterial route. The distribution of Batson's venous plexus, as well as the overall skeletal vascularity, results in a predilection for hematogenous spread to the axial skeleton and the proximal long bones.

Pathophysiology of Metastases

To develop rational therapies for inhibiting or reversing bone alterations, one must understand the mechanisms involved in the pathogenesis of a bone metastasis and its complication. When cancer cells establish in bone because of chemotaxis of membrane receptor affinity for bone marrow cells, they disturb the normal process of bone turnover. Skeletal imbalance and uncoupled resorption destroy bone architecture, with consequent implications for skeletal strength. Bone destruction results from interactions between tumor cells and bone cells normally responsible for the maintenance of skeletal integrity. The disruption of continuity weakens the connective structure, decreasing the resistance of the skeleton to both compressive and bending forces (107).

Mechanisms of Bone Destruction

Tumor-mediated bone disease has two classifications: focal bone disease associated with metastases, and generalized bone disease (e.g., in myelomatosis). In turn, metastatic disease is either osteolytic or osteosclerotic. In practice, the distinction is difficult because the features are commonly associated. In all these contexts, however, bone disease arises from three principal disturbances in the bone remodeling sequence.

Increased Turnover. Metastatic bone disease involves increased resorption, and biochemical and histomorphometric evidence exists for increased bone formation (111). This suggests that all the elements of bone turnover increase. An increment in bone turnover alone reduces skeletal mass because resorption precedes formation. A fivefold increase in bone turnover diminishes bone mass by approximately 20% at cancellous bone sites.

Imbalance. The amount of bone deposited in a resorption cavity may not equal the volume of bone removed. This leads to skeletal imbalance without necessarily implying a disorder of coupling. Skeletal imbalance contributes to bone loss that occurs in myeloma and the generalized increase in bone resorption associated with some solid tumors. When bone turnover increases, skeletal losses accelerate. Why imbalance occurs at remodeling sites is still unknown. Possible mediators include decreased circulating levels of parathyroid hormone and calcitriol, which have trophic effects on osteoblasts. Inhibitors of bone resorption, including chemotherapy, bisphosphonates, and mithramycin (plicamycin), increase circulating levels of calcitriol and alkaline phosphatase in hypercalcemic patients, suggesting a decrease in the inhibition of osteoblast activity (112). Also, the production of cytokines such as tumor necrosis factor and interleukins may directly suppress osteoblastic activity

(113).

Uncoupling. High tumor cell burdens are associated with a lack of coupling in that bone resorption occurs at a locus that is not the subsequent site for new bone formation. This, in turn, accelerates skeletal losses. Repeated waves of bone resorption without repair lead to the destruction of bone architecture and osteolytic foci. Osteosclerotic metastases are commonly caused by uncoupled bone formation, namely, the deposition of new bone, not at sites of prior bone resorption, but on quiescent bone surfaces or arising from stromal condensations within the marrow cavity. As in the case of osteolytic disease, bone formation is mediated by osteoblasts rather than directly by tumor cells. Most sclerotic lesions are mixed lesions in which uncoupled bone resorption and formation occur together but at different sites. Conversely, many osteolytic lesions seen radiographically are mixed lesions in which uncoupled osteolysis predominates (114).

Determinants of Skeletal Disease and Osteoclast Activation

Skeletal Metastases. Bone is the preferential site for metastases for some cancers but not for others. For example, skeletal disease affects more than 70% of women with breast cancer but only 5% of patients with gastric cancer. However, this may reflect only the duration of disease (the time from diagnosis to death) rather than differences in predilection for skeletal sites. Predictors of skeletal disease include estrogen receptor status. Breast cancers expressing high concentrations of estrogen receptors are more likely to metastasize to skeletal rather than soft tissue sites. Receptor status alone, however, does not predict metastatic disease. Other factors, such as circulating glycoproteins, fetal proteins, indices of proliferation, and the presence of cancer cells in marrow, predict metastatic disease with various degrees of accuracy. These variables do not influence the likelihood of skeletal disease. The expression of PTHrP is more common in skeletal metastases than in soft tissue metastases. The same distribution occurs in patients with both types of metastases when the primary tumor does not express PTHrP. This suggests that PTHrP expression occurs after the metastatic event. Because estrogen receptor status and PTHrP expression are unrelated, PTHrP expression may occur preferentially in the skeletal environment. The attachment of tumor cells to distant sites may require large numbers of laminin receptors, which are important for attachment to basement membrane collagen. Laminin antagonists inhibit the formation of osteolytic metastases of melanoma cells in nude mice, whereas laminin potentiates the process (115). The effect is unlikely to be skeleton specific, because these drugs have similar effects on pulmonary metastases. Other proteins affecting cell adhesion include the glycoprotein E-cadherin, and its expression in breast cancer cells is associated with decreased numbers of skeletal metastases (116,117).

Osteoclast Activation. Histologic specimens obtained from patients with solid tumors reveal unusually large numbers of osteoclasts near tumor cells (114). The mechanism for osteoclast activation differs across different tumor types. More knowledge exists about the mechanisms for osteoclast activation in myelomatosis than for solid tumors. At least three cytokines activate bone resorption, including tumor necrosis factor-b or lymphotoxin, interleukin-1, and interleukin-6. Candidates for osteoclast activation in solid tumors include prostaglandins, procathepsin D, tumor-necrosis factor, PTHrP, and the transforming growth factors. Most histologic evidence suggests the hypothesis that increased bone resorption in breast cancer patients depends on increased numbers of osteoclasts (114). Tumor cell–mediated bone resorption may supervene in the late stages of the disorder. Many squamous cell tumors, particularly of the lung and breast, express PTHrP. High PTHrP values also occur in some patients with renal cell, transitional cell, and liver carcinoma, all of which may be associated with “humoral hypercalcemia” in the absence of skeletal metastases. The division of hypercalcemia patients with solid tumors according to the presence or absence of metastatic bone disease is an oversimplification because humoral mechanisms increasing bone resorption and renal tubular reabsorption of calcium also occur in patients with evidence of metastatic bone disease.

Enhanced osteoclastic bone resorption, stimulated by bone-resorbing factors, is a major factor in the development of bone metastases. Osteoclasts are activated either directly by tumor products or indirectly through an influence on other cells (118). Tumor cells frequently produce factors that can activate immune cells, which release osteoclastic stimulating substances such as tumor necrosis factor and interleukin-1 (119). Tumor products may also act directly on bone cells.

In the late stages of metastatic disease, malignant cells appear to cause bone destruction directly. The role of prostaglandins in osteolysis is moot. They may stimulate osteoclastic cells, thus mediating osteolytic metastases. However, no demonstrated relationship exists between subsequent bony recurrence and tumor prostaglandin production (120). Moreover, prostaglandins may cause a transient inhibition of osteoclastic activity or potentiate other mediators of osteolysis. The mechanisms responsible for osteoclast activation differ across malignancies. In myeloma, bone resorption predominates because of secretion of osteoclast-activating substances with low osteoblastic activity.

Bone resorption caused by increased osteoclastic activation decreases bone density and disrupts skeletal architecture, either at focal sites or generally throughout the skeleton. The periosteum is densely innervated and nerves enter bones via the blood vessels. Microfractures occur in bony trabeculae at the site of metastases, causing bone distortion. Periosteal stretching by tumor expansion, mechanical stress of weakened bone, nerve entrapment by tumor, or direct bone destruction with consequent collapse are possibly associated mechanisms (121,122). Weakening of bone trabeculate and cytokines, which mediate osteoclastic bone destruction, may activate nociceptors. The release of algesic chemicals within the marrow probably accounts for the observation that pain produced by tumors is often disproportionate to their size or degree of bone involvement. Reactive muscle spasm may produce further nociception. Nerve root infiltration and nerve compression are other sources of pain.

Characteristics of Metastatic Bone Pain

Nociception from bony metastases can produce a variety of symptoms, such as muscle spasms or paroxysms of stabbing pain. Hematologic malignancies (especially acute leukemias) may produce a syndrome of generalized and migrating bone pain as a result of marrow infiltration (123). Limb pain is the most common presentation, and local bone tenderness (especially on long bone diaphyses) is a frequent finding. The vertebrae are the most common sites of bone metastases. The thoracic spine is affected in more than 66% of cases, the lumbosacral spine in 20%, and the cervical spine in 10%. Multiple vertebral lesions are common. Pain from metastases involving T-12 and L-1 often is referred to the iliac crest or sacroiliac joint unilaterally or bilaterally. Patients with tumor invasion of the upper cervical vertebrae may present with pain in the neck that is referred to the occipital region and skull vertex. Neck flexion typically exacerbates the pain.

Patients with osteolytic bone metastases commonly present with bone pain, pathologic fractures, hypercalcemia, or more rarely, with swelling or neurologic complaints. The vertebrae, pelvis, ribs, femur, and skull are the sites most frequently involved (96). Pain gradually develops during a period of weeks or months, becoming progressively more severe. The pain is usually well localized in a particular area and is often strongest at night or on weight bearing. Patients describe the pain as dull in character, constant in presentation, and gradually progressive in intensity. Pain increases with pressure on the involved area. Continuous pain may be moderate on resting and then increase with different movements or positions, such as standing, walking, or sitting. Breakthrough pain can result from weight bearing or instability because of incipient or actual pathologic fractures. Although the locus of bone pain usually corresponds to the site of the underlying lesion, characteristic patterns of referral to noncontiguous cutaneous areas occur (e.g., hip pain caused by a hip lesion referred to the knee).

Clinical Consequences

Bone metastases lead to significant morbidity: pain, impaired mobility, hypercalcemia, pathologic fracture, spinal cord or nerve root compression, and bone marrow infiltration. Spinal instability is the cause of back pain in 10% of cancer patients (124). Metastatic destruction of bone reduces its load-bearing capabilities, initially producing trabecular disruption and microfractures and subsequently total loss of bony integrity. Rib fractures and vertebral collapse are most common, resulting in loss of height, kyphoscoliosis, and a degree of restrictive lung disease. However, the fracture of a long bone or epidural extension of tumor into the spine causes the most disability. The probability of developing a pathologic fracture increases with the duration of metastatic involvement. It is therefore paradoxically more common in patients with disease confined to bone who have a relatively good prognosis. Because a fracture is so devastating to a cancer patient, it is important to predict which metastatic sites are at risk of fracture for a particular patient, to use surgery prophylactically, and to administer long-term bisphosphonates (125).

Patients with osteolytic metastases have a high baseline serum calcium level. Hypercalcemia affects 10% to 40% of the oncology population during the course of their illnesses (126). The extent of metastatic bone disease does not correlate with hypercalcemia (119). The pathophysiologic mechanisms of pain in patients with bone metastases in the absence of a fracture are still unclear. The presence or intensity of pain does not correlate with the type of tumor, location, number and size of metastases, gender, or age of patients (127). Although approximately 80% of patients with breast cancer develop osteolytic or osteoblastic metastases, approximately two-thirds of demonstrated sites of bone metastases are painless (33).

The main complications of vertebral metastases are vertebral collapse, radiculopathy, and epidural spinal cord compression. Collapse of vertebral bodies is particularly frequent in the thoracic spine. Radiculopathies can occur at any level; patients feel the pain in the spine, deep in the muscles innervated by the affected nerve root, and in the corresponding dermatome.

Metastatic spinal cord compression is a serious complication of vertebral metastases (see Back Pain and Metastatic Epidural Spinal Cord Compression, later in this

chapter).

Clinical Imaging

The frequency of detection of metastatic disease varies considerably with the type of primary tumor and with the methodology used for detection. For some types of tumors, such as breast carcinoma, skeletal metastases are readily identifiable by imaging studies. For other conditions, such as chordoma, disseminated skeletal metastases are often evident at autopsy but rarely apparent during the patient's life.

Four clinical imaging methods are commonly used to help identify and characterize skeletal metastases: plain film radiography, CT scanning, radioisotope scanning, and MRI (see Chapter 14). FDG-PET scanning is currently an area of intense clinical research.

Radiography has proven useful for evaluating symptomatic sites and for confirming findings on other imaging studies. It is poorly suited for screening because of its low sensitivity. A positive radiograph result confirms the presence of metastasis, but a negative radiograph result does not rule it out. For patients with multiple myeloma, a radiographic survey is still valuable because of the relatively poor sensitivity of the radioisotope scan. The appearance of a radiograph may help distinguish metastases from other conditions and also help identify the primary tumor. Bone density must change by approximately 40% before plain radiography can identify bone metastases.

In contrast to plain radiography, bone scintigraphy can detect change of 5% to 10% in bone density. Bone scintigraphy results are positive in 14% to 34% of patients who have no radiographic evidence of bone metastases. However, the method is less sensitive for the detection of purely osteolytic metastases.

For approximately 25 years, the radioisotope bone scan has been the standard initial imaging method for detection of skeletal metastases. Tracer accumulates in the reactive new bone formed in response to the lesion. The amount of accumulation depends on the level of blood flow. Thus, although most metastatic lesions are *hot*, some, particularly aggressive metastases, are *cold* because of the complete absence of reactive bone or poor blood flow. Tracer may accumulate diffusely throughout the skeleton (super scan). This occasionally occurs in disseminated skeletal disease, leading to the false impression of a normal scan result.

Tracer accumulation may occur at any skeletal site with an elevated rate of bone turnover. It is thus nonspecific and may accompany trauma (even remote trauma), infection, arthropathy, or even acute osteopenia of disuse. In a patient with a known primary tumor, a scan showing multiple lesions strongly suggests metastases. However, only 50% of solitary foci represent metastases, even in patients with cancer. Because of this lack of specificity, positive scan results require radiographic correlation.

Advances in isotope scanning methods have improved the detection of metastases. One of the most important of these is single photon emission computed tomography (SPECT) scanning. SPECT imaging has improved both the sensitivity and the specificity of bone scanning (128). SPECT proves useful in such an evaluation because it allows for precise localization of a lesion to the vertebral body, disk space, or vertebral arch (129). This anatomic distinction is necessary for accurate diagnosis of the underlying condition detected by the bone scan. Most bony abnormalities result in focal areas of abnormal tracer activity, but do not affect all components of a vertebra with equal frequency, or do not have a random pattern of involvement. Vertebral diseases tend to conform to predictable patterns that can be more readily identified by SPECT than planar imaging. Other isotope scanning techniques have shown varying degrees of promise. Quantitation of whole body diphosphonate uptake has been disappointing. FDG-PET scanning detects abnormal areas of glucose metabolism. FDG-PET can detect prostate carcinoma metastases to bone with moderate sensitivity (65%) and high specificity (98%) and may have some value in lesion detection (130). However, FDG does not accumulate in Paget's disease and thus may prove useful for separating Paget's disease and other benign conditions from metastases or sarcomatous degeneration (131). Currently, no established clinical role exists for bone PET scanning.

Bone marrow scanning is more sensitive than conventional bone scanning for the detection of metastases from prostate carcinoma (132). In one study, bone marrow imaging with technetium 99m anti–non-specific cross-reacting antigen–95 monoclonal antibody detected almost twice the number of lesions observed on conventional methylene diphosphonate scans; however, the number of patients identified as having metastases was the same (13 in both instances) (133).

For certain types of primary tumors, especially lymphomas and soft tissue sarcomas, gallium scanning may be a useful staging tool, detecting metastases that would not otherwise be observed (134). It may also be helpful in following the effects of treatment in these patients (135).

CT scanning has proven minimally useful for the detection of skeletal metastases. Although CT is more sensitive than conventional radiography for the detection of destructive bone lesions, it is a cumbersome tool for screening the entire skeleton. It may help confirm suspicions raised by bone scans and aid in clarifying which anatomic sites are affected. CT can detect metastases within bone marrow before bone destruction has occurred. The lesion manifests as an increase in attenuation of the normally fatty bone marrow. CT is superior for diagnosing early metastatic involvement of bone, particularly of the spine (118).

MRI is highly sensitive to skeletal metastases, in large part because of its ability to demonstrate abnormalities in bone marrow. Because bone marrow (including hematopoietic or *red* marrow) contains a high percentage of fat, T1-weighted MRIs generally reveal metastases as focal areas of low signal intensity. Lesions differ from normal deposits of red marrow on T1-weighted images because they are more localized. Other advantages of MRI scanning include delineation of the whole spine, identification of multiple sites of cord and vertebral involvement, the paravertebral epidural extension, and integrity of the spinal cord. It also allows for differentiation between traumatic, osteoporotic, or pathologic fractures and compressions without the invasive techniques. Unfortunately, MRI often cannot distinguish among changes that are caused by treatment, fracture, and tumor. MRI can demonstrate metastases that are not apparent on radioisotope bone scans (136), and it is well suited to detecting spinal metastases. Planar scintigraphy detects approximately one-third to two-thirds of the lesions revealed by MRI. Some authors contend that SPECT makes the two techniques comparable, with MRI better for vertebral body lesions and SPECT better for the posterior elements (137).

Advantages of the isotope scan include a large field of view, inexpensive radiopharmaceuticals, low morbidity, and the ability to provide functional and vascular information. MRI may be a simpler and faster method for evaluating the axial skeleton, but is less well suited to screening the long bones. MRI, like bone scan, can be problematic for the *super scan* of diffuse bone marrow replacement. A number of specific categories exist of patients for whom bone scanning is superior to MRI. They include patients with contraindications to MRI, such as claustrophobia and pacemakers, and patients with thyroid cancer who receive iodine for scanning. MRI is preferred for patients with bone marrow diseases, such as myeloma and Waldenström's macroglobulinemia (138).

The factors that influence the choice of imaging modalities continue to evolve. Progress in MRI is rapid, and practical, cost-effective methods for evaluation of the entire skeleton probably are forthcoming. Until this happens, isotope scanning, especially with SPECT imaging, continues to have an important role.

The integration of multiple imaging modalities in the assessment of musculoskeletal neoplasia is complex (139). A combination of conventional radiography and MRI is the best way to assess most soft tissue masses. Initial bone scintigraphy is optimal for skeletal screening without localizing symptomatology that includes axial and appendicular skeleton. Optimal screening of the axial skeleton in the presence of clinical symptomatology or with a strong suspicion of axial skeletal metastases or pathology requires a total spine screening examination with MRI and specialized pulsing sequences. CT is reserved primarily for assessment of cortical and juxtacortical lesions, fracture fragment positioning and configuration, and characterization of lesion matrix calcification or ossification when conventional radiographic results are indeterminate.

Radionuclide bone scintigraphy still is the first choice in routine follow-up of asymptomatic patients with metastatic disease of the skeleton. A negative scan result requires reevaluation with other findings, with emphasis on the possibility of a false-negative result. The best approach for screening for metastases in patients with local symptoms or pain is a combination of radiography and MRI. Approximately 30% of patients with known cancer have benign causes of radiographic abnormalities (140). Most of these are related to degenerative diseases and are usually easy to diagnose.

Prognosis

In general, the prognosis for patients presenting with bone metastases is poor (Table 35-15). Patients with fewer metastases or solitary lesions appear to have a better outlook than those with multiple metastatic deposits. Once tumor cells spread to the skeleton, the disease is usually incurable and it may be best to shift the focus of treatment to palliation. Patients suffering from metastatic breast disease survive 34 months on average after detection of the first metastasis, with a range of 1 to 90 months (141). Survival with metastatic prostate cancer averages 24 months, and lung cancer patients have a prognosis less than 1 year (98).

	Incidence in advanced disease (%)	Median survival (mo)	5-Yr survival (%)
Myeloma	95–100	20	10
Breast	65–75	24	20
Prostate	65–75	40	25
Lung	30–40	<6	<5
Kidney	20–25	6	10
Thyroid	60	48	40
Melanoma	14–45	<6	<5

TABLE 35-15. Incidence and prognosis of bone metastases

Factors that influence prognosis in patients with metastatic disease include the interval between primary diagnosis and the development of metastases, and the Karnofsky performance status (Table 35-16). The Karnofsky score after palliative irradiation reliably predicts survival (142). Other factors that predict survival include the site of the primary disease and whether single or multiple bone metastases are present (143,144,145,146,147 and 148). No one as yet has developed a classification system, such as a staging system, that can predict the overall prognosis and subsequent patterns of metastatic spread from multiple factors. Staging systems currently in use predict probability of disease control and patterns of failure.

Grade	Performance level
100	Normal, no complaints, no evidence of disease
90	Able to carry on normal activity; minor signs or symptoms of disease
80	Normal activity with effort, some signs or symptoms of disease
70	Cares for self; unable to carry on normal activity or to do active work
60	Requires occasional assistance, but is able to care for most of his or her needs
50	Requires considerable assistance and frequent medical care
40	Disabled, requires special care and assistance
30	Severely disabled, hospitalization indicated; death not imminent
20	Very sick, hospitalization necessary, active supportive treatment necessary
10	Moribund, fatal processes, progressing rapidly
0	Dead

TABLE 35-16. Karnofsky performance status

The incidence of distant metastases in patients with prostate carcinoma increases with the presenting stage of disease, occurring in 21% of patients with stage A $_2$ (T_{1b}) and B (T_2) disease, 40% of patients with stage C (T_3) disease, and 62% of patients with stage D_1 (T_4) disease presentations (145). The risk for the subsequent development of distant metastases diminishes significantly when the primary tumor is controlled. Survival rates after an isolated recurrence of disease in the prostate depend on the initial stage of the disease and the disease-free interval from initial treatment. With or without associated local recurrence of the prostate carcinoma, the survival rate is significantly worse when distant metastases are present. The survival rates at 5 and 10 years after pelvic recurrence alone equal 50% and 22%, respectively; with distant metastases, the survival rate at 5 years is 20% and less than 5% at 10 years (145,146). Age significantly influences the 5-year survival rate for patients with prostate carcinoma, independent of race and extent of disease. Five-year survival rates are only 74% with localized disease, 55% with regional disease, and 29% with distant metastases in prostate carcinoma patients older than 75 years. In contrast, the 5-year survival rates are 86% (p <.01), 73% (p <.01), and 31% (p <.05), respectively, in patients 65 to 74 years of age (147,149).

The distribution of metastases on bone scans also has prognostic significance. Patients with metastatic carcinoma survive significantly longer if their metastases respond to salvage hormone therapy and do not spread beyond the pelvis or lumbar spine (146). Diffuse bone metastases tend to occur in patterns of anaplastic histologic features, visceral metastases, and lymph node metastases (146).

After bone metastases diagnosis, the median survivals are 12 months for patients with breast carcinoma, 6 months for patients with prostate carcinoma, and 3 months for patients with lung carcinoma. The median survival rate is 48 months when metastases are confined to the skeletal system in patients with breast carcinoma, but it decreases to only 9 months if visceral metastases also are present (148,150).

VISCERAL PAIN

Visceral infiltration is a common cause of pain in cancer patients. Table 35-17 lists the common pain syndromes associated with tumor infiltration.

Esophageal mediastinal pain
Shoulder pain from diaphragmatic infiltration
Epigastric pain from pancreatic or other upper abdominal tumor
Right upper quadrant pain from hepatic capsule distension
Left upper quadrant pain from splenomegaly
Diffuse abdominal pain from abdominal or peritoneal disease with or without obstruction
Pleural infiltration
Gastrointestinal perforation
Biliary obstruction
Ureteric obstruction
Suprapubic pain from bladder infiltration
Perineal pain from infiltration of rectum or perirectal tissue

TABLE 35-17. Pain syndromes related to tumor infiltration of viscera

Mechanism

Visceral pain is defined as pain emanating from organs in the thorax, abdomen, or pelvis. The main factors capable of inducing pain in visceral structures include abnormal distension and contraction of hollow visceral walls, rapid stretching of the capsules of solid visceral organs, ischemia of visceral musculature, formation and accumulation of algogenic substances, direct action of chemical stimuli on compromised mucosa, and traction or compression of ligaments, vessels, or mesentery (151,152 and 153). Mechanical insult to normal mucosa causes no pain, implying that preceding inflammation is necessary.

Localization of visceral pain is difficult. Afferent nerves from viscera to the spinal cord are relatively few in number and account for only 2% to 15% of all afferents to the spinal cord (154,155). These visceral nociceptive afferents can excite many second-order neurons in the spinal cord, which in turn generate extensive divergence within the CNS, sometimes involving supraspinal loops. Such a divergent input activates several systems (sensory, motor, and autonomic) and thus triggers the general reactions that are characteristic of visceral nociception: a diffuse and referred pain and prolonged autonomic and motor activity (151).

The origin of nociceptive impulses determines the site and type of pain. Visceral pain is either true, referred, nonreferred parietal, or referred parietal. True parietal abdominal pain is dull and poorly localized; it occurs in the region of the epigastric, periumbilical, or lower midabdominal region. Patients may describe the pain as gnawing or cramping, and often it is associated with nausea, sweating, pallor, and, occasionally, vomiting. Referred visceral pain is more precisely localized, usually in the dermatomal or myosomal regions of the same segments of the spinal cord involved. Parietal pain may localize directly over the organ without referral.

Patients locate referred parietal pain in a body region distant from the nociceptive site. For example, patients complain of pain in the shoulder area when the cause is inflammation in the middle of the diaphragm.

Tumor invasion of adjacent blood vessels can generate nociception. Mechanisms include perivascular lymphangitis causing vasospasm, occlusion with resultant ischemia, venous engorgement, and edema.

Obstruction of hollow viscera from tumor with resultant distension may cause pain. Distension causes intense contraction of smooth muscle that generates nociception. Patients experience visceral pain that is poorly localized and diffuse but usually localized in the same dermatomal area of the cord segments of the viscera.

Pain from tumor involvement of parenchymal viscera such as liver, spleen, pancreas, and kidney typically results from acute distension of the pain-sensitive fascia. These fascia contain many mechanicoreceptors, and nociception occurs when they are acutely stretched or placed under tension. This type of pain is poorly defined, dull, and generally located in the dermatomal region of the involved organ. The properties of visceral pain are discussed in Chapter 60, Chapter 61, Chapter 62, Chapter 63, Chapter 64, Chapter 65, Chapter 66, Chapter 67, Chapter 68, Chapter 69, Chapter 70, Chapter 71, Chapter 72, Chapter 73 and Chapter 74.

Pain Descriptions by Site

Esophageal cancer usually elicits a history of heartburn, a burning or gnawing substernal discomfort. Patients usually describe the pain as being located in the epigastric or retrosternal areas, which often radiates to the back or interscapular region. The pain occurs often after eating and possibly relates to body position changes such as reclining or bending forward (see Chapter 63).

Gastric pain has a colicky quality associated with delayed emptying and slowed motility and digestive symptoms. The pain also localizes in the epigastrium, is usually sharply focused, and may radiate into the back (see Chapter 66).

Small intestine pain is usually crampy or colicky and localized in the periumbilical area. The cause of pain is usually a lesion causing distension with resultant abnormal mobility. Eating usually precipitates the pain, and defecation or fasting may afford relief. Colon pain tends to occur in the lower abdomen, varying according to which portion of the colon is affected. Change in bowel habits and occult blood in the stool often accompany symptoms of discomfort. Peritoneal carcinomatosis is frequently found with abdominal tumors and advanced ovarian cancer. Pain may result from peritoneal irritation, mesenteric involvement, and abdominal distension with ascites. Bowel obstruction often complicates peritoneal carcinomatosis (see Chapter 69).

Liver parenchyma is insensitive to tumor distension and associated chemical changes. Right upper quadrant pain from liver pathology occurs only when there is acute distension of the liver capsule. It is usually a dull aching sensation in the right upper abdominal quadrant and flank and is often referred to the right scapula and shoulder (see Chapter 67).

Perineal pain, worse when sitting and with an aching and pressurelike quality is the first and, can be for a long time, the only symptom of pelvic tumors (see Chapter 70). The pain may be associated with tenesmus. Fistulas and recurrent infections can aggravate the pain syndrome. Ureteral obstruction is frequent. Direct invasion of the sacrum, sacral roots, plexus, or cauda equina is a frequent complication. Pain from the fundus of the uterus typically occurs in the hypogastrium. Pain originating from the uterine cervix is commonly referred to the low back and sacral area as well as to the hypogastrium. Ovarian pain results from stretching of the surrounding peritoneum to which the ovaries adhere.

NEUROPATHIC PAIN

The following are among the most common cancer pain syndromes that present with a major neuropathic component.

Neuropathic Pain Secondary to Cancer-Related Pathology in Cranial Nerves

Painful cranial neuralgias may occur secondary to base of skull metastases, leptomeningeal metastases, or head and neck cancers (156). Base of skull metastases produce several well-described pain syndromes (157) and are often associated with primary tumors of the breast, lung, and prostate. Constant localized aching pain from bone destruction and neurologic deficits from progressive cranial nerve palsies are cardinal manifestations.

The middle cranial fossa syndrome presents with facial numbness, paresthesias, or dysesthetic neuropathic pain in the distribution of the second or third divisions of the trigeminal nerve. Associated motor deficits include weakness in the masseter or temporalis muscles or abducens palsy.

The jugular foramen syndrome may present as glossopharyngeal neuralgia (158). This pain is distributed over the ear or mastoid region and may radiate to the neck or shoulder. Associated deficits include a Horner's syndrome and paresis of the palate, vocal cords, sternocleidomastoid muscle, or trapezius muscle. Some attribute this syndrome to leptomeningeal metastases (159) and local extension of head and neck malignancies (160). It is sometimes associated with syncope (161).

A syndrome that clinically mimics classical trigeminal neuralgia can occur secondary to tumors in the middle or posterior fossa (161,162,163,164 and 165) or from leptomeningeal metastases (159). This association between trigeminal neuralgia and tumor is uncommon, and cancer patients with a new onset of trigeminal neuralgia should have careful imaging of the base of the skull (163). Trigeminal neuralgia secondary to tumor usually presents as a constant, dull, well-localized pain related to the underlying pathology involving bone and other somatic structures associated with paroxysmal episodes of lancinating or throbbing pain.

Squamous cell carcinomas of the face, which commonly extend by perineural spread, are an important cause of complex trigeminal syndromes (166). Perineural spread, when present, typically involves cranial nerves V and VII because of their extensive subcutaneous distributions (167). Glossopharyngeal neuralgia commonly results from local nerve infiltration in the neck or base of skull. It typically produces throat and neck pain, radiating to the ear and mastoid and is aggravated by swallowing. Occasionally, syncope accompanies severe pain (168,169).

Cervical Plexopathy

Tumor infiltration of the cervical plexus can produce several pain syndromes, depending on the pattern of nerve involvement (170) (see Chapter 55). The upper four cervical ventral rami join to form the cervical plexus. The plexus lies close to the C-1 through C-4 vertebrae. The four cutaneous branches emerge from the posterior border of the sternocleidomastoid muscle into the posterior triangle of the neck. Because sensory afferents from the cervical plexus enter the spinal tract of the trigeminal along with the sensory afferents from cranial nerves V, VII, IX, and X, nociceptive referral patterns from the face and neck overlap. Symptoms usually include local pain with lancinating or dysesthetic components referred to the retroauricular and nuchal areas (lesser and greater auricular nerves), preauricular area (greater auricular nerve), anterior neck and shoulder (transverse cutaneous and supraclavicular nerves), and jaw (156). Associated findings include ipsilateral Horner's syndrome or hemidiaphragmatic paralysis. CT or MRI evaluation may be necessary to rule out associated epidural cord compression. Common clinical settings include local extension of a head and neck tumor or cervical lymph node metastases. In patients with head and neck tumors who have undergone radical neck dissection followed by radiation treatment, new onset or worsening pain includes a differential diagnosis of postradical neck dissection syndrome or tumor recurrence. Infections often complicate and exacerbate pain.

Tumor-Related Mononeuropathy

The most commonly described tumor-related painful mononeuropathy is intercostal nerve injury secondary to rib metastases with local extension. Patients with tumor

invasion of the sciatic notch may present with symptoms resembling sciatica.

Radicular Pain and Radiculopathy

Radiculopathy is a pattern of pain corresponding to the dermatomal territory innervated by the dorsal spinal roots. Patients with cancer-related radiculopathy may present with pain on either or both sides of the midline. The pain tends to be unilateral in the cervical and lumbosacral regions and bilateral in the thorax. In cancer patients, radiculopathy typically results from epidural tumor mass or leptomeningeal metastases. Coughing, sneezing, recumbency, and strain exacerbate the pain, which often has dysesthetic qualities. Radiculopathy may also develop secondary to leptomeningeal metastases. Clinically, leptomeningeal metastases may produce multifocal neurologic signs and symptoms at a variety of levels, including cranial neuralgias. Most commonly, they produce a generalized headache with radicular pain in the low back and buttocks (171).

Leptomeningeal Metastases

Infiltration of tumor into the subarachnoid space produces carcinomatous meningitis. Carcinomatous meningitis is diffuse involvement of the leptomeninges by infiltrating malignant cells. Over the past 15 years, oncologists and neurologists have increasingly reported diffuse leptomeningeal metastases of extracranial malignant tumors (171,172 and 173). This complication occurs most commonly with adenocarcinoma of the lung and breast, lymphomas, and melanomas.

Carcinomatous meningitis may occur in up to 5% of patients with breast cancer (174). Although the incidence of metastatic lesions in the brain is high in patients with small cell carcinoma, clinical problems from metastases to the spinal cord or leptomeninges have been rare (175). Meningeal involvement was once a common complication of acute lymphoblastic leukemia, before the advent of CNS prophylaxis. Now this problem occurs in fewer than 5% of patients. Carcinomatous meningitis develops in 1% to 8% of patients with systemic cancer (176), and has a poor prognosis with a median survival of 3 to 6 months (177). Untreated, the prognosis is dismal, with an average survival of 6 weeks (178).

Tumor cells may reach the leptomeninges by several different routes. This may result from direct extension of a parenchymal brain metastasis. Alternatively, cells may enter the CSF as a direct extension from a paravertebral lymph node metastasis, infiltrating along a spinal nerve root into the spinal canal. The tumor may also seed hematogenously via the capillaries of the arachnoid villi. Leptomeningeal tumors can encase the spinal and cranial nerves or may directly invade them and produce demyelination and axon destruction.

The hallmark of the clinical presentation of carcinomatous meningitis is the simultaneous occurrence of symptoms and signs at more than one area of the neuraxis. The clinical presentation of leptomeningeal metastasis is pleomorphic and commonly affects the cerebral hemispheres, cranial nerves, or spinal cord, and its roots. It is best to describe the symptoms by their location along the neuraxis. Symptoms are usually multifocal and more diffuse than one discrete lesion allows. Symptoms include headache, back and radicular pain, multiple cranial and spinal nerve involvement, and change in mental status. Pain may occur in 30% to 76% of cases (171,179). Table 35-18 lists the frequency of spinal cord symptoms and signs in patients with carcinomatous meningitis.

Symptoms or signs	Percentage
Weakness	33
Paresthesia	31
Back pain	25
Radicular pain	19
Bowel and bladder dysfunction	13
Reflex asymmetry	67
Weakness	4
Cauda equina syndrome	33
Sensory loss	31
Positive straight leg raise sign	13
Decreased tone of anal sphincter	12
Nuchal rigidity	11

TABLE 35-18. Frequency of spinal cord symptoms and signs in patients with carcinomatous meningitis

Identification of malignant cells in CSF is diagnostic. In patients with negative CSF cytology results, MRI and contrast- enhanced CT may be both suggestive and diagnostic and are probably most useful in demonstrating bulky disease (180).

Brachial Plexopathy

Brachial plexopathy can present from either compression or tumor infiltration of the brachial plexus from contiguous structures, such as axillary or supraclavicular nodes, or by tumors in the apex of the lung. Neuropathic pain caused by tumor infiltration of the brachial plexus usually stems from lymph node metastases from breast carcinoma or lymphoma, or direct extension from lung carcinoma (i.e., Pancoast's tumor). The designation of Pancoast's tumors relates to the symptom complex or syndrome caused by a tumor arising in the superior sulcus of the lung that involves the sympathetic nerve trunks, including the stellate ganglion. Superior pulmonary sulcus syndrome associated with a Pancoast's tumor is defined as progressively intense pain in the shoulder and ulnar side of the arm, associated with sensory and motor deficits and Horner's syndrome caused by tumor (25).

In neoplastic brachial plexopathy, pain is usually the first symptom in 85% of patients and often precedes neurologic deficits (181,182). The key features of malignant plexopathy are the neuropathic nature of the pain, with numbness, paresthesias, allodynia, and hyperesthesias. Typically, the pain begins in the shoulder girdle where it is often described as pressurelike or aching and may radiate to the elbow, medial forearm, and fourth and fifth fingers. It may also appear to localize at the posterior arm or elbow. The patient may report a burning quality to the pain, with hyperesthesia along the ulnar aspect of the forearm.

Involvement of the lower plexus occurs when tumor arises from the lung apex; associated pain and dysesthesias involve the elbow, medial forearm, and fourth and fifth fingers (C-7, C-8, and T-1). Upper plexus involvement (C-5, C-6), if it occurs alone, usually develops into a panplexopathy. Upper plexus pain typically involves the shoulder girdle, with burning pain in the tips of both the index finger and thumb. Lung tumors can also present with pain involving the axilla and upper chest wall in the distribution of the intercostobrachial nerve (183).

In more than 75% of patients, neurologic signs follow the appearance of dysesthesias. These signs include focal weakness, atrophy, and sensory changes in the distribution of C-7, C-8, and T-1 roots (181). Early loss of the triceps reflex usually occurs. Associated findings can include Horner's syndrome and adjacent vertebral disease. Such patients are at high risk for concurrent epidural extension (179,184). For patients with brachial plexopathy secondary to tumor, we recommend imaging the contiguous epidural space before radiation treatment so that the radiation oncologist can include this area in the treatment field. A Spurling's maneuver * can help to identify the spinal canal as the site of pathology (185). Paraspinal involvement may help to predict epidural extension of tumor.

Neuroradiologic evaluations of choice for brachial plexopathy are CT and MRI. However, Ahmad and colleagues (186) demonstrated that FDG-PET scanning is a useful tool in the evaluation of patients with suspected metastatic plexopathy, particularly if other imaging studies are normal. It may also be useful in distinguishing between radiation-induced and metastatic plexopathy. Electromyography can also help distinguish malignant brachial plexopathy from radiation-induced brachial plexopathy or cervical radiculopathy (Table 35-19). In patients with brachial plexopathy, electromyography usually shows fibrillation potentials and positive waves (evidence of denervation) in affected muscles. Radiation-induced brachial plexopathy is discussed in a following section. Neoplastic brachial plexopathy may differ clinically from radiation-induced plexopathy. Patients with neoplastic plexopathy have a higher frequency of pain as the initial and predominant symptom, a shorter duration of symptoms prior to diagnosis of plexopathy, and a higher incidence of Horner's syndrome (187).

	Tumor infiltration	Radiation fibrosis	Reversible radiation injury
Incidence of pain as initial predominant symptom	80%	10%	40%
Severity of pain	Moderate to severe severe in 22% of patients	All the moderate severe in 15% of patients	Mild
Nature of pain	Dull aching in shoulder. Excruciating pain in elbow and other aspect of hand; occasional dysesthesia, burning, or freezing sensations	Aching shoulder pain; glumes. Paresis in hand and forearm	Aching shoulder pain; paresthesias in hand and forearm
Typical location of pain	Shoulder, upper arm, elbow, radiating to fourth and fifth fingers	Shoulder, wrist, hand	Hand, forearm
