Dedication

To my wife, Deborah, whose love, patience and understanding makes my work possible.

Foreword to the Twelfth Edition

In 1940, Emil Novak published the first edition of what has been known as "Novak's Textbook." Dr. Novak was a mentor and exemplar to so many of those of us who studied gynecology and gynecologic pathology. He clearly saw the importance of this study and this field of medicine, and he provided each of us who have followed in his footsteps with a wonderful example. To us, Emil Novak was the ultimate doctor, a man who saw the study of medicine as a way to provide aid to those who suffered illness. We are indebted to him for having begun this work, taught so many who have worked in this specialty, and provided the means by which his textbook could carry on his work.

It is a pleasure and a privilege to have been asked to pen this foreword, as it has been my pleasure and privilege to have worked on this textbook and to have as colleagues in this endeavor so many superb physicians. Dr. Novak would endorse and be thankful that the text is being updated for your use. He knew, as we do, that the pursuit of academic medicine is imperative to the development of medicine in general and our field in particular. In order to provide you with the same superb resource that Emil Novak began 55 years ago, Novak's **Textbook of Gynecology** must be updated, and a new generation of men and women must accept his challenge.

Medicine as a profession has changed and will continue to change, but the basic message that Emil Novak presented in the first textbook is the same: doctors must be concerned with the welfare of patients, and in order to accomplish this task, they must have access to the latest and best information and training. Jonathan Berek and his colleagues are well schooled in the legacy of Emil Novak and all of those who have worked on this book. It is with confidence in the quality of their work that I endorse this 12th edition of **Novak's Gynecology**.

J. Donald Woodruff, MD
Richard W. TeLinde Professor Emeritus
Johns Hopkins University School of Medicine
Baltimore, Maryland

*Dr. J. Donald Woodruff passed away in 1996. He was a particularly gifted teacher and clinician who helped guide the development of our specialty. I feel it is important to retain the thoughtful comments he contributed to our twelfth edition for this edition of **Novak's Gynecology**.*

Jonathan S. Berek

Preface to the Thirteenth Edition

Novak's Gynecology, 13th edition, has been thoroughly updated and revised to be certain that its contents and bibliography are current and accurate. Its essence is the same as the original—a comprehensive general textbook in gynecology. The substance reflects the wealth of information that has emerged and evolved during the 62 years since the inception of *Novak's Textbook of Gynecology*. It is an honor to have been asked to continue to shepherd this important book and I hope will retain its value to inform and assist our colleagues for many years.

The textbook, originated by the faculty of the Johns Hopkins University School of Medicine, continues to reflect the contributions of that great institution. The book was inaugurated by Dr. Emil Novak, a pioneer in gynecology and pathology. After the fifth edition and subsequent death of Dr. Novak in 1957, many physicians on the faculty of Johns Hopkins, and subsequently some members of the Vanderbilt faculty, have helped carry the torch—Dr. Edmund R. Novak through the ninth edition in 1979; Drs. Howard W. Jones, Jr. and Georgeanna Seegar Jones through the tenth edition in 1981; and Drs. Howard W. Jones, III, Lonnie S. Burnett, and Anne Colston Wentz through the 11th edition in 1988. These editors, assisted by many contributors who have been faculty at Johns Hopkins, especially Drs. J. Donald Woodruff and Conrad G. Julian, have helped define the specialty of gynecology over the latter half of the 20th century. These physicians and authors are responsible for the ideas that shaped the specialty of gynecology as we know it today—its surgical and medical therapies, reproductive endocrinology, assisted reproductive technologies, gynecologic oncology, urogynecology, and infectious diseases. As a graduate of Johns Hopkins University School of Medicine, I am proud to contribute to that rich tradition.

Starting with the twelfth edition, this textbook utilized a new format. The design of the book was established by Dr. Leon Speroff and his colleagues in the textbook *Clinical Gynecologic Endocrinology and Infertility* and was adapted for the book *Practical Gynecologic Oncology*. This presentation style should facilitate the study of gynecology for the student as well as the specialist.

Novak's Gynecology, 13th edition, is presented in six sections. The first, "Principles of Practice," includes the initial assessment of the gynecologic patient, the history and physical examination, and communication skills. This section addresses ethical principles of patient care, quality assessment and improvement, and the epidemiology of gynecologic conditions. The second section, "Basic Sciences," summarizes the scientific basis for the specialty—atomy and embryology, molecular biology and genetics, and reproductive physiology. The third section, "Preventive and Primary Care," reflects the importance of primary health care for women, which has evolved to address preventive care, screening, family planning, sexuality, and common psychiatric problems. The fourth section, "General Gynecology," reviews benign diseases of the female reproductive tract, the evaluation of pelvic infections, pain, intraepithelial diseases, the management of early pregnancy loss and ectopic pregnancy, the evaluation of benign breast disease, and the operative management of benign gynecologic conditions. The fifth section, "Reproductive Endocrinology," summarizes the major disorders affecting the growth, development, and function of women from puberty through menopause. The sixth section, "Gynecologic Oncology," covers malignant diseases of the female reproductive tract and breast cancer.

I have purposely abbreviated the discussion of the historical development of the subjects in each chapter. Space limitations have required a shift in emphasis from the achievements of the past to the relevant issues of the present.

I am especially grateful to the many individuals who contributed to this book. Rebecca Rinehart provided superb editorial assistance, manuscript review, and revision. Drs. Paula Hillard and Eli Adashi served as excellent Assistant Editors. Tim Hengst, an outstanding medical illustrator, designed and created the original artwork. At the publishers, Lippincott Williams & Wilkins, Ms. Lisa McAllister supported the editorial process with great enthusiasm. Working with her, Ray Reter, Steven Martin and the rest of their team skillfully produced the manuscript. Expert secretarial support was provided by Kevin Wong and Sergio Huidor.

I acknowledge the efforts of my mentors and colleagues—Dean Sherman Mellinkoff, Drs. J. Donald Woodruff, Kenneth J. Ryan, Isaac Schiff, J. George Moore, William J. Dignam, Gautum Chaudhuri, and Neville F. Hacker. Each of these physicians and scholars provided me with guidance, wisdom, and encouragement during the years we shared at our respective university medical schools.

My thanks to Nicole Kidman, the chair of the advisory board for the UCLA Women's Reproductive Cancer Program—whose support and friendship has helped stimulate this project.

I hope that this book will be a useful resource for my colleagues and for students of the specialty of gynecology. I look forward to the continued impact of the specialty on the enhancement of health care for women throughout the world.

Jonathan S. Berek

Preface to the First Edition

Since the plan and scope of this book represent something of a departure from those followed in other textbooks of gynecology, the author feels impelled to state the ideas which furnished the incentive for the preparation of this work, and which dictated its character and scope.

First of all, no especial apology seems necessary for the combined title. While gynecology was formerly often spoken of as a branch of surgery, this is certainly not its present status. Only a small proportion of gynecological patients require surgical treatment. On the other hand, the biological aspects of gynecology have assumed vast importance, chiefly because of the amazing developments in the field of reproductive physiology and endocrinology. Many of these advances find daily application in the interpretation and management of functional disorders in women. In other words, female endocrinology is now an integral and important part of gynecology and it is so considered in this book.

Second, it has always seemed to me that the great majority of readers of textbooks on gynecology must be not at all interested in the details of operative technique, to the consideration of which most authors have devoted many pages. Certainly this applies to the general practitioner, while medical educators are now generally agreed that the medical student should not be burdened with such details in his undergraduate years. Since this book is designed for these two groups primarily, the indication seemed clear to omit the consideration of operative details. The plan followed is to carry the patient up to the point of operation, and to discuss the indications, scope and purpose of the latter, without going into descriptions of the technique itself.

Diagnosis and treatment have been accented throughout the book, as I believe most readers would wish. The traditional chapters on anatomy, history-taking, and methods of examination have been boiled down to the essentials. On the other hand, functional disorders, including especially the large group of gynecological endocrinopathies, have been treated rather elaborately, in keeping with the avowed plan of covering the combined fields of gynecology and female endocrinology. The list of references appended to each chapter makes no pretense of exhaustiveness, and preference has been given to publications most worth while, those most recent, and those written in English. The pathological aspects of gynecological disease, so fundamental to a proper understanding of the whole subject, have received adequate but not disproportionate consideration.

In the consideration of various endocrine disorders a disturbing problem presented itself. In the discussion of endocrine preparations which might be indicated in treatment, there is no doubt that the mention of various products by their commercial names would have had some advantages. On the other hand, these have appeared to be definitely outweighed by the disadvantages of such a plan, apart from its questionable delicacy. These proprietary preparations are constantly multiplying, and their commercial names are being changed from day to day. For example, there are now well over forty estrogenic preparations on the market. It would be almost impossible, in any enumeration of such therapeutic products, to avoid omission of some of them, and this might be very unfair to products perhaps just as effective as those which might be included. A complete list published today is quite likely to be very incomplete within a few months.

The sensible plan seemed to be to rely on the intelligence and initiative of the reader, who should have no difficulty in ascertaining good commercial preparations of estrogen, progesterone, chorionic hormone or any other hormone principle to which reference is made in the treatment of various disorders.

It will be noted that the work is devoted to "straight" gynecology and male endocrinology and that it does not include a consideration of disorders in allied fields which concededly obtrude themselves frequently into the practice of the gynecologist. For example, many gynecologists include female urology in their practices, while anorectal and abdominal surgical problems are often encountered, as may be problems in almost any field of medicine. For textbook purposes, however, the line must be drawn fairly sharply, and the reader will naturally expect to go to the proper sources for information in any of these allied fields.

In short, the purpose of this book is to present to the reader as much information as is possible in as practical a fashion as possible on the subjects of gynecology and female endocrinology. Whether right or wrong, the ideas behind the book represent the crystallization of many years of teaching and practice in gynecology. The author's goal has been to produce a book which would not only be suited to the needs of the medical student, but which could be carried with him into the practice of his profession.

It is a pleasant obligation to express my indebtedness to those who have been helpful to me in the preparation of this book. To a number of my friends, especially Dr. R.B. Greenblatt, of Augusta, Georgia, I am grateful for the loan of illustrations; to Dr. E.L. Krieg, for the excellent colored illustrations as well as for other photographic work; to Mr. Chester Reather, for most of the photomicrographs; to Miss Eva Hildebrandt, technician in the Laboratory of Gynecological Pathology at The Johns Hopkins Hospital and to Sister Mary Lucy, technician at Bon Secours Hospital for help in the preparation of sections for microscopic illustration; to my artist, Miss Frances Shultz, for many of the illustrations; and to my faithful secretary, Miss Helen L. Clayton, for much help throughout the project. For permission to use illustrations which have appeared in previously published articles of my own I am indebted to the publishers of the Journal of the American Medical Association; the American Journal of Obstetrics and Gynecology; Surgery, Gynecology and Obstetrics; and the Bulletin of The Johns Hopkins Hospital.

Certain illustrations which appeared in one of my previous books, Gynecological and Obstetrical Pathology, do not have a credit line in the caption. For permission to use these I wish to thank WB Saunders Company, the publishers.

Finally, it is a genuine pleasure to acknowledge the efficient and wholehearted cooperation of the publishers, Little, Brown and Co., throughout the preparation of this work.

The practice of gynecology requires many skills. In addition to medical knowledge, the gynecologist should develop interpersonal and communication skills that promote patient–physician interaction and trust. The assessment must be of the “whole patient,” not only of her general medical status. It should include any apparent medical condition as well as the psychological, social, and family aspects of her situation. Environmental and cultural issues that affect the patient must be taken into account to view her in the appropriate context. This approach is of value in routine assessments, providing opportunities for preventive care and counseling on a continuing basis, as well as in the assessment of medical conditions.

Communication

Good communication is essential to patient assessment and treatment. The patient–physician relationship is based on communication conducted in an open, honest, and careful manner so that the patient’s situation and problems can be accurately understood and effective solutions determined. Good communication requires patience, dedication, and practice.

The foundation of communication is based on key skills: empathy, attentive listening, expert knowledge, and rapport. These skills can be learned and refined (1). After establishing the initial relationship with the patient, the physician must vigilantly pursue interviewing techniques that create opportunities to foster an understanding of the patient’s concerns (2). Trust is the fundamental element that encourages the patient to communicate her feelings, concerns, and thoughts openly, without withholding information.

Although there are many styles of interacting with patients and each physician must determine the best way that he or she can relate to patients, physicians must convey that they are able and willing to listen and that they receive the information with utmost confidentiality (3). **The Hippocratic oath demands that physicians be circumspect with all patient-related information.**

Variables that Affect Patient Status

Many external variables exert an influence on the patient and on the care she receives. Some of these factors include the patient’s “significant others”—her family, friends, and personal relationships (Table 1.1). These external variables also include psychological, genetic, biologic, social, and economic issues. Factors that affect a patient’s perception of disease and pain and the means by which she has been taught to cope with illness include her education, attitudes, understanding of human reproduction and sexuality, family history of disease, and, in some cases, need for attention (3,4 and 5). Cultural factors, socioeconomic status, religion, ethnicity, and sexual preference are important considerations in understanding the patient’s response to her care in both illness and health.

Patient
Age
History of illness
Attitudes and perceptions
Sexual preference
Habits (e.g., use of drugs, smoking)
Family
Patient’s status (e.g., married, separated, divorced)
Siblings (e.g., number, ages)
History (e.g., disease)
Environment
Socioeconomic environment
Religion
Culture and ethnic background

Table 1.1. Variables that Influence the Status of the Patient

We are all products of our environment, our background, and our culture. The importance of ascertaining the patient’s general, social, and familial situation cannot be overemphasized (1). The context of the family can and should be ascertained directly. The family history, including a careful analysis of those who have had significant illnesses, such as cancer, must be obtained. The psychological and sexual practices of the patient should be understood, and her functional level of satisfaction in these areas should be determined. **The physician must avoid being judgmental, particularly with respect to questions about sexual practices and preferences** (see Chapter 11 and Chapter 12).

Communication Skills

It is essential for the physician to communicate with a patient in a manner that allows her to continue to seek appropriate medical attention. Not only the words used, but also the patterns of speech, the manner in which the words are delivered, even body language and eye contact, are important aspects of the patient–physician interaction. The traditional role of the physician has been rather paternalistic, with the physician being expected to deliver direct commands and specific guidance on all matters (1). Patients are now demanding more balanced communication with their physicians, and although they do not in most cases command an understanding of medicine, they do expect to be treated with appropriate deference, respect for their intellect, and a manner more equal in stature with the physician (6). There is some evidence that giving the patient more control in the relationship with her doctor can lead to better health outcomes (3, 7, 8).

Physician–Patient Interaction

The pattern of the physician's speech can influence interactions with the patient. Some important components of effective communication between patients and physicians are presented in Table 1.2. For this communication to be effective, the patient must feel that she is able to discuss her problems fully. In addition, if the patient perceives that she participates in the decision and that she is given as much information as possible, she will react to the proposed treatment with lower levels of anxiety and depression. There is ample evidence that patient communication and understanding and treatment outcome are improved when discussions with physicians are more dialogue than lecture. In addition, when patients feel they have some room for negotiation, they tend to retain more information regarding health care plans (9).

The physician is:
A good listener
Empathetic
Honest
Caring
The physician uses:
Understandable language
Appropriate body language
A collaborative approach
Open dialogue
Appropriate emotional content
Humor and warmth
The physician is not:
Confrontational
Conclusive
Condescending
Overbearing
Authoritarian

Table 1.2 Important Components of Communication between the Patient and Physician: The Physician's Role

The notion of collaborative planning between patients and physicians has developed (9). This means that the patient becomes more vested in the process of determining health care choices. For example, if the patient is informed about the risks and benefits of hormone replacement therapy and clearly understands them, she may be more likely to comply with the plan once it has been set jointly by she and her physician.

There is some evidence that when patients are heard, understood, more vocal, and more inquisitive, their health improves (2). Good communication is essential for the maintenance of a relationship between the patient and physician that fosters ongoing care. Health maintenance, therefore, can be linked directly to the influence of positive, genial interactions. Patients who are comfortable with their physician may be more likely to raise issues or concerns or convey information about potential health risks and may be more receptive to the physician's recommendations. This degree of rapport may promote the effectiveness of early interactions, including behavior modification. It also helps ensure that patients return for regular care because they feel the physician is genuinely interested in their welfare.

When patients are ill, they feel vulnerable, physically and psychologically exposed, and powerless. Because the physician has power by virtue of knowledge and status, this relationship can be intimidating. Therefore, it is essential that the physician be aware of this disparity so that the “balance of power” does not shift too far away from the patient. Shifting it back from the physician to the patient may help improve outcomes (3, 7, 8).

In assessing the effects of the patient–physician interaction on the outcome of chronic illness, three characteristics that are associated with better health care outcomes have been identified (8):

1. Empathetic physician and more patient control of the interview
2. Expression of emotion by both patient and physician
3. Provision of information by the physician in response to the patient's inquiries

These findings related to the control of diastolic blood pressure and the reduction of hemoglobin A_{1c} in patients with diabetes, who experienced improved function and subjective evaluation of health in the presence of these characteristics. The best responses were achieved when an empathetic physician provided as much information and clarification as possible, responded to the patients' questions openly and honestly, and expressed a full range of emotions, including humor, and when the relationship was not entirely dominated by the physician (8).

In studies of gender and language, men tend to talk more than women, successfully interrupt women, and control the topics of the conversation (10). As a result, male physicians may tend to take control and be more assertive than female physicians. Men's speech tends to be characterized by interruptions, command, and lectures, and women's speech is characterized by silence, questions, and proposals (11, 12). Some patients may simply feel more reticent in the presence of a male physician, whereas others may be more forthcoming with a male than a female physician (13). Although these generalizations clearly do not apply to all physicians, they can raise awareness about the various styles of communication. These patterns indicate the need for all physicians, regardless of their gender, to be attentive to their style of speech because it may affect their ability to elicit open and free responses from their patients (14, 15). Women tend to speak openly in order to express their feelings and to have them validated and shared in an attempt to gain understanding of their concerns (9, 10 and 11).

With regard to communication relating to gynecologic issues, it is important to understand that different styles of communication may affect the physician's ability to perceive the patient's status and to achieve the ultimate goal of optimal assessment and compliance with medical and surgical therapies. The intimate and highly personal nature of many gynecologic conditions requires particular sensitivity to evoke an honest response.

Style

In general, the art of communication and persuasion is based on mutual respect and development of the patient's understanding of the circumstances of her health (2). Insight is best achieved when the patient is encouraged to query her physician and when she is not pressured to make decisions (3, 9). Patients who feel “backed into a corner” have the lowest compliance with recommended treatments (7).

Following are techniques to help achieve rapport with patients:

1. **Use positive language** (e.g., agreement, approval, and humor).
2. **Build a partnership** (e.g., acknowledgment of understanding, asking for opinions, paraphrasing, and interpreting the patient's words).
3. **Ask rephrased questions.**
4. **Give complete responses to the patient's questions.**

The manner in which a physician guides a discussion with a patient will determine the patient's level of understanding and her compliance. For example, in providing a prescription, if a command is given to take the medication without a discussion of the rationale for it, patients may not comply, particularly if they become confused about the instructions (9). It is obviously inappropriate to prescribe hormone replacement therapy with a statement of simply, “Just take one of these pills every night

before you go to bed,” without a discussion of the risks and benefits of taking estrogen and progesterone.

The style of the presentation of information is key to its effectiveness. The physician should avoid “speaking down” to patients, both figuratively and literally. The latter occurs when discussions take place with the patient in the supine or the lithotomy position. Such a position creates a vulnerable situation in which the patient does not feel she is an equal partner in the relationship. Serious discussions about diagnosis and management strategies should be conducted when the patient is fully clothed and face-to-face with a doctor in a private room, with or without an intervening desk.

Body language is also important in interactions with patients. The physician should avoid an overly casual stance, which can communicate a lack of caring or lack of compassion. The patient should be viewed directly and spoken to with eye contact so that the physician is not perceived as “looking off into the distance” (2).

Laughter and Humor

Humor is an essential component that promotes open communication. It can be either appropriate or inappropriate. Appropriate humor allows the patient to diffuse anxiety and understand that (even in difficult situations) laughter can be healthy (16). Inappropriate humor would horrify, disgust, or offend a patient or generally make her uncomfortable or seem disrespectful of her. Laughter can be used as an appropriate means of relaxing the patient and making her feel better.

Laughter is a “metaphor for the full range of the positive emotions” (16). It is the response of human beings to incongruities and one of the highest manifestations of the cerebral process. It helps to facilitate the full range of positive emotions—love, hope, faith, the will to live, festivity, purpose, and determination (16). Laughter is a physiologic response, a release that helps us all feel better and allows us to accommodate the collision of logic and absurdity. Illness, or the prospect of illness, heightens our awareness of the incongruity between our existence and our ability to control the events that shape our lives and our outcomes. We use laughter to combat stress, and stress reduction is an essential mechanism used to cope with illness.

Strategies for Improving Communication

All physicians should understand the art of communication during the medical interview. It is essential that interactions with patients are professional, honorable, and honest. Issues that are important to physicians regarding patient–physician interactions are presented in [Table 1.3](#). Following are some general guidelines that can help to improve communication:

Rank	Physicians' Request Services	Always or Often (%)	Rarely or Never (%)
1	Answering the patient's questions about the disease and its treatment, side effects, and possible cures	99	1
2	Making sure that the patient clearly understands the explanation of the medical treatment procedures	99	1
3	Encouraging the patient to develop an attitude of hope and optimism concerning treatment outcome	95	5
4	Adjusting treatment plans to enhance compliance when the patient exhibits noncompliance	88	12
5	Directly counseling family members	87	13
6	Continuing to serve as primary physician when the patient receives supplementary treatment at another facility	85	15
7	Providing referral to social support groups	83	17
8	Providing the patient with educational materials	80	20
9	Helping the patient develop methods to improve the quality of his or her life	74	26
10	Assessing the patient in determining which of his or her coping mechanisms are most productive and helping to enhance them	62	38
11	Providing referral to psychological counseling services	57	43

*Results of a physician survey of self-perceptions in regard to patient-physician communication. Modified from Kessler, H. (1984). *How the doctor of hope and the healing power of the human spirit*. New York: Plenum Press, 1984, 220, with permission.

Table 1.3 Importance Attached to the Patient–Physician Relationship

1. Listen more and talk less.
2. Encourage the pursuit of topics introduced by and important to patients.
3. Minimize controlling speech habits such as interrupting, issuing commands, and lecturing.
4. Seek out questions and provide full and understandable answers.
5. Become aware of discomfort in an interview, recognize when it originates in an attempt by the physician to take control, and redirect that attempt.
6. Assure patients that they have the opportunity to discuss their problem fully.

Recognize when patients may be seeking empathy and validation of their feelings rather than a solution. Sometimes all that is necessary is to be there as a compassionate human being.

In conducting interviews, it is important for the physician to understand the patient's concerns. In studies of interviewing techniques, it has been shown that although clinicians employ many divergent styles, the successful ones tend to look for “windows of opportunity” (i.e., careful, attentive listening with replies or questions at opportune times) (2). This skill of communication is particularly effective in exploring psychological and social issues during brief interviews. The chief skill essential to allowing the physician to perceive problems is the ability to listen attentively.

An interview that permits maximum transmission of information to the physician is best achieved by the following approach (2):

1. Begin with an open-ended question.
2. As the patient begins to speak, pay attention not only to her answers but also to her emotions and general body language.
3. Extend a second question or comment, encouraging the patient to talk.
4. Allow the patient to respond without interrupting, perhaps by employing silence, nods, or small facilitative comments, encouraging the patient to talk while the physician is listening.
5. Summarize and express empathy and understanding at the completion of the interview.

Attentiveness, rapport, and collaboration characterize good medical interviewing techniques. Open-ended questions are generally desirable, particularly coupled with good listening skills (“How are you doing?” “How does that make you feel?”).

Premature closure of an interview and inability to get the complete information to the patient may occur for several reasons (2). It may arise from a lack of recognition of the patient's particular concern, from not providing appropriate opportunity for discussion, from the physician's becoming uncomfortable in sharing the patient's emotion, or perhaps from the physician's lack of confidence that he or she can deal with the patient's concern. One of the principal factors undermining the success of the interview is lack of time. However, skilled physicians can facilitate considerable interaction even in a short time by encouraging open communication (17).

Many patients lack accurate information about their illness. Lack of full understanding of an illness can produce dissatisfaction with medical care, increased anxiety, distress, coping difficulties, noncompliance with treatment, and poor treatment response (18,19 and 20). As patients increasingly request more information about their illnesses and more involvement in decisions about their treatment, and as physicians attempt to provide more open negotiation, communication problems become more significant. Poor patient understanding stems from poor communication techniques, lack of consultation time, patient anxiety, patient denial, and in some cases, the withholding of information considered detrimental to patient welfare (18).

If clinical findings or confirmatory testing strongly suggest a serious condition (e.g., malignancy), the gravity and urgency of this situation must be conveyed in a manner that does not unduly alarm or frighten the individual. Honest answers should be provided to any specific questions the patient may want to discuss (19, 20).

Allowing time for questions is important, and scheduling a follow-up visit to discuss treatment options after the patient has had an opportunity to consider the options and recommendations may be valuable (19, 20). The patient should be encouraged to bring a partner or family member with her to provide moral support and to assist with questions. The patient should also be encouraged to write down any concerns she may have and bring them with her because important

issues may not come to mind easily during an office visit. If the patient desires a second opinion or if a second opinion is mandated by her insurance coverage, it should be facilitated.

Valuable information can be provided by interviews with ancillary support staff and by providing pamphlets and other materials produced for patient education. Some studies have demonstrated that the use of pamphlets is highly effective in promoting an understanding of the condition and treatment options. Others have shown that the use of audiotapes and videotapes has a positive impact on knowledge and can decrease anxiety (18).

There are numerous medicine websites on the Internet that can be accessed, although the accuracy of the information is variable and must be carefully reviewed by physicians before recommending to patients.

The relationship between the patient and her physician is subject to constant change, as is true of all features of social interchange. The state of our health is dynamic. Many of us are fortunate to be in a good state of health for much of our lives, but some are not so fortunate. The goal of open communication between patient and physician is to achieve maximum effectiveness in diagnosis, treatment, and compliance for all patients.

Talk to the heart, speak to the soul.

Look to the being and embrace the figure's form.

Reach deeply, with hands outstretched.

Talk intently, to the seat of wisdom, as life resembles grace.

Achieve peace within a fragile countenance.

Seek the comfort of the placid hour.

Through joyous and free reflection

know the other side of the flesh's frame.

JSB

History and Physical Examination

After a dialogue has been established, the patient assessment proceeds with obtaining a complete history and performing a physical examination. Both of these aspects of the assessment rely on good patient–physician interchange and attention to details. During the history and physical examination, the identification of risk factors that may require special attention should be sought. These factors should be reviewed with the patient in developing a plan for her future care (see [Chapter 8](#)).

History

After the ascertainment of the chief complaint and characteristics of the present illness, the history of the patient should be obtained. It should include her complete medical and surgical history, her reproductive history (including menstrual history), and a thorough family and social history.

A technique for obtaining information about the present illness is presented in [Table 1.4](#). The physician should determine what other consultations may be needed to complete the evaluation. In some cases, referral to a social worker, psychologist, psychiatrist, or sexual counselor would be helpful. These issues are covered in Section III, Primary and Preventative Care (see [Chapter 8](#), [Chapter 9](#), [Chapter 10](#), [Chapter 11](#) and [Chapter 12](#)). Laboratory testing for routine care and high-risk factors are presented in [Chapter 8](#).

Table 1.4 Technique of Taking the History of the Present Illness

Physical Examination

A thorough general physical examination should be performed during each patient assessment ([Table 1.5](#)). In addition to evaluation of the vital signs, examination of the breast, abdomen, and pelvis is an essential part of the gynecologic examination.

Table 1.5 Method of the Female Pelvic Examination

Abdominal Examination

With the patient in the supine position, an attempt should be made to have the patient relax as much as possible. Her head should be leaned back and supported gently by a pillow so that she does not tense her abdominal muscles.

The abdomen should be inspected for signs of an intraabdominal mass, organomegaly, or distention that would, for example, suggest ascites or intestinal obstruction. Initial palpation of the abdomen is performed to evaluate the size and configuration of the liver, spleen, and other abdominal contents. Evidence of fullness or mass effect should be noted. This is particularly important in evaluating patients who may have a pelvic mass and in determining the extent of omental involvement, for example, with metastatic ovarian cancer. A fullness in the upper abdomen could be consistent with an “omental cake.” All four quadrants should be carefully palpated

for any evidence of mass, firmness, irregularity, or distention. A systematic approach should be used (e.g., clockwise, starting in the right upper quadrant). Percussion should be used to measure the dimensions of the liver. The patient should be asked to inhale and exhale during palpation of the edge of the liver.

Auscultation should be performed to ascertain the nature of the bowel sounds. The frequency of intestinal sounds and their quality should be noted. In a patient with intestinal obstruction, “rushes,” as well as the occasional high-pitched sound, can be heard. Bowel sounds associated with an ileus may be less frequent but at the same pitch as normal bowel sounds.

Pelvic Examination

The pelvic examination is typically performed with the patient in the dorsal lithotomy position ([Fig. 1.1](#)). The patient's feet should rest comfortably in stirrups with the edge of the buttocks at the lower end of the table so that the vulva can be readily inspected and the speculum can be inserted in the vagina without obstruction from the table.

Figure 1.1 The lithotomy position for the pelvic examination.

The vulva and perineal area should be carefully inspected. Evidence of any lesions, erythema, pigmentation, masses, or irregularity should be noted. The skin quality should be noted as well as any signs of trauma, such as excoriations or ecchymosis. The presence of any visible lesions should be quantitated and carefully described with regard to their full appearance and characteristics on palpation (i.e., mobility, tenderness, consistency). Ulcerative or purulent lesions of the vulva should be cultured as outlined in subsequent chapters, and biopsy should be performed on any lesions.

After thorough visualization and palpation of the external genitalia, including the mons pubis and the perianal area, a speculum is inserted in the vagina. In a normal adult who is sexually active, a Pederson or Graves speculum is used. The types of specula that are used in gynecology are presented in [Fig. 1.2](#). In general, the smallest speculum necessary to produce adequate visualization should be used. The speculum should be warmed before it is inserted into the vagina, and warm water generally provides sufficient lubrication for this procedure. The patient should be alerted to the fact that the speculum will be inserted so that she is not surprised by its placement. After insertion, the cervix and all aspects of the vagina should be carefully inspected. Particular attention should also be paid to the vaginal fornices because lesions (e.g., warts) may be present in those areas and are not readily visualized unless care is taken to do so.

Figure 1.2 Vaginal specula: 1, Graves extra long; 2, Graves regular; 3, Pederson extra long; 4, Pederson regular; 5, Huffman “virginal”; 6, pediatric regular; and 7, pediatric narrow.

The appropriate technique for a Papanicolaou's (Pap) test is presented in Chapter 16. Any obvious lesions on the cervix or in the vagina should undergo biopsy. An endometrial biopsy is usually performed with a flexible cannula or a Novak curette (see [Chapter 13](#)). Any purulence in the vagina or cervix should be cultured (see [Chapter 15](#)).

After the speculum is removed and the pelvis palpated, the first and second fingers are inserted gently into the vagina after adequate lubrication has been applied to the examination glove. In general, in right-handed physicians, the right hand is inserted into the vagina and the left hand is used on the abdomen to provide counter pressure as the pelvic viscera are moved ([Fig. 1.3](#)). The vagina, its fornices, and the cervix are palpated carefully for any masses or irregularities. The fingers are placed gently into the posterior fornix so that the uterus can be moved. With the abdominal hand in place, the uterus can usually be palpated just above the surface pubis. In this manner, the size, shape, mobility, contour, consistency, and position of the uterus are determined.

Figure 1.3 The bimanual examination.

The adnexa are then palpated gently on both sides, paying particular attention to any enlargements. Again, the size, shape, mobility, and consistency of any adnexal structures should be carefully noted.

A rectal examination is suggested periodically in women 40 years of age and older (see [American College of Obstetricians and Gynecologists guidelines](#), Chapter 8) and in all premenopausal women in whom there is any difficulty ascertaining the adnexal structures ([Fig 1.4](#)). Rectovaginal examination should also be performed in these women to exclude the possibility of concurrent rectal disease ([21](#)). In postmenopausal women who undergo rectal examination, a stool guaiac test can be performed. During rectal examination, the quality of the sphincter muscles, support of the pelvis, and evidence of masses such as hemorrhoids or lesions intrinsic to the rectum should be noted.

Figure 1.4 The rectovaginal examination.

At the completion of the physical examination, the patient should be informed about the findings. When the results of the examination are normal, the patient can be reassured accordingly. When there is a possible abnormality, the patient should be informed immediately. A plan to evaluate the findings should be outlined briefly and in clear, understandable language. The implications of any proposed procedure (e.g., biopsy) should be discussed, and the patient should be informed when the results of any tests will be available.

Pediatric Patients

A careful examination is indicated when a child presents with genital complaints. The examiner should be familiar with the normal appearance of the prepubertal genitalia. The normal unestrogenized hymenal ring and vestibule can appear mildly erythematous. The technique of examination is different from that used for examining an adult and may need to be tailored to the individual child based on her age, size, and comfort with the examiner. A young child can usually be examined best in a “frog-leg” position on the examining table. Some very young girls (toddlers or infants) do best when held in their mother's arms. Sometimes, the mother can be positioned, clothed, on the examination table (feet in stirrups, head of table elevated) with the child on her lap, the child's legs straddling her mother's. The knee-chest position may also be helpful for the examination ([22](#)). The child who is relaxed and warned about touching will usually tolerate the examination satisfactorily. Some children who have been abused, who have had particularly traumatic previous examinations, or who are unable to allow an examination may need to be examined with the use of anesthesia, although a gentle office examination should almost always be attempted first. If no obvious case of bleeding is visible externally or within the distal vagina, an examination under anesthesia may be indicated to visualize the vagina and cervix completely. A hysteroscope, cytoscope, or other endoscopic instrument can be used to provide magnification and light source.

Adolescent Patients

A pelvic examination may be less revealing in an adolescent than in an older woman, particularly if it is the patient's first examination or if it takes place on an emergency basis. Although other diagnostic techniques (such as pelvic ultrasound) can supplement an inadequate or poorly revealing examination, an examination should usually be attempted. The keys to a successful examination lie in earning the patient's trust, explaining the components of her examination, performing only the essential components, and using a very careful and gentle technique. It is important to ascertain whether the patient has had a previous pelvic examination.

An adolescent should have a pelvic examination if she has had intercourse, if the results of a pregnancy test are positive, if she has abdominal pain, if she is markedly anemic, or if she is bleeding heavily enough to compromise hemodynamic stability. The pelvic examination occasionally may be deferred in young teenagers who have a classic history of irregular cycles soon after menarche, who have normal hematocrit levels, who deny sexual activity, and who will reliably return for follow-up.

Before a first pelvic examination is performed, a brief explanation of the planned examination (which may or may not need to include a speculum), instruction in relaxation techniques, and the use of lidocaine jelly as a lubricant can be helpful. The patient should be encouraged to participate in the examination through voluntary relaxation of the introital muscles or by using a mirror if she wishes. If significant trauma is suspected or the patient finds the examination too painful and is truly unable to cooperate, an examination under anesthesia may occasionally be necessary. The risks of general anesthesia must be weighed against the value of information that would be obtained by the examination.

Confidentiality is an important issue in adolescent health care. A number of medical organizations, including the American Medical Association, the American Academy of Pediatrics, and the American College of Obstetrics and Gynecologists, have endorsed adolescents' rights to confidential medical care. Particularly with regard to issues as sensitive as sexual activity, it is critical that the adolescent be interviewed alone, without a parent in the room. The patient should be asked if she has engaged in sexual intercourse, if she used any method of contraception, and if she feels there is any possibility of pregnancy.

Follow-up

Arrangements should be made for the ongoing care of patients, regardless of their health status. Patients with no evidence of disease should be counseled regarding health behaviors and the need for routine care. For those with signs and symptoms of a medical disorder, further assessments and a treatment plan should be discussed. The physician must determine whether he or she is equipped to treat a particular problem or whether the patient should be directed to another health professional, either in obstetrics and gynecology or another specialty. If the physician believes it is necessary to refer the patient elsewhere for care, the patient should be reassured that this measure is being undertaken in her best interests and that continuity of care will be ensured.

Summary

The management of patients' gynecologic symptoms, as well as abnormal findings and signs detected during examination, requires the full use of a physician's skills and knowledge and poses challenges to practice the art of medicine in a manner that leads to effective alliances between physicians and their patients. Physicians must listen carefully to what patients are saying about the nature and severity of their symptoms. The art of medical history taking must not be minimized. Physicians also must listen carefully for what patients may not be saying: their fears, anxieties, and personal experiences that lead them to react in a certain manner when faced with what is often, to them, a crisis (the diagnosis of an abnormality on examination, laboratory testing, or pelvic imaging).

Physicians must use their knowledge of gynecology gained through formal education, personal experience, teachers and mentors, and textbooks, always striving to have the latest information about a given problem. Patients often present a unique set of circumstances, medical issues, or combination of diseases. Today, the use of a textbook chapter is only a beginning. Computers have made the world of information management accessible. Physicians must learn to practice evidence-based medicine—based on the very latest of what is known, not just impressions, recollections, or advice of colleagues. Physicians need to search the medical literature to help discover what they do not know. Patients are searching the medical literature, using computer online services to gain access to medical subject talk-groups, research reports, and the same literature read by physicians. Knowledge derived from an evidence base must be applied, using the art of medicine, to interact with patients to maintain health, alleviate suffering, and manage and cure disease.

The practice of gynecology, as with all branches of medicine, is based on ethical principles that guide patient care. These principles and concepts create a framework for ethical decision making that applies to all aspects of practice:

- **Autonomy:** a person's right to self-rule, to establish personal norms of conduct, and to choose a course of action based on a set of personal values and principles derived from them
- **Beneficence:** the obligation to promote the well-being of others
- **Confidentiality:** a person's right to decide how and to whom personal medical information will be communicated
- **Covenant:** a binding agreement between two or more parties for the performance of some action
- **Fiduciary relationship:** a relationship founded on faith and trust
- **Informed consent:** the patient's acceptance of a medical intervention after adequate disclosure of the nature of the procedure, its risks and benefits, and alternatives
- **Justice:** the right of individuals to claim what is due them based on certain personal properties or characteristics
- **Maleficence:** the act of committing harm (*nonmaleficence* obliges one to avoid doing harm)

Patient and Physician

Health care providers fulfill a basic need—to preserve and advance the health of human beings. Despite the challenges imposed by the commercial aspects of the current medical environment, for most physicians, the practice of medicine remains very much a “calling,” a giving of oneself to the greater good. Although much of medicine is contractual in nature, it cannot be understood in only those terms: “The kind of minimalism that a contractualist understanding of the professional relationship encourages produces a professional too grudging, too calculating, too lacking in spontaneity, too quickly exhausted to go the second mile with his patients along the road of their distress” (1). There is a relationship between physician and patient that extends beyond a contract and assumes the elements of a fiduciary relationship—a covenant between parties. **The physician, having knowledge about the elements of health care, assumes a trust relationship with the patient whereby her interests are held paramount. Both the patient and the physician have rights and responsibilities in this relationship, and both are rewarded when those rights and responsibilities are upheld. Confidentiality and informed consent are two expressions of that trust or covenantal relationship.**

Confidentiality

The patient seeking assistance from a health professional has the right to be assured that the information exchanged during that interaction is private. Privacy is essential to the trust relationship between doctor and patient. Discussions are privileged information. **The right to privacy prohibits a physician from revealing information regarding the patient unless the patient waives that privilege.** Privileged information belongs to the patient except when it impinges on the legal and ethical rights of institutions and society at large, regardless of the setting. In a court situation, for example, physicians cannot reveal information about their patients unless that privilege is waived by the patient. If privilege is waived, the physician may not withhold such testimony.

The privilege of privacy must be maintained even when it does not seem intrinsically obvious. A patient's family, friend, or spiritual guide, for example, has no right to medical information regarding the patient unless the patient specifically releases it. This may seem obvious but often can be overlooked, such as when a health care giver receives a call from a concerned parent, spouse, or relative inquiring about the status of a patient. The response may be a natural attempt to reassure and inform a caring individual about the patient's status. However, for her own reasons, the patient may not want certain individuals informed of her medical condition. Thus, confidentiality has been breached. It is wise to ask patients about who may be involved in decision making and who may be informed about their status. If a health care giver is unclear of the patient's wishes regarding the person requesting information, the reply should indicate that the patient's permission is necessary before discussing her status. Finally, when trying to contact individual patients for follow-up of medical findings, it is never appropriate to reveal the reason to an individual other than the patient.

Record Keeping

Health care professionals are part of a record-keeping organization. Those records are used for multiple purposes in medicine and are a valuable tool in patient care. Unfortunately, there is an increasing tendency for ancillary organizations to collect, maintain, and disclose information about individuals to whom they have no direct connection (2). Given the present lack of universal and nondiscriminatory access to health insurance in the United States, physicians must be aware of this practice and its ramifications. Patients sign a document, often without understanding its meaning, upon registering with a health care institution or insurance plan. That document waives the patient's privilege to suppress access and gives access to the medical record to insurers and often other health care providers who request it. The consequences of such disclosure for patients can be significant in terms of insurance coverage and potential job discrimination (3). This concern must be weighed against the need for all health care providers involved with an individual to be informed about past or present diseases or activities that may interfere with or complicate management. The use of illegal drugs, a positive human immunodeficiency virus (HIV) test result, and even a history of cancer or psychiatric illness are all exceptionally important to health care providers in evaluating individual patients. When revealed to outside institutions, however, these factors may affect the patient's ability to obtain and keep medical coverage, insurance, or even credit. It is axiomatic that everything that is written in a patient's record should be important to the medical care of that patient and that extrinsic information should be avoided. Furthermore, it is appropriate for physicians to discuss with patients the nature of medical records and their release to other parties so that patients can make an informed choice about such release. Additional guidelines from the Department of Health and Human Services (DHHS) to protect the security of patient records, known as the Healthcare Information Privacy and Protection Act (HIPPA), will translate into additional requirements for access to these records for clinical research as well as guidelines for electronic medical records protections. The security of medical

records, then, is a concern not just for individual patients and physicians but also for health systems and researchers.

Legal Issues

The privilege of patients to keep their records or medical information private can be superseded by the needs of society, but only in rare circumstances.

The classic legal decision quoted for the needs of others superseding individual patient rights is that of *Tarasoff v. Regents of the University of California* (4). That decision establishes that the special relationship between a patient and doctor may support affirmative duties for the benefit of third persons. It requires disclosure if “necessary to avert danger to others” but still in a fashion “that would preserve the privacy of the patient to the fullest extent compatible with the prevention of the threatened danger.” This principle also is compatible with the various codes of ethics that allow physicians to reveal information in order to protect the welfare of the individual or the community. In other words, “the protective privilege ends where the public peril begins” (4). Legislation can also override individual privilege. The most frequent example is the recording of births and deaths, which is the responsibility of physicians. Various diseases are required to be reported depending on state law [e.g., HIV status may or may not be reportable in individual states, whereas acquired immunodeficiency syndrome (AIDS) is reportable in all states]. Reporting injuries caused by lethal weapons, rapes, and battering (e.g., elder and child abuse) is mandatory in some states and not others. The regulations for the reporting of these conditions are codified by law and can be obtained from the state health department. These laws are designed to protect the individual's privacy as much as possible while still serving the public interest. Particularly in the realm of abuse, physicians have a complex ethical role regardless of the law. Victims of abuse, for example, must feel supported and assured that the violent act they have survived will not make a difference in how they are treated as people. Their sense of vulnerability and their actual vulnerability may be so great that reporting an incident may increase their risk for medical harm. Despite the laws, physicians also have an ethical responsibility to see to the patient's best interest, and weighing that ethical responsibility can be difficult.

Informed Consent

Informed consent is a process that involves an exchange of information directed toward reaching mutual understanding and informed decision making.

Ideally, informed consent should be the practical manifestation of respect for patient preferences (autonomy) (5,6). Unfortunately, an act of informed consent is often misunderstood as procurement of a signature on a document. Furthermore, the intent of the individual involved in the consent process often is the protection of the physicians from liability. Nothing could be further from either the legal or ethical meaning of this concept.

Informed consent is a conversation between physician and patient that teaches the patient about the medical condition, explores her values, and informs her about the reasonable medical alternatives.

Informed consent is an interactive discussion in which one participant has greater knowledge about medical information and the other participant has greater knowledge about that individual's value system and circumstances affected by the information. This process does not require an arduous lecture on the medical condition or extensive examination of the patient's psyche. It does require adjustment of the information to the educational level of the patient and respectful elicitation of concerns and questions. It also requires acknowledgement of the various fears and concerns of both parties. Fear that the information may frighten patients, fear of hearing the information by the patient, lack of ability to decode technical information, and inability to express lack of comprehension are among the many barriers facing physicians and patients engaging in this conversation. Communication skills are part of the art of medicine, and observation of good role models, practice, and good intent can help to instill this ability in physicians (7).

Autonomy

Informed consent arises from the concept of autonomy. Pellegrino (8) defines an autonomous person as “one who, in his thoughts, work, and actions, is able to follow those norms he chooses as his own without external constraints or coercion by others.” This definition contains the essence of what health care providers must consider as informed consent. The choice to receive or refuse medical care must be in concert with the patient's values and freely chosen, and the options must be considered in light of the patient's values.

Autonomy is not respect for a patient's wishes against good medical judgment. Consider the example of a patient with inoperable, advanced-stage cervical cancer who demands surgery and refuses radiation therapy. The physician's ethical obligation is to seek the best for the patient's survival (beneficence) and avoid the harm (maleficence) of surgery, even though that is what the patient wishes. Although physicians are not obligated to offer treatment that is of no benefit, the patient does have the right to refuse treatment if it does not fit into her values. Thus, this patient could refuse treatment for her cervical cancer, but she does not have the right to be given any treatment she wishes.

Surrogate Decision Makers

If the ability to make choices is diminished by extreme youth, mental processing difficulties, extreme medical illness, or loss of awareness, surrogate decision making may be required. In all circumstances, the surrogate must make every attempt to act as the patient would have acted (9). The hierarchy of surrogate decision makers is specified by statutory law in each state and differs slightly from state to state. For adults, the first surrogate decision maker is a court-appointed guardian if one exists and second is a durable power of attorney, followed by relatives by degree of presumed familiarity (e.g., spouse, adult children, parents).

For children, parents are the surrogate decision makers, except in circumstances in which the decision is life-threatening and might not be the choice a child would make later, when adult beliefs and values are formed. The classic example of this is the Jehovah's Witness parents who refuse life-saving transfusions for their child (10). Although this case is the extreme, it illustrates that the basic principle outlined for surrogate decision making should also apply to parents. Bias that influences decision making (in protection of parental social status, income, or systems of beliefs) needs to be considered by physicians because the potential conflict may lead parents to decisions that are not in the best interest of the child. If there is a conflicting bias that does not allow decisions to be made in the best interest of the child or that involves a medical threat to a child, legal action to establish guardianship (normally through a child protective agency) may be necessary. This action can destroy not only the patient (child)–physician relationship but also the parent–physician relationship and may affect the long-term health and well-being of the child, who must return to the care of the parents. Such decisions should be made only after all attempts to educate, clarify, and find alternatives have been tried.

The legal age at which adolescents may make their own decisions regarding their health care varies by state (11). However, there is a growing trend to increase the participation of adolescents who are capable of decision making in decisions about their health care. Because minors often have developed a value system and the capacity to make informed choices, their ability to be involved in decisions should be assessed individually rather than relying solely on the age criteria of the law and their parents' views.

A unique area for consideration of informed consent is in the international context, either conducting care or clinical research in foreign settings or caring for individuals from other countries with widely differing viewpoints regarding individual informed consent. For example, if the prevailing standard for decision making by a woman is that her closest male relative makes it for her, how is that standard accommodated within our present autonomy-based system? In international research, these issues have presented major concerns when women were assigned to placebo or treatment groups and consent was accepted from male relatives (12). Furthermore, the coercive effect of access to health care through clinical trials when no other access to health care is available creates real questions about the validity and freedom of choice for participants in these studies (13). Guidelines for limiting coercion and ensuring the ability to choose participation in research are being developed for international research. However, it is important to recognize that these same issues exist in a microcosm when caring for patients from certain cultures and foreign countries in daily practice. Ensuring that the patient can make the choice herself or freely chooses to have a relative make it for her remains an important element of informed consent between individual physicians and individual patients.

Beneficence and Nonmaleficence

The principles of beneficence and nonmaleficence are the basis of medical care—the “to do good and no harm” of Hippocrates. However, these issues are often clouded by other decision makers, consultants, family pressures, and sometimes financial constraints or conflicts of interests. Of all the principles of good medical care, benefit is the one that continually must be reassessed. Simple questions often have no answers. What is the medical indication? How does the proposed therapy address this issue? How much will this treatment benefit the patient? How much will it extend the patient's life? Furthermore, when confronted with multiple medical problems and consultants, physicians should ask how much treatment will be of benefit given all the patient's problems (e.g., failing kidneys, progressive cardiomyopathy, HIV-positive status, and respiratory failure) rather than necessarily attempting intubation and respiratory support to treat the immediate problem.

The benefit or futility of the treatment, along with quality-of-life considerations, should be considered in all aspects of patient care. It is best to weigh all of the relevant issues in a systematic fashion. Some systematic approaches depend on a sequential gathering of all the pertinent information in four domains: medical indications (benefit and harm), patient preferences (autonomy), quality of life, and contextual issues (justice) ([5](#)). Other approaches identify decision makers, followed by facts, and then ethical principles. It is important for physicians to select an ethical model of analysis with which to practice so that, when faced with troubling and complex decisions, a system is available to help clarify the issues.

Medical Futility

The essence of good medical care is to attempt to be as clear as possible about the outcomes of the proposed interventions. If the proposed intervention (e.g., continued respiratory support or initiating support) has a very low or highly unlikely chance of success, intervention might be considered futile. Physicians have no obligation to continue or initiate therapies of no benefit ([14](#)). The decision to withdraw or withhold care, however, is one that must be accompanied by an effort to ensure that the patient or her surrogate decision maker is educated about the decision and agrees with it. Other issues, such as family concerns, can and should modify decisions if the overall well-being of the patient and of the family is best served. For example, waiting (within reason) to withdraw life support may be appropriate to allow a family to reach consensus or a distant family member to see the patient for a last time.

Quality of Life

Quality of life is a much used, often unclear term. In the care of patients, quality of life is the effect of therapy on the patient's experience of living based on her perspective. It is perilous and wholly speculative to assume that physicians know what quality of life represents for a particular patient judging from a personal reaction. It is instructive, however, to attempt to guess what it means and then seek the patient's perspective. The results may be surprising. For example, when offered a new drug for ovarian cancer, a patient might prefer to decline the treatment because the side effects may not be acceptable even when there may be a reasonable chance that her life may be slightly prolonged. In some instances, the physician may not believe that further treatment is justified but the patient finds joy and fulfillment in preserving her existence as long as possible.

Controversy exists regarding whether currently available quality-of-life measurement systems will provide information to help patients make decisions ([15](#)). Information from quality-of-life studies might be judged by criteria that include whether the measured aspects of the patient's life were based on the patient's views or the physician's clinical experience ([16](#)). Informing patients of others' experiences with alternative treatments may help in their decision making, but it is never a substitute for the individual patient's decisions.

Professional Relations

Conflict of Interest

All professionals have multiple interests that affect their decisions. Contractual and covenantal relationships between physician and patient are intertwined and complicated by health care payers and colleagues, which creates considerable pressure. The conflict with financial considerations directly influences how patients' lives are affected, often without their consent. Rennie ([17](#)) described that pressure eloquently: "Instead of receiving more respect (for more responsibility), physicians feel they are being increasingly questioned, challenged, and sued. Looking after a patient seems less and less a compact between two people and more a match in which increasing numbers of spectators claim the right to interfere and referee." An honest response to this environment is for the physician to attempt to protect his or her efforts by assuming that the physician-patient relationship is contractual, and only contractual, in nature. This allocation of responsibility and authority for the contract precludes the need for the covenant between the physician and patient. For example, a contract, insurance, or managed care plan may discourage referral to a more knowledgeable specialist, removing the physician's responsibility. Thus, the contract establishes the extent of the physician-patient relationship. All health care providers must decide whether they will practice within a covenantal or contractual relationship and whether the relationship they develop remains true to this decision. In either setting, a reasonable perception of that relationship is "one that allows clients as much freedom as possible to determine how their lives are affected as is reasonably warranted on the basis of their ability to make decisions" ([18](#)).

Health Care Payers

An insurance coverage plan may demand that physicians assume the role of gatekeeper and administrator. Patients can be penalized for a lack of knowledge about their future desires or needs and the lack of alternatives to address the changes in those needs. Patients are equally penalized when they develop costly medical conditions that would not be covered if they moved from plan to plan. These situations often place the physician in the position of being the arbiter of patients' coverage rather than acting as an advocate and adviser. It is an untenable position for physicians because they often cannot change the conditions or structure of the plan but are made to be the administrators of it.

In an effort to improve physician compliance with and interest in decreasing costs, intense financial conflicts of interest can be brought to bear on physicians by health care plans. If a physician's profile on costs or referral is too high, he or she might be excluded from the plan, thus decreasing his or her ability to earn a living or to provide care to certain patients with whom a relationship has developed. Conversely, a physician may receive a greater salary or bonus if the plan makes more money. The ability to earn a living and to see patients in the future is dependent on maintaining relationships with various plans and other physicians. These are compelling loyalties and conflicts that cannot be ignored ([19,20](#) and [21](#)).

These conflicts are substantially different from those of older fee-for-service plans, although the ultimate effect on the patient can be the same. In fee-for-service plans, financial gain may result in failure to refer a patient, or referral is restricted to those cases in which the financial gain is derived by return referral of other patients ([22](#)). Patients may be unaware of these underlying conflicts, a situation that elevates conflict of interest to an ethical problem. A patient has a right to know what her plan covers, to whom she is being referred and why, and the credentials of those to whom she is referred. The reality is that health care providers make many decisions under the pressure of multiple conflicts of interest. Physicians are potentially caught between self-interest and professional integrity. Whether it is the more blatant lying about indications for a procedure in order to receive reimbursement or a more subtle persuasion to sign up for a certain protocol because of points earned for a study group, the outcome for individual and society's relationship with health care providers is damaged by failure to recognize and specifically address conflicts of interest that impede decision making ([23](#)). Focusing clearly on the priority of the patient's best interest and responsibly rejecting choices that compromise the patient's needs are ethical requirements.

Institutions, third-party payers, and legislatures have avoided accountability for revealing conflicts of interest to those to whom they offer services. The restrictions of health care plans are never placed in as equally prominent a position as the coverage. The coverage choices can be quite arbitrary, and there is rarely an easily accessible and usable system for challenging them. The social and financial conflicts of interest of these payers can directly affect the setting and nature of the relationship between physician and patient. To deal with ambiguous and sometimes capricious decision making, revelation of the conflicts of interest and accountability for choices should be demanded by physician and patient ([24](#)).

Legal Problems

Abuses of the system (e.g., referral for financial gain) have led to proposals and legislation, often referred to as Stark I and II, affecting physicians' ability to send patients to local laboratories and facilities in which they have a potential for financial gain. Although there have been clearly documented abuses, the same legislation would affect rural clinics and laboratories in which the only capital available is obtained through the rural physicians. States vary on the statutory legislation regarding this issue. Regardless of the laws, however, it is ethically required that financial conflicts of interest be revealed to patients ([25,26,27](#) and [28](#)).

Another abuse of the physician-patient relationship caused by financial conflicts of interest is fraudulent Medicare and Medicaid billings. This activity resulted in the Fraud and Abuse Act of 1987 (42 U.S.C. at 1320a-7b), which prohibits any individual or entity making false claims or soliciting or receiving any remuneration in cash or any kind, directly or indirectly, overtly or covertly, to induce a referral. Indictments under these laws are felonies, with steep fines, jail sentences, and loss of the license to practice medicine. Physicians should be aware of the legal ramifications of their referral and billing practices ([23,29](#)).

Harassment

The goal of medicine is excellence in the care of patients and, often, research and education that will advance the practice of medicine. Thus, everyone involved in the process should be able to pursue the common goal on equal footing and without harassment that interferes with employees' or colleagues' ability to work or be equally promoted in that environment. Every office and institution must have written policies on discrimination and sexual harassment that detail inappropriate behavior and state specific steps to be taken to correct an inappropriate situation. The legal sanction for this right is encoded in both statutory law through the Civil Rights Act of 1964 [42 U.S.C.A. at 2000e–2000e–17 (West 1981 and Supp. 1988)] and reinforced with judicial action (case or precedential law) by state and U.S. Supreme Court decisions. In particular, charges of sexual harassment can be raised as a result of unwelcome sexual conduct or a hostile workplace (such as areas of medicine that have been known for antifeminist attitudes in the past). As stated in one legal case, “a female does not assume the risk of harassment by voluntarily entering an abusive, antifemale environment” (*Barbetta v. Chemlawn Service Co.*, 669 F, Supp. 569, WDNY, 1989). The environment must change; it is not acceptable to expect the men or women to adapt because “they knew what it would be like.” The tension in the legal debate regarding harassment (sexual, racial, disability) always hinges on the weight of protection of free speech and the right of the individual to equality and a nonhostile work environment.

Stress Management

There is little doubt that the day-to-day stress of practicing medicine is significant. Besides the acknowledged stress of the time pressures and responsibility of medicine, the current health care environment has had a detrimental effect on physicians' job security, with concurrent health risks ([30](#)). Stress takes a toll not only on cardiac function ([31](#)) but also on the practice of medicine and life outside of medicine ([32](#)).

Responding to stress through drug or alcohol abuse increases overall health and marital problems and decreases effectiveness in practice. In a long-term prospective study of medical students, individuals with high-risk (e.g., volatile, argumentative, aggressive) temperaments have been shown to have a high rate of premature death (particularly before 55 years of age) ([33](#)). Adequate sleep, reasonable working hours, exercise, and nutritional balance have been shown to be directly related to decreases in psychological distress ([34](#)). Simple relaxation training has been shown to decrease gastroesophageal reflux in response to stress ([35](#)).

The pace that physicians maintain has a seductive quality that can easily mask the need for stress reduction by means of good health practices, exercise, and relaxation training. The answer to increased stress is not to work harder and extract the time to work harder from the relaxing and enjoyable pursuits that exist outside medicine. The outcome (in terms of psychological and physical optimal functioning) of that strategy is in neither the physician's nor the patient's best interest. Both the welfare of the patient and the welfare of the physician are enhanced by a planned strategy of good health practices and relaxation. Furthermore, such a strategy is important to all members of the health care team. By providing such leadership, physicians can contribute to a better work and health care environment for everyone.

Society and Medicine

Justice

Some of the ethical and legal problems in the practice of gynecology relate to the fair and equitable distribution of burdens and benefits. How benefits are distributed is a matter of great debate. There are various methods of proposed distribution:

- Equal shares (everyone has the same number of health care dollars per year)
- Need (only those people who need health care get the dollars)
- Queuing (the first in line for a transplant gets it)
- Merit (those with more serious illnesses receive special benefits)
- Contribution (those who have paid more into their health care fund get more health care)

Each of these principles could be appropriate as a measure of just allocation of health care dollars, but each will affect individual patients in different ways. Only recently has just distribution become a major issue in health care. The principles of justice apply only when the resource is desired or beneficial and to some extent scarce ([36](#)).

The traditional approach to medicine has been for practitioners to accept the intense focus on the individual patient. However, the current changes in medicine will alter the focus from the patient to a population ([37](#))—“in the emerging medicine, the presenting patient, more than ever before, will be a representative of a class, and the science that makes possible the care of the patient will refer prominently to the population from which that patient comes.” Physicians are increasingly bound by accumulating outcomes data (population statistics) to modify the treatment of an individual in view of the larger population statistics. If, for example, the outcome of liver transplantation is only 20% successful in a patient with a certain set of medical problems, that transplant may instead be offered to someone who has an 85% chance of success. Theoretically, the former individual might have a successful transplant and the procedure might fail in the latter, but population statistics have been used to allocate this scarce resource. The benefit has been measured by statistics that predict success, not by other forms of justice allocation by need, queuing, merit, or contribution. This approach represents a major change in the traditional dedication of health care to the benefits of individual patients. With scarce resources, the overall benefits for all patients are considered in conjunction with the individual benefits for one patient.

There has always been an inequity in the distribution of health care access and resources. This inequity has not been seen by many health care providers who do not care for those patients who are unable to gain access, such as those who lack transportation or live in rural areas or where limits are imposed by lack of health care providers, time, and financial resources. Social discrimination sometimes leads to inequity of distribution of health care. Minorities are less likely to see private physicians or specialists, regardless of their income or source of health care funding ([38,39](#) and [40](#)). Thus, health care is rationed by default.

Health care providers must shift the paradigm from the absolute “do everything possible for this patient” to the proportionate “do everything reasonable for all patients” ([5](#)). To reform the health care system requires not just judicial, legislative, or business mandates but also attention to the other social components that can pose obstacles to efforts to expand health care beyond a focus on individual patients.

Health Care Reform

The tension between understanding health as an inherently individual matter (in which the receipt of health care is critical to individual well-being) and as a communal resource (in which distribution of well-being throughout society is the goal) underpins much of the political and social debate surrounding health care reform ([41](#)). The questions of health care reform are: What is the proper balance between individual and collective good? and Who will pay for basic health care? Because much of health care reform requires a balancing of competing goals, legislation should specifically address how this balance can be achieved. The role of government would be the following:

- Regulating access of individuals to health care
- Regulating potential harms to the public health (e.g., smoking, pollution, drug use)
- Promoting health practices of benefit to large populations (e.g., immunization, fluoridation of water)

Decisions regarding both the amount and distribution of resources are often made by health care payers, not individual providers. The health insurance industry determines what are “reasonable and customary” charges and what will be covered. The government decides (often with intense special-interest pressure) what will be covered by Medicare and Medicaid ([42,43](#)). These decisions directly affect patient care. For that reason, health care providers cannot ethically remain silent when the health and well-being of their individual patients and their communities are adversely affected by health care reform decisions. Health care providers should assess proposed reforms in light of their value to the community and to individual patients and then formulate their own criteria for judging proposals for health care reform ([44,45,46](#) and [47](#)). Furthermore, initiation and support of research focused on the outcomes of care delivered by gynecologists (financial aspects, quality-of-life measures, survival, morbidity, and mortality) will allow the discipline to have a real voice in determining what choices are made for health care for women.

[Summary](#)

[References](#)

For more than 20 years, the need to maintain or increase the quality of health care while controlling its cost has stimulated a great deal of interest and activity in quality assessment and performance improvement. A report from the Institute of Medicine (IOM) on patient safety has generated intense public interest and concern about the high estimated number of preventable deaths caused by medical errors (1). Although the conclusions of this report are controversial, it raises fundamental and disturbing questions about health care quality and performance.

The annual United States per capita expenditure for health care (in constant dollars) had risen steadily from about \$950 in 1970 to about \$3,400 in 1992 (about 12% increase per year). Although efforts in the 1990s to “manage” care and its costs were reasonably successful in slowing annual health care cost increases, they have recently been returning to double digits. Currently, annual United States per capita expenditure is estimated to exceed \$4,500 (about 3.2% increase per year since 1992). The “political” failure and public distrust of 1990s-style managed care has resulted in predictions of its demise despite well-documented economic success (2). Before the mid-1990s, much of the increase in health care costs had been shifted from individuals to state and federal governments and to employers (Fig. 3.1). More recently, employers have been setting limits on their contributions to health care benefits and shifting more of the increased costs to their employees. Currently, the United States spends more on health care (about 14% of gross domestic product) than on education and defense combined. Despite this enormous outlay of resources, there is concern about the overall quality of health care (3,4). The health status of U.S. residents (in terms of life expectancy, neonatal mortality, and rates of illness and disability) is poorer than that of people living in most European and Scandinavian countries, the United Kingdom, Japan, and Canada, although these countries spend far less per capita on health care. Quality improvement programs in other industries have shown that management methods can both increase quality and reduce costs. Because of concerns about quality, cost, and safety, patients, as well as private and public third-party payers, are demanding ongoing quality assessment and performance improvement programs in health care delivery systems.

Figure 3.1 Sources of spending in U.S. health care, 1960–1990. Note that third-party payment steadily replaced direct payment during this interval. After a long decline, out of pocket spending is expected to rise. (Data from U.S. Congressional Budget Office, 1992).

Quality Assurance

The medical profession traditionally has focused its efforts on assessing and improving the quality of health services through internal, self-imposed, retrospective peer review. Examples of such mechanisms are morbidity and mortality (M&M) conferences, medical society–sponsored and state-legislated peer-review programs, surgical case reviews (tissue committees), and the specialty board certification processes. These programs review adverse occurrences retrospectively (e.g., assessment of medical and surgical complications and review of misdiagnoses). **Although useful as part of the peer-review process, these quality assurance (QA) programs are not aimed at prevention of errors and are not designed to assess and improve the effectiveness of health care services and procedures (5).**

The differences between traditional QA programs and newer performance improvement and quality management programs, such as continuous quality improvement (CQI) or total quality management (TQM), are presented in Fig. 3.2. QA programs are designed to identify and eliminate the small percentage of substandard care represented on the left side of the normal curve (the “bad apple” approach). Most “standard” care occurs in the middle of the curve, however, and is the focus of newer programs like CQI. Such programs are designed to study prospectively the processes of care based on need and to improve outcomes by the reduction of unintended variation (6). The right side of the curve represents state-of-the-art practice usually performed under protocols at universities and other large centers of excellence that are monitored by institutional review boards and national research groups such as the National Cancer Institute and the Gynecologic Oncology Group. As more emphasis is placed on quality management programs in health care, innovations should come from both traditional research and performance improvement efforts.

Figure 3.2 The hypothetical relationship between quality assurance (QA) and quality or performance improvement.

Quality management programs such as CQI, TQM, and performance improvement each have three essential elements (7):

1. To understand customers (patients, payers, and other clients) and to link that knowledge to the activities of the organization
2. To mold the culture (beliefs and performance characteristics) of the organization through the deeds of leaders; to foster pride, enjoyment, collaboration, and scientific thinking
3. To increase knowledge (of how to improve performance) continuously and to control variation (unintended and wasteful differences in performance) by scientific methods

Health care professionals often do not like to refer to health care services as products and patients as customers or consumers. The older, paternalistic attitude (i.e., patients passively agreeing to health care procedures that were determined largely by health care providers) is being replaced by a more egalitarian view of patients as intelligent and informed consumers who should participate in their care (8). The consumerism movement in health care is predicated on the belief that health care services should conform to acceptable standards of quality, efficiency, and safety (9). This newer attitude may lead to improved communication and shared decision making (between patient and provider) and should alter the wasteful practice of “defensive medicine,” which has been shown to increase health care costs significantly (10,11).

Principles of Quality Assessment

Quality means different things in different situations. The concept of quality in products (e.g., consumer goods and state-of-the-art machinery) is different than that of complex services (e.g., health care delivery to people). However, many of the principles of quality assessment and improvement that have been shown to improve the quality of consumer goods and services can also be applied to the evaluation and improvement of health services. There are certain principles of quality assessment that should be considered when attempting to measure and improve health care quality.

Efficacy, Effectiveness, and Efficiency

Efficacy and effectiveness are similar terms that are often used interchangeably to describe evaluations of outcomes of health care services and procedures. As defined by the Institute of Medicine, **efficacy** refers to what an intervention or procedure can accomplish under ideal conditions and when applied to appropriate patients (12). **Effectiveness** refers to the actual performance in customary practice of an intervention or procedure. An example of this difference is the theoretical success rate (**efficacy**) of oral contraception used for one year (99% successful at preventing pregnancy) versus the actual or **use-rate**, effectiveness, usually reported to be 93% to 97%. Most health care decisions have been based on efficacy rates obtained from controlled clinical trials rather than the actual effectiveness of such decisions. One of the major challenges for quality assessment and management programs is to develop and use measurements that reflect the actual, or real-life, success rates of treatment options so that **evidence-based** decision making can replace **authority-based** decision making. Also, strategies need to be developed to improve patient compliance rates in order to increase the likelihood that the actual effectiveness is as close as possible to theoretical efficacy (13).

Efficiency describes the relative “waste” or resource use (complications and costs) of alternative effective interventions. To realize meaningful improvements in health services, health professionals and organizations must develop more efficient interventions (e.g., medical therapy or expectant management versus surgical treatment for abnormal bleeding) when appropriate. The goal of health care quality improvement is optimal value. **Value is defined as quality divided by the cost, or as the quotient of outcomes (benefits) divided by resources used:**

$$\text{Value} = \text{outcomes} / \text{resource use}$$

Optimal versus Maximal Care

The assessment of the quality of health care depends on whether the goal of the system is to provide maximally effective or optimally effective care (14). Figure 3.3 shows a theoretical representation of the difference between maximally effective health care (**Point B**), in which every conceivable intervention is offered regardless of cost to those who can afford it, and optimally effective health care (**Point A**), in which resources are used in a manner that will provide the most good for as many people as possible. Maximized health care emphasizes individual intervention, whereas optimized care emphasizes public health care and prevention. When optimal health care becomes the goal of a health care system, conflicting individual and societal needs must be resolved.

Figure 3.3 The “optimal” versus the “maximal” benefits and costs of medical treatments. On the *top panel*, the benefits to health and the costs of care are plotted. On the *bottom panel*, the cost is subtracted from the benefits, illustrating that after a certain point, additions of care may detract from the benefits. (From Donabedian A. The quality of care: How can it be assessed. *JAMA* 1988;260:1743–1748, with permission.)

Assessing Outcomes

A widely accepted system for assessing the quality of health care is based on the measurement of indicators of structure, process, and outcome (15). **Structure** includes the resources, equipment, and people who provide health care. **Process** is the method by which a procedure or course of action is executed. **Outcome** includes the complications, adverse events, and short-term results of interventions, as well as the patient’s health status and

health-related quality of life after treatment, which reflects the effectiveness of the intervention.

Evaluation of health care structure involves the assessment of the stable and tangible resources needed to provide care, such as safe and adequately sized operating rooms and properly functioning equipment. Other examples of structural elements include the aspects of the medical staff's qualifications, such as school accreditation, licensure, continuing medical education credits, and specialty board certification. Although these elements form the foundation of a health care organization or system, there is a weak correlation between structural assessment and other measures of the quality of care, such as clinical outcomes (16). Therefore, many health services researchers believe that organizations need to measure clinical outcomes directly (including not only death and short-term morbidity but also disability and health-related quality-of-life issues) if they hope to improve both the effectiveness and efficiency of health care delivery. Their research also emphasizes measurement of clinical or health outcomes that are defined as those that patients can experience and value without the interpretation of a health care provider. Examples of clinical or health outcomes and their corresponding intermediate or surrogate end points are presented in [Table 3.1](#). Ultimately, longevity and quality-of-life factors may be the only relevant outcomes of health care.

Clinical or Health Outcomes	Intermediate or Surrogate Endpoints
Longevity	Dilated coronary arteries
Quality of life	Five-year survival rate
Take baby home	Pregnancy
Pain relief	Fewer adhesions
No transfusion	Less blood loss

Table 3.1. Clinical and Health Outcomes and Their Corresponding Intermediate or Surrogate Endpoints: Some Examples

Quality-of-Life Measurement

In the past, traditional quality assessment programs have tended to focus on the assessment of short-term risks and the confirmation of pathologic diagnoses. This effort has usually been limited to quantification of mortality and major morbidity—such as infection, blood transfusion, and reoperation—occurring while the patient was hospitalized and verified by tissue diagnosis. Most standardized lists of clinical QA indicators are from the medical model of outcomes assessment. Although the importance of these kinds of indicators seems obvious, these indicators may have little or no relevance to the more fundamental question of actual effectiveness of a procedure in terms of preserving or enhancing quality of life. For example, if a patient with pelvic pain undergoes a hysterectomy for leiomyomas, experiences no short-term complications, and has a diagnosis that is confirmed histologically, the procedure may be considered successful from the standpoint of surgical risk management, short-term outcome, and histologic verification. However, if the patient continues to experience pain and has no improvement in the quality of her life, the surgery has been, in reality, unsuccessful. Short-term risk indicators often have little or no bearing on whether the procedure actually works.

Behavioral Model of Health Outcomes

Efforts to measure the success or the effectiveness of health care procedures in the United States are based on the traditional medical model in which a patient is evaluated for a symptom, diagnosed as having a condition, and treated for that diagnosis. A procedure is usually considered successful if the diagnosis is confirmed.

Medicine has traditionally relied on short-term risk indicators and histologic confirmation because these measurements seem more objective and quantifiable. Death and infection rates, blood loss, and rates of histologic verification can all be measured and expressed numerically. Crucial to the application of a more predictive behavioral model in clinical outcomes research are several statistically valid and reliable methods to measure health-related quality of life. Many measures have been developed and validated, but few are used in clinical practice (17).

Using the *behavioral model* of effectiveness, the concept of *quality-adjusted life-years* (QALY) has been proposed to measure the benefit, in both quantity and quality of life, of a health care procedure (18). The number of QALYs is determined by combining the extra years of life that a procedure offers with a validated measure of eight categories of disability and four measures of distress. The use of this methodology allows standardized comparison of the cost of entirely different health care procedures. Despite its inadequacies, the medical model has been the standard, but the behavioral model of outcomes is now becoming incorporated into health care evaluation and research (19). Scales of health-related quality-of-life issues, called the *SF-36* and the *SF-12* (short form 36 and short form 12, the health-status tool derived from the RAND Medical Outcomes Survey), have been developed (20).

Performance Improvement

Most methods for the assessment of the quality of health care and the delivery of health services have been based on the premise that quality is the sole responsibility of the health care practitioner. Because the practitioner's technical skills, knowledge, and interpersonal interactions are the basis for quality of patient care and its delivery, many regulatory agencies [e.g., the Joint Commission on the Accreditation of Health Care Organizations (JCAHO)] and hospitals have created traditional QA models that focus mostly on the practitioner. However, quality of care is determined by many interacting forces, and the practitioner clearly does not deliver care in isolation. The delivery of health care requires the integration and management of many processes. The practitioner's ability to deliver care is influenced by the environment, the ability and skill of support staff, policies and procedures, facilities, governing processes, methods of work, and equipment and materials available, as well as innumerable patient variables such as severity of illness, concurrent illness (comorbidity), and social support. Historically, QA efforts attempted to monitor these processes to document bad outcomes. However, this approach has not proved to be adequate in improving the quality of care (21). Regulatory agencies and hospitals are now focusing on the overall performance of health care organizations in terms of clinical or health outcomes.

Performance improvements in health care have been based on knowledge that physicians and other health care professionals acquired in medical and other professional schools. Improvements have been brought about by clinicians applying knowledge developed by discipline-specific experts (22). The recent national emphasis on health care reform is an indication that the past rate of improvements is not sufficient to meet the financial needs and expectations of society. Performance improvements in efficiency must be made at a faster pace because consumers are seeking greater value for and access to health care services. A theoretical basis for organizational change that promotes continuous improvement includes knowledge of a system, knowledge of variation, and the theory of knowledge (23,24).

Knowledge of a System

The first component of continuous performance improvement is knowledge of a system. A *system* is defined as a network of interdependent components that work together to accomplish its aim. A system does not exist without an aim and is only capable of improving if there is a connection between the aim, the means of production, and the means of improving. An *open system* is one that permits continued access from outside the system. Because health care organizations are accountable to patients and to the community as a whole, they are considered open systems. The aim of an organization involves the integration of the knowledge of the social needs and the needs of patients.

Knowledge of a system includes the following aspects:

Customer knowledge. This is the basis of an organization's aim. The aim is derived by identifying the organization's customers and by understanding the measures used to judge quality. Meeting patient expectations is one of the most accurate ways to define quality.

How the organization provides its services. This is the means of producing a service, which involves knowledge of what is delivered, the processes or steps taken

to deliver the services, the information and materials used to provide services, and the suppliers.

How the organization improves what it delivers. This involves knowledge of the aim and identification of areas for improvement that are likely to have the greatest impact.

Understanding the interrelationships between the aim, the customers, the primary areas for improvement, and the specific processes that can be improved is known as *systems thinking*. When a health care organization is focused on providing as many services as possible without consideration for the needs of the community and their customers, it will eventually fail to deliver quality services. Proper perspective for customer needs and preferences gained through a process called *strategic planning* may even lead to a competitive advantage for a health care organization (25).

Knowledge of Variation

Another element of continuous improvement is knowledge of variation. Variation is present in every aspect of our lives. Variation is inherent to everyone's behavior, learning styles, and ways of performing a task. Although the presence of variation, or uniqueness, can be considered a kind of quality, most services are judged on the basis of predictability and a low level of variation. When a service is thought to be of high quality, we expect it to be exactly the same each time, and if there is to be any variation, it must be better.

To improve health products and services continually, it is necessary to know the customers, their needs, and how they judge the quality of health services. The processes by which health services are delivered must be understood and unintended variations reduced. If an organization is to improve and be innovative, it must plan changes that are based on knowledge of what can be better. Two types of variation found in production processes are those that occur by chance (common cause) and those due to assignable causes (special causes) (26). The ability to differentiate between these two types of variation is essential to making improvements in health care.

Clinicians regularly make decisions in their practices based on variation. For example, a physician making frequent rounds may note a change in a patient's temperature and may decide to treat or to observe the patient based on the temperature change and on experience (i.e., judgment). If the temperature variation is seen as special cause (i.e., infection), a decision may be made to add an antibiotic. However, if the change or variation is interpreted as common cause variation in temperature due to short-term, normal changes or chance, it may be ignored. If this happens often, the physician may alter the frequency of observation, thereby making an improvement to the monitoring process. Frequently, however, common cause variation is not recognized in health care, and the variation is acted on prematurely, resulting in the overuse of resources and a lower quality of care (7). If the approach is to measure and change, too many costly changes might be made.

Learning how to respond appropriately to variation in health care processes is a major challenge. Understanding and controlling variation in health care services should be the main emphasis of quality management. The notion of controlling variation, however, causes concern and skepticism in many health care professionals. Physicians who fear any effort to control variation are worried about the loss of options and about restrictions on their judgment. As Berwick points out (7), however, "The (problem) is not considered, intentional variation, but rather unintended or misinterpreted variation in the work of health care. Unintended variation is stealing health care blind today. In controlling it, the health care system could potentially recover a bounty in wasted resources that would dwarf the puny rewards of cost-containment to date."

Variation in Utilization

One of the earliest and most compelling influences on modern health care quality assessment in the United States was a series of investigations that demonstrated a wide variation in the use of health care procedures (27). Although previous investigations had documented a twofold to fourfold difference in the rates of selected procedures both within the United States and between the United States and other industrialized countries, these variations usually were disregarded as secondary to population differences. However, a small-area analysis documented similar or even greater magnitudes of variation within small (25 to 50 miles) geographic regions that could not be explained by differences in patient characteristics or appropriate differences in standards of care (28).

Variations in utilization have now been analyzed for virtually all major surgical procedures, including hysterectomy and cesarean delivery (29,30). Also, variation in the performance of medical procedures, such as those used in the management of acute myocardial infarction and sepsis, have been identified (31). On the basis of these analyses, significant variation has been documented in utilization and in important outcomes such as complications, cost, and derived benefit (32). This type of analysis does not usually allow accurate assessment of which rate of utilization or outcome is appropriate. However, it can help to focus attention on the quality of health services and the complexities of using statistically valid methods to measure health care quality.

Variation in utilization of health care services can be categorized as follows:

1. Necessary and intended variation because of well-recognized patient differences such as severity of illness, comorbidity, and legitimate patient preferences
2. Acceptable but reducible variation because of uncertainty and lack of accurate information about outcomes
3. Unacceptable variation because of nonclinical factors, such as habitual differences in practice style, which are not grounded in knowledge or reason

Most of the differences in utilization rates of many health care procedures result from the last two categories.

Variation in Women's Health Care

Overall, the rate of inpatient surgery for females aged 15 to 44 years is more than 3 times that of males, excluding vaginal deliveries. The most commonly performed major surgical procedure in the United States is cesarean delivery, with about 950,000 procedures performed annually in the United States. Rates of cesarean delivery vary by region, state, and small geographic areas. Overall, the rate of cesarean deliveries is 12% to 40%, and the national mean is about 23%. Comparative rates for the United Kingdom are 6% to 12%.

Hysterectomy is the second most frequent inpatient surgical procedure in the United States. The total annual occurrence of hysterectomy for all ages, all indications, and all institutions (federal and nonfederal) in the United States is about 550,000. Hysterectomy rates in the southern and western United States are 50% to 75% higher than those in the Midwest and New England. A twofold to fivefold variation in utilization rates has been documented within states and small geographic areas within the United States (29). National rates in the United States are twice those in the United Kingdom and more than 3 times the rates in Sweden and Norway (33).

Hysterectomy utilization in the United States varies by both provider and patient characteristics. Studies of utilization patterns have demonstrated that older physicians are more likely to recommend hysterectomy than are younger physicians and that (when controlled for age) gender does not appear to influence hysterectomy decision making (34). With respect to patient variables, although hysterectomy utilization is similar among African American women and white women (35,36), low income and low educational level are risk factors for hysterectomy (37). By 65 years of age, the prevalence of hysterectomy is 40% for women with a high school education and 20% for women with a college education.

Short-term outcomes of hysterectomy vary significantly by race. African American women have a substantially higher relative risk (RR) for morbidity and in-hospital mortality (RR = 3.1) compared with age- and condition-matched white women (38). The reasons for this variation are not known. Quality management techniques are being applied to research in an attempt to reduce these wasteful variations.

The Theory of Knowledge

The final component of knowledge for improvement is the theory of knowledge. The *theory of knowledge* refers to the need for the application of a scientific method for improving performance. One model for testing small-scale change is called the **Plan, Do, Study, Act** (PDSA) method (24). Unlike the ideal scientific method recommended for clinical trials, the PDSA method does not include a control group. Although randomized controlled trials have been considered to be the best way to determine the value of health care interventions, they have two distinct disadvantages: they are expensive, and they tend to define the efficacy of an intervention such as a drug or a surgical procedure. Because efficacy is the way an intervention works under ideal conditions, compared with effectiveness, which is the way an intervention works in everyday practice, health services researchers now recognize that it may not be possible to generalize about an intervention's effectiveness

based on its efficacy as measured in a randomized trial. Also, it is too expensive to perform randomized trials in all situations in which the effectiveness of health care services need to be improved.

The PDSA cycle has been modified as the **F**ind a process, **O**rganize a team, **C**larify the process, **U**nderstand the variation, and **S**elect an improvement (**FOCUS**). The PDCA cycle has tested FOCUS for application to health care improvements (24). In this model, the **P** represents the need to *plan* an improvement by first identifying a change that might lead to improvement and then testing the change on a small scale. During this phase, who will do what, when the change will occur, and how the change will be communicated to those who will be affected are detailed. The **D** stands for *doing* or implementing the plan (change to the process) and collecting the data. The **C** stands for *checking* the data to determine whether the change to the process represents an improvement, and the **A** stands for *acting* or incorporating the change into the process if it is found to be an improvement. A new cycle with another change is started if an improvement was not recognized.

Health care organizations are seeking efficient ways to optimize their delivery of and to improve health care services. The notion that high-quality health care automatically means high cost is no longer accepted without question. At a time when many businesses have transformed themselves by using newer methods of quality management, enabling them to deliver high-quality goods and services at reasonable costs, health care professionals and organizations are beginning to test these improvement methods in medical and surgical practice.

Newer Methods for Improving Performance

Health services researchers and clinicians are beginning to develop and validate newer methods for the measurement and improvement of health care quality. For example, there is a need to make valid comparisons of quality between divergent populations and to correlate clinical performance with measurable processes of care. The goal of a new branch of investigation called *clinical outcomes sciences* is to obtain valid measures of relevant outcomes that are correlated with measurable processes of care so that changes in process can be identified and initiated, thereby improving outcomes. This discipline incorporates methodologies from divergent areas, such as epidemiology, clinical research, management, engineering, economics, and behavioral sciences.

Statistical adjustments are used to allow clinically dissimilar populations, such as high-risk and low-risk patients and those with complicated and uncomplicated conditions, to be compared. This procedure is called *case-mix adjustment* and controls for severity of illness and comorbidity (39,40). Outcomes that are assessed include traditional (medical model) measures, such as complications and adverse occurrences, as well as newer, well-validated measures of satisfaction, health, and functional status.

Concurrently, the processes of care are assessed. This would include measurement of resources used during an episode of care (e.g., supplies, medications, specialized personnel) and practice parameters (e.g., physician orders and nursing practices).

Measurement of the processes and outcomes of health care can be prohibitively expensive if this measurement is not integrated into the daily clinical care. For this reason, another goal of clinical quality outcomes research is to develop and incorporate methods of quality assessment into routine practice. This mechanism could be accomplished, for example, by using the SF-36 as a standard nursing intake form at the time of admission.

Analytic methods in clinical outcomes science rely heavily on multivariate statistics and iterative outcomes databases to provide valid correlations between measurable (and changeable) processes and outcomes. However, the mere identification of process changes that would improve outcomes does not ensure that they will, in fact, be used. For this reason, process and outcomes data must be linked to methods that will allow this information to be incorporated into clinical and operational decision making if they are to change behavior and improve outcomes. These analyses must be readily available both geographically and temporally at the point of care (the place and time that the decision is made) if they are to improve outcomes.

One approach to QA, performance improvement, and medical decision making that has been recommended (the PREPARED system) uses a checklist to analyze the value of a health care procedure before it is performed (9,41). The purpose is to review sequentially the critical data categories of information, each represented by a letter in the word *PREPARED*, that should be used to determine the most appropriate course of action or choice (42):

- P**rocedure: & the course of action being considered
- R**eason: & the indication or rationale
- E**xpectation: & the chances of benefit and failure
- P**references: & patient-centered priorities (utilities) affecting choice
- A**lternatives: & other reasonable options
- R**isks: & the potential for harm from procedures
- E**xpenses: & all direct and indirect costs
- D**ecision: & fully informed collaborative choice

Standardized procedural analysis using this sequenced checklist has been shown to improve health care decision making by increasing patient satisfaction and self-efficacy, thereby facilitating patient choice. It has the potential to improve the assessment of the quality and appropriateness of both provider and patient decision making.

Outcomes Research and Outcome-derived Clinical Guidelines

In the past, clinical practice guidelines or parameters have been largely derived by expert opinion and consensus. A major goal of clinical outcomes science is to allow for the development of guidelines based on actual measured outcomes that could self-adjust based on performance and newer methods of diagnosis and treatment. One such process for incorporating outcomes data into clinical practice is the *critical pathway–case management* method (43). In this method, consensus practice parameters for a given condition (e.g., management of preterm labor) are initially developed by a multidisciplinary team consisting of all professional, allied, and support services involved in the care of the target population. This list of parameters is called a *critical path* or *clinical map*. The critical path details all laboratory, dietary, consultative, medical, teaching, and nursing activities that are thought to be necessary to obtain specific clinical outcomes. Outcomes of care, as well as variations from the “path,” are monitored and collected continuously.

Positive and negative outcomes are then analyzed and correlated with variances from the critical pathway. These data are then returned to the multidisciplinary team, which recommends changes in the entire path based on the outcomes and variance analyses.

In one pilot study of a critical pathway method for cesarean delivery, length of stay and cost were reduced by 13% and 14%, respectively. Additionally, five of seven measurements of satisfaction, including quality of care, were improved, and health status was unchanged (43). A relatively new federal government agency, the Agency for Healthcare Research and Quality (AHRQ), formerly known as the Agency for Health Care Policy and Research (AHCPR), is responsible for funding developmental efforts, collecting information about clinical care guidelines, and disseminating information.

Managed Care

Measuring and improving health care quality and performance have received progressively greater support and validation. Health care reform activity and rapidly changing reimbursement patterns are moving away from traditional fee-for-service plans toward negotiated fee-for-service plans, prospective payment, and capitation-based contracting. This trend has led to a rapid application of modern quality management techniques and performance improvement activity aimed at reducing costs. Managed care contracts are being awarded on the basis of both clinical outcomes and cost.

Many states and federal agencies have enacted legislation that requires health care providers to collect and disseminate comparative outcomes data in their practices. The National Committee on Quality Assurance (NCQA), which is sponsored by managed care organizations, has mandated the collection of quality performance indicators, referred to as *HEDIS*, which stands for **H**ealthplan and **E**mployer **D**ata **I**nformation **S**et. If data are collected and analyzed appropriately, these initiatives could improve health care quality and reduce costs by facilitating rational decision making by consumers, providers, and third-party payers. If done hastily or inappropriately, efforts to use outcomes data, although well intended, could undermine these goals. For these reasons, standardized and validated methods for measuring the processes and outcomes of health care must be developed and integrated into daily clinical and operational practice (44).

Patient Safety

Patient safety has been identified by the IOM as one of the most important dimensions of health care QA and performance improvement. According to a recent report from the IOM, it is estimated that between 44,000 and 98,000 preventable deaths may be due to medical error (1). Although there continues to be controversy about the validity of methods used in these analyses, critics admit that even if the actual number of preventable deaths from error is much smaller than estimated, efforts should be made to eliminate as many as possible.

Patient safety has its roots in traditional risk management (RM) but there are important conceptual differences between the two (Fig. 3.4). RM is retrospective and is focused on individual outliers. It is also outcomes oriented and addresses significant adverse (sentinel) events. The goals of RM include sanctions for substandard providers with far less attention to finding systems-oriented improvements that could prevent recurrent medical errors. Patient safety initiatives are prospective, interdisciplinary, and focused on health care process in addition to outcomes. They are designed to be nonpunitive and to recognize that most adverse outcomes are because of systems deficiencies and not individual error. Therefore, system changes in the overall process of delivery of care are necessary to prevent future problems. For example, when the wrong extremity is removed during a therapeutic amputation, RM efforts usually focus on legal liability issues, holding surgeons and operating room personnel accountable. A patient safety initiative would ideally study the entire process of care using a root-cause analysis approach (Fig. 3.5). All of the members of the health care team, from admission to discharge, would be involved in order to identify and implement preventive measures. This “going beyond blame” approach was a significant recommendation in the IOM report, and it is the approach that is commonly used in other industries, such as aviation safety (1). Process changes and improvements, such as having the patient and surgeon sign the correct extremity using indelible ink at the time of admission and sharing the responsibility during the process so that several individuals (operating room personnel, anesthesia personnel, and members of the surgical team) would verify that the correct extremity is prepared and eventually removed. This team accountability approach is now being applied in all specialties, including obstetrics and gynecology.

CONCEPTUAL EVOLUTION				
Risk Management	Quality Assurance	Quality Assurance & Improvement	Continuous Quality Improvement	Patient Safety
Individual Focus	Departmental Focus	Interdisciplinary

Process Outcomes		Process & Outcomes		
Eliminate Problems		Eliminate or Mitigate		

Figure 3.4 A conceptual evolution of the characteristics of risk management (RM), quality assurance (QA), continuous quality improvement (CQI), and patient safety.

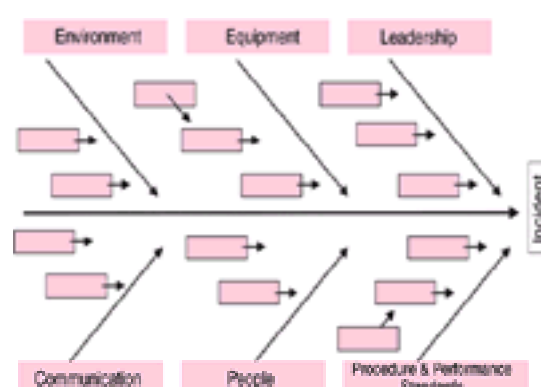

Figure 3.5 Root-cause(s) analysis: getting to the single or multiple causes of adverse outcomes.

The JCAHO has been very active and influential in the evolution of patient safety activities. Starting with an initial requirement that all significant (sentinel) events be reported, it now requires that root-cause(s) analysis be used to investigate the incident, identify contributing factors, and improve the process of care (45). Starting with all JCAHO surveys performed after June 2001, the Joint Commission requires documented evidence that a health care organization being reviewed has invested in a “top-down” commitment to patient safety improvement.

Business and government are also interested in promoting patient safety activities. A business committee called the Leapfrog Group representing the National Business Roundtable and corporations such as General Electric, General Motors, and Verizon have announced that they will give purchasing preference to health care organizations that have at least the following three patient safety programs that have been shown to improve performance: (a) 24-hour, 7 days per week in-house coverage by intensive care specialists; (b) computerized physician-order systems; and (c) high volume, optimal outcomes, and low complication rates for high-risk procedures such as cardiovascular and transplant surgeries. There are currently several legislative bills before the United States congress addressing patient safety issues, such as practice reform and confidentiality. In addition, government programs such as Medicare and Medicaid are putting into place financial and other incentives for patient safety initiatives.

Leaders in health care assessment and performance improvement have recommended five principles to help make health systems safer:

1. Leadership should commit to patient safety in the organization to provide the necessary personnel and financial resources.
2. System design should recognize human limitations. The noted health care improvement researcher, David Eddy, has stated that “the complexity of modern medicine exceeds the limitations of the unaided human mind.” The one-person (“captain-of-the-ship”) accountability of the past may actually lead to more errors in the current health care system.
3. Working and training in teams can help deliver safer care and more dependable accountability.
4. Training should anticipate the unexpected.
5. The organization should foster a learning environment for continual improvement of patient safety.

There is a growing consensus that there will need to be a nonpunitive reporting system to identify not only errors but also “near misses” and other hazards so that they may be corrected before the patient is harmed. The aviation industry is a prime example of how measures can be taken to improve safety. Operations are simplified and standardized. Crew resource management empowers the most appropriate individual to correct a problem, even if that person is not the pilot. Simulators and team training are widely employed. The industry has a system, the airline safety reporting system (ASRS), for reporting actual incidents and near misses. Furthermore, this system is confidential and separated from the Federal Aviation Agency (their main regulatory body) by the National Aviation and Space Agency (NASA).

Summary

Quality assessment and performance improvement activities are becoming increasingly important components of health care delivery. Although retrospective peer review and other QA efforts are still necessary, newer, prospectively focused methods to improve performance are being introduced. In the past, managing the cost of health care has been a major rationale for quality assessment and performance improvement programs. Recently, however, concerns about patient safety and deficiencies in quality have been prompted by several IOM reports (1,3). The complexity of modern health care delivery now requires a multidisciplinary team

approach to quality management and error reduction. Health care professionals need to move away from an atmosphere of blame and individual accountability to a more effective *systems approach* to improve health care quality and safety significantly.

Chapter 4 Epidemiology for the Gynecologist

Daniel W. Cramer

[Study Designs](#)
[Descriptive Studies](#)
[Analytic Studies](#)
[Gynecologic Considerations](#)
[Reproductive Events](#)
[Illnesses](#)
[References](#)

Epidemiology is the study of the occurrence of health events in human populations. Epidemiologic studies may encompass broad topics, such as how birth or death rates vary among people of different nationalities, or more narrow topics, such as how risk for a specific disease changes after a specific exposure. A common theme of most epidemiologic studies is the relationship between disease and exposure, but the design, strengths, weaknesses, and validity of epidemiologic studies vary considerably ([1](#),[2](#),[3](#),[4](#),[5](#) and [6](#)).

Some definitions that are commonly used in epidemiology are as follows:

- **Age-specific incidence:** the number of new events occurring in 5- or 10-year age groups per year
- **Attributable risk:** the difference between the occurrence measure in the exposed and the unexposed cohort
- **Bias:** a systematic error in the design, conduct, or analysis of a study
- **Clinical trial:** a prospective cohort study to evaluate treatments for disease in humans
- **Cohort:** a group of people who have some factor in common
- **Confidence interval (CI):** a component of statistical inference in which an interval is provided to give the reader some idea of the range in which the “true” statistical measure calculated (e.g., mean, proportion, and relative risk) is expected to occur
- **Confounder:** an extraneous variable that accounts for the apparent effect of the study variable or masks the true association
- **Incidence:** the rate of occurrence of new cases of a disease or condition over a specific time interval
- **Predictive value of a negative test:** the number of true negative results out of all those screened with negative results
- **Predictive value of a positive test:** the number of true positive results out of all those screened with positive results
- **Prevalence:** the existing number of cases at a specific point in time
- **Recall bias:** a type of information bias that may occur if cases are more likely than controls to remember or to reveal past exposures
- **Relative risk:** the occurrence in the exposed cohort divided by occurrence in the nonexposed cohort
- **Sensitivity:** the proportion of persons with a true positive screening result out of all those who have the disease
- **Specificity:** the proportion of persons with a true negative screening result out of all those who do not have the disease
- **Statistical significance:** the application of a statistical method to test the null hypothesis (i.e., the hypothesis that two or more factors are not associated)
- **Yield:** the exposure odds ratio (or simply *odds ratio*) in a case-control study (i.e., the ratio of exposed cases to unexposed cases divided by the ratio of exposed to unexposed controls)

Study Designs

Epidemiologic studies are primarily descriptive or analytic (i.e., designed to test a hypothesis about an association). This distinction is important in evaluating a medical study.

Descriptive Studies

Studies in which the characteristics of a disease are described are among the most common type of study. **The two principal types of descriptive studies are case series and cross-sectional studies.**

Case Reports or Series

A simple type of study is the case report or case series in which the characteristics of individuals who have a particular disease are described. Hypotheses about the cause of the disease or its treatment are frequently developed from case series and then explored in analytic studies. For example, a link between oral contraceptives and thromboembolism was first suggested by case reports ([7](#)) and later confirmed in a case-control study ([8](#)). Occasionally, when case series describe the co-occurrence of rare exposures and rare diseases, they are compelling enough on their own to suggest a cause-and-effect relationship. Links between thalidomide and fetal limb reduction ([9](#)), the Dalkon shield intrauterine device and septic abortion ([10](#)), and sequential oral contraceptives and premenopausal endometrial cancer ([11](#)) emerged through case series that were persuasive enough to initiate public health action without the performance of formal epidemiologic studies. In general, however, just because a high number of members of a case series share a particular characteristic, one cannot assume that there is a cause-and-effect relationship. A number of selection factors could have contributed to the observation.

Because of their potential importance, attention should be paid to details of the case selection in case reports or series (e.g., incident or prevalent cases, record-based or personal contact with patients). Investigators should strive to be sure that clear criteria exist for the definition of disease or study variables and that identification of cases was complete. Case series that extend over a long period may suffer from changes in the diagnosis or treatment of the condition that may confuse objectives. Interobserver or reviewer reliability may need to be assessed. Careful assembly of a case series is the first step in performing a case-control study as the logical extension of a case series.

A case series does not usually yield any formal epidemiologic measures other than estimates of the frequency of a particular characteristic among members of the case series. This is often referred to as the *incidence* of a particular characteristic among cases, but *prevalence* is usually the more appropriate term.

Cross-sectional Studies

Design

Cross-sectional studies are larger in scope than case series and generally do not focus on a particular disease. Individuals are surveyed to provide a “snapshot” of health events in the population at a particular time. The U.S. Census Bureau counts the population by categories of age, sex, and ethnicity. The U.S. National Center for Health Statistics compiles a wide variety of data on the health of the population, such as occurrence of hospitalization for various conditions. State health departments are required to count the number of births and deaths annually in their population, and some maintain registries to count the number of individuals who have cancer.

Yield

Incidence is the rate of occurrence of new cases of diseases or conditions over a specific time. Cross-sectional studies often yield incidence rates in which births, new disease cases, or deaths are counted annually for a specified census region and divided by the population size to yield events per population per year. The rate is usually multiplied by a base (1,000, 10,000, or 100,000) to give numbers that can more easily be tabulated. Incidence is an important concept in epidemiology and is often used to calculate other measures of disease frequency, such as prevalence and lifetime risk.

Age-specific incidence refers to the number of new events occurring in 5- or 10-year age groups per year. Because of marked differences by age for most illnesses, age-specific incidence rates are the best way to describe event occurrence in a population. If the incidence rate is not specified with regard to age, it is described as “crude.”

Prevalence is the existing number of cases at a specific point in time. Prevalence is another measure frequently developed from cross-sectional studies. For example, in 1988, the Family Growth Survey Branch of the National Center for Health Statistics interviewed a sample of married couples and found the prevalence of infertility among married women younger than 45 years of age in the United States to be about 8.0% (12). Because prevalence measures disease status in a population rather than events occurring over time, prevalence is a proportion.

Although cross-sectional studies are primarily descriptive, they may contribute information on the cause of a disease by showing how that disease varies by age, sex, race, or geography. In *ecologic studies*, disease rates in various populations are correlated with other population characteristics (e.g., endometrial cancer rates worldwide are positively correlated with per capita fat consumption and negatively correlated with cereal and grain consumption) (13). Such observations are valuable in suggesting topics for analytic studies or supporting the consistency of an association.

Analytic Studies

The purpose of an analytic epidemiologic study is to test a hypothesis about and to measure an association between exposure (or treatment) and disease occurrence (or prevention) (Fig. 4.1). Analytic studies may be subdivided into *nonexperimental* and *experimental studies*.

Figure 4.1 The essential design of an epidemiologic study showing the relationship between exposure (or treatment) and disease.

Nonexperimental analytic studies include cohort and case-control studies and take advantage of “natural experiments” in which individuals do or do not have a particular disease and have or have not had an exposure of potential interest. *Experimental studies*, such as clinical trials, should meet more rigid criteria than nonexperimental studies. Features they should include are randomization (in which participants are randomly assigned to exposures) and measures to ensure unbiased assessment of outcome.

Nonexperimental Studies

Cohort Studies

Design A cohort is a group of people who have some factor in common. In the context of a survival analysis, the cohort begins with a population that is 100% well at a particular time and is followed over time to calculate the percentage of the cohort still well at later times. Survival analysis describes mortality after disease (i.e., cancer patients who died within 5 years) but can be adapted to other events (e.g., the percentage of women who continue to menstruate after 50 years of age or the percentage of infertile women who conceive after therapy).

A cohort is defined by subsets of a population who are, have been, or may in the future be exposed to factors hypothesized to influence the occurrence of a given disease (Fig. 4.2). The exposed and nonexposed subjects are observed long enough to generate *person-years* as the denominator for incidence or mortality rates in exposed and nonexposed subsets.

Figure 4.2 The format and calculations for a cohort study design.

Cohort studies are also called *follow-up, longitudinal, or prospective studies*. Although these terms suggest that the exposure is identified before outcome, a retrospective cohort study may also be performed in which the exposure and outcome have already occurred when the study is begun. For example, studies of radiation and subsequent cancer are often based on records of patients who received radiation therapy many years previously. Medical records and death certificates

are used to determine whether a second cancer occurred after the radiation therapy.

Yield Cohort studies may yield two measures of an association between exposure and illness. These measures are an *attributable risk* and a *relative risk*.

Attributable risk is the difference between the occurrence measure in the exposed and the unexposed cohort. The null value is zero—a positive number indicates how many cases of disease may be caused by the exposure, and a negative number indicates how many cases of disease may be prevented by the exposure.

Relative risk divides occurrence in the exposed cohort by occurrence in the nonexposed cohort. The null value for the relative risk is 1. A value greater than 1 indicates that exposure may increase risk for the disease (i.e., a relative risk of 1.5 indicates that exposed individuals had 1.5 times, or 50% greater, the risk for disease as unexposed individuals). A value less than 1 indicates that exposure may decrease risk for disease (i.e., a relative risk of 0.5 indicates that the rate in exposed individuals was half that of the rate in the nonexposed individuals).

Strengths and Weaknesses The ability to obtain both attributable and relative risks is a strength of cohort studies. In addition, cohort studies are less susceptible to selection and recall bias. Misclassification of exposure and confounding variables can occur, however. Disadvantages of a cohort study generally include higher cost and longer time for completion. Cohort studies are most useful for examining the occurrence of common diseases after a rare exposure. For rare exposures, an investigator may use the general population as the unexposed group. In this type of study, the observed number of cases in the exposed cohort is divided by the number of cases expected if general population rates had prevailed in the exposed cohort. This comparison is called the standardized morbidity or mortality ratio (SMR) and is equivalent to relative risk.

Case-control Studies

Design A case-control study starts with the identification of individuals with a disease or outcome of interest and a suitable control population without the disease or outcome of interest. The relationship of a particular attribute or exposure to the disease is studied by comparing how the cases and controls differed in that exposure. An alternate term frequently used to describe a case-control study is *retrospective* because the exposures are assessed after the disease has occurred.

Yield The yield of a case-control study is the exposure odds ratio. It is the ratio of exposed cases to unexposed cases divided by the ratio of exposed to unexposed controls. If an entire population could be characterized by its exposure and disease status, the exposure odds ratio would be identical to the relative risk obtainable from a cohort study of the same population. Although it is not feasible to survey the entire population, so long as the sampling of cases or controls from the population was not influenced by their exposure status, the exposure odds ratio will approximate the relative risk. Attributable risk is not directly obtainable in a case-control study (Fig. 4.3).

Figure 4.3 The case-control study design.

Strengths and Weaknesses The advantages of case-control studies are that they are generally lower in cost and easier to conduct than other analytic studies. Case-control studies are most feasible for examining the association between a relatively common exposure and a relatively rare disease. Disadvantages include greater potential for selection bias, information bias, and confounding variables.

Because an investigator must assign exposures according to a strict protocol, human experimental studies are limited to the study of measures that will prevent disease or the consequences of disease. Examples of experimental studies are clinical trials and field and community intervention trials.

Experimental Studies

Clinical Trials

The clinical trial is a prospective cohort study to evaluate treatments for disease in humans. Randomization of the treatment assignment is the cornerstone of a good clinical trial because it minimizes bias, which can result from confounding variables or preferential assignment of treatment based on patient characteristics. Evidence must be provided that factors that might influence outcome, such as stage of disease, were similar in patients assigned to the study protocol compared with patients assigned to placebo or traditional treatment. Criteria for successful treatment must be clearly defined. Blinding the subject and clinician to the treatment modality may help ensure unbiased assessment of the outcome. A properly designed clinical trial will have a sufficient number of subjects enrolled to ensure that a “negative” study is powerful enough to rule out a treatment effect.

Field and Community Intervention Trials

Field and community intervention trials evaluate measures that may prevent disease, such as vaccines, dietary interventions, or screening procedures. In a field trial, the intervention is applied to individuals. In a community intervention trial, the intervention (e.g., water fluoridation) is applied on a community-wide basis rather than to individuals. Both types of studies include subjects who do not yet have disease and may require large numbers of participants, especially for studies of screening procedures to prevent cancer. In the latter context, issues related to the validity of screening tests (i.e., *sensitivity*, *specificity* and *predictive value*) are quite important (Table 4.1).

Status Determined by Screening	True Disease Status		Total
	Positive	Negative	
Positive	a (true positives)	b (false positives)	a + b (all screened positive)
Negative	c (false negatives)	d (true negatives)	c + d (all screened negative)
Total	a + c (all diseased)	b + d (all nondiseased)	N (all subjects)
Sensitivity	Definition		Formula
	True positives / All diseased		$\frac{a}{a + c}$
Specificity	Definition		Formula
	True negatives / All nondiseased		$\frac{d}{b + d}$
Predictive value of a positive screen	Definition		Formula
	True positives / All screened positive		$\frac{a}{a + b}$

Table 4.1. Measures of Validity for a Screening Procedure

Features

Features of an analytic study that are considered in judging its scientific validity include statistical significance, biases, dose response, consistency, and biologic credibility.

Statistical significance is determined by application of a statistical method to test the null hypothesis (i.e., the hypothesis that two or more factors are not associated).

The degree of conflict between the test result and the result predicted by the null hypothesis is indicated by the *p value*. Typically, $p < 0.05$ is used to determine statistical significance and indicates a 5% chance of incorrectly rejecting the null hypothesis.

Confidence Interval

The **confidence interval (CI)** is a component of statistical inference in which an interval is provided to give the reader some idea of the range in which the true statistical measure calculated (e.g., mean, proportion, and relative risk) is expected to occur. A 95% CI implies that, if a study were to be repeated many times within the same population, the measures assessed would be expected to fall in this interval 95% of the time. Confidence intervals of 95% for an odds ratio that includes the null value of 1 would not be statistically significant.

Bias

Bias is a systematic error in the design, conduct, or analysis of a study. Such errors result in a mistaken conclusion and can take various forms.

Information Bias *Information bias* occurs when subjects are classified incorrectly with respect to exposure or disease. This may occur if records are incomplete or if the criteria for exposure or outcome were poorly defined, leading to misclassification.

Recall bias is another type of information bias that may occur if cases are more likely than controls to remember or to reveal past exposures. In addition to adequate criteria and complete records, information bias may be reduced by making interviewers unaware of the status of the subjects or the purpose of the study.

Selection Bias *Selection bias* may occur when correlates of the exposure or outcome influence sampling from the larger population of potentially eligible subjects. An example of selection bias that may arise in a hospital-based case-control study occurs when the combination of the disease under study and a particular exposure is more likely to lead to hospital admission (14). Using incident cases from more than one hospital, obtaining high participation rates, and attempting to describe nonparticipants are several ways to reduce or at least evaluate the potential for selection bias.

Confounding

A third source of potential error is **confounding**. A **confounder** is an extraneous variable that accounts for the apparent effect of the study variable or masks the true association. When a factor differs between cases and controls or cohort members and is associated with both the study exposure and the study outcome, a distortion of the true association between the exposure and the disease may be produced. Age, race, and socioeconomic status are likely confounders; results must be adjusted for these variables by using statistical techniques such as stratification or multivariate analysis. Stratification involves examining the association of interest only within groups that are similar with respect to a potential confounder. Multivariate analysis is a statistical technique commonly used in epidemiologic studies that controls a number of confounders simultaneously. After an analysis to control for confounding variables, the investigator presents the adjusted risk ratio that presumably reflects an association free of confounding.

Dose Response

Dose response means that a change in the amount, intensity, or duration of an exposure is associated with either a consistent increase or decrease in risk for a specified disease or outcome. Trend tests are used to determine whether a dose response exists.

Consistency and Metaanalysis

Consistency between findings in different populations, at different times, and by different methods or investigators is an important criterion used to judge whether there is likely to be a causal relationship. A formal method for studying consistency and pooling results from different studies is metaanalysis.

Metaanalysis is the process of combining results from several independent studies examining the same exposure (or treatment) and same outcome in order to conduct a more powerful test of the null hypothesis. A metaanalysis is conducted by assembling measures of the association from different studies, such as relative risks, weighting them by the variance of the measure, and taking an overall average. In the weighting process, the studies with the largest sample size contribute the greatest information. A properly performed metaanalysis also has a qualitative component that establishes criteria for acceptance of a study (e.g., only randomized studies might be chosen for a metaanalysis of the effect of a particular treatment on a particular disease).

Biologic Credibility

Biologic credibility means that an association is plausible, taking into consideration all aspects of what is known about the natural history or demographics of a disease or what has been observed in relevant experimental models. Whereas an imaginative epidemiologist can find an explanation for any single association, a key issue is whether a model can be proposed accounting for a variety of exposures as well as experimental data and cross-sectional observations.

Gynecologic Considerations

In epidemiologic terms, *exposure* refers to events that could be linked to an increased risk of disease. Exposures that are important to women's health are either gynecologic exposures that affect common diseases or common exposures that affect gynecologic diseases.

Reproductive Events

Age at menarche, characteristics of menstrual cycles, number of pregnancies, contraceptives or hormones used, and age at menopause are important events that may have broad impact on many diseases, including endometriosis (15), fibroids (16), heart disease (17), osteoporosis (18), and cancers of the breast, endometrium, or ovary (19,20 and 21). Gynecologists should maintain careful records of reproductive landmarks, both for their potential usefulness in advising patients and for their relevance to clinical research.

Contraception and Sterilization

Barrier Contraception

A protective effect of barrier contraception against pelvic inflammatory disease (PID) (22), tubal infertility (23), ectopic pregnancy (24), and cervical cancer (25) has been consistently observed.

Intrauterine Devices

Current or past use of an intrauterine device (IUD) has been linked with risk for PID (26), ectopic pregnancy (27), and tubal infertility (28). It is likely that these risks could be reduced by restricting IUD use to women at low risk for genital infections (e.g., parous women in a monogamous relationship).

Oral Contraceptives

Early epidemiologic literature on oral contraceptives (OCs) focused on adverse events, including thromboembolism (particularly with high-dose formulations) (29), hypertension (30), myocardial infarction (especially in women older than 40 years of age who also smoked) (31), and liver adenomas (32). Protective effects of OCs have more recently been appreciated, including lower risk for benign breast disease (33), ovarian cysts (34), ovarian cancer (35), and PID (36). Controversy exists concerning the relationship between OC use and cervical and breast cancer. Progression of intraepithelial cervical lesions may be more rapid among OC users (37). A large case-control study of breast cancer in England suggested use of preparations containing 50 mg or more of estrogen may increase the risk for breast cancer (38). However, the possible increased risk associated with past OC use for developing breast cancer at an early age may be more than offset by a decreased risk for developing breast cancer at an older age (39).

Sterilization

Concerns that sterilization might induce early menopause (40) have not been proved. An unexpected protective effect of female sterilization has been suggested for ovarian cancer (41). This protection may derive from the reduction of uterine growth factors that reach the ovary as a result of the interruption of the uteroovarian circulation or from closure of the female tract, which would prevent substances in the vagina or uterus from reaching the ovaries (42).

Hormone Replacement Therapy

Similar to early studies of OCs, studies of menopausal hormones focused on adverse events, including endometrial cancer, associated with unopposed estrogen use (43). This association has likely been obviated by the use of combined estrogen-progesterone regimens (44). More recent studies suggest protective effects on heart disease (45), osteoporosis (46), and even Alzheimer's disease (47). The association between menopausal hormones and breast cancer continues to be debated. However, a recent metaanalysis of studies of menopausal hormone use and breast cancer provided reassurance that the effect of such agents on breast cancer risk is modest (48).

Sexually Transmitted Disease

Worldwide, sexually transmitted diseases are possibly the most important preventable cause of morbidity in women. This morbidity includes not only PID from gonorrhea and chlamydia but also chronic disease from syphilis and genitally transmitted viruses, including hepatitis, human papillomavirus, and human immunodeficiency virus (HIV). The importance of public health measures to prevent the spread of sexually transmitted diseases, especially the use of barrier contraception, cannot be overemphasized because the morbidity from these infections may carry over to the offspring of those infected.

Lifestyle

Factors relating to an individual's lifestyle can increase the risk for potential problems. Often, the risk can be minimized by identifying these factors and altering behavior.

Smoking

Adverse effects of smoking on the lungs and heart are well known; however, it is less widely appreciated that smoking may be linked to tubal infertility (49), ectopic pregnancy (50), cervical cancer (51), and early menopause (52).

Alcohol

In moderation, alcohol use is associated with decreased risk for cardiovascular disease (53), which may come at the expense of an increased risk for breast cancer (54). It is possible that both of these effects are mediated by the ability of alcohol to retard the metabolism of estrogen, thereby leading to higher circulating levels of estrogen (55).

Exercise and Nutrition

Although aspects of exercise and nutrition cannot be fairly summarized in a single paragraph, it can be stated that gynecologic problems can occur at either extreme. The lean athlete in training who becomes amenorrheic may lose bone mass because of a lack of estrogen, as might the patient with anorexia (18). In obese women, menstrual difficulties may occur that are related to higher estrogen levels, which may, in the longer term, be associated with a higher risk for endometrial cancer (56).

Talc

Use of talc in genital hygiene is an exposure emphasized as a potential risk factor for ovarian cancer (57). Because there are no benefits of genital talc use, other than aesthetic, this practice should be discouraged.

Illnesses

Many gynecologists are primary care providers for women, and they may increasingly assume this role in the future. It is important, therefore, for gynecologists to have an overview of the major causes of mortality in women. Reliable incidence data for gynecologic cancers and benign gynecologic problems are sometimes difficult to find, but statistics are available to guide clinical interventions.

Table 4.2 shows the 10 leading causes of death in 1998 for females in the United States by age from the National Center for Health Statistics data (58). Heart disease remains the major cause of death in women overall, but there is considerable age variation. Accidents, homicides, and suicides are most important at ages younger than 40 years, and cancer is most important at ages 40 to 79 years.

Age Group	15-19	20-24	25-29	30-34	35-39	40-44	45-49	50-54	55-59	60-64	65-69	70-74	75-79	80-84	85-89	90-94	95-99

Table 4.2. Reported Deaths for the 10 Leading Causes of Death by Age, United States, 1998

Table 4.3 shows the five leading causes of cancer mortality in women by various ages. In women, lung cancer now accounts for more deaths than breast cancer. Colon and rectal cancers are second overall, highlighting the importance of colon cancer screening in women older than 50 years of age. Pancreatic and ovarian cancers occur with about equal frequency, and both remain elusive to screening.

Age Group	<20 Yr	20-39 Yr	40-59 Yr	60-79 Yr	≥80 Yr
All sites	All sites: 520	All sites: 5,107	All sites: 43,872	All sites: 111,017	All sites: 75,326
Long and bronchus	280	1,604	11,889	19,877	13,352
Breast	Brain and CNS: 233	Uterine cervix: 634	Long and bronchus: 19,335	Breast: 18,292	Colon and rectum: 12,124
Colon and rectum	28,959	Soft tissue: 73	Leukemia: 836	Colon and rectum: 3,472	Breast: 9,949
Pancreas	14,529	Endocrine system: 68	Long and bronchus: 442	Cherry: 2,843	Pancreas: 5,193
Ovary	13,371	Brain and CNS: 62	Pancreas: 1,775	Ovary: 7,218	Non-Hodgkin's lymphoma: 3,881

Note: "All sites" excludes in situ carcinoma except urinary bladder, CNS, other nervous system.

Table 4.3. Reported Deaths for the Five Leading Cancer Sites for Females by Age, United States, 1998

Figure 4.4 illustrates the age-specific incidence of genital malignancies in all females in the United States around 1991 (59). The incidence of invasive cervical cancer remains steady across all ages, whereas ovarian and endometrial cancer increase markedly during the perimenopausal years and predominate after 50 years of age. The sharp increase in endometrial and ovarian cancer rates around the time of menopause may reflect anovulatory cycles associated with unopposed estrogen and increased levels of gonadotropins. Although ovarian cancer appears to rank second to endometrial cancer in terms of incidence, mortality from ovarian cancer currently exceeds the combined mortality of endometrial and cervical cancer (58).

Figure 4.4 Age-specific incidence of gynecologic cancers, all U.S. females (1991). (From Ries LAG, Miller BA, Hankey BF, et al. *hype SEER cancer statistics review, 1973-1991, tables and graphs*. Bethesda, MD: Surveillance Program, Division of Cancer Prevention and Control, National Cancer Institute, NIH Pub No. 94-2789, 1994, with permission.)

The estimated number of hospital admissions listing various benign gynecologic conditions as a discharge diagnosis, shown in Table 4.4, is based on data collected by the National Hospital Discharge Survey for 1988 to 1990 and by the Division of Reproductive Health of the Centers for Disease Control and Prevention (60). These data pertain to women 15 to 45 years of age and are based on discharges from nonmilitary hospitals. PID is the most frequent discharge diagnosis, with nearly 300,000 women hospitalized annually. Of almost equal frequency are hospitalizations for benign ovarian cysts, endometriosis, and fibroids, each of which accounts for the hospitalization of almost 200,000 women annually.

Group of Diagnosis	Hospitalizations*
Pelvic inflammatory disease	287,349
Benign cysts of the ovary	190,548
Endometriosis	188,825
Menstrual disorders	182,988
Uterine leiomyomas	177,082
Prolapse/leakage incontinence	101,937
Cervical intraepithelial neoplasia	60,320

*Based on discharge diagnoses for women 15 through 45 years of age in nonmilitary hospitals averaged for the period 1988-1990.
From: Veledil P, Wingo PA, Xia A, et al. Rate of hospitalization for gynecologic disorders among reproductive-age women in the United States. *Obstet Gynecol* 1995;86:764-769, with permission.

Table 4.4. Estimated Number of Annual Hospitalizations among Women of Reproductive Age in the United States

The estimated age-specific incidence of PID, ovarian cysts, fibroids, and endometriosis is shown in Fig. 4.5. Notable are the higher incidence of PID in women in their 20s and the increasing incidence of endometriosis and fibroids into the 40s. The high frequency of the latter two conditions, combined with a lack of information on their cause, suggests that these conditions should be targets for more epidemiologic research.

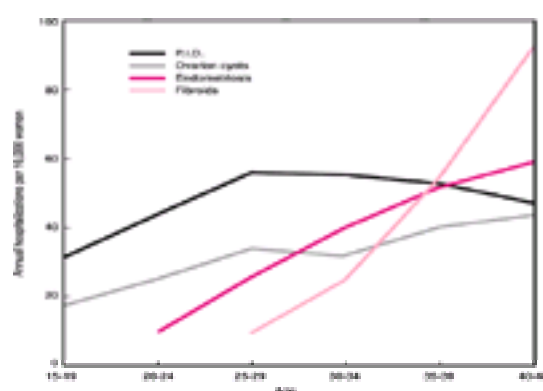

Figure 4.5 Age-specific incidence of hospitalization for various benign gynecologic conditions around 1990. (From Veledil P, Wingo PA, Xia A, et al. Rate of hospitalization for gynecologic disorders among reproductive-age women in the United States. *hype Obstet Gynecol* 1995;86:764-769, with permission.)

In 1989, there were about 88,400 ectopic pregnancies in the United States, with a rate of about 16.0 per 1,000 reported pregnancies, compared with 4.5 per 1,000 in 1970 (61). In 1970, however, the case-fatality rate was 35.5 per 10,000 ectopic pregnancies, compared with 3.8 per 10,000 ectopic pregnancies in 1989, which accounted for about 13% of all maternal deaths that year. Ectopic pregnancy continues to contribute to maternal mortality, particularly among nonwhite populations.

Gynecologic exposures and gynecologic diseases have always been major focuses for epidemiologic research. However, gynecologists have infrequently been involved in the design and interpretation of such studies, and therefore, the physiologic and clinical relevance of various associations often have been inadequately discussed. Even if the gynecologist does not actually perform epidemiologic research, an understanding of epidemiologic principles allows for a more critical reading of the medical literature and sharpens the practice of preventive medicine in gynecology.

[Summary](#)

[References](#)

Nothing is more fundamental to the knowledge base of the practicing gynecologist than an understanding of the anatomy of the female pelvis. Although the basic facts of anatomy and their relevance to gynecologic practice do not change with time, our understanding of specific anatomic relationships and the development of new clinical and surgical correlations continue to evolve.

The anatomy of the fundamental supporting structures of the pelvis and the genital, urinary, and gastrointestinal viscera are presented in this chapter. Because significant variation has developed in the names of many common anatomic structures, the terms used here reflect current standard nomenclature according to the *Nomina Anatomica* (1); however, other commonly accepted terms are included in parentheses.

Pelvic Structure

Bony Pelvis

The skeleton of the pelvis is formed by the sacrum and coccyx and the paired hipbones (coxal, innominate), which fuse anteriorly to form the symphysis pubis. [Figure 5.1](#) illustrates the bony pelvis as well as its ligaments and foramina.

Figure 5.1 The female pelvis. The pelvic bones (the innominate bone, sacrum, and coccyx) and their joints, ligaments, and foramina.

Sacrum and Coccyx

The sacrum and coccyx are an extension of the vertebral column resulting from the five fused sacral vertebrae and the four fused coccygeal vertebrae. They are joined by a symphyseal articulation (sacrococcygeal joint), which allows some movement.

The essential features of the sacrum and coccyx are as follows:

1. **Sacral promontory**—the most prominent and anterior projection of the sacrum, this is an important landmark for insertion of a laparoscope. It is located at the level of bifurcation of the common iliac arteries.
2. **Four paired anterior and posterior sacral foramina**—exit sites for the anterior and posterior rami of the corresponding sacral nerves; anterior foramina are also traversed by the lateral sacral vessels.
3. **Sacral hiatus**—results from incomplete fusion of the posterior lamina of the fifth sacral vertebra, offering access to the sacral canal, which is clinically important

for caudal anesthesia.

Laterally, the alae ("wings") of the sacrum offer auricular surfaces that articulate with the hipbones to form synovial sacroiliac joints.

Os Coxae

The paired os coxae, or hipbones, have three components: the ilium, the ischium, and the pubis. These components meet to form the acetabulum, a cup-shaped cavity that accommodates the femoral head.

Ilium

1. **Iliac crest**—provides attachments to the iliac fascia, abdominal muscles, and fascia lata.
2. **Anterior superior and inferior spine**—superior spine provides the point of fixation of the inguinal ligament.
3. **Posterior superior and inferior spine**—superior spine is the point of attachment for the sacrotuberous ligament and the posterior sacral iliac ligament.
4. **Arcuate line**—marks the pelvic brim and lies between the first two segments of the sacrum.
5. **Iliopectineal eminence (linea terminalis)**—the line of junction of the ilium and the pubis.
6. **Iliac fossa**—the smooth anterior concavity of the ilium, covered by the iliacus muscle.

Ischium

1. **Ischial spine**—delineates the greater and lesser sciatic notch above and below it. It is the point of fixation for the sacrospinous ligament; the ischial spine represents an important landmark in the performance of pudendal nerve block and sacrospinous ligament vaginal suspension; vaginal palpation during labor allows detection of progressive fetal descent.
2. **Ischial ramus**—joins that of the pubic rami to encircle the obturator foramen; provides the attachment for the inferior fascia of the urogenital diaphragm and the perineal musculofascial attachments.
3. **Ischial tuberosity**—the rounded bony prominence upon which the body rests in the sitting position.

Pubis

1. **Body**—formed by the midline fusion of the superior and inferior pubic rami.
2. **Symphysis pubis**—a fibrocartilaginous symphyseal joint where the bodies of the pubis meet in the midline; allows for some resilience and flexibility, which is critical during parturition.
3. **Superior and inferior pubic rami**—join the ischial rami to encircle the obturator foramen; provide the origin for the muscles of the thigh and leg; provide the attachment for the inferior layer of the urogenital diaphragm.
4. **Pubic tubercle**—a lateral projection from the superior pubic ramus, to which the inguinal ligament, rectus abdominis, and pyramidalis attach.

Pelvic Bone Articulations

The pelvic bones are joined by four articulations:

1. **Two cartilaginous symphyseal joints—the sacrococcygeal joint and the symphysis pubis**—these joints are surrounded by strong ligaments anteriorly and posteriorly, which are responsive to the effect of relaxin and facilitate parturition.
2. **Two synovial joints—sacroiliac joints**—these are stabilized by the sacroiliac ligaments, the iliolumbar ligament, the lateral lumbosacral ligament, the sacrotuberous ligament, and the sacrospinous ligament.

The pelvis is divided into the *greater* and *lesser pelvis* by an oblique plane passing through the sacral promontory, the *linea terminalis (arcuate line of the ilium)*, the *pectineal line of the pubis*, the *pubic crest*, and the *upper margin of the symphysis pubis*. This plane lies at the level of the superior pelvic aperture (*pelvic inlet*) or pelvic brim. The inferior pelvic aperture or *pelvic outlet* is irregularly bound by the tip of the coccyx, the symphysis pubis, and the ischial tuberosities. The dimensions of the superior and inferior pelvic apertures have important obstetric implications.

Ligaments and Foramina

Four ligaments of the bony pelvis are of special importance to the gynecologic surgeon.

Inguinal Ligament

The inguinal ligament is important surgically in the repair of inguinal hernia. The inguinal ligament:

1. Is formed by the lower border of the aponeurosis of the external oblique muscle folded back upon itself.
2. Is fused laterally to the iliacus fascia and inferiorly to the fascia lata.
3. Flattens medially into the lacunar ligament, which forms the medial border of the femoral ring.

Cooper's Ligament

Cooper's ligament is used frequently in bladder suspension procedures. Cooper's ligament:

1. Is a strong ridge of fibrous tissue extending along the pectineal line—also known as the pectineal ligament.
2. Merges laterally with the iliopectineal ligament and medially with the lacunar ligament.

Sacrospinous Ligament

The sacrospinous ligament is often used for vaginal suspension. This ligament offers the advantage of a vaginal surgical route. The sacrospinous ligament:

1. Extends from the ischial spine to the lateral aspect of the sacrum.
2. Is separated from the rectovaginal space by the rectal pillars.
3. Lies anterior to the pudendal nerve and the internal pudendal vessels at its attachment to the ischial spine.
4. The inferior gluteal artery, with extensive collateral circulation, is found between the sacrospinous and sacrotuberous ligaments and may be injured during sacrospinous suspension (2).

Sacrotuberous Ligament

The sacrotuberous ligament is sometimes used as a point of fixation for vaginal vault suspension. The sacrotuberous ligament:

1. Extends from the ischial tuberosity to the lateral aspect of the sacrum.
2. Merges medially with the sacrospinous ligament.
3. Lies posterior to the pudendal nerve and the internal pudendal vessels.

The bony pelvis and its ligaments delineate three important foramina that allow the passage of the various muscles, nerves, and vessels to the lower

perineum, the wall of the anal canal, the anococcygeal ligament, the coccyx, and the vaginal wall.

The levator ani assists the anterior abdominal wall muscles in containing the abdominal and pelvic contents. It supports the vagina, facilitates defecation, and aids in maintaining fecal continence. During parturition, the levator ani supports the fetal head while the cervix dilates. The levator ani is innervated by S3 to S4, the inferior rectal nerve.

Urogenital Diaphragm

The muscles of the urogenital diaphragm reinforce the pelvic diaphragm anteriorly and are intimately related to the vagina and the urethra. They are enclosed between the inferior and superior fascia of the urogenital diaphragm. The muscles include the deep transverse perineal and sphincter urethrae ([Table 5.1](#)).

Blood Vessels

The pelvic blood vessels supply genital structures as well as the following:

- Urinary and gastrointestinal tracts.
- Muscles of the abdominal wall, pelvic floor and perineum, buttocks, and upper thighs.
- Fasciae, other connective tissue, and bones.
- Skin and other superficial structures.

Classically, vessels supplying organs are known as *visceral vessels* and those supplying supporting structures are called *parietal vessels*.

Major Blood Vessels

The course of the major vessels supplying the pelvis is illustrated in [Fig. 5.4](#); their origin, course, branches, and venous drainage are presented in [Table 5.2](#). In general, the venous system draining the pelvis closely follows the arterial supply and is named accordingly. Not infrequently, a vein draining a particular area may form a plexus with multiple channels. Venous systems, which are paired, mirror each other in their drainage patterns, with the notable exception of the ovarian veins. Unusual features of venous drainage are also listed in [Table 5.2](#).

Figure 5.4 The blood supply to the pelvis. **A:** The sagittal view of the pelvis without the viscera. **B:** The blood supply to one pelvic viscera.

Vessel	Origin	Course	Branches	Drainage
Common Iliac Artery	Aorta	Through the greater sciatic foramen	Internal and External Iliac Arteries	Common Iliac Vein
Internal Iliac Artery	Common Iliac Artery	Along the anterior surface of the lesser sciatic foramen	Superior Gluteal, Inferior Gluteal, Obturator Foramina, Hypogastric, and Iliolumbar Arteries	Internal Iliac Vein
External Iliac Artery	Common Iliac Artery	Through the lesser sciatic foramen	None	External Iliac Vein
Superior Gluteal Artery	Internal Iliac Artery	Through the greater sciatic foramen	None	Internal Iliac Vein
Inferior Gluteal Artery	Internal Iliac Artery	Through the greater sciatic foramen	None	Internal Iliac Vein
Obturator Foramina Artery	Internal Iliac Artery	Through the lesser sciatic foramen	None	Internal Iliac Vein
Hypogastric Artery	Internal Iliac Artery	Along the anterior surface of the lesser sciatic foramen	None	Internal Iliac Vein
Iliolumbar Artery	Internal Iliac Artery	Along the anterior surface of the lesser sciatic foramen	None	Internal Iliac Vein

Table 5.2. The Major Blood Vessels of the Pelvis

General Principles

“Control blood supply” and “maintain meticulous hemostasis” are two of the most common exhortations to young surgeons. In developing familiarity with the pattern of blood flow in the pelvis, several unique characteristics of this vasculature should be understood and may have implications for surgical practice:

1. **The pelvic vessels play an important role in pelvic support.** They provide condensations of endopelvic fascia that act to reinforce the normal position of pelvic organs (3).
2. **There is significant anatomic variation between individuals in the branching pattern of the internal iliac vessels.** There is no constant order in which branches divide from the parent vessel; some branches may arise as common trunks or may spring from other branches rather than from the internal iliac. Occasionally, a branch may arise from another vessel entirely (e.g., the obturator artery may arise from the external iliac or inferior epigastric artery). This variation may also be found in the branches of other major vessels; the ovarian arteries have been reported to arise from the renal arteries or as a common trunk from the front of the aorta on occasion. The inferior gluteal artery may originate from the posterior or the anterior branch of the internal iliac (hypogastric) artery (2). Patterns of blood flow may be asymmetric from side to side, and structures supplied by anastomoses of different vessels may show variation from person to person in proportion of vascular support provided by the vessels involved. The pelvic surgeon must be prepared for deviations from “textbook” vascular patterns.
3. **The pelvic vasculature is a high-volume, high-flow system with enormous expansive capabilities throughout reproductive life.** Blood flow through the uterine arteries increases to about 500 mL/min in late pregnancy. In nonpregnant women, certain conditions, such as uterine fibroids or malignant neoplasms, may be associated with neovascularization and hypertrophy of existing vessels and a corresponding increase in pelvic blood flow. Understanding of the volume and flow characteristics of the pelvic vasculature in different clinical situations will enable the surgeon to anticipate problems and take appropriate preoperative and intraoperative measures (including blood and blood product availability) to prevent or manage hemorrhage.
4. **The pelvic vasculature is supplied with an extensive network of collateral connections (Fig. 5.5) that provides a rich anastomotic communication between different major vessel systems.** This degree of redundancy is important to ensure adequate supply of oxygen and nutrients in the event of major trauma or other vascular compromise. *Hypogastric artery ligation continues to be used as a strategy for management of massive pelvic hemorrhage when other measures have failed. Bilateral hypogastric artery ligation, particularly when combined with ovarian artery ligation, dramatically reduces pulse pressure in the pelvis, converting flow characteristics from that of an arterial system to a venous system and allowing use of collateral channels of circulation to continue blood supply to pelvic structures. The significance of collateral blood flow is demonstrated by reports of successful pregnancies occurring after bilateral ligation of both hypogastric and ovarian arteries (4).* [Table 5.3](#) lists the collateral channels of circulation in the pelvis.

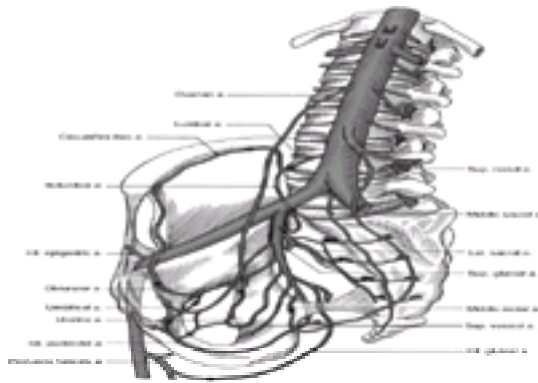

Figure 5.5 The collateral blood vessels of the pelvis. (Modified from Kamina P. *Anatomie gynécologique et obstétricale*. Paris: Maloine Sa Éditeur, 1984:125, with permission.)

Primary Artery	Collateral Arteries
Aorta	
Ovarian artery	Uterine artery
Superior rectal artery (inferior mesenteric artery)	Middle rectal artery
	Inferior rectal artery (internal pudenda)
Lumbar arteries	Iliolumbar artery
Vertebral arteries	Iliolumbar artery
Middle sacral artery	Lateral sacral artery
External iliac	
Deep iliac circumflex artery	Iliolumbar artery
Inferior epigastric artery	Superior gluteal artery
	Obturator artery
Femoral	
Medial femoral circumflex artery	Obturator artery
Lateral femoral circumflex artery	Inferior gluteal artery
	Superior gluteal artery
	Iliolumbar artery

Table 5.3. Collateral Arterial Circulation of the Pelvis

Special Vascular Considerations

When inserting a laparoscopic trocar into the anterior abdominal wall, the gynecologic surgeon must keep in mind certain anatomic relationships in order to avoid injury to vascular structures and resultant hemorrhage. The inferior epigastric artery is a branch of the external iliac artery, arising from the parent vessel at the medial border of the inguinal ligament and coursing cephalad lateral to and posterior to the rectus sheath at the level of the arcuate line. It lies about 1.5 cm lateral to the medial umbilical fold, which marks the site of the obliterated umbilical artery. The aortic bifurcation occurs at the level of L4 to L5, just above the sacral promontory. Palpation of the sacral promontory to guide trocar insertion allows the surgeon to avoid the major vascular structures in this area (see [Fig. 21.4](#) in Chapter 21).

Lymphatics

The pelvic lymph nodes are generally arranged in groups or chains and follow the course of the larger pelvic vessels, for which they are usually named. Smaller nodes that lie close to the visceral structures are usually named for those organs. Lymph nodes in the pelvis receive afferent lymphatic vessels from pelvic and perineal visceral and parietal structures and send efferent lymphatics to more proximal nodal groups. The number of lymph nodes and their exact location is variable; however, certain nodes tend to be relatively constant:

1. Obturator node in the obturator foramen, close to the obturator vessels and nerve.
2. Nodes at the junction of the internal and external iliac veins.
3. Ureteral node in the broad ligament near the cervix, where the uterine artery crosses over the ureter.
4. The *Cloquet* or *Rosenmüller* node—the highest of the deep inguinal nodes that lies within the opening of the femoral canal.

[Figure 5.6](#) illustrates the pelvic lymphatic system. [Table 5.4](#) outlines the major lymphatic chains of relevance to the pelvis and their primary afferent connections from major pelvic and perineal structures. There are extensive interconnections between lymph vessels and nodes; more than one lymphatic pathway is usually available for drainage of each pelvic site. Bilateral and crossed extension of lymphatic flow may occur, and entire groups of nodes may be bypassed to reach more proximal chains.

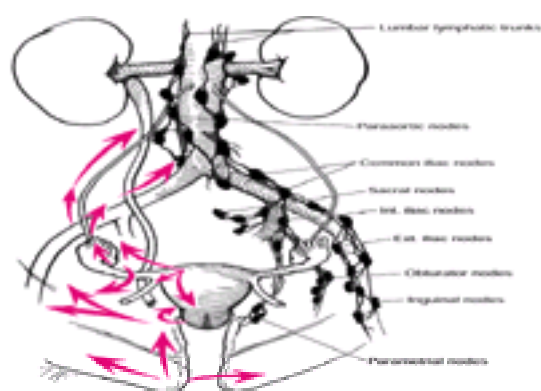

Figure 5.6 The lymphatic drainage of the female pelvis. The vulva and lower vagina drain to the superficial and deep inguinal nodes, sometimes directly to the iliac nodes (along the dorsal vein of the clitoris) and to the other side. The cervix and upper vagina drain laterally to the parametrial, obturator, and external iliac nodes and posteriorly along the uterosacral ligaments to the sacral nodes. Drainage from these primary lymph node groups is upward along the infundibulopelvic ligament, similar to drainage of the ovary and fallopian tubes to the paraaortic nodes. The lower uterine body drains in the same manner as the cervix. Rarely, drainage occurs along the round ligament to the inguinal nodes.

Nodes	Primary Afferent Connections
Aortic/paraortic	Ovary, fallopian tube, uterine corpus (upper); drainage from common iliac nodes
Common iliac	Drainage from external and internal iliac nodes
External iliac	Upper vagina, cervix, uterine corpus (upper); drainage from inguinal nodes
Internal iliac	Upper vagina, cervix, uterine corpus (lower)
Lateral sacral	
Superior gluteal	
Inferior gluteal	
Obturator	
Vertebral	
Rectal	
Paraaortic	
Inguinal	
Superficial	Vulva, lower vagina, (ure: uterus, tube, ovary)
Deep	

Table 5.4. Primary Lymph Node Groups Providing Drainage to Genital Structures

The natural history of most genital tract malignancies directly reflects the lymphatic drainage of those structures, although the various interconnections, different lymphatic paths, and individual variability make the spread of malignancy somewhat unpredictable. Regional lymph node metastasis is one of the most important factors in formulation of treatment plans for gynecologic malignancies and prediction of eventual outcome.

Nerves

The pelvis is innervated by both the autonomic and somatic nervous systems. The autonomic nerves include both *sympathetic* (adrenergic) and *parasympathetic* (cholinergic) fibers and provide the primary innervation for genital, urinary, and gastrointestinal visceral structures and blood vessels.

Somatic Innervation

The *lumbosacral plexus* (Fig. 5.7) and its branches provide motor and sensory somatic innervation to the lower abdominal wall, the pelvic and urogenital diaphragms, the perineum, and the hip and lower extremity. The nerves originating from the muscles, the lumbosacral trunk, the anterior divisions of the upper four sacral nerves (*sacral plexus*), and the anterior division of the coccygeal nerve and fibers from the fourth and fifth sacral nerves (*coccygeal plexus*) are found on the anterior surface of the piriformis muscle and lateral to the coccyx, respectively, deep in the posterior pelvis. Table 5.5 lists each major branch by spinal segment and structures innervated. In addition to these branches, the lumbosacral plexus includes nerves that innervate muscles of the lateral pelvic wall (obturator internus, piriformis), posterior hip muscles, and the pelvic diaphragm. A visceral component, the pelvic splanchnic nerve, is also included.

Figure 5.7 The sacral plexus. (Modified from Kamina P. *Anatomie gynécologique et obstétricale*. Paris: Maloine Sa Éditeur, 1984:90, with permission.)

Nerve	Spinal Segment	Innervation
Iliohypogastric	L1, L2	Sensory—cutaneous thigh, groin, and pubic (anterior) regions
Ilioinguinal	L2	Sensory—upper medial thigh, scrotum, and vulva
Obturator internus	L2, L3	Sensory—lateral thigh to level of knee
Obturator externus	L3, L4, L5	Sensory—lateral thigh to level of knee; motor—hip and knee, hip and knee
Genitofemoral	L2, L3	Sensory—genital and scrotal (thigh, scrotum) and femoral (leg and foot) regions
Pudendal	S2, S3, S4	Sensory—perineum, anterior thigh, scrotum, and vulva
Coccygeal	S4, S5	Sensory—perineum, scrotum, and vulva
Obturator	L3, L4, L5	Sensory—medial thigh and leg, hip, and knee joints
Superior gluteal	L4, L5, S1	Motor—gluteal muscles
Inferior gluteal	L4, L5, S1, S2	Motor—gluteal muscles
Posterior femoral cutaneous	S1, 2	Sensory—cutaneous, posterior
Sciatic	L4, L5, S1, S2, S3	Sensory—most of leg, foot, knee, and ankle joints; Motor—posterior thigh, knee, leg, and foot muscles
Pudendal	S2, S3, S4	Sensory—perineum, scrotum, and vulva; Motor—external and internal anal sphincters, external anal sphincter, urethral and vaginal muscles, uterine and vaginal muscles

Table 5.5. Lumbosacral Plexus

Nerves supplying the cutaneous aspects of the anterior, medial, and lateral lower extremities, as well as the deep muscles of the anterior thigh, primarily leave the pelvis by passing beneath the inguinal ligament. Nerves supporting the posterior cutaneous and deep structures of the hip, thigh, and leg lie deep in the pelvis and should not be vulnerable to injury during pelvic surgery. *The obturator nerve travels along the lateral pelvic wall to pass through the obturator foramen into the upper thigh, and it may be encountered in more radical dissections involving the lateral pelvic wall and in paravaginal repairs.*

The pudendal nerve crosses over the piriformis to travel with the internal pudendal vessels into the ischioanal fossa, where it divides into its three terminal branches to provide the primary innervation to the perineum. Other nerves contribute to the cutaneous innervation of the perineum:

1. **The anterior labial nerve branches of the ilioinguinal nerve**—these nerves emerge from within the inguinal canal and through the superficial inguinal ring to the mons and upper labia majora.
2. **The genital branch of the genitofemoral nerve**—this branch enters the inguinal canal with the round ligament and passes through the superficial inguinal ring to the anterior vulva.
3. **The perineal branches of the posterior femoral cutaneous nerve**—after leaving the pelvis through the greater sciatic foramen, these branches run in front of the ischial tuberosity to the lateral perineum and labia majora.
4. **Perforating cutaneous branches of the second and third sacral nerves**—these branches perforate the sacrotuberous ligament to supply the buttocks and contiguous perineum.
5. **The anococcygeal nerves**—these nerves arise from S4 to S5 and also perforate the sacrotuberous ligament to supply the skin overlying the coccyx.

Autonomic Innervation

Functionally, the innervation of the pelvic viscera may be divided into an *efferent* component and an *afferent*, or sensory, component. In reality, however, afferent and efferent fibers are closely associated in a complex interlacing network and cannot be separated anatomically.

Efferent Innervation

Efferent fibers of the autonomic nervous system, unlike motor fibers in the somatic system, involve one synapse outside the central nervous system, with two neurons required to carry each impulse. In the *sympathetic (thoracolumbar) division*, this synapse is generally at some distance from the organ being innervated; conversely, the synapse is on or near the organ of innervation in the *parasympathetic (craniosacral) division*.

Axons from preganglionic neurons emerge from the spinal cord to make contact with peripheral neurons arranged in aggregates known as *autonomic ganglia*. Some of these ganglia, along with interconnecting nerve fibers, form a pair of longitudinal cords called the *sympathetic trunks*. Located lateral to the spinal column from the base of the cranium to the coccyx, the sympathetic trunks lie along the medial border of the psoas muscle from T12 to the sacral prominence and then pass behind

the common iliac vessels to continue into the pelvis on the anterior surface of the sacrum. On the anterolateral surface of the aorta, the *aortic plexus* forms a lacy network of nerve fibers with interspersed ganglia. Rami arising from or traversing the sympathetic trunks join this plexus and its subsidiaries.

The ovaries and part of the fallopian tubes and broad ligament are innervated by the *ovarian plexus*, a network of nerve fibers accompanying the ovarian vessels and derived from the aortic and renal plexuses. The *inferior mesenteric plexus* is a subsidiary of the *celiac plexus* and *aortic plexus* and is located along the inferior mesenteric artery and its branches, providing innervation to the left colon, sigmoid, and rectum.

The *superior hypogastric plexus (presacral nerve)* (Fig. 5.8) is the continuation of the aortic plexus beneath the peritoneum in front of the terminal aorta, the fifth lumbar vertebra, and the sacral promontory, medial to the ureters. Embedded in loose areolar tissue, the plexus overlies the middle sacral vessels and is usually composed of two or three incompletely fused trunks. It contains preganglionic fibers from lumbar nerves, postganglionic fibers from higher sympathetic ganglia and from the sacral sympathetic trunks, and visceral afferent fibers.

Figure 5.8 The presacral nerves.

Just below the sacral promontory, the superior hypogastric plexus divides into two loosely arranged nerve trunks, the *hypogastric nerves*. These nerves course inferiorly and laterally to connect with the inferior *hypogastric plexuses (pelvic plexuses)* (Fig. 5.8), which are a dense network of nerves and ganglia that lie along the lateral pelvic sidewall overlying branches of the internal iliac vessels.

The inferior hypogastric plexus includes efferent sympathetic fibers, afferent (sensory) fibers, and parasympathetic fibers arising from the pelvic splanchnic nerves (S2 to S4, *nervi erigentes*).

This paired plexus is the final common pathway of the pelvic visceral nervous system and is divided into three portions, representing distribution of innervation to the viscera:

1. **Vesical plexus**
 - Innervation: bladder and urethra
 - Course: along vesical vessels
2. **Middle rectal plexus (hemorrhoidal)**
 - Innervation: rectum
 - Course: along middle rectal vessels
3. **Uterovaginal plexus (Frankenhäuser ganglion)**
 - Innervation: uterus, vagina, clitoris, vestibular bulbs
 - Course: along uterine vessels and through cardinal and uterosacral ligaments; sympathetic and sensory fibers derive from T10, L1; parasympathetic fibers derive from S2 to S4.

Afferent Innervation

Afferent fibers from the pelvic viscera and blood vessels traverse the same pathways to provide sensory input to the central nervous system. They are also involved in reflex arcs needed for bladder, bowel, and genital tract function. The afferent fibers reach the central nervous system to have their first synapse within posterior spinal nerve ganglia.

Presacral neurectomy, in which a segment of the superior hypogastric plexus is divided and resected in order to interrupt sensory fibers from the uterus and cervix, has been associated with relief of dysmenorrhea secondary to endometriosis in about 50% to 75% of cases in which it has been employed (5,6). Because efferent fibers from the adnexa travel with the ovarian plexus, pain originating from the ovary or tube is not relieved by resection of the presacral nerve. Because this plexus also contains efferent sympathetic and parasympathetic nerve fibers intermixed with afferent fibers, disturbance in bowel or bladder function may result. An alternative surgical procedure advocated in recent years is resection of a portion of the uterosacral ligaments; because they contain numerous nerve fibers with more specific innervation to the uterus, it is postulated that bladder and rectal function is less vulnerable to compromise.

An anesthetic block of the pudendal nerve is performed most often for pain relief with uncomplicated vaginal deliveries but may also provide useful anesthesia for minor perineal surgical procedures. This nerve block may be accomplished transvaginally or through the perineum. A needle is inserted toward the ischial spine with the tip directed slightly posteriorly and through the sacrospinous ligament. As anesthetic agent is injected, frequent aspiration is required to avoid injection into the pudendal vessels, which travel with the nerve.

Pelvic Viscera

Embryonic Development

The female urinary and genital tracts are closely related, not only anatomically but also embryologically. Both are derived largely from primitive mesoderm and endoderm, and there is evidence that the embryologic urinary system has an important inductive influence on the developing genital system. **About 10% of infants are born with some abnormality of the genitourinary system, and anomalies in one system are often mirrored by anomalies in another system (7).**

Developmental defects may play a significant role in the differential diagnosis of certain clinical signs and symptoms and have special implications in pelvic surgery (7,8,9,10 and 11). This is important for the practicing gynecologist to have a basic understanding of embryology.

Following is a presentation of the urinary system, internal reproductive organs, and external genitalia in order of their initial appearance, although much of their development proceeds concurrently. The development of each of these three regions proceeds synchronously at an early embryologic age (Table 5.6).

Weeks of Gestation	Genital Development	Urinary Development
4-6	Ureteral system Formation of dorsal kidneys, genital tubercle	Pronephros Mesonephros Metanephros
	Genital ridges	Embryology of mesonephric ducts and ureters into Wolffian duct
6-7	End of indifferent phase of genital development	Atresia, minor calyces form
	Development of primitive sex cords	Kidneys begin to ascend
	Formation of paramesonephric ducts Labromental swellings	
8-11	Distal paramesonephric ducts begin to fuse Formation of mesonephric bulbs	Kidney becomes functional
12	Development of testes and vaginal canal	
19	Canalization of vaginal plate	
32		Renal collecting duct system complete

Table 5.6. Development of Genital and Urinary Tracts by Embryologic Age

Urinary System

Kidneys, Renal Collecting System, Ureters

The kidneys, renal collecting system, and ureters derive from the longitudinal mass of mesoderm (known as the *nephrogenic cord*) found on each side of the primitive aorta. This process gives rise to three successive sets of increasingly advanced urinary structures, each developing more caudal to its predecessor.

The *pronephros*, or “first kidney,” is rudimentary and nonfunctional; it is succeeded by the “middle kidney,” or *mesonephros*, which is believed to function briefly before regressing. Although the *mesonephros* is transitory as an excretory organ, its duct, the *mesonephric (wolffian) duct*, is of singular importance for the following reasons:

1. It grows caudally in the developing embryo to open, for the first time, an excretory channel into the primitive cloaca and the “outside world.”
2. It serves as the starting point for development of the metanephros, which becomes the definitive kidney.
3. It ultimately differentiates into the sexual duct system in the male.
4. Although regressing in female fetuses, there is evidence that the mesonephric duct may have an inductive role in development of the paramesonephric or müllerian duct (8).

Development of the *metanephros* is initiated by the ureteric buds, which sprout from the distal mesonephric ducts; these buds extend cranially and penetrate the portion of the nephrogenic cord known as the *metanephric blastema*. The ureteric buds begin to branch sequentially, with each growing tip covered by metanephric blastema. The metanephric blastema ultimately forms the renal functional units (the nephrons), whereas the ureteric buds become the collecting duct system of the kidneys (collecting tubules, minor and major calyces, renal pelvis) and the ureters. Although these primitive tissues differentiate along separate paths, they are interdependent on inductive influences from each other—neither can develop alone.

The kidneys initially lie in the pelvis but subsequently ascend to their permanent location, rotating almost 90 degrees in the process as the more caudal part of the embryo in effect grows away from them. Their blood supply, which first arises as branches of the middle sacral and common iliac arteries, comes from progressively higher branches of the aorta until the definitive renal arteries form; previous vessels then regress.

Bladder and Urethra

The cloaca forms as the result of dilation of the opening to the fetal exterior. The cloaca is partitioned by the mesenchymal urorectal septum into an anterior urogenital sinus and a posterior rectum. The bladder and urethra form from the most superior portion of the urogenital sinus, with surrounding mesenchyme contributing to their muscular and serosal layers. The remaining inferior urogenital sinus is known as the *phallic or definitive urogenital sinus*.

Concurrently, the distal mesonephric ducts and attached ureteric buds are incorporated into the posterior bladder wall in the area that will become the bladder trigone. As a result of the absorption process, the mesonephric duct ultimately opens independently into the urogenital sinus below the bladder neck.

The *allantois*, which is a vestigial diverticulum of the hindgut that extends into the umbilicus and is continuous with the bladder, loses its lumen and becomes the fibrous band known as the *urachus or median umbilical ligament*. In rare instances, the urachal lumen remains partially patent, with formation of urachal cysts, or completely patent, with the formation of a urinary fistula to the umbilicus.

Genital System

Although genetic sex is determined at fertilization, the early genital system is indistinguishable between the two sexes in the embryonic stage. This is known as the “indifferent stage” of genital development, during which both male and female fetuses have gonads with prominent cortical and medullary regions, dual sets of genital ducts, and external genitalia that appear similar. Clinically, **gender is not apparent until about the twelfth week of embryonic life and depends on the elaboration of testis-determining factor (TDY) and, subsequently, androgens by the male gonad.** Female development has been called the “basic developmental path of the human embryo,” requiring not estrogen but the absence of testosterone.

Internal Reproductive Organs

The *primordial germ cells* migrate from the yolk sac through the mesentery of the hindgut to the posterior body wall mesenchyme at about the tenth thoracic level, which is the initial site of the future ovary (Fig. 5.9 and Fig. 5.10). Once the germ cells reach this area, they induce proliferation of cells in the adjacent mesonephros and celomic epithelium to form a pair of *genital ridges* medial to the mesonephros. The development of the gonad is absolutely dependent on this proliferation because these cells form a supporting aggregate of cells (the primitive sex cords) that invest the germ cells and without which the gonad would degenerate.

Figure 5.9 The comparative changes of the female and male during early embryonic development.

Figure 5.10 The embryonic development of the female genital tract. The formation of the uterus and vagina. **A:** The uterus and superior end of the vagina begin to form as the paramesonephric ducts fuse together near their attachment to the posterior wall of the primitive urogenital sinus. **B, C:** The ducts then zipper together in a superior direction between the third and fifth months. As the paramesonephric ducts are pulled away from the posterior body wall, they drag a fold of peritoneal membrane with them, forming the broad ligaments of the uterus. **A–C:** The inferior end of the vagina forms from the sinovaginal bulbs on the posterior wall of the primitive urogenital sinus.

Müllerian Ducts The *paramesonephric* or *müllerian ducts* form lateral to the mesonephric ducts; they grow caudally and then medially to fuse in the midline. They contact the urogenital sinus in the region of the posterior urethra at a slight thickening known as the *sinusal tubercle*. Subsequent sexual development is controlled by the presence or absence of TDY, encoded on the Y chromosome and elaborated by the somatic sex cord cells. TDY results in the degeneration of the gonadal cortex and differentiation of the medullary region of the gonad into Sertoli cells.

The Sertoli cells secrete a glycoprotein known as *anti-müllerian hormone (AMH)*, which causes regression of the paramesonephric duct system in the male embryo and is the likely signal for differentiation of Leydig cells from the surrounding mesenchyme. The Leydig cells produce testosterone and, with the converting enzyme 5 α -reductase, dihydrotestosterone. Testosterone is responsible for evolution of the mesonephric duct system into the vas deferens, epididymis, ejaculatory ducts, and seminal vesicle; at puberty, testosterone leads to spermatogenesis and changes in primary and secondary sex characteristics. Dihydrotestosterone results in development of the male external genitalia and the prostate and bulbourethral glands. In the absence of TDY, the medulla regresses, and the cortical sex cords break up into isolated cell clusters (the primordial follicles).

The germ cells differentiate into oogonia and enter the first meiotic division as primary oocytes, at which point development is arrested until puberty. In the absence of AMH, the mesonephric duct system degenerates, although in at least one fourth of adult women (9), remnants may be found in the mesovarium (*epoophoron*, *paroophoron*) or along the lateral wall of the uterus or vagina (*Gartner duct cyst*).

The paramesonephric duct system then develops. The inferior fused portion becomes the *uterovaginal canal*, which later becomes the epithelium and glands of the uterus and the upper vagina. The endometrial stroma and myometrium differentiate from surrounding mesenchyme. The cranial unfused portions of the paramesonephric ducts open into the celomic (future peritoneal) cavity and become the *fallopian tubes*.

The fusion of the paramesonephric ducts brings together two folds of peritoneum, which become the broad ligament and divide the pelvic cavity into a posterior rectouterine and anterior vesicouterine pouch or cul-de-sac. Between the leaves of the broad ligament, mesenchyme proliferates and differentiates into loose areolar connective tissue and smooth muscle.

Vagina The *vagina* forms in the third month of embryonic life. While the uterovaginal canal is forming, the endodermal tissue of the sinusal tubercle begins to proliferate, forming a pair of *sinovaginal bulbs*, which become the inferior 20% of the vagina. The most inferior portion of the uterovaginal canal becomes occluded by a solid core of tissue (*the vaginal plate*), the origin of which is unclear. This tissue elongates over the subsequent 2 months and canalizes by a process of central desquamation, and the peripheral cells become the vaginal epithelium. The fibromuscular wall of the vagina originates from the mesoderm of the uterovaginal canal.

Accessory Genital Glands The female accessory genital glands develop as outgrowths from the urethra (*paraurethral* or *Skene*) and the definitive urogenital sinus (*greater vestibular* or *Bartholin*). Although the ovaries first develop in the thoracic region, they ultimately arrive in the pelvis by a complicated process of descent. This descent by *differential growth* is under the control of a ligamentous cord called the *gubernaculum*, which is attached to the ovary superiorly and to the fascia in the region of the future labia majora inferiorly. The gubernaculum becomes attached to the paramesonephric ducts at their point of superior fusion so that it becomes divided into two separate structures. As the ovary and its mesentery (the mesovarium) are brought into the superior portion of the broad ligament, the more proximal part of the gubernaculum becomes the *ovarian ligament*, and the distal gubernaculum becomes the *round ligament*.

External Genitalia

Early in the fifth week of embryonic life, folds of tissue form on each side of the cloaca and meet anteriorly in the midline to form the genital tubercle (Fig. 5.11). With the division of the cloaca by the urorectal septum and consequent formation of the perineum, these cloacal folds are known anteriorly as the *urogenital folds* and posteriorly as the *anal folds*. The genital tubercle begins to enlarge, but in the female embryo, its growth gradually slows to become the clitoris, and the urogenital folds form the labia minora. In the male, the genital tubercle continues to grow to form the penis, and the urogenital folds are believed to fuse to enclose the penile urethra. Lateral to the urogenital folds, another pair of swellings develops, known in the indifferent stage as *labioscrotal swellings*. In the absence of androgens, they remain largely unfused to become the labia majora. The definitive urogenital sinus gives rise to the vaginal vestibule, into which open the urethra, vagina, and greater vestibular glands.

Figure 5.11 The comparative development of the female and male external genitalia. **A:** In both sexes, the development follows a uniform pattern through the seventh week and thereafter begins to differentiate. **B:** The male external genitalia. **C:** The female external genitalia.

Clinical Correlations

Developmental abnormalities of the urinary and genital systems can be explained and understood by a consideration of female and male embryologic development. Because of the intertwined development of these two systems, it is easy to understand how abnormalities in one may be associated with abnormalities in the other (10).

Urinary System

Urinary tract anomalies arise from defects in the ureteric bud, the metanephric blastema, or their inductive interaction with each other.

Renal Agenesis Renal agenesis occurs when one or both ureteric buds fail to form or degenerate, and the metanephric blastema is therefore not induced to differentiate into nephrons. Bilateral renal agenesis is incompatible with postnatal survival, but infants with only one kidney usually survive, and the single kidney undergoes compensatory hypertrophy. Unilateral renal agenesis is often associated with absence or abnormality of fallopian tubes, uterus, or vagina—the paramesonephric duct derivatives.

Abnormalities of Renal Position Abnormalities of renal position result from disturbance in the normal ascent of the kidneys. A malrotated pelvic kidney is the most common result; a horseshoe kidney, in which the kidneys are fused across the midline, occurs in about 1 in 600 individuals and also has a final position lower than usual because its normal ascent is prevented by the root of the inferior mesenteric artery.

Duplication of the Upper Ureter and Renal Pelvis Duplication of the upper ureter and renal pelvis are relatively common and result from premature bifurcation of the ureteric bud. If two ureteric buds develop, there will be complete duplication of the collecting system. In this situation, one ureteric bud will open normally into the posterior bladder wall, and the second bud will be carried more distally within the mesonephric duct to form an ectopic ureteral orifice into the urethra, vagina, or vaginal vestibule; incontinence is the primary presenting symptom. Most of the aforementioned urinary abnormalities remain asymptomatic unless obstruction or infection supervenes. In that case, anomalous embryologic development must be included in the differential diagnosis.

Genital System

Because the early development of the genital system is similar in both sexes, congenital defects in sexual development, usually arising from a variety of chromosomal abnormalities, tend to present clinically with ambiguous external genitalia. These conditions are known as *intersex conditions* or *hermaphroditism* and are classified according to the histologic appearance of the gonads (see [Chapter 24](#)).

True Hermaphroditism Individuals with true hermaphroditism have both ovarian and testicular tissue, most commonly as composite ovotestes but occasionally with an ovary on one side and a testis on the other. In the latter case, a fallopian tube and single uterine horn may develop on the side with the ovary because of the absence of local AMH. True hermaphroditism is an extremely rare condition associated with chromosomal mosaicism, mutation, or abnormal cleavage involving the X and Y chromosomes.

Pseudohermaphroditism In individuals with pseudohermaphroditism, the genetic sex indicates one gender, and the external genitalia has characteristics of the other gender. Males with pseudohermaphroditism are genetic males with feminized external genitalia, most commonly manifesting as hypospadias (urethral opening on the ventral surface of the penis) or incomplete fusion of the urogenital or labioscrotal folds. Females with pseudohermaphroditism are genetic females with virilized external genitalia, including clitoral hypertrophy and some degree of fusion of the urogenital or labioscrotal folds. Both types of pseudohermaphroditism are caused either by abnormal levels of sex hormones or abnormalities in the sex hormone receptors.

Another major category of genital tract abnormalities involves various types of uterovaginal malformations ([Fig. 5.12](#)), which occur in 0.16% of women ([12](#)). These malformations are believed to result from one or more of the following situations:

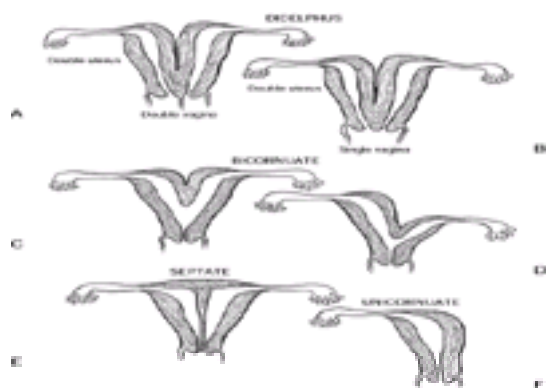

Figure 5.12 Types of congenital abnormalities. **A:** Double uterus (uterus didelphys) and double vagina. **B:** Double uterus with single vagina. **C:** Bicornuate uterus. **D:** Bicornuate uterus with a rudimentary left horn. **E:** Septate uterus. **F:** Unicornuate uterus.

1. Improper fusion of the paramesonephric ducts
2. Incomplete development of one paramesonephric duct
3. Failure of part of the paramesonephric duct on one or both sides to develop
4. Absent or incomplete canalization of the vaginal plate

Genital Structures

Vagina

A sagittal section of the female pelvis is presented in [Fig. 5.13](#).

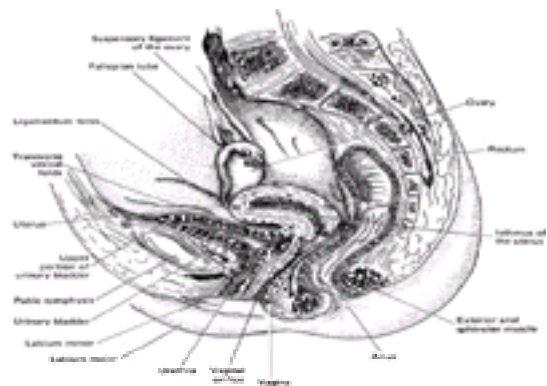

Figure 5.13 The pelvic viscera. A sagittal section of the female pelvis with the pelvic viscera and their relationships.

The vagina is a hollow fibromuscular tube extending from the vulvar vestibule to the uterus. In the dorsal lithotomy position, the vagina is directed posteriorly toward the sacrum, but its axis is almost horizontal in the upright position. It is attached at its upper end to the uterus just above the cervix. The spaces between the cervix and vagina are known as the *anterior*, *posterior*, and *lateral vaginal fornices*. Because the vagina is attached at a higher point posteriorly than anteriorly, the posterior

Peritoneum covers most of the corpus of the uterus and the posterior cervix and is known as the *serosa*. Laterally, the broad ligament, a double layer of peritoneum covering the neurovascular supply to the uterus, inserts into the cervix and corpus. Anteriorly, the bladder lies over the isthmic and cervical region of the uterus.

Blood Supply The blood supply to the uterus is the uterine artery, which anastomoses with the ovarian and vaginal arteries.

Innervation The nerve supply to the uterus is the uterovaginal plexus.

Fallopian Tubes

The fallopian tubes and ovaries collectively are referred to as the *adnexa*. The fallopian tubes are paired hollow structures representing the proximal unfused ends of the müllerian duct. They vary in length from 7 to 12 cm, and their function includes ovum pickup, provision of physical environment for conception, and transport and nourishment of the fertilized ovum.

The tubes are divided into several regions:

1. **Interstitial**—narrowest portion of the tube, lies within the uterine wall and forms the tubal ostia at the endometrial cavity.
2. **Isthmus**—narrow segment closest to the uterine wall.
3. **Ampulla**—larger diameter segment lateral to the isthmus.
4. **Fimbria (infundibulum)**—funnel-shaped abdominal ostia of the tubes, opening into the peritoneal cavity; this opening is fringed with numerous finger-like projections that provide a wide surface for ovum pickup. The fimbria ovarica is a connection between the end of the tube and ovary, bringing the two closer.

The tubal mucosa is ciliated columnar epithelium, which becomes progressively more architecturally complex as the fimbriated end is approached. The muscularis consists of an inner circular and outer longitudinal layer of smooth muscle. The tube is covered by peritoneum and, through its mesentery (mesosalpinx), which is situated dorsal to the round ligament, is connected to the upper margin of the broad ligament.

Blood Supply The vascular supply to the fallopian tubes is the uterine and ovarian arteries.

Innervation The innervation to the fallopian tubes is the uterovaginal plexus and the ovarian plexus.

Ovaries

The ovaries are paired gonadal structures that lie suspended between the pelvic wall and the uterus by the infundibulopelvic ligament laterally and the uteroovarian ligament medially. Inferiorly, the hilar surface of each ovary is attached to the broad ligament by its mesentery (mesovarium), which is dorsal to the mesosalpinx and fallopian tube. Primary neurovascular structures reach the ovary through the infundibulopelvic ligament and enter through the mesovarium. **The normal ovary varies in size, with measurements up to 5 × 3 × 3 cm.** Variation in dimension results from endogenous hormonal production, which varies with age and with each menstrual cycle. Exogenous substances, including oral contraceptives, gonadotropin-releasing hormone agonists, or ovulation-inducing medication, may either stimulate or suppress ovarian activity and, therefore, affect size.

Each ovary consists of a cortex and medulla and is covered by a single layer of flattened cuboidal to low columnar epithelium that is continuous with the peritoneum at the mesovarium. The cortex is composed of a specialized stroma and follicles in various stages of development or attrition. The medulla occupies a small portion of the ovary in its hilar region and is composed primarily of fibromuscular tissue and blood vessels.

Blood Supply The blood supply to the ovary is the ovarian artery, which anastomoses with the uterine artery.

Innervation The innervation to the ovary is the ovarian plexus and the uterovaginal plexus.

Urinary Tract

Ureters

The ureter is the urinary conduit leading from the kidney to the bladder; it measures about 25 cm in length and is totally retroperitoneal in location.

The lower half of each ureter traverses the pelvis after crossing the common iliac vessels at their bifurcation, just medial to the ovarian vessels. It descends into the pelvis adherent to the peritoneum of the lateral pelvic wall and the medial leaf of the broad ligament and enters the bladder base anterior to the upper vagina, traveling obliquely through the bladder wall to terminate in the bladder trigone.

The ureteral mucosa is a transitional epithelium. The muscularis consists of an inner longitudinal and outer circular layer of smooth muscle. A protective connective tissue sheath, which is adherent to the peritoneum, encloses the ureter.

Blood Supply The blood supply is variable, with contributions from the renal, ovarian, common iliac, internal iliac, uterine, and vesical arteries.

Innervation The innervation is through the ovarian plexus and the vesical plexus.

Bladder and Urethra

Bladder

The bladder is a hollow organ, spherically shaped when full, that stores urine. Its size varies with urine volume, normally reaching a maximum volume of at least 500 mL. The bladder is often divided into two areas, which are of physiologic significance:

1. The **base of the bladder** consists of the urinary trigone posteriorly and a thickened area of detrusor anteriorly. The three corners of the trigone are formed by the two ureteral orifices and the opening of the urethra into the bladder. The bladder base receives a-adrenergic sympathetic innervation and is the area responsible for maintaining continence.
2. The **dome of the bladder** is the remaining bladder area above the bladder base. It has parasympathetic innervation and is responsible for micturition.

The bladder is positioned posterior to the pubis and lower abdominal wall and anterior to the cervix, upper vagina, and part of the cardinal ligament. Laterally, it is bounded by the pelvic diaphragm and obturator internus muscle.

The bladder mucosa is transitional cell epithelium and the muscle wall (detrusor). Rather than being arranged in layers, it is composed of intermeshing muscle fibers.

Blood Supply The blood supply to the bladder is from the superior, middle, and inferior vesical arteries, with contribution from the uterine and vaginal vessels.

Innervation The innervation to the bladder is from the vesical plexus, with contribution from the uterovaginal plexus.

Urethra

The vesical neck is the region of the bladder that receives and incorporates the urethral lumen. The female urethra is about 3 to 4 cm in length and extends

from the bladder to the vestibule, traveling just anterior to the vagina.

The urethra is lined by nonkeratinized squamous epithelium that is responsive to estrogen stimulation. Within the submucosa on the dorsal surface of the urethra are the paraurethral or Skene glands, which empty through ducts into the urethral lumen. Distally, these glands empty into the vestibule on either side of the external urethral orifice. Chronic infection of Skene glands, with obstruction of their ducts and cystic dilation, is believed to be an inciting factor in the development of suburethral diverticula.

The urethra contains an inner longitudinal layer of smooth muscle and outer, circularly oriented smooth muscle fibers. The inferior fascia of the urogenital diaphragm or perineal membrane begins at the junction of the middle and distal thirds of the urethra. Proximal to the middle and distal parts of the urethra, voluntary muscle fibers derived from the urogenital diaphragm intermix with the outer layer of smooth muscle, increasing urethral resistance and contributing to continence. At the level of the urogenital diaphragm, the skeletal muscle fibers leave the wall of the urethra to form the sphincter urethrae and deep transverse perineal muscles.

Blood Supply The vascular supply to the urethra is from the vesical and vaginal arteries and the internal pudendal branches.

Innervation The innervation to the urethra is from the vesical plexus and the pudendal nerve.

The lower urinary and genital tracts are intimately connected anatomically and functionally. In the midline, the bladder and proximal urethra can be dissected easily from the underlying lower uterine segment, cervix, and vagina through a loose avascular plane. The distal urethra is essentially inseparable from the vagina. Of surgical significance is the location of the bladder trigone immediately over the middle third of the vagina. Unrecognized injury to the bladder during pelvic surgery may result in development of a vesicovaginal fistula.

Fortunately, dissection to the level of the trigone is rarely required, and damage to this critical area is unusual. If dissection is carried too far laterally away from the midline, attachments between the bladder and cervix or vagina become much more dense and vascularized, resulting in increased blood loss and technical difficulty.

Lower Gastrointestinal Tract

Sigmoid Colon

The sigmoid colon begins its characteristic S-shaped curve as it enters the pelvis at the left pelvic brim (Fig. 5.15). The columnar mucosa and richly vascularized submucosa are surrounded by an inner circular layer of smooth muscle and three overlying longitudinal bands of muscle called *tenia coli*. A mesentery of varying length attaches the sigmoid to the posterior abdominal wall.

Figure 5.15 The rectosigmoid colon, its vascular supply, and muscular support. (Coronal view: peritoneum removed on right.)

Blood Supply The blood supply to the sigmoid colon is from the sigmoid arteries.

Innervation The nerves to the sigmoid colon are derived from the inferior mesenteric plexus.

Rectum

The sigmoid colon loses its mesentery in the midsacral region and becomes the rectum about 15 to 20 cm above the anal opening. The rectum follows the curve of the lower sacrum and coccyx and becomes entirely retroperitoneal at the level of the rectouterine pouch or posterior cul-de-sac. It continues along the pelvic curve just posterior to the vagina until the level of the anal hiatus of the pelvic diaphragm, at which point it takes a sharp 90-degree turn posteriorly and becomes the anal canal, separated from the vagina by the perineal body.

The rectal mucosa is columnar epithelium characterized by three transverse folds that contain mucosa, submucosa, and the inner circular layer of smooth muscle. The tenia of the sigmoid wall broaden and fuse over the rectum to form a continuous longitudinal external layer of smooth muscle to the level of the anal canal.

Anal Canal

The anal canal begins at the level of the sharp turn in the direction of the distal colon and is 2 to 3 cm in length. At the anorectal junction, the mucosa changes to stratified squamous epithelium (the pectinate line), which continues until the termination of the anus at the anal verge, where there is a transition to perianal skin with typical skin appendages. It is surrounded by a thickened ring of circular muscle fibers that is a continuation of the circular muscle of the rectum, the internal anal sphincter. Its lower part is surrounded by bundles of striated muscle fibers, the external anal sphincter (12).

Fecal continence is primarily provided by the puborectalis muscle and the internal and external anal sphincters. The puborectalis surrounds the anal hiatus in the pelvic diaphragm and interdigitates posterior to the rectum to form a rectal sling. The external anal sphincter surrounds the terminal anal canal below the level of the levator ani.

The practicing gynecologist must be familiar with the lower gastrointestinal tract because of its anatomic proximity to the lower genital tract. This is particularly important during surgery of the vulva and vagina. Lack of attention to this proximity during repair of vaginal lacerations or episiotomies can lead to damage of the rectum and resulting fistula formation or injury to the external anal sphincter with development of fecal incontinence. Because of the avascular nature of the rectovaginal space, it is relatively easy to dissect the rectum from the vagina in the midline, which is routinely done in the repair of rectoceles.

Blood Supply The vascular supply to the rectum and anal canal is from the superior, middle, and inferior rectal arteries. The venous drainage is a complex submucosal plexus of vessels that, under conditions of increased intraabdominal pressure (pregnancy, pelvic mass, ascites), may dilate and become symptomatic with rectal bleeding or pain as hemorrhoids.

Innervation The nerve supply to the anal canal is from the middle rectal plexus, the inferior mesenteric plexus, and the pudendal nerve.

The Genital Tract and Its Relations

The genital tract is situated at the bottom of the intraabdominal cavity and is related to the intraperitoneal cavity and its contents, the retroperitoneal spaces, and the

pelvic floor. Its access through the abdominal wall or the perineum requires a thorough knowledge of the anatomy of these areas and their relationships.

The Abdominal Wall

The anterior abdominal wall is bound superiorly by the xiphoid process and the costal cartilage of the seventh to tenth ribs and inferiorly by the iliac crest, anterosuperior iliac spine, inguinal ligament, and pubic bone. It consists of skin, muscle, fascia, and nerves and vessels.

P>

Skin

The lower abdominal skin may exhibit striae, or “stretch marks,” and increased pigmentation in the midline in parous women. The subcutaneous tissue contains a variable amount of fat.

Muscles

Five muscles and their aponeuroses contribute to the structure and strength of the anterolateral abdominal wall ([Fig. 5.16](#); [Table 5.7](#)).

Figure 5.16 The abdominal wall muscles.

Muscle	Origin	Insertion	Action
External oblique	Tenues, 10th, 11th, 12th ribs, anterior iliac spine	Pubic tubercle, iliac crest, anterior superior iliac spine, anterior inferior iliac spine, pubic crest, pubic tubercle	Flexion and lateral flexion of the trunk, expiration
Internal oblique	Thoracic vertebrae 10, 11, 12, anterior iliac spine, anterior superior iliac spine, anterior inferior iliac spine, pubic crest, pubic tubercle	Pubic crest, pubic tubercle, iliac crest, anterior superior iliac spine, anterior inferior iliac spine, pubic crest, pubic tubercle	Flexion and lateral flexion of the trunk, expiration
Transversus abdominis	7th, 8th, 9th, 10th, 11th, 12th thoracic vertebrae, lumbar vertebrae 1, 2, 3, anterior iliac spine, anterior superior iliac spine, anterior inferior iliac spine, pubic crest, pubic tubercle	Pubic crest, pubic tubercle, iliac crest, anterior superior iliac spine, anterior inferior iliac spine, pubic crest, pubic tubercle	Expiration, lateral flexion of the trunk
Pyramidalis	Pubic tubercle	Anterior inferior iliac spine	Flexion of the hip

Table 5.7.

Fascia

Superficial Fascia

The superficial fascia consists of two layers:

1. **Camper fascia**—the most superficial layer, which contains a variable amount of fat and is continuous with the superficial fatty layer of the perineum
2. **Scarpa fascia**—a deeper membranous layer continuous in the perineum with Colles fascia (superficial perineal fascia) and with the deep fascia of the thigh (fascia lata).

Rectus Sheath

The aponeuroses of the external and internal oblique and the transversus abdominis combine to form a sheath for the rectus abdominis and pyramidalis, fusing medially in the midline at the linea alba and laterally at the semilunar line ([Fig. 5.17](#)). Above the arcuate line, the aponeurosis of the internal oblique muscle splits into anterior and posterior lamella ([Fig. 5.17A](#)). Below this line, all three layers are anterior to the body of the rectus muscle ([Fig. 5.17B](#)). The rectus is then covered posteriorly by the transversalis fascia, providing access to the muscle for the inferior epigastric vessels.

Figure 5.17 A transverse section of the rectus abdominis. The aponeurosis of the external and internal oblique and the transversus abdominis from the rectus abdominis. **A:** Above the arcuate line. **B:** Below the arcuate line.

Transversalis Fascia and Endopelvic Fascia

The transversalis fascia is a firm membranous sheet on the internal surface of the transversus abdominis muscle that extends beyond the muscle and forms a fascia lining the entire abdominopelvic cavity. Like the peritoneum, it is divided into a parietal and a visceral component. It is continuous from side to side across the linea alba and covers the posterior aspect of the rectus abdominis muscle below the arcuate line. Superiorly, it becomes the inferior fascia of the diaphragm. Inferiorly, it is

attached to the iliac crest, covers the iliac fascia and the obturator internus fascia, and extends downward and medially to form the superior fascia of the pelvic diaphragm.

Characteristically, the transversalis fascia continues along blood vessels and other structures leaving and entering the abdominopelvic cavity and contributes to the formation of the visceral (*endopelvic*) pelvic fascia (13). The pelvic fascia invests the pelvic organs and attaches them to the pelvic sidewalls, thereby playing a critical role in *pelvic support*. In the inguinal region, the fascial relationships result in the development of the inguinal canal, through which the round ligament exits into the perineum. The fascia is separated from the peritoneum by a layer of preperitoneal fat. Areas of fascial weaknesses or congenital or posttraumatic and surgical injuries result in herniation of the underlying structures through a defective abdominal wall. The incisions least likely to result in damage to the integrity and innervation of the abdominal wall muscles include a midline incision through the linea alba and a transverse incision through the recti muscle fibers that respects the integrity of its innervation (14).

Nerves and Vessels

The tissues of the abdominal wall are innervated by the continuation of the inferior intercostal nerves T4 to T11 and the subcostal nerve T12. The inferior part of the abdominal wall is supplied by the first lumbar nerve through the iliohypogastric and the ilioinguinal nerves. The primary blood supply to the anterior lateral abdominal wall includes the following:

1. The **inferior epigastric and deep circumflex iliac arteries**, branches of the external iliac artery
2. The **superior epigastric artery**, a terminal branch of the internal thoracic artery

The inferior epigastric artery runs superiorly in the transverse fascia to reach the arcuate line, where it enters the rectus sheath. It is vulnerable to damage with abdominal incisions in which the rectus muscle is completely or partially transected or with excessive lateral traction on the rectus. The deep circumflex artery runs on the deep aspect of the anterior abdominal wall parallel to the inguinal ligament and along the iliac crest between the transverse abdominis muscle and the internal oblique muscle. The superior epigastric vessels enter the rectus sheath superiorly just below the seventh costal cartilage.

The venous system drains into the saphenous vein, and the lymphatics drain to the axillary chain above the umbilicus and to the inguinal nodes below it. The subcutaneous tissues drain to the lumbar chain.

Perineum

The perineum is situated at the lower end of the trunk between the buttocks. Its bony boundaries include the lower margin of the pubic symphysis anteriorly, the tip of the coccyx posteriorly, and the ischial tuberosities laterally. These landmarks correspond to the boundaries of the pelvic outlet. The diamond shape of the perineum is customarily divided by an imaginary line joining the ischial tuberosities immediately in front of the anus, at the level of the perineal body, into an anterior urogenital and a posterior anal triangle (Fig. 5.18).

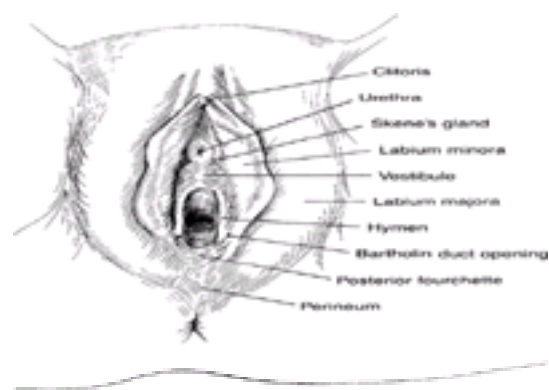

Figure 5.18 Vulva and perineum.

Urogenital Triangle

The urogenital triangle includes the external genital structures and the urethral opening (Fig. 5.18). These external structures cover the superficial and deep perineal compartments (Fig. 5.19 and Fig. 5.20) and are known as the *vulva*.

Figure 5.19 Superficial perineal compartment.

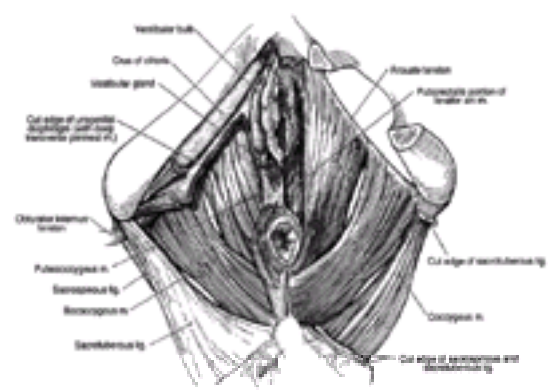

Figure 5.20 Deep perineal compartment

Vulva

Mons Pubis

The mons pubis is a triangular eminence in front of the pubic bones that consists of adipose tissue covered by hair-bearing skin up to its junction with the abdominal wall.

Labia Majora

The labia majora are a pair of fibroadipose folds of skin that extend from the mons pubis downward and backward to meet in the midline in front of the anus at the posterior fourchette. They include the terminal extension of the round ligament and occasionally a peritoneal diverticulum, the *canal of Nuck*. They are covered by skin with scattered hairs laterally and are rich in sebaceous, apocrine, and eccrine glands.

Labia Minora

The labia minora lie between the labia majora, with which they merge posteriorly and are separated into two folds as they approach the clitoris anteriorly. The anterior folds unite to form the prepuce or hood of the clitoris. The posterior folds form the frenulum of the clitoris as they attach to its inferior surface. The labia minora are covered by hairless skin overlying a fibroelastic stroma rich in neural and vascular elements. The area between the posterior labia minora forms the vestibule of the vagina.

Clitoris

The clitoris is an erectile organ that is 2 to 3 cm in length. It consists of two crura and two corpora cavernosa and is covered by a sensitive rounded tubercle (the glans).

Vaginal Orifice

The vaginal orifice is surrounded by the hymen, a variable crescentic mucous membrane that is replaced by rounded caruncles after its rupture. The opening of the duct of the *greater vestibular (Bartholin) glands* is located on each side of the vestibule. Numerous lesser vestibular glands are also scattered posteriorly and between the urethral and vaginal orifices.

Urethral Orifice

The urethral orifice is immediately anterior to the vaginal orifice about 2 to 3 cm beneath the clitoris. The *Skene (paraurethral) gland* duct presents an opening on its posterior surface.

Superficial Perineal Compartment

The superficial perineal compartment lies between the superficial perineal fascia and the inferior fascia of the urogenital diaphragm (perineal membrane) ([Fig. 5.19](#)). The superficial perineal fascia has a superficial and deep component. The superficial layer is relatively thin and fatty and is continuous superiorly with the superficial fatty layer of the lower abdominal wall (*Camper fascia*). It continues laterally as the fatty layer of the thighs. The deep layer of the superficial perineal (*Colles*) fascia is continuous superiorly with the deep layer of the superficial abdominal fascia (*Scarpa fascia*), which attaches firmly to the ischiopubic rami and ischial tuberosities. The superficial perineal compartment is continuous superiorly with the superficial fascial spaces of the anterior abdominal wall, allowing spread of blood or infection along that route. Such spread is limited laterally by the ischiopubic rami, anteriorly by the transverse ligament of the perineum, and posteriorly by the superficial transverse perineal muscle. The superficial perineal compartment includes the following.

Erectile Bodies

The vestibular bulbs are 3-cm, highly vascular structures surrounding the vestibule and located under the bulbocavernosus muscle. The body of the clitoris is attached by two crura to the internal aspect of the ischiopubic rami. They are covered by the ischiocavernosus muscle.

Muscles

The muscles of the vulva are the ischiocavernosus, the bulbocavernosus, and superficial transverse perineal.

Ischiocavernosus

- Origin—ischial tuberosity
- Insertion—ischiopubic bone
- Action—compresses the crura and lowers the clitoris

Bulbocavernosus

- Origin—perineal body
- Insertion—posterior aspect of the clitoris; some fibers pass above the dorsal vein of the clitoris in a slinglike fashion
- Action—compresses the vestibular bulb and dorsal vein of the clitoris

Superficial Transverse Perineal

- Origin—ischial tuberosity
- Insertion—central perineal tendon
- Action—fixes the perineal body

Vestibular Glands

The vestibular glands are situated on either side of the vestibule under the posterior end of the vestibular bulb. They drain between the hymen and the labia minora. Their mucus secretion helps maintain adequate lubrication. Infection in these glands can result in an abscess.

Deep Perineal Compartment

The deep perineal compartment is a fascial space bound inferiorly by the perineal membrane and superiorly by a deep fascial layer that separates the urogenital diaphragm from the anterior recess of the ischioanal fossa ([Fig. 5.20](#)). It is stretched across the anterior half of the pelvic outlet between the ischiopubic rami. The deep compartment may be directly continuous with the pelvic cavity superiorly ([15](#)). Indeed, the posterior pubourethral ligaments, functioning as winglike elevations of the fascia ascending from the pelvic floor to the posterior aspect of the symphysis pubis, provide a point of fixation to the urethra and support the concept of the continuity of the deep perineal compartment with the pelvic cavity.

The anterior pubourethral ligaments represent a similar elevation of the inferior fascia of the urogenital diaphragm and are joined by the intermediate pubourethral ligament, with the junction between the two fascial structures arcing under the pubic symphysis ([16](#)). The urogenital diaphragm includes the *sphincter urethrae (urogenital sphincter)* and the *deep transverse perineal (transversus vaginae)* muscle.

The sphincter urethrae ([Fig. 5.21](#)) is a continuous muscle fanning out as it develops proximally and distally, including the following:

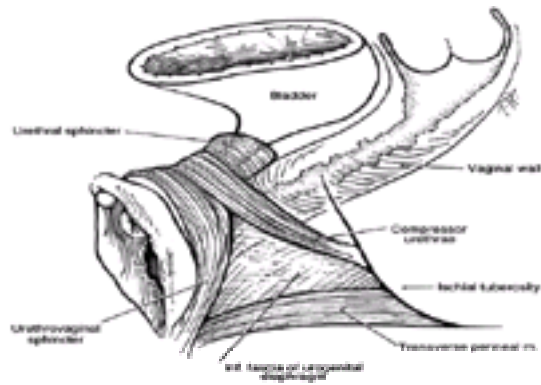

Figure 5.21 The complete urogenital sphincter musculature, bladder, and vagina.

1. The **external urethral sphincter**, which surrounds the middle third of the urethra
2. The **compressor urethrae**, arcing across the ventral side of the urethra
3. The **urethrovaginal sphincter**, which surrounds the ventral aspect of the urethra and terminates in the lateral vaginal wall

The deep transverse perineal muscle originates at the internal aspect of the ischial bone, parallels the muscle compressor urethrae, and attaches to the lateral vaginal wall along the perineal membrane.

There is a common reliance of the urinary and genital tracts on several interdependent structures for support. **The cardinal and uterosacral ligaments are condensations of endopelvic fascia that support the cervix and upper vagina over the levator plate. Laterally, endopelvic fascial condensations attach the midvagina to the pelvic walls at the arcus tendineus fascia pelvis anteriorly and the arcus tendineus levator ani posteriorly. The distal anterior vagina and urethra are anchored to the urogenital diaphragm, and the distal posterior vagina to the perineal body.**

Anteriorly, the pubourethral ligaments and pubovesical fascia and ligaments provide fixation and stabilization for the urethra and bladder. Posteriorly, they rely on the vagina and lower uterus for support. Partial resection or relaxation of the uterosacral ligaments often leads to relaxation of the genitourinary complex, resulting in the formation of a cystocele. Various types and degrees of genital tract prolapse or relaxation are almost always associated with similar findings in the bladder, urethra, or both.

Blood Supply The blood supply to the vulva is as follows:

1. External pudendal artery (from femoral artery), internal pudendal artery
2. Venous drainage—internal pudendal veins

The blood supply to the superficial and deep perineal compartments is as follows:

1. Internal pudendal artery, dorsal artery of the clitoris
2. Venous drainage—internal pudendal veins, which are richly anastomotic
3. Lymphatic drainage—internal iliac chain

Innervation The innervation to the vulva is from branches of the following nerves:

1. Ilioinguinal nerve
2. Genitofemoral nerve (genital branch)
3. Lateral femoral cutaneous nerve of the thigh (perineal branch)
4. Perineal nerve (branch of pudendal)

Superficial and deep perineal compartments are innervated by the perineal nerve.

Perineal Body

The perineal body or central perineal tendon is critical to the posterior support of the lower aspect of the anterior vaginal wall. It is a triangle-shaped structure separating the distal portion of the anal and vaginal canals that is formed by the convergence of the tendinous attachments of the bulbocavernosus, the external anal sphincter, and the superficial transverse perineal muscle. Its superior border represents the point of insertion of the *rectovaginal (Denonvilliers) fascia*, which extends to the underside of the peritoneum covering the cul-de-sac of Douglas, separating the anorectal from the urogenital compartment ([17](#)). The perineal body also plays an important anchoring role in the musculofascial support of the pelvic floor. It represents the central connection between the two layers of support of the pelvic floor—the pelvic and urogenital diaphragm. It also provides a posterior connection to the anococcygeal raphe. Thus, it is central to the definition of the bilevel support of the floor of the pelvis.

Anal Triangle

The anal triangle includes the lower end of the anal canal. The external anal sphincter surrounds the anal triangle, and the ischioanal fossa is on each side.

Posteriorly, the *anococcygeal body* lies between the anus and the tip of the coccyx and consists of thick fibromuscular tissue (of levator ani and external anal sphincter origin) giving support to the lower part of the rectum and the anal canal.

The *external anal sphincter* forms a thick band of muscular fibers arranged in three layers running from the perineal body to the anococcygeal ligament. The subcutaneous fibers are thin and surround the anus and, without bony attachment, decussate in front of it. The superficial fibers sweep forward from the anococcygeal ligament, and the tip of the coccyx around the anus inserts into the perineal body. The deep fibers arise from the perineal body to encircle the lower half of the anal canal to form a true sphincter muscle, which fuses with the puborectalis portion of the levator ani.

The *ischioanal fossa* is mainly occupied by fat and separates the ischium laterally from the median structures of the anal triangle. It is a fascia-lined space located between the perineal skin inferiorly and the pelvic diaphragm superiorly; it communicates with the contralateral ischioanal fossa over the anococcygeal ligament. Superiorly, its apex is at the origin of the levator ani muscle from the obturator fascia. It is bound medially by the levator ani and the external sphincter with their fascial covering, laterally by the obturator internus muscle with its fascia, posteriorly by the sacrotuberous ligament and the lower border of the gluteus maximus muscle, and anteriorly by the base of the urogenital diaphragm. It is widest and deepest posteriorly and weakest medially. *Thus, an ischioanal abscess should be drained without delay, or it will extend into the anal canal.* The cavity is filled with fat that cushions the anal canal and is traversed by many fibrous bands, vessels, and nerves, including the pudendal and the inferior rectal nerves. The perforating branch of S2 and S3 and the perineal branch of S4 also run through this space.

The *pudendal (Alcock) canal* is a tunnel formed by a splitting of the inferior portion of the obturator fascia running anteromedially from the ischial spine to the posterior

edge of the urogenital diaphragm. It contains the pudendal artery, vein, and nerve in their traverse from the *pelvic* cavity to the perineum.

Blood Supply The blood supply to the anal triangle is from the inferior rectal (hemorrhoidal) artery and vein.

Innervation The innervation to the anal triangle is from the perineal branch of the fourth sacral nerve and the inferior rectal (hemorrhoidal) nerve.

Retroperitoneum and Retroperitoneal Spaces

The subperitoneal area of the true pelvis is partitioned into potential spaces by the various organs and their respective fascial coverings and by the selective thickenings of the endopelvic fascia into ligaments and septa (Fig. 5.22). It is imperative that surgeons operating in the pelvis be familiar with these spaces, which include the following:

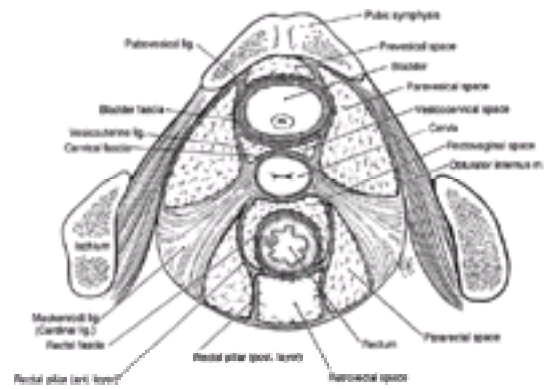

Figure 5.22 Schematic sectional drawing of the pelvis shows the firm connective tissue covering. The bladder, cervix, and rectum are surrounded by a connective tissue covering. The Mackenrodt ligament extends from the lateral cervix to the lateral abdominal pelvic wall. The vesicouterine ligament originating from the anterior edge of the Mackenrodt ligament leads to the covering of the bladder on the posterior side. The sagittal rectum column spreads both to the connective tissue of the rectum and the sacral vertebrae closely nestled against the back of the Mackenrodt ligament and lateral pelvic wall. Between the firm connective tissue bundles is loose connective tissue (paraspaces). (From Von Peham H, Amreich JA. *Gynaekologische Operationslehre*. Berlin: S Karger, 1930, with permission.)

Prevesical Space

The prevesical (Retzius) space is a fat-filled potential space bound anteriorly by the pubic bone, covered by the transversalis fascia, and extending to the umbilicus between the medial umbilical ligaments (obliterated umbilical arteries); posteriorly, the space extends to the anterior wall of the bladder. It is separated from the paravesical space by the ascending bladder septum (bladder pillars).

Upon entering the prevesical space, the pubourethral ligaments may be seen inserting the posterior aspect of the symphysis pubis as a thickened prolongation of the arcus tendineus fascia. With combined abdominal and vaginal bladder neck suspensory procedures, the point of entry is usually the Retzius space between the arcus tendineus and the pubourethral ligaments.

Paravesical Space

The paravesical spaces are fat filled and limited by the fascia of the obturator internus muscle and the pelvic diaphragm laterally, the bladder pillar medially, the endopelvic fascia inferiorly, and the lateral umbilical ligament superiorly.

Vesicovaginal Space

The vesicovaginal space is separated from the Retzius space by the endopelvic fascia. This space is limited anteriorly by the bladder wall (from the proximal urethra to the upper vagina), posteriorly by the anterior vaginal wall, and laterally by the bladder septa (selective thickenings of the endopelvic fascia inserting laterally into the arcus tendineus). *A tear in these fascial investments and thickenings medially, transversely, or laterally allows herniation and development of a cystocele.*

Rectovaginal Space

The rectovaginal space extends between the vagina and the rectum from the superior border of the perineal body to the underside of the rectouterine Douglas pouch. It is bound anteriorly by the rectovaginal septum (firmly adherent to the posterior aspect of the vagina), posteriorly by the anterior rectal wall, and laterally by the descending rectal septa separating the rectovaginal space from the pararectal space on each side. The rectovaginal septum represents a firm membranous transverse septum dividing the pelvis into rectal and urogenital compartments, allowing the independent function of the vagina and rectum and providing support for the rectum. It is fixed laterally to the pelvic sidewall by rectovaginal fascia (part of the endopelvic fascia) along a line extending from the posterior fourchette to the arcus tendineus fasciae pelvis, midway between the pubis and the ischial spine (18). An anterior rectocele often results from a defective *septum* or an avulsion of the septum from the perineal body. Reconstruction of the perineum is critical for the restoration of this important compartmental separation as well as for the support of the anterior vaginal wall (19). **Lateral detachment of the rectovaginal fascia from the pelvic sidewall may constitute a “pararectal” defect analogous to anterior paravaginal defects.**

Pararectal Space

The pararectal space is bound laterally by the levator ani, medially by the rectal pillars, and posteriorly above the ischial spine by the anterolateral aspect of the sacrum. It is separated from the retrorectal space by the posterior extension of the descending rectal septa.

Retrorectal Space

The retrorectal space is limited by the rectum anteriorly and the anterior aspect of the sacrum posteriorly. It communicates with the pararectal spaces laterally above the uterosacral ligaments and extends superiorly into the presacral space.

Presacral Space

The presacral space is the superior extension of the retrorectal space and is limited by the deep parietal peritoneum anteriorly and the anterior aspect of the sacrum posteriorly. It harbors the middle sacral vessels and the hypogastric plexi between the bifurcation of the aorta invested by loose areolar tissue. Presacral neurectomy requires a good familiarity and working knowledge of this space.

Peritoneal Cavity

The female pelvic organs lie at the bottom of the abdominopelvic cavity covered superiorly and posteriorly by the small and large bowel. Anteriorly, the uterine wall is in contact with the posterosuperior aspect of the bladder. The uterus is held in position by the following structures:

1. The **round ligaments** coursing inferolaterally toward the internal inguinal ring

cardinal ligaments), septation (vesicovaginal and rectovaginal), and definition of pelvic spaces (prevesical, vesicovaginal, rectovaginal, paravesical, pararectal, and retrorectal).

For its support, the pelvic floor relies on the complementary role of the pelvic diaphragm and its fascia resting on the perineal fibromuscular complex. It is composed of the perineal membrane (urogenital diaphragm) anteriorly, and the perineal body joined to the anococcygeal raphe by the external anal sphincter posteriorly. This double-layered arrangement, when intact, provides optimal support for the pelvic organs and counterbalances the forces pushing them downward with gravity and with any increase in intraabdominal pressure (Fig. 5.25).

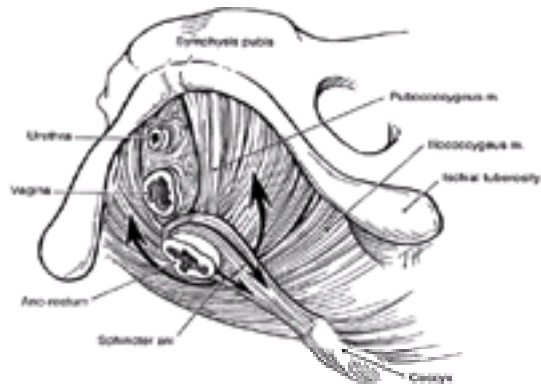

Figure 5.25 The double-layered muscular support of the pelvic diaphragm.

Summary

Continuing review and education in anatomy are important for every pelvic surgeon. New surgical approaches are being developed to solve old problems and often require surgeons to revisit familiar anatomy from an unfamiliar perspective (e.g., through a laparoscope) or with a different understanding of complex anatomic relationships. Anatomic alterations secondary to disease, congenital variation, or intraoperative complications may make even familiar surgical territory suddenly seem foreign. All of these situations require surgeons to be perpetual students of anatomy, regardless of breadth or depth of experience.

Several strategies for continuing education in anatomy are suggested:

1. Review relevant anatomy before each surgical procedure.
2. Study the gynecologic literature on an ongoing basis—numerous publications have documented the evolution of newer concepts regarding anatomic issues such as pelvic support.
3. Operate with more experienced pelvic surgeons, particularly when incorporating new surgical procedures into practice.
4. Periodically dissect fresh or fixed cadaveric specimens; this practice can generally be arranged through local or regional anatomy boards or medical schools or by special arrangement at the time of autopsy.

Significant scientific advances in molecular biology and genetics have occurred in the recent past. Completion of the human genome project, the emergence of new areas of investigation such as proteomics, and the development of new technologies for the manipulation of cells *ex vivo* are just some of the accomplishments that will have an impact on the specialty of obstetrics and gynecology. To place the significance of these advances in perspective, one must understand the basic concepts of molecular and cellular biology.

Normal cells are characterized by discrete metabolic, biochemical, and physiologic functions and responses. The observed functions and responses are influenced by the specific cell type and its genetic complement ([Fig. 6.1](#)). To orchestrate a coordinated and appropriate response, an external stimulus must be converted to an intracellular signal that is reliably transduced to the nucleus and then converted to specific genetic messages. Through these steps, extracellular signals prompt changes in cellular function, differentiation, and proliferation. Although specific cell types and tissues by definition exhibit unique functions and characteristics, there are also many aspects of cell biology and genetics that are common to all eukaryotic cells.

Figure 6.1 External stimuli affect the cell, which has a specific coordinated response.

Cell Cycle

Normal Cell Cycle

The cell cycle and the factors that influence it are key to cell biology. Control of the cell cycle is the result of multiple levels of complex molecular regulation, most of which is incompletely understood. **Progression through the cell cycle occurs through four distinct phases: G_1 , S, G_2 , and M ([Fig. 6.2](#)).** The duration of the cell cycle (e.g., the generation time) may be quite variable, although most human cells complete the cell cycle within approximately 24 hours. Variations in cell-cycle time reflect different durations of the G_1 phase. With respect to the cell cycle, there are three subpopulations of cells:

Figure 6.2 The cell cycle.

1. **Terminally differentiated cells** cannot reenter the cell cycle.
2. **Quiescent (G_0) cells** can enter the cell cycle if appropriately stimulated.
3. **Dividing cells** are currently in the cell cycle.

Red blood cells, striated muscle cells, uterine smooth muscle cells, and nerve cells are terminally differentiated. Other cells, such as fibroblasts, exist in the G_0 phase and are considered to be out of the cell cycle. These cells are stimulated to enter the cell cycle following exposure to specific stimuli, such as growth factors and steroid hormones. Dividing cells are found in the gastrointestinal tract, the skin, and the cervix.

G₁ Phase

In response to specific external stimuli, cells enter the cell cycle by moving from the G_0 phase into the G_1 phase. The G_1 phase of the cell cycle is characterized by diverse biosynthetic activities. The synthesis of enzymes and regulatory proteins necessary for DNA synthesis occurs during this phase. **Variation in the duration of the G_1 phase of the cell cycle, ranging from less than 8 hours to longer than 100 hours, accounts for the different generation times exhibited by different types of cells.**

S Phase

The nuclear DNA content of the cell is copied during the S phase of the cell cycle. It is not known what actually triggers the initiation of DNA synthesis, but once it begins, it proceeds as an "all-or-none" phenomenon. Upon completion of this phase, the DNA content of the cell is doubled.

G₂ Phase

RNA and protein synthesis occurs during the G₂ phase of the cell cycle. The burst of biosynthetic activity provides the metabolic substrates and enzymes to meet the metabolic requirements of the two daughter cells. Another important event that occurs during the G_2 phase of the cell cycle is repair of errors of DNA replication that may have occurred during the S phase. Failure to detect and correct these genetic errors can result in a broad spectrum of adverse consequences for the organism as well as the individual cell ([1](#)). Defects in the DNA repair mechanism have been associated with an increased incidence of cancer ([2](#)).

M Phase

During mitosis, or the M phase of the cell cycle, nuclear division occurs. During this phase, cellular DNA is equally distributed to each of the daughter cells. Mitosis provides a diploid (2n) DNA complement to each somatic daughter cell. Following mitosis, eukaryotic mammalian cells normally contain diploid DNA reflecting a karyotype that includes 44 somatic chromosomes and an XX or XY sex chromosome complement. Exceptions to the diploid cellular content include hepatocytes (4n) and the functional syncytium of the placenta.

Ploidy

Germ cells contain a haploid (1n) genetic complement after meiosis. After fertilization, a 46,XX or 46,XY diploid DNA complement is restored. Restoration of the normal cellular DNA content is crucial to normal function. Abnormalities of cellular DNA content cause distinct phenotypic abnormalities as exemplified by hydatidiform molar pregnancy (see [Chapter 34](#)). With complete hydatidiform mole, an oocyte without any nuclear genetic material (e.g., an empty ovum) is fertilized by one sperm. The haploid genetic content of the fertilized ovum is then duplicated and the diploid cellular DNA content is restored, resulting in a homozygous 46,XX gamete. Less often, a complete hydatidiform mole results from the fertilization of an empty ovum by two sperm, resulting in a heterozygous 46,XX or 46,XY gamete. In complete molar pregnancies, the nuclear DNA is paternally derived, embryonic structures do not develop, and trophoblast hyperplasia occurs. A partial hydatidiform mole follows the fertilization of a haploid ovum by two sperm, resulting in a 69,XXX, 69,XXY, or 69,XYY karyotype. A partial mole contains paternal and maternal DNA, and both embryonic and placental development occur.

Both the 69,YYY karyotype and the 46,YY karyotype are incompatible with embryonic and placental development. These observations indicate the importance of the maternal genetic contribution, in general, and the X chromosome, in particular, to normal embryonic and placental development.

In addition to total cellular DNA content, the chromosome number is an important determinant of cellular function. Abnormalities of chromosome number, which are often the result of nondisjunction during meiosis, result in well-characterized clinical syndromes such as trisomy 21 (Down's syndrome), trisomy 18, and trisomy 13.

Nuclear division and the allocation of replicated DNA to the daughter cells is closely followed by cytoplasmic division (e.g., cytokinesis). Exceptions are hepatocytes and syncytiotrophoblasts, in which several nuclei exist in a common cytoplasm. After mitosis and completion of cellular division, the daughter cells continue in G_1 , enter the G_0 phase, or undergo programmed cell death. The option that is pursued by the daughter cell has important implications for the integrity of the tissue and the organ.

Genetic Control of the Cell Cycle

Cellular proliferation must occur to balance normal cell loss and maintain tissue and organ integrity. This process requires the coordinated expression of many genes at discrete times during the cell cycle ([3](#)). To successfully complete the cell cycle, a number of cell division cycle (*cdc*) genes are activated. In addition, the cell must traverse two checkpoints, one at the G_1/S boundary and one at the G_2/M boundary ([4,5](#)). **The G_1/S boundary marks the point at which a cell commits to proliferation and the G_2/M boundary marks the point at which repair of any DNA damage must be completed ([6,7](#)).**

Cell Division Cycle Genes

Among the factors that regulate the cell cycle checkpoints, proteins encoded by the *cdc2* family of genes and the cyclin proteins appear to play particularly important roles ([8,9](#)). **The accumulation and degradation of cyclins regulate the checkpoint at the G_1/S boundary.** It has been hypothesized that these proteins bind to specific chromosomal sites. When the chromosomal sites are fully occupied, a critical threshold is exceeded, the free intracellular concentration of cyclins increases, and the cell enters the S phase of the cycle. By an unknown mechanism, cyclins can also inhibit progression through the cell cycle in the presence of DNA damage.

The *p53* tumor suppressor gene also appears to participate in delay of the cell cycle in order for DNA repair to be completed. As an example, cells exposed to radiation therapy exhibit an S-phase arrest that is accompanied by increased expression of *p53*. This delay permits the repair of radiation-induced DNA damage. When the *p53* gene is mutated, the S-phase arrest that normally follows radiation therapy does not occur ([10,11](#)). A normal *p53* gene that is not mutated can be inactivated when human papillomavirus 16 E6 protein is present, and the S-phase arrest in response to ultraviolet-induced DNA damage does not occur ([12](#)).

Mitosis is initiated by activation of the *cdc* gene at the G_2/M checkpoint ([13,14](#)). The p34 *cdc2* protein and specific cyclins form a complex heterodimer referred to as *mitosis-promoting factor (MPF)*, which catalyzes protein phosphorylation and drives the cell into mitosis. Once the G_2/M checkpoint has been passed, the cell undergoes mitosis. In the presence of abnormally replicated chromosomes, progression past the G_2/M checkpoint does not occur.

Following cytoplasmic division, the daughter cells exit the cell cycle (e.g., enter the G_0 phase), continue in the G_1 phase of the cell cycle, or undergo programmed cell death. Failure of the progeny cells to respond to the signals that regulate cellular proliferation at this point in the cell cycle is a fundamental characteristic of the neoplastic phenotype.

Apoptosis

The regulation and maintenance of normal tissue mass requires a balance between cell proliferation and programmed cell death, or *apoptosis*. When proliferation exceeds programmed cell death, the result is hyperplasia. When programmed cell death exceeds proliferation, the result is atrophy. Programmed cell death is a crucial concomitant of normal embryologic development. This mechanism accounts for deletion of the interdigital webs (15), palatal fusion (16), and development of the intestinal mucosa (17). Programmed cell death is also an important phenomenon in normal physiology (18). The reduction in the number of endometrial cells following alterations in steroid hormone levels during the menstrual cycle is, in part, a consequence of programmed cell death (19,20). In response to androgens, granulosa cells undergo programmed cell death (e.g., follicular atresia (21).

Programmed cell death, or apoptosis, is an energy-dependent, active process that is initiated by the expression of specific genes. It is a process distinct from cell necrosis, although both mechanisms result in a reduction in total cell number. In programmed cell death, cells shrink and undergo phagocytosis. Apoptosis is an energy-dependent process that results from the expression of specific genes. Conversely, in cell necrosis, groups of cells expand and lyse, and it is an energy-independent process that results from noxious stimuli. Programmed cell death is triggered by a variety of factors, including intracellular signals and exogenous stimuli such as radiation exposure, chemotherapy, and hormones. Cells undergoing programmed cell death may be identified on the basis of histologic, biochemical, and molecular biologic changes. Histologically, apoptotic cells exhibit cellular condensation and fragmentation of the nucleus. Biochemical correlates of impending programmed cell death include an increase in transglutaminase expression and fluxes in intracellular calcium concentration. The molecular mechanisms of programmed cell death are the subject of intense investigation (22,23).

Programmed cell death has recently emerged as an important factor in the growth of neoplasms. Historically, neoplastic growth has been characterized by uncontrolled cellular proliferation that resulted in a progressive increase in tumor burden. It is now recognized that **the increase in tumor burden associated with progressive disease reflects an imbalance between cell proliferation and cell death**. Cancer cells not only fail to respond to the normal signals to stop proliferating, but they may also fail to recognize the physiologic signals that trigger programmed cell death.

Modulation of Cell Growth and Function

The normal cell exhibits an orchestrated response to the changing extracellular environment. The three groups of substances that signal these extracellular changes are steroid hormones, growth factors, and cytokines. The capability to respond to these stimuli requires a cell surface recognition system, an intracellular signal transduction system, and a means to elicit the expression of specific genes in a coordinated fashion to affect changes in cell structure and function.

Oncogenes and Tumor Suppressor Genes

Among the genes that participate in cell growth and function, *protooncogenes* and *tumor suppressor genes* are particularly important (24,25, and 26). *Protooncogenes* encode growth factors, membrane and cytoplasmic receptors, proteins that play key roles in the intracellular signal transduction cascade, and nuclear DNA binding proteins (Table 6.1). More than 50 protooncogene products that contribute to growth regulation have been identified. As a group, protooncogenes exert positive effects upon cellular proliferation. In contradistinction, *tumor suppressor genes* exert inhibitory regulatory effects on cellular proliferation (Table 6.2).

Protooncogenes	Gene Product/Function

Steroid Hormones

Steroid hormones play crucial roles in reproductive biology as well as in general physiology. To mention only a few of their roles, steroid hormones influence pregnancy, phenotype, cardiovascular function, bone metabolism, and an individual's sense of general well-being. Steroid hormone action reflects the intracellular and genetic mechanisms that are necessary for the transduction of an extracellular signal to the nucleus to affect a physiologic response. Estrogen diffuses through the cell membrane and binds to estrogen receptors that are located in the nucleus. The receptor-steroid complex then binds to the DNA at specific sequences designated as *estrogen-response elements (EREs)*. These steroid-responsive elements are located near the promoter regions of genes that are regulated by estrogen (27). In the uterus, these interactions result in discrete changes in gene expression, protein synthesis, and cellular and tissue function (28). In any estrogen-responsive tissue, the estrogen receptor plays a pivotal role.

The estrogen receptor has been characterized in terms of its molecular biology, structure, function, and tissue distribution. As is the case for all hormone receptors, specificity of action is conferred by the ligand-binding and the DNA-binding domains (EREs). The role of hormone receptors in normal tissue and organ function, as well as their role in the cause and progression of clinically defined estrogen responsive neoplasms, is much more complicated than originally appreciated.

The estrogen receptor actually represents two distinct receptors, E₂R-a and E₂R-b that are encoded by different genes on different chromosomes. Both E₂R-a and E₂R-b bind estrogen and regulate transcription through interactions with EREs. These receptors exhibit different affinities and responsiveness not only to estrogen but also to *selective estrogen receptor modulators (SERMs)*. Compared with E₂R-a, the E₂R-b receptor requires 5- to 10-fold higher concentrations of estradiol for maximal transcriptional activity. **Tamoxifen is a mixed agonist/antagonist for E₂R-a but it is a pure antagonist for E₂R-b.** The E₂R-b receptor is ubiquitously expressed in hormone-responsive tissues, whereas the expression of E₂R-a fluctuates in response to the hormonal milieu. The cellular and tissue effects

of an estrogenic compound appear to reflect a dynamic interplay between the actions of these estrogen receptor isoforms. These observations underscore the complexity of estrogen interactions with both normal and neoplastic tissue.

Mutations of hormone receptors and their functional consequences illustrate their important contributions to normal physiology. For example, absence of E₂R- α in a male human has been reported (29). The clinical sequelae attributed to this mutation include incomplete epiphyseal closure, increased bone turnover, tall stature, and impaired glucose tolerance. The androgen insensitivity syndrome is caused by mutations of the androgen receptor (30). Mutations of the receptors for growth hormone and thyroid-stimulating hormone that result in a spectrum of phenotypic alterations have also been identified. It is speculated that mutations of hormone receptors may contribute to the progression of neoplastic disease and resistance to hormone therapy (31,32).

Growth Factors

Growth factors are polypeptides that are produced by a variety of cell types and exhibit a wide range of overlapping biochemical actions (23). Growth factors bind to high-affinity cell membrane receptors and trigger complex positive and negative signaling pathways that regulate cell proliferation and differentiation (33). **In general, growth factors exert positive or negative effects upon the cell cycle by influencing gene expression related to events that occur at the G₁/S cell cycle boundary (34).**

Because of their short half-life in the extracellular space, growth factors generally act over limited distances through autocrine or paracrine mechanisms. The autocrine mechanism of growth control involves the elaboration of a growth factor that acts on the cell that produced it. The paracrine mechanism of growth control involves the elaboration of a growth factor that acts on another cell in proximity.

More than 40 growth factors have been described. Those that appear to play important roles in female reproductive physiology are listed in Table 6.3. The biologic response of a cell to a specific growth factor depends on the cell type and the other stimuli that are concomitantly acting on the cell. Two growth factors acting in concert may produce a very different effect from either factor independently.

Growth Factor	Source	Targets	Action
Fibroblast-derived growth factor (PDGF)	Placenta, platelets, proangiogenesis arteries, endothelial cells	Endothelial cells, trophoblasts	Mitogen
Epidermal growth factor (EGF)	Submaxillary gland, theca cells	Granulosa cells, endometrium, ovum	Mitogen
Transforming growth factor- α (TGF- α)	Embryo, placenta, theca cell, ovarian stromal cell	Placenta, granulosa cells	Mitogen
Transforming growth factor- β (TGF- β)	Embryo, theca cells	Endometrium, granulosa cells, theca cells	Mitogen
Insulin-like growth factor 1 (IGF-1)	Granulosa cells	Theca cells, granulosa cells	Indicates growth hormone activity
Insulin-like growth factor 2 (IGF-2)	Theca cells	Theca cells	Insulin-like effects
Fibroblast growth factor (FGF)	Granulosa cells	Granulosa cells	Angiogenic activity, mitogen

Table 6.3. Growth Factors that Play Important Roles in Female Reproductive Physiology

The regulation of ovarian function occurs through *autocrine, paracrine, and endocrine mechanisms* (35, 36, 37, 38, 39, 40 and 41). The growth and differentiation of ovarian cells are particularly influenced by the insulin-like growth factors (IGF) (Fig. 6.3). The IGF amplify the actions of gonadotropin hormones on autocrine and paracrine growth factors found in the ovary. As an example, IGF-1 acts on granulosa cells to cause an increase in cyclic adenosine monophosphate (cAMP), progesterone, oxytocin, proteoglycans, and inhibin. Insulin-like growth factor 1 acts on theca cells to cause an increase in androgen production. The theca cells in turn produce tumor necrosis factor- α (TNF- α) and epidermal growth factor (EGF), both of which are also regulated by follicle-stimulating hormone (FSH). Epidermal growth factor acts on granulosa cells to stimulate mitogenesis. Insulin-like growth factor 2 is the principal growth factor found in follicular fluid although other factors, including IGF-1, TNF- α , TNF- β , and EGF, also play important roles. **Disruption of these autocrine and paracrine intraovarian pathways may be the basis of polycystic ovarian disease and disorders of ovulation.**

Figure 6.3 The regulation of ovarian function occurs through autocrine, paracrine, and endocrine mechanisms.

Transforming growth factor (TGF)- β activates intracytoplasmic serine threonine kinases and inhibits cells in the late G₁ phase of the cell cycle (41). It appears to play an important role in embryonic remodeling. Müllerian inhibiting substance (MIS), which is responsible for regression of the müllerian duct, is structurally and functionally related to TGF- β (42).

Transforming growth factor α is an EGF homologue that binds to the EGF receptor and acts as an autocrine factor in normal cells. Like EGF, TGF- α promotes entry of G₀ cells into the G₁ phase of the cell cycle. The role of growth factors in endometrial growth and function has been the subject of several reviews (36, 37, 38, 39, 40 and 41). Similar to the ovary, autocrine, paracrine, and endocrine mechanisms of control also occur in endometrial tissue.

Intracellular Signal Transduction

Growth factors trigger intracellular biochemical signals by binding to cell membrane receptors. In general, these membrane-bound receptors are *protein kinases that convert an extracellular signal into an intracellular signal*. The interaction between growth factor ligand and its receptor results in receptor dimerization, autophosphorylation, and tyrosine kinase activation. Activated receptors in turn phosphorylate substrates in the cytoplasm and trigger the intracellular signal transduction system (Fig. 6.4). The intracellular signal transduction system relies on serine threonine kinases, *src*-related kinases, and G proteins. Intracellular signals in turn activate nuclear effectors that regulate gene expression. **Many of the proteins that participate in the intracellular signal transduction system are encoded by protooncogenes that are conveniently divided into subgroups based on their cellular location or enzymatic function (43,44) (Fig. 6.5).**

Figure 6.4 Pathways of intracellular signal transduction.

Figure 6.5 Protooncogenes are divided into subgroups based on their cellular location or enzymatic function.

The *raf* and *mos* protooncogenes encode proteins with serine threonine kinase activity. These kinases integrate signals originating at the cell membrane with those that are forwarded to the nucleus (45,46). Protein kinase C (PKC) is an important component of the second messenger system that exhibits serine threonine kinase activity. This enzyme plays a central role in phosphorylation, which is a general mechanism for activating and deactivating proteins. It also plays an important role in cell metabolism and division (47).

The Scr family of tyrosine kinases is related to PKC and includes protein products encoded by the *scr*, *yes*, *fgr*, *hck*, *lyn*, *fyn*, *lck*, *alt*, and *fps/fes* protooncogenes. These proteins bind to the inner cell membrane surface.

The *G proteins* are guanyl nucleotide-binding proteins. The heterotrimeric or large G proteins link receptor activation with effector proteins such as adenylyl cyclase, which activates the cAMP-dependent, kinase-signaling cascade (48,49). The monomeric or small G proteins, encoded by the *ras* protooncogene family, are designated p21 and are particularly important regulators of mitogenic signals (50). The p21 Ras protein exhibits guanyl triphosphate (GTP) binding and GTPase activity. Hydrolysis of GTP to guanyl diphosphate (GDP) terminates p21 Ras activity. The p21 Ras protein influences the production of deoxyguanosine (dG) and inositol phosphate (IP) 3, arachidonic acid production, and IP turnover.

Gene Expression

Regulation of genetic transcription and replication is crucial to the normal function of the daughter cells as well as the tissues and ultimately the organism. Transmission of external signals to the nucleus by way of the intracellular signal transduction cascade culminates in the transcription and translation of specific genes that ultimately affect the structure, function, and proliferation of the cell.

The human genome project has resulted in the determination of the sequence of DNA of the entire human genome. With the completion of this project, it appears that the human genetic complement consists of approximately 30,000 genes. Sequencing the human genome is a major scientific achievement that opens the door for more detailed studies of structural and functional genomics. Structural genomics involves the study of three-dimensional structures of proteins based on their amino acid sequences. Functional genomics provides a way to correlate structure and function. Proteomics involves the identification and cataloging of all proteins used by a cell, and cytomics involves the study of cellular dynamics, including intracellular system regulation and response to external stimuli. Each of these areas of investigation requires an understanding of basic genetic alterations.

Gene replication, transcription, and translation are imperfect processes and the fidelity is less than 100% (51). Genetic errors may result in abnormal structure and function. Genomic alterations have been identified in premalignant, malignant, and benign neoplasms of the female genital tract (52, 53 and 54).

In view of the critical roles that oncogenes and tumor suppressor genes play in the regulation of normal cell growth, it is understandable that mutations of these genes may causally contribute to the neoplastic phenotype. By convention, mutated protooncogenes are referred to as *c-oncogenes*. Mutations may occur by one of several mechanisms (Fig. 6.6).

Figure 6.6 Genes can be amplified or undergo mutation, deletion, or rearrangement.

Genetic abnormalities, such as amplification, point mutations, and deletions or rearrangements, are progressive in successive generations. One error tends to permit additional aberrations. A variety of genetic abnormalities have been associated with the neoplastic phenotype. The end result of the genetic abnormalities found in transformed cells is defective control of the cell cycle. Proliferation may be abnormally increased with inoperative normal constraints on cell growth, programmed cell death may fail to occur, or some combination of the two processes may exist.

A single genetic mutation that causes cancer has not been identified. In fact, specific genetic mutations may not be as important as the accumulation of some critical number of mutations in a cell. Available data suggest that cancer results from the accumulation of mutations over time in several genes (55). From this perspective,

exposure to factors that increase the likelihood of genetic mutations over time assumes importance in assessing cancer risk.

Amplification

Amplification refers to an increase in the copy number of a gene. Amplification results in enhanced gene expression by increasing the amount of template DNA that is available for transcription. Protooncogene amplification is a relatively common event in malignancies of the female genital tract.

Point Mutations

Point mutations of a gene, in which the codon sequence is altered, may result in altered gene action by qualitatively altering the gene product. The *ras* gene family is perhaps the best example of oncogene-encoded proteins that disrupt the intracellular signal transduction system following mutation. Transforming Ras proteins contain point mutations in critical codons (i.e., 11, 12, 59, 61) that reduce GTPase activity so that Ras is constitutively active in the GTP-bound form. Point mutations of the *p53* gene are the most common genetic mutation described in solid tumors. These mutations occur at preferential “hot spots” that coincide with the most highly conserved regions of the gene. Loss of normal *p53* gene activity removes one of the inhibitors of cell proliferation and also increases the likelihood that DNA damage may be successfully passed to daughter cells. Mutations of the *p53* gene occur in approximately 50% of ovarian cancers and 30% to 40% of endometrial cancers. In contrast, point mutations of *p53* are uncommon in cervical cancer. However, in cervical cancer, *p53* activity is often abnormal as a consequence of interactions between the p53 protein and the E6 protein encoded by the human papillomavirus.

As with *p53*, the *BRCA1* and *BRCA2* genes also play a role in DNA repair, and the activity of these genes may be altered by point mutations. Unlike the situation with *p53*, mutations of *BRCA1* and *BRCA2* do not occur at preferential positions. The “random” location of mutations coupled with the large size of these genes make genetic screening a complicated task. Mutations of the *BRCA1* and *BRCA2* genes may be associated with an increased risk of ovarian and breast cancer.

Deletions and Rearrangements

Deletions and rearrangements reflect gross changes in the DNA template that may result in the synthesis of a markedly altered protein product. As an example, deletion mutations of the EGF receptor affect tyrosine kinase activity. The mutated receptor is activated constitutively and transmits a signal to the cytoplasm for cellular proliferation in the absence of a bound ligand.

Immunology

The immune system plays an essential part in host defense and can respond to host cells that have undergone transformation to become neoplastic cells. These responses, whether natural or induced, can in some cases lead to tumor regression. As more is learned about the regulation of immune responses, new opportunities for novel immunotherapeutic approaches develop. Immunodiagnostic procedures using antitumor marker antibodies also show great promise as diagnostic and prognostic tools.

Immunologic Mechanisms

The human immune system has the potential to respond to abnormal or tumor cells in various ways. Some of these immune responses occur in an innate or antigen-nonspecific manner, whereas others are adaptive or antigen specific. Adaptive responses are specific to a given antigen and also establish a memory, allowing a more rapid and vigorous response to the same antigen in future encounters (55). Various innate and adaptive immune mechanisms are involved in responses to tumors, including cytotoxicity directed to tumor cells mediated by cytotoxic T cells, natural killer (NK) cells, macrophages, and antibody-dependent cytotoxicity mediated by complementation activation (56).

Adaptive or specific immune responses are made up of humoral and cellular responses. *Humoral immune responses* refer to the production of antibodies that are antigen reactive, soluble, bifunctional molecules composed of specific antigen-binding sites that react with foreign antigens. They are associated with a constant region that directs the biologic activities of the antibody, such as the binding of antibody molecules to cells, including phagocytic cells, or the activation of complement. *Cellular immune responses* are antigen-specific immune responses mediated directly by activated immune cells rather than by the production of antibodies. The distinction between humoral and cellular responses is historical and originates from the experimental observation that humoral immune function can be transferred by serum, whereas cellular immune function requires the transfer of cells. Most immune responses include both humoral and cellular components.

Several types of cells, including cells from both the myeloid and lymphoid lineages, make up the immune system. Specific humoral and cellular immune responses to foreign antigens involve the coordinated action of populations of lymphocytes operating in concert with each other and with phagocytic cells (macrophages). These cellular interactions include both direct cognate interactions involving cell-to-cell contact and cellular interactions involving the secretion of and response to cytokines or lymphokines. Lymphoid cells are found in lymphoid tissues, such as lymph nodes or spleen, or in the peripheral circulation. The cells that make up the immune system originate from stem cells in the bone marrow.

B Cells, Hormonal Immunity, and Monoclonal Antibodies

The cells that synthesize and secrete antibodies are B lymphocytes (56). Mature, antigen-responsive B cells develop from pre-B cells (committed B-cell progenitors) and differentiate to become plasma cells, which produce large quantities of antibodies. Pre-B cells originate from bone marrow stem cells in adults, after the rearrangement of immunoglobulin genes from their germ-cell configuration to that seen in B cells. Mature B cells express cell surface immunoglobulin molecules, which these cells use as their receptors for antigen.

Following interaction with antigen, and in the presence of appropriate cell—cell stimulatory signals and cytokines, mature B cells respond to become antibody-producing cells. Although the generation of antibodies directed to tumor cells is generally not thought to have a central role in antitumor immune responses, the production of monoclonal antibodies to tumor cell antigens has shown great potential for immunotherapy and tumor detection.

Kohler and Milstein developed monoclonal antibody technology more than 20 years ago, and there has been considerable interest in the use of monoclonal antibodies for detection and monitoring of tumors and for treatment (57). Monoclonal antibodies that react with tumor-associated antigens may provide new therapeutic agents for cancer. Immunotoxin-conjugated monoclonal antibodies directed to human ovarian adenocarcinoma antigens can induce tumor cell killing and can prolong survival in mice implanted with a human ovarian cancer cell line (58). However, many obstacles limit the clinical use of monoclonal antibodies, including tumor cell antigenic heterogeneity, modulation of tumor-associated antigens, and cross-reactivity of normal host and tumor-associated antigens. No unique tumor-specific antigens have been identified; all tumor antigens that have been identified to date are tumor-related antigens, which are expressed to a lesser extent by nonmalignant tissues. Because most monoclonal antibodies are murine, the host's immune system can also recognize and respond to these foreign mouse proteins. The use of the genetically engineered monoclonal antibodies composed of human-constant regions with specific antigen-reactive murine variable regions should result in reduced antigenicity to the host (58). This may help eliminate many of the problems associated with the use of murine monoclonal antibodies.

T Lymphocytes and Cellular Immunity

T lymphocytes have a central role in the generation of immune responses by acting as helper cells in both humoral and cellular immune responses and by acting as effector cells in cellular responses (55). T-cell precursors originate in bone marrow and move to the thymus, where they mature into functional T cells. During their thymic maturation, T cells learn to recognize antigen in the context of the *major histocompatibility complex (MHC)* type of the individual person. It also seems that self-responding T cells are removed during development in the thymus (54, 55 and 56).

T cells can be distinguished from other types of lymphocytes by their cell surface phenotype based upon the pattern of expression of various molecules as well as by differences in their biologic functions. All mature T cells express certain cell surface molecules such as the cluster determinant 3 (CD3) molecular complex and the T-cell antigen receptor, which is found in close association with the CD3 complex. The availability of monoclonal antibody reagents specific for cell surface markers has led to great progress in understanding the organization of the immune system in recent years. Certainly, such monoclonal antibodies are of great

value in monitoring the effects on the human immune system of experimental treatment with biologic response modifiers or cytokines.

T cells recognize antigen through the cell surface T-cell antigen receptor (TCR). The structure and molecular organization of this molecule are similar to those of antibody molecules, which are the B-cell receptors for antigen. During T-cell development, the T-cell receptor gene undergoes gene arrangements similar to those seen in B cells, but there are important differences between the antigen receptors on B cells and T cells. The T-cell receptor is not secreted, and its structure is somewhat different from that of antibody molecules. The way in which the B-cell and T-cell receptors interact with antigens is also quite different. T cells can respond to antigens only when these antigens are presented in association with MHC molecules on antigen-presenting cells. Effective antigen presentation involves the processing of antigen into small fragments of peptide within the antigen-presenting cell and the subsequent presentation of these fragments of antigen in association with MHC molecules expressed on the surface of the antigen-presenting cell. T cells can respond to antigen only when presented in this manner, unlike B cells, which can bind antigen directly, without processing and presentation by antigen-presenting cells (56).

There are two major subsets of mature T cells that are phenotypically and functionally distinct: T helper/inducer cells, which express the CD4 cell surface marker, and the T suppressor/cytotoxic cells, which express the CD8 marker. The expression of these markers is acquired during the passage of T cells through the thymus. CD4 T cells can provide help to B cells, resulting in the production of antibodies by B cells, and interact with antigen presented by antigen-presenting cells in association with MHC class II molecules. CD4 T cells can also act as helper cells for other T cells. CD8 T cells include cells that are cytotoxic (cells that can kill target cells bearing appropriate antigens), and they interact with antigen presented on target cells in association with MHC class I molecules. The CD8 T-cell subset also contains suppressor T cells. These T cells can inhibit the biologic functions of B cells or other T cells (56). Although the primary biologic role of *cytotoxic T cells (CTLs)* seems to be lysis of virus-infected autologous cells, cytotoxic immune T cells can mediate the lysis of tumor cells directly. Presumably, CTLs recognize antigens associated with MHC class I molecules on tumor cells through their antigen-specific T-cell receptor, setting off a series of events that ultimately results in the lysis of the target cell.

Monocytes and Macrophages

Monocytes and macrophages, which are myeloid cells, have important roles in both innate and adaptive immune responses; macrophages play a key part in the generation of immune receptors. T cells do not respond to foreign antigens unless those antigens are processed and presented by antigen-presenting cells. **Macrophages (and B cells) express MHC class II molecules and are effective antigen-presenting cells for CD4 T cells (55).** Helper-inducer (CD4) T cells that bear a T-cell receptor of appropriate antigen and self-specificity are activated by this antigen-presenting cell to provide help (various factors—lymphokines—that induce the activation of other lymphocytes). In addition to their role as antigen-presenting cells, macrophages play an important part in innate responses by ingesting and killing microorganisms. Activated macrophages, in addition to their many other functional capabilities, can act as cytotoxic, antitumor killer cells.

Natural Killer Cells

A third major population of lymphocytes includes NK cells (55). These cells do not consistently bear cell surface markers that are characteristic of T or B cells, although they can share certain cell surface molecules with other types of lymphocytes. Characteristically, NK cells have a large granular lymphocyte morphology (59).

Natural killer cells are effector cells in an innate type of immune response: the nonspecific killing of tumor cells and virus-infected cells. Therefore, **NK activity represents an innate form of immunity that does not require an adaptive, memory response for optimal biologic function, but the antitumor activity can be increased by exposure to several agents, particularly cytokines such as interleukin-2 (IL-2).**

Although NK cells can express certain cell surface receptors, particularly a receptor for the crystallizable fragment (Fc) portion of antibodies and other NK-associated markers, it seems that cells with NK function are phenotypically heterogeneous, at least when compared with T or B cells. The cells that can carry out antibody-dependent cellular cytotoxicity, or antibody-targeted cytotoxicity, seem to be NK-like cells. Antibody-dependent cellular cytotoxicity by NK-like cells has been shown to result in the lysis of tumor cells in vitro. The mechanisms of this tumor cell killing are not clearly understood, although close cellular contact between the effector cell and the target cell seems to be required.

Biologic Response Modifiers

Most immunotherapeutic agents used in the treatment of cancer have been nonspecific agents that, when introduced into the human system, elicit a generalized inflammatory reaction and immune response, probably mediated by the secretion of a range of cytokines by many different types of cells. These agents have diverse and broad biologic effects and are often referred to as immunomodulators or biologic response modifiers.

The response of a given patient to treatment with biologic response modifiers depends on the ability to react to treatment with a generalized immune response. It is possible that some elements of the immune response elicited by immunotherapeutic agents or biologic response modifiers may be counterproductive, possibly causing immune suppression, inducing the production of cytokines that enhance tumor growth, or inducing an unfavorable or inappropriate immune response.

Bacille Calmette-Guerin (BCG) vaccine has been widely used in many tumor systems, either systemically, by injection into the lesion, or by scarification (60). Occasionally, it has been mixed with whole irradiated tumor cells and injected into the patient as a vaccine. In a large series, intracutaneous injection of melanoma lesions with BCG resulted in some tumor regression in patients with cutaneous recurrence (61), but visceral or parenchymal metastatic disease is resistant to this treatment. Although there have been some preliminary observations about the use of BCG as an adjuvant in children with acute lymphocytic leukemia and with stage II melanoma, randomized studies have not shown any appreciable responses.

Cytokines, Lymphokines, and Immune Mediators

Many events in the generation of immune responses (as well as during the effector phase of immune responses) require or are enhanced by cytokines, which are soluble mediator molecules (Table 6.4) (62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81 and 82). Cytokines are pleiotropic, in that they have multiple biologic functions that depend on the type of target cell or its maturational state. Cytokines are also heterogeneous in the sense that most cytokines share little structural or amino acid homology. *Cytokines* (also called *monokines* if they are derived from monocytes, *lymphokines* if they are derived from lymphocytes, *interleukins* if they exert their actions on leukocytes, or *interferons* [IFNs] if they have antiviral effects) are produced by a wide variety of cell types and seem to have important roles in many biologic responses outside the immune response, such as hematopoiesis. They may also be involved in the pathophysiology of a wide range of diseases and show great potential as therapeutic agents in immunotherapy for cancer.

Cytokine	Cellular Source	Target Cells	Biological Activity
IL-1	Macrophages, T cells, Endothelial cells	T cells, B cells, Endothelial cells	Systemic inflammation
IL-2	T cells (CD4+)	T cells, B cells	Cellular proliferation
IL-3	T cells	B cells, Macrophages	Cellular proliferation

Table 6.4. Sources, Target Cells, and Biological Activities of Cytokines Involved

Although cytokines are a heterogeneous group of proteins, they share some characteristics. For instance, most cytokines are low- to intermediate-molecular-weight

(10–60 kd) glycosylated secreted proteins. They are also involved in immunity and inflammation, are produced transiently and locally (they act in autocrine and paracrine rather than an endocrine manner), are extremely potent in small concentrations, and interact with high-affinity cellular receptors that are specific for each cytokine. The cell surface binding of cytokines by specific receptors results in signal transduction followed by changes in gene expression and, ultimately, by changes in cellular proliferation or altered cell behavior, or both. Their biologic actions overlap, and exposure of responsive cells to multiple cytokines can result in synergistic or antagonistic biologic effects.

Interleukins

Many different cytokines are involved in immune responses, particularly the interleukins (IL-1, IL-2, IL-3, IL-4, IL-6, IL-7, IL-10, IL-11, and IL-12) (Table 6.4). The interleukins are heterogeneous and do not constitute a family of growth-related molecules.

Interleukin-1 Interleukin-1 has a wide range of biologic activities, including direct effects on several cells involved in immune responses (62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81 and 82). It is involved in fever and inflammatory responses and may play a role in the pathogenesis of several diseases, such as rheumatoid arthritis. There are two defined forms of IL-1, IL-1a and IL-1b, which have similar biologic activities. Interleukin-1 can be released as a soluble form or can be found as a cell-associated molecule on the cell surface of macrophages. The primary sources of IL-1 are macrophages, the phagocytic cells of the liver and spleen, some B cells, epithelial cells, certain brain cells, and the cells lining the synovial spaces. Interleukin-1 has a broad range of target cells and biologic activities, as do most lymphokines. A principal role of IL-1 is in the initiation of early events in immune responses (62,68).

Interleukin-2 Interleukin-2 is a lymphokine that was originally called *T-cell growth factor*, which indicates one of the major biologic activities of this molecule. Failure of T cells to produce IL-2 results in the absence of a T-cell immune response and a diminution of the antibody response. Natural human IL-2 is a 15-kd glycoprotein and is produced primarily by activated T cells. For IL-2 to exert its proliferation-inducing effects, it has to interact with a specific receptor for IL-2 on the surface of the target cell. The high-affinity receptor for IL-2 consists of two polypeptides, the α (75 kd) and β (55 kd) chains. After activation, T cells express greatly increased numbers of this high-affinity receptor for IL-2 and respond to IL-2 with increased proliferation. Stimulation of resting T cells with antigen presented in the context of self (antigen associated with an MHC molecule on the surface of an antigen-presenting cell) and with IL-1 therefore induces synthesis and secretion of IL-2. During this activation process, responding T cells undergo an alteration in their cell surface receptors, including the expression of cell surface receptors for IL-2. Continuing exposure to IL-2 leads to the proliferation of T cells bearing the IL-2 receptor, thereby serving as an activation and response-amplification stage in the generation of immune responses. Activated T cells not only respond to IL-2 but also produce IL-2. Interleukin-2 can therefore act in an autocrine manner (the cells producing the lymphokine then respond to it) or in a paracrine fashion (the IL-2 produced by a T cell is taken up and responded to by neighboring cells). Since its original description as a T-cell growth hormone, IL-2 has been shown to have various other immune functions, including the promotion of B-cell activation and maturation and activation of monocytes and NK cells. Interleukin-2 can also lead directly or indirectly to the stimulation of the production of interferon and other cytokines.

Interleukin-3 Interleukin-3, a factor that can increase the early differentiation of hematopoietic cells (82), may find a role in immunotherapy because of its ability to induce hematopoietic differentiation in people undergoing aggressive chemotherapeutic treatment or bone marrow transplantation.

Tumor necrosis factor is a cytokine that can be directly cytotoxic for tumor cells, can increase immune cell—mediated cellular cytotoxicity, and can activate macrophages and induce secretion of monokines. Other biologic activities of TNF- α include the induction of cachexia, inflammation, and fever; it is an important mediator of endotoxic shock.

Interleukin-4, Interleukin-5, and Interleukin-6 B-lymphocyte activation and differentiation to immunoglobulin-secreting plasma cells are increased by cytokines produced by helper T lymphocytes or monocytes (Table 6.4) (55,56). Several cytokines originally described as B-cell stimulating factors (IL-4, IL-5, and IL-6) have additional biologic activities. For instance, IL-6 (a factor that can induce B-lymphocyte differentiation to immunoglobulin-secreting cells) is a pleiotropic cytokine with biologic activities that include the induction of cytotoxic T-lymphocyte differentiation, the induction of acute-phase reactant production by hepatocytes, and activity as a colony-stimulating factor for hematopoietic stem cell (63). Interleukin-6 is produced primarily by activated monocyte-macrophages and T lymphocytes. Interestingly, several types of tumor cells produce IL-6, and it has been proposed as an autocrine-paracrine growth factor for different types of neoplasms (64, 65, 66, 67, 68 and 69). It may prove to be an effective antitumor agent by virtue of its ability to enhance antitumor T-cell—mediated immune responsiveness (69,70).

Interleukin-8 and Interleukin-10 Interleukin-10, a 35- to 40-kd cytokine, also called *cytokine synthesis inhibitory factor* because of its activity as an inhibitor of cytokine production, is produced by a subset of CD4 cells, type 2 (T_H2) cells, and inhibits the cytokine production by another CD4 cell subset, type 1 (T_H1) cells (71). **T_H1 and T_H2 are two helper T-cell subpopulations that control the nature of an immune response by secreting a characteristic and mutually antagonistic set of cytokines: Clones of T_H1 produce IL-2 and IFN- α , while T_H2 clones produce IL-4, IL-5, IL-6, and IL-10 (72).** A similar dichotomy between T_H1 - and T_H2 -type responses has been reported in humans (73,74). Human IL-10 inhibits the production of IFN- γ and other cytokines by human peripheral blood mononuclear cells (75) and by suppressing the release of cytokines (IL-1, IL-6, IL-8, and TNF- α) by activated monocytes (76, 77 and 78). Interleukin-10 also downregulates class II MHC expression on monocytes, resulting in a strong reduction in the antigen-presenting capacity of these cells (78). Together, these observations support the concept that IL-10 has an important role as an immune-inhibitory cytokine.

Because epithelial cancers of the ovary usually remain confined to the peritoneal cavity, even in the advanced stages of the disease, it has been suggested that the growth of ovarian cancer intraperitoneally could be related to a local deficiency of antitumor immune effector mechanisms (79). Studies have shown that ascitic fluid from patients with ovarian cancer contained increased concentrations of IL-10 (80). Various other cytokines are also seen in ascitic fluid obtained from women with ovarian cancer including IL-6, IL-10, TNF- α , *granulocyte colony-stimulating factor (G-CSF)*, and *granulocyte-macrophage colony-stimulating factor (GM-CSF)* (81). A similar pattern was seen in serum samples from women with ovarian cancer with elevations of IL-6 and IL-10. Preliminary results have revealed that ovarian cancer cells do not produce IL-10, so high concentrations of IL-10 could certainly result in a peritoneal environment characterized by immune unresponsiveness and promotion of tumor growth.

Interferons

There are three types of interferons: IFN- α , IFN- β , and IFN- γ (54,55,83). They can interfere with viral production in infected cells and have various effects on the immune system as well as direct antitumor effects. For instance, IFN- α , a cytokine produced by T lymphocytes, can affect immune function by increasing the induction of MHC molecule expression, increasing the activity of antigen-presenting cells, and thereby increasing T-lymphocyte activation.

Cytokines in Cancer Therapy

Cytokines are extraordinarily pleiotropic with a bewildering array of biologic activities, including some outside the immune system (54,55,63,69). Because some cytokines have direct or indirect antitumor and immune-enhancing effects, several of these factors have been used in the experimental treatment of cancer.

The precise roles of cytokines in antitumor responses have not been elucidated. Cytokines can exert antitumor effects by many different direct or indirect activities. It is possible that a single cytokine could increase tumor growth directly by acting as a growth factor, while at the same time increasing immune responses directed toward the tumor. The potential of cytokines to increase antitumor immune responses has been tested in experimental adoptive immunotherapy by exposing the patient's peripheral blood cells or tumor-infiltrating lymphocytes to cytokines such as IL-2 *in vitro*, thus generating activated cells with antitumor effects that can be given back to the patient (84, 85 and 86). Some cytokines can also exert direct antitumor effects. Tumor necrosis factor can induce cell death in sensitive tumor cells.

The effects of cytokines on patients with cancer might be modulated by soluble receptors or blocking factors. For instance, blocking factors for TNF and for lymphotoxin were found in ascitic fluid from patients with ovarian cancer (87). Such factors could inhibit the cytolytic effects of TNF or lymphotoxin and should be taken into account in the design of clinical trials of intraperitoneal infusion of these cytokines.

Cytokines have growth-increasing effects on tumor cells in addition to inducing antitumor effects. They can act as autocrine or paracrine growth factors for human tumor cells, including those of nonlymphoid origin. For instance, IL-6 (which is produced by various types of human tumor cells) can act as a growth factor for human myeloma, Kaposi's sarcoma, renal carcinoma, and epithelial ovarian cancer cells (63, 64, 65, 66, 67, 68 and 69).

Clearly, cytokines are of great potential value in the treatment of cancer, but because of their multiple, even conflicting biologic effects, a thorough understanding of

cytokine biology is essential for their successful use ([83](#), [84](#), [85](#), [86](#), [87](#), [88](#), [89](#), [90](#) and [91](#)).

Adoptive Immunotherapy

Recently, the *ex vivo* enhancement of antitumor immune cell responses, including the generation of lymphokine-activated killer (LAK) cells or the activation of tumor-infiltrating lymphocytes (TIL), has provided new immune system—based approaches for antitumor responses. The simultaneous treatment of patients with *ex vivo* activated autologous cells, along with IL-2, is the basis of adoptive immunotherapy, a form of experimental antitumor immunotherapy. In particular, adoptive immunotherapy with IL-2 can produce regression of tumor in various animals and human tumors, such as melanoma and renal cell carcinoma, when used in conjunction with the adoptive transfer of autologous LAK cells ([84,85](#)).

Exposure of peripheral blood mononuclear cells to cytokines *in vitro* (particularly IL-2) leads to the generation of cytotoxic effect cells called *LAK cells* ([85](#)). These cells are cytotoxic for various tumor cells, including those that are resistant to NK-cell— or T-cell—mediated lysis.

Experimental treatment of human subjects with autologous *ex vivo*-generated LAK cells and IL-2 has yielded tumor regression in some cases ([84](#), [85](#), [86](#), [87](#) and [88](#)). This treatment has resulted in some complete responses ([86](#)); the combined response rate was 27% in 146 patients with cancer who were treated in two separate studies ([88](#), [89](#) and [90](#)). The overall response rate to LAK treatment is low, however, and this type of adoptive immunotherapy causes high morbidity ([90](#)). It is also costly and impractical in most medical settings.

Much current experimental work is aimed at developing more efficient and practical applications of adoptive immunotherapy ([91](#), [92](#), [93](#), [94](#), [95](#), [96](#) and [97](#)). One approach involves the *ex vivo* generation of immune effector cells from TILs, which are lymphocytes that are isolated from tumors and activated and expanded *in vitro* by exposure to IL-2. These cells are then administered to the patient with IL-2 ([91,92](#)). This approach is hampered by the need to expand a limited number of TILs *in vitro* to generate enough effector cells for treatment. Recently, attention has been directed toward the development of new methods for the generation of LAK cells or TILs, including methods that use cytokines other than IL-2 to stimulate these cells.

Another promising approach that has been explored in animal studies involves the targeting of activated T lymphocytes with a bifunctional monoclonal antibody that binds to the CD3—T-cell receptor complex (on the target tumor cell) ([93](#)). This approach has the potential advantage of allowing a large number of the activated lymphocytes to target their effects directly on tumor cells, thereby reducing the need to amplify a large number of effector cells from TILs. It also has the potential to avoid some of the side effects associated with LAK treatment, which is a more nonspecific form of adoptive immunotherapy.

Factors that Trigger Neoplasia

Cell biology is characterized by considerable redundancy and functional overlap, so that a defect in one mechanism does not invariably jeopardize the function of the cell. However, with a sufficient number of abnormalities in structure and function, normal cell function is jeopardized and uncontrolled cell growth or cell death results. Either end point may result from accumulated genetic mutations over time. Factors have been identified that enhance the likelihood of genetic mutations, jeopardize normal cell biology, and may increase the risk of cancer.

Increased Age

Increasing age is considered the single most important risk factor for the development of cancer ([98](#)). Cancer is diagnosed in as much as 50% of the population by 75 years of age ([99](#)). It has been suggested that the increasing risk of cancer with age reflects the accumulation of critical genetic mutations over time that ultimately culminate in neoplastic transformation. The basic premise of the multistep somatic mutation theory of carcinogenesis is that genetic or epigenetic alterations of numerous independent genes results in cancer. Factors that have been associated with an increased likelihood of cancer include exposure to exogenous mutagens, altered host immune function, and certain inherited genetic syndromes and disorders.

Environmental Factors

A mutagen is a compound that results in a genetic mutation. A number of environmental pollutants act as mutagens when tested *in vitro*. Environmental mutagens usually produce specific types of mutations that can be differentiated from spontaneous mutations. As an example, activated hydrocarbons tend to produce G-T transversions ([100](#)). A carcinogen is a compound that can produce cancer. It is important to recognize that all carcinogens are not mutagens and that all mutagens are not necessarily carcinogens.

Smoking

Cigarette smoking is perhaps the best known example of mutagen exposure that is associated with the development of lung cancer when the exposure is of sufficient duration and quantity in a susceptible individual. An association between cigarette smoking and cervical cancer has been recognized for decades. More recently, it has been determined that the mutagens in cigarette smoke are selectively concentrated in cervical mucus ([52](#)). It has been hypothesized that exposure of the proliferating epithelial cells of the transformation zone to cigarette smoke mutagens may increase the likelihood of DNA damage and subsequent cellular transformation.

Radiation

Radiation exposure can also be considered an environmental mutagen that increases the risk of cancer. This statement does not apply to exposure secondary to diagnostic radiology studies, which is not associated with an increased risk of cancer. Interestingly, the overall risk of radiation-induced cancer is approximately 10% greater in women than in men ([101](#)). This difference has been attributed to gender-specific cancers, including breast cancer. With respect to gynecology, radiation therapy for cervical cancer is associated with a small increase in the risk of colon cancer and thyroid cancer.

Radiation-induced cancer may be the result of sublethal DNA damage that is not repaired ([101](#)). Normally, radiation damage prompts an S-phase arrest so that DNA damage is repaired. This requires normal *p53* gene function. If DNA repair does not occur for some reason, the damaged DNA is propagated to daughter cells following mitosis. If a sufficient number of critical genes are mutated, cellular transformation may result.

Immune Function

Systemic immune dysfunction has been recognized as a risk factor for cancer for decades. The immunosuppressed renal transplant patient may have a 40-fold increased risk of cervical cancer ([52](#)). Patients infected with human immunodeficiency virus (HIV) who have a depressed CD4 cell count have been reported to be at increased risk of cervical dysplasia and invasive disease ([96](#)). Individuals who have undergone high-dose chemotherapy with stem cell support may be at increased risk of developing a variety of solid neoplasms. These examples illustrate the importance of immune function in host surveillance for transformed cells.

Another interesting example of altered immune function that may be related to the development of cervical dysplasia is the alteration in mucosal immune function that occurs in women who smoke cigarettes ([52](#)). The Langerhans cell population of the cervix is decreased in women who smoke. Langerhans cells are responsible for antigen processing. It is postulated that a reduction in these cells increases the likelihood of successful human papillomavirus infection of the cervix.

Diet

The role of diet in disease prevention and predisposition is widely recognized but poorly understood ([96,99](#)). Dietary fat intake has been correlated with the risk of colon and breast cancer. Fiber is considered protective against colon cancer. With respect to the female reproductive system, epidemiologic studies provide conflicting results. Deficiencies of folic acid and vitamins A and C have been associated with the development of cervical dysplasia and cervical cancer. Considerable

research must be performed to clarify the impact of diet on cancer prevention and development.

Neuroendocrinology

Neuroendocrinology represents facets of two traditional fields of medicine: endocrinology, which is the study of hormones (i.e., substances secreted into the bloodstream that have diverse actions at sites remote from the point of secretion), and neuroscience, which is the study of the action of neurons. The discovery of neurons that transmit impulses and secrete their products into the vascular system to function as hormones themselves, a process known as neurosecretion, demonstrates that the two systems are intimately linked. For instance, the menstrual cycle is regulated through the feedback of hormones on the neural tissue of the central nervous system (CNS).

Anatomy

Hypothalamus

The hypothalamus is a small neural structure situated at the base of the brain above the optic chiasm and below the third ventricle ([Fig. 7.1](#)). It is connected directly to the pituitary gland and is the part of the brain that is the source of many pituitary secretions. Anatomically, the hypothalamus is divided into three zones: periventricular (adjacent to the third ventricle), medial (primarily cell bodies), and lateral (primarily axonal). Each zone is further subdivided into structures known as nuclei, which represent locations of concentrations of similar types of neuronal cell bodies ([Fig. 7.2](#)).

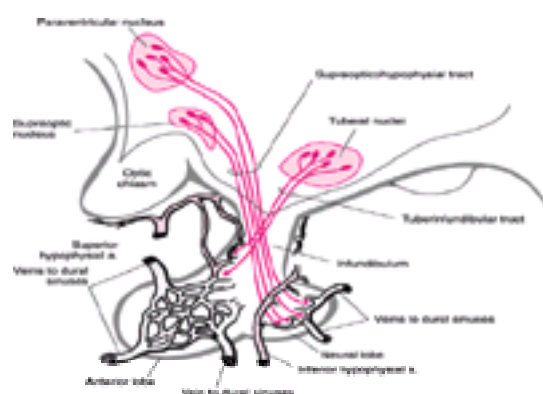

Figure 7-1 The hypothalamus and its neurologic connections to the pituitary.

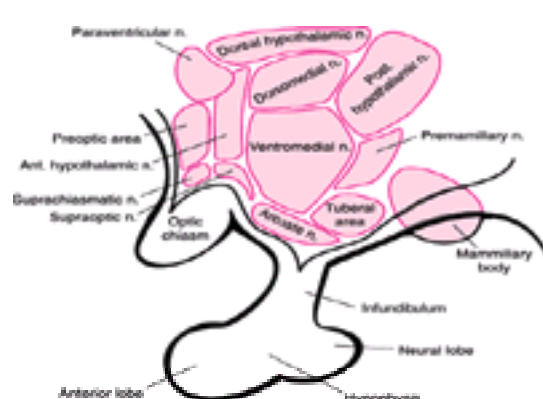

Figure 7-2 The neuronal cell bodies of the hypothalamus.

The hypothalamus is not an isolated structure within the CNS; instead, it has multiple interconnections with other regions in the brain. In addition to the well-known pathways of hypothalamic output to the pituitary, there are numerous less well-characterized pathways of output to diverse regions of the brain, including the limbic system (amygdala and hippocampus), the thalamus, and the pons ([1](#)). Many of these pathways form feedback loops to areas supplying neural input to the hypothalamus.

Several levels of feedback to the hypothalamus exist and are known as the long, short, and ultrashort feedback loops. The long feedback loop is composed of endocrine input from circulating hormones, just as feedback of androgens and estrogens onto steroid receptors is present in the hypothalamus (2,3). Similarly, pituitary hormones may feed back to the hypothalamus and serve important regulatory functions in short-loop feedback. Finally, hypothalamic secretions may directly feed back to the hypothalamus, itself, in an ultrashort feedback loop.

The major secretory products of the hypothalamus are the pituitary-releasing factors (Fig. 7.3):

Figure 7-3 The hypothalamic secretory products function as pituitary releasing factors that control the endocrine function of the ovaries, the thyroid, and the adrenal glands.

1. **Gonadotropin-releasing hormone (GnRH)**, which controls the secretion of **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**
2. **Corticotropin-releasing hormone (CRH)**, which controls the release of **adrenocorticotrophic hormone (ACTH)**
3. **Growth hormone-releasing hormone (GHRH)**, which regulates the release of **growth hormone (GH)**
4. **Thyrotropin-releasing hormone (TRH)**, which regulates the secretion of **thyroid-stimulating hormone (TSH)**.

The hypothalamus is the source of all neurohypophyseal hormone production. The neural posterior pituitary can be viewed as a direct extension of the hypothalamus connected by the finger-like infundibular stalk. The discovery that the capillaries in the median eminence differ from those in other regions of the brain was a major one. Unlike the usual tight junctions that exist between adjacent capillary endothelial lining cells, the capillaries in this region are fenestrated in the same manner as capillaries outside the CNS. As a result, there is no blood-brain barrier in the median eminence.

Pituitary

The pituitary is divided into three regions or lobes: *anterior*, *intermediate*, and *posterior*. The *anterior pituitary (adenohypophysis)* is quite different structurally from the *posterior neural pituitary (neurohypophysis)*, which is a direct physical extension of the hypothalamus. The adenohypophysis is derived embryologically from epidermal ectoderm from an infolding of Rathke's pouch. Therefore, it is not composed of neural tissue, as is the posterior pituitary, and does not have direct neural connections to the hypothalamus. Instead, a unique anatomic relationship exists that combines elements of neural production and endocrine secretion. The adenohypophysis itself has no direct arterial blood supply. Its major source of blood flow is also its source of hypothalamic input—the portal vessels. Blood flow in these portal vessels is primarily from the hypothalamus to the pituitary. Blood is supplied to the posterior pituitary via the superior, middle, and inferior hypophyseal arteries. In contrast, the anterior pituitary has no direct arterial blood supply. Instead, it receives blood via a rich capillary plexus of the portal vessels that originate in the median eminence of the hypothalamus and descend along the pituitary stalk. This pattern is not absolute, however, and retrograde blood flow has been demonstrated (4). This blood flow, combined with the location of the median eminence outside the blood-brain barrier, permits bidirectional feedback control between the two structures.

The specific secretory cells of the anterior pituitary have been classified based on their hematoxylin- and eosin-staining patterns. Acidophilic-staining cells primarily secrete GH and prolactin and, to a variable degree, ACTH (5). The gonadotropins are secreted by basophilic cells, and TSH is secreted by the neutral-staining chromophobes.

Reproductive Hormone

Hypothalamus

Gonadotropin-releasing Hormone

Gonadotropin-releasing hormone (GnRH) (also called *luteinizing hormone-releasing hormone*, or *LHRH*) is the controlling factor for gonadotropin secretion (6). It is a decapeptide produced by neurons with cell bodies primarily in the arcuate nucleus of the hypothalamus (7,8 and 9) (Fig. 7.4). Embryologically, these neurons originate in the olfactory pit and then migrate to their adult locations (10). These GnRH-secreting neurons project axons that terminate on the portal vessels at the median eminence where GnRH is secreted for delivery to the anterior pituitary. Less clear in function are multiple other secondary projections of GnRH neurons to locations within the CNS.

Figure 7-4 Gonadotropin-releasing hormone (GnRH) is a decapeptide.

Pulsatile Secretion

GnRH is unique among releasing hormones in that it simultaneously regulates the secretion of two hormones—FSH and LH. It also is unique among the body's hormones because it must be secreted in a pulsatile fashion to be effective, and the pulsatile release of GnRH influences the release of the two gonadotropins (11,12 and 13). Using animals that had undergone electrical destruction of the arcuate nucleus and have no detectable levels of gonadotropins, a series of experiments were performed with varying dosages and intervals of GnRH infusion (13,14). Continual infusions did not result in gonadotropin secretion, whereas a pulsatile pattern led to physiologic secretion patterns and follicular growth. Continual exposure of the pituitary gonadotroph to GnRH results in a phenomenon called *downregulation*, through which the number of gonadotroph cell surface GnRH receptors is decreased (15). Similarly, intermittent exposure to

GnRH will “upregulate” or “autoprime” the gonadotroph to increase its number of GnRH receptors (16). This allows the cell to have a greater response to subsequent GnRH exposure. Similar to the intrinsic electrical pacemaker cells of the heart, this action most likely represents an intrinsic property of the GnRH-secreting neuron, although it is subject to modulation by various neuronal and hormonal inputs to the hypothalamus.

The continual pulsatile secretion of GnRH is necessary because GnRH has an extremely short half-life (only 2 to 4 minutes) as a result of rapid proteolytic cleavage. The pulsatile secretion of GnRH varies in both frequency and amplitude throughout the menstrual cycle and is tightly regulated (17,18) (Fig. 7.5). The follicular phase is characterized by frequent, small-amplitude pulses of GnRH secretion. In the late follicular phase, there is an increase in both frequency and amplitude of pulses. During the luteal phase, however, there is a progressive lengthening of the interval between pulses as well as a decrease in the amplitude. This variation in pulse amplitude and frequency is directly responsible for the magnitude and relative proportions of gonadotropin secretion from the pituitary, although additional hormonal influences on the pituitary will modulate the GnRH effect.

Figure 7-5 The pulsatile secretion of GnRH in the follicular and luteal phases of the cycle.

Although GnRH is primarily involved in endocrine regulation of gonadotropin secretion from the pituitary, it is now apparent that this molecule has autocrine and paracrine functions throughout the body. The decapeptide is found in both neural and nonneural tissues; receptors are present in many extrapituitary structures, including the ovary and placenta. The role of GnRH in the extrapituitary sites remains to be fully elucidated.

Gonadotropin-releasing Hormone Agonists

Mechanism of Action Used clinically, GnRH agonists are modifications of the native molecule to either increase receptor affinity or decrease degradation (19). Their use, therefore, leads to a persistent activation of GnRH receptors, as if continuous GnRH exposure existed. As would be predicted by the constant GnRH infusion experiments, this leads to suppression of gonadotropin secretion. An initial release of gonadotropins followed by a profound suppression of secretion is observed. The initial release of gonadotropins represents the secretion of pituitary stores in response to receptor binding and activation. With continued activation of the gonadotroph GnRH receptor, however, there is a downregulation effect and a decrease in the concentration of GnRH receptors. As a result, gonadotropin secretion decreases and sex steroid production falls to castrate levels (20).

Additional modification of the GnRH molecule results in an analogue that has no intrinsic activity but competes with GnRH for the same receptor site (21). These GnRH antagonists produce a competitive blockade of GnRH receptors, preventing stimulation by endogenous GnRH and causing an immediate fall in gonadotropin and sex steroid secretion (22). Compared with that of GnRH agonists, this action greatly reduces the time for therapy to become effective. Moreover, antagonists may not function solely as competitive inhibitors: recent evidence suggests they may also produce downregulation of GnRH receptors (23), further contributing to the loss of gonadotropin activity.

Structure—Agonists and Antagonists As a peptide hormone, GnRH is degraded by enzymatic cleavage of bonds between its amino acids. Pharmacologic alterations of the structure of GnRH have led to the creation of agonists and antagonists (Fig. 7.4). The primary sites of enzymatic cleavage are between amino acids 5 and 6, 6 and 7, and 9 and 10. Substitution of the position-6 amino acid glycine with large bulky amino acid analogues makes degradation more difficult and creates a form of GnRH with a relatively long half-life. Substitution at the carboxyl terminus produces a form of GnRH with increased receptor affinity. The resulting high affinity and slow degradation produces a molecule that mimics continuous exposure to native GnRH (19). Thus, as with constant GnRH exposure, downregulation occurs. GnRH agonists are now widely used to treat disorders that are dependent on ovarian hormones (20). They are used to control ovulation induction cycles and to treat precocious puberty, ovarian hyperandrogenism, leiomyomas, endometriosis, and hormonally dependent cancers. The development of GnRH antagonists proved more difficult, in that a molecule was needed that maintained the binding and degradation resistance of agonists but failed to activate the receptor. Early attempts involved modification of amino acids 1 and 2, as well as those previously utilized for agonists. Commercial antagonists currently have structural modifications at amino acids 1, 2, 3, 6, and 10. The treatment spectrum is expected to be similar to that of GnRH agonists.

Endogenous Opioids and Effects on GnRH The endogenous opioids are three related families of naturally occurring substances produced in the CNS that represent the natural ligands for the opioid receptors (24,25 and 26). There are three major classes of endogenous opioids, each derived from precursor molecules:

1. *Endorphins* are named for their endogenous morphine-like activity. These substances are produced in the hypothalamus from the precursor proopiomelanocortin (POMC) and have diverse activities, including regulation of temperature, appetite, mood, and behavior (27).
2. *Enkephalins* function primarily in regulation of the autonomic nervous system. Proenkephalin A is the precursor for the two enkephalins of primary importance: met-enkephalin and leu-enkephalin.
3. *Dynorphins* are endogenous opioids produced from the precursor proenkephalin B that serve a function similar to that of the endorphins.

The endogenous opioids play a significant role in the regulation of hypothalamic-pituitary function. Endorphins appear to inhibit GnRH release within the hypothalamus, resulting in inhibition of gonadotropin secretion (28). Ovarian sex steroids can increase the secretion of central endorphins, further depressing gonadotropin levels (29).

Endorphin levels vary significantly throughout the menstrual cycle, with peak levels in the luteal phase and a nadir during menses (30). This inherent variability, although helping to regulate gonadotropin levels, may contribute to cycle-specific symptoms experienced by ovulatory women. For example, the dysphoria experienced by some women in the premenstrual phase of the cycle may be related to a withdrawal of endogenous opiates (31).

Pituitary Hormone Secretion

Anterior Pituitary

The anterior pituitary is responsible for the secretion of the major hormone-releasing factors: FSH, LH, TSH, and ACTH, as well as GH and prolactin. Each hormone is released by a specific pituitary cell type.

Gonadotropins

The gonadotropins FSH and LH are produced by the anterior pituitary gonadotroph cells and are responsible for ovarian follicular stimulation. Structurally, there is great similarity between FSH and LH (Fig. 7.6). They are both glycoproteins that share identical a subunits and differ only in the structure of their b subunits, which confer receptor specificity (32,33). The synthesis of the b subunits is the rate-regulating step in gonadotropin biosynthesis (34). TSH and placental chorionic gonadotropin also share identical a subunits with the gonadotropins. There are several forms of each gonadotropin, which differ in carbohydrate content as a result of posttranslational modification. The degree of modification varies with steroid levels and is an important regulator of gonadotropin bioactivity.

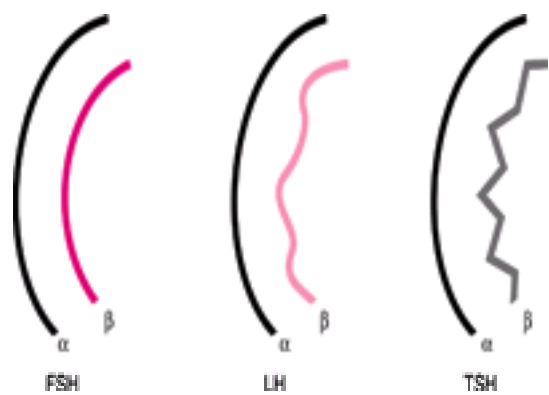

Figure 7-6 The structural similarity between FSH, LH, and TSH. The α subunits are identical and the β subunits differ.

Prolactin

Prolactin, a 198–amino acid polypeptide secreted by the anterior pituitary lactotroph, is the primary trophic factor responsible for the synthesis of milk by the breast (35). Several forms of this hormone, which are named according to their size and bioactivity, are normally secreted (36). Prolactin production is under tonic inhibitory control by the hypothalamic secretion of dopamine (37). Therefore, disease states characterized by decreased dopamine secretion or any condition that interrupts transport of dopamine down the infundibular stalk to the pituitary gland will result in increased synthesis of prolactin. In this respect, prolactin is unique in comparison to all other pituitary hormones: it is predominantly under tonic inhibition, and release of control produces an increase in secretion. **Clinically, increased prolactin levels are associated with amenorrhea and galactorrhea, and hyperprolactinemia should be suspected in any individual with symptoms of either of these conditions.**

Although prolactin appears to be primarily under inhibitory control, many stimuli can elicit its release, including breast manipulation, drugs, stress, exercise, and certain foods. The existence of a releasing factor or factors for prolactin has been long hypothesized. Whereas such a factor has been identified in a variety of animal species, no physiologically significant releasing factor has been definitively identified in humans, although TRH appears to play this role to a large extent (38). Other hormones that may stimulate prolactin release include vasopressin, γ -aminobutyric acid (GABA), dopamine, b-endorphin, vasoactive intestinal peptide (VIP), epidermal growth factor, and angiotensin II (39,40). The relative contributions of these substances under normal conditions remain to be determined.

Thyroid-stimulating Hormone, Adrenocorticotropic Hormone, and Growth Hormone

The other hormones produced by the anterior pituitary are TSH, ACTH, and GH. Thyroid-stimulating hormone is secreted by the pituitary thyrotrophs in response to TRH. As with GnRH, TRH is synthesized primarily in the arcuate nucleus of the hypothalamus and is then secreted into the portal circulation for transport to the pituitary. In addition to stimulating TSH release, TRH is also a major stimulus for the release of prolactin. Thyroid-stimulating hormone stimulates release of T_3 and T_4 from the thyroid gland, which in turn has a negative feedback effect on pituitary TSH secretion. Abnormalities of thyroid secretion (both hyper- and hypothyroidism) are frequently associated with ovulatory dysfunction as a result of diverse actions on the hypothalamic-pituitary-ovarian axis (41).

ACTH is secreted by the anterior pituitary in response to another hypothalamic-releasing factor, CRH, and stimulates the release of adrenal glucocorticoids. Unlike the other anterior pituitary products, ACTH secretion has a diurnal variation with an early morning peak and a late evening nadir. As with the other pituitary hormones, ACTH secretion is negatively regulated by feedback from its primary end product, which in this case is cortisol.

The anterior pituitary hormone that is secreted in the greatest absolute amount is GH. It is secreted in response to the hypothalamic releasing factor, GHRH, as well as by thyroid hormone and glucocorticoids. This hormone is also secreted in a pulsatile fashion but with peak release occurring during sleep. In addition to its vital role in the stimulation of linear growth, GH plays a diverse role in physiologic hemostasis. The hormone has been shown to play a role in bone mitogenesis, CNS function (improved memory, cognition, and mood), body composition, breast development, and cardiovascular function. It also affects insulin regulation and acts anabolically. Growth hormone appears to have a role in the regulation of ovarian function, although the degree to which it serves this role in normal physiology is unclear (42).

Posterior Pituitary

Structure and Function

The posterior pituitary (neurohypophysis) is composed exclusively of neural tissue and is a direct extension of the hypothalamus. It lies directly adjacent to the adenohypophysis but is embryologically distinct, derived from an invagination of neuroectodermal tissue in the third ventricle. Axons in the posterior pituitary originate from neurons with cell bodies in two distinct regions of the hypothalamus, the supraoptic and paraventricular nuclei, named for their anatomic relationship to the optic chiasm and the third ventricle. Together these two nuclei comprise the hypothalamic magnocellular system. These neurons can secrete their synthetic products directly from axonal boutons into the general circulation to act as hormones. This is the mechanism of secretion of the hormones of the posterior pituitary, oxytocin and arginine vasopressin (AVP). Although this is the primary mode of release of these hormones, numerous other secondary pathways have been identified, including secretion into the portal circulation, intrahypothalamic secretion, and secretion into other regions of the CNS (43).

In addition to the established functions of oxytocin and vasopressin, several other diverse roles have been suggested in animal models. These include modulation of sexual activity and appetite, learning and memory consolidation, temperature regulation, and regulation of maternal behaviors (44). It remains to be seen which, if any, of these functions also exist in humans.

Oxytocin Oxytocin is a nine–amino acid peptide primarily produced by the paraventricular nucleus of the hypothalamus (Fig. 7.7). The primary function of this hormone in humans is the stimulation of two specific types of muscular contractions (Fig. 7.8). The first type, uterine muscular contraction, occurs during parturition. The second type of muscular contraction regulated by oxytocin is breast lactiferous duct myoepithelial contractions that occur during the milk letdown reflex. Oxytocin release may be stimulated by suckling, triggered by a signal from nipple stimulation transmitted via thoracic nerves to the spinal cord and then to the hypothalamus, where oxytocin is released in an episodic fashion (45). Oxytocin release also may be triggered by olfactory, auditory, and visual clues, and it may play a role in the conditioned reflex in nursing animals. Stimulation of the cervix and vagina can cause significant release of oxytocin, which may trigger reflex ovulation (the Ferguson reflex) in some species, although it is unclear to what extent this effect exists in humans.

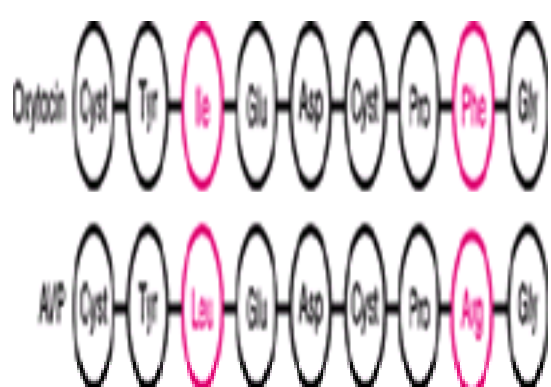

Figure 7-7 Oxytocin and arginine-vasopressin (AVP) are nine–amino acid peptides produced by the hypothalamus. They differ in only two amino acids.

Arginine-vasopressin AVP (also known as antidiuretic hormone, or ADH) is the second major secretory product of the posterior pituitary (Fig. 7.7). It is synthesized primarily by neurons with cell bodies in the supraoptic nuclei (Fig. 7.8). Its major function is the regulation of circulating blood volume, pressure, and osmolality (45). Specific receptors throughout the body can trigger the release of AVP. Osmoreceptors located in the hypothalamus sense changes in blood osmolality from a mean of 285 mOsm/kg. Baroreceptors sense changes in blood pressure caused by alterations in blood volume and are peripherally located in the walls of the left atrium, carotid sinus, and aortic arch (46). These receptors can respond to changes in blood volume of more than 10%. In response to decreases in blood pressure or volume, AVP is released and causes arteriolar vasoconstriction and renal free-water conservation. This in turn leads to a decrease in blood osmolality and an increase in blood pressure. Activation of the renal renin–angiotensin system can also activate AVP release.

Figure 7-8 Oxytocin stimulates muscular contractions of the uterus during parturition and the breast lactiferous duct during the milk letdown reflex. Arginine-vasopressin (AVP) regulates circulating blood volume, pressure, and osmolality.

Menstrual Cycle Physiology

In the normal menstrual cycle, there is an orderly cyclic hormone production and parallel proliferation of the uterine lining in preparation for implantation of the embryo. Disorders of the menstrual cycle and, likewise, disorders of menstrual physiology may lead to various pathologic states, including infertility, recurrent miscarriage, and malignancy.

Disorder of menstruation is one of the most frequent reasons women seek medical care (Table 7.1). Although helpful in formulating a diagnostic or therapeutic plan, specific abnormalities of menstrual flow are not directly related to specific defects.

Oligomenorrhea	Infrequent, irregularly timed episodes of bleeding usually occurring at intervals of more than 35 days
Polymenorrhea	Frequent but regularly timed episodes of bleeding usually occurring at intervals of 21 days or less
Menorrhagia	Regularly timed episodes of bleeding that are excessive in amount (>80 ml) and duration of flow (>5 days)
Metrorrhagia	Irregularly timed bleeding
Menometrorrhagia	Excessive, prolonged bleeding that occurs at irregularly timed, frequent intervals
Hypomenorrhea	Regularly timed bleeding that is decreased in amount
Intermenstrual bleeding	(usually not of an excessive amount) that occurs between bleeding otherwise normal menstrual cycles

Table 7.1. Definitions of Menstrual Cycle Irregularities

Normal Menstrual Cycle

The normal human menstrual cycle can be divided into two segments: the ovarian cycle and the uterine cycle, based on the organ under examination. The ovarian cycle may be further divided into follicular and luteal phases, whereas the uterine cycle is divided into corresponding proliferative and secretory phases (Fig. 7.9). The phases of the ovarian cycle are characterized as follows:

Figure 7-9 The menstrual cycle. The top panel shows the cyclic changes of FSH, LH, estradiol (E2), and progesterone (P) relative to the time of ovulation. The bottom panel correlates the ovarian cycle in the follicular and luteal phases and the endometrial cycle in the proliferative and secretory phases.

1. **Follicular phase**—hormonal feedback promotes the orderly development of a single dominant follicle, which should be mature at midcycle and prepared for ovulation. The average length of the human follicular phase ranges from 10 to 14 days, and variability in this length is responsible for most variations in total cycle length.
2. **Luteal phase**—the time from ovulation to the onset of menses, with an average length of 14 days.

A normal menstrual cycle lasts from 21 to 35 days, with 2 to 6 days of flow and an average blood loss of 20 to 60 ml. However, studies of large numbers of women with normal menstrual cycles have shown that only approximately two-thirds of adult women have cycles lasting 21 to 35 days (47). The extremes of reproductive life (after menarche and perimenopause) are characterized by a higher percentage of anovulatory or irregularly timed cycles (48,49).

Hormonal Variations

The relative pattern of ovarian, uterine, and hormonal variation along the normal menstrual cycle is shown in [Fig. 7.9](#).

1. At the beginning of each monthly menstrual cycle, levels of gonadal steroids are low and have been decreasing since the end of the luteal phase of the previous cycle.
2. With the demise of the corpus luteum, FSH levels begin to rise and a cohort of growing follicles is recruited. These follicles each secrete increasing levels of estrogen as they grow in the follicular phase. This, in turn, is the stimulus for uterine endometrial proliferation.
3. Rising estrogen levels provide negative feedback on pituitary FSH secretion, which begins to wane by the midpoint of the follicular phase. Conversely, LH initially decreases in response to rising estradiol levels, but late in the follicular phase the LH level is increased dramatically (biphasic response).
4. At the end of the follicular phase (just prior to ovulation), FSH-induced LH receptors are present on granulosa cells and, with LH stimulation, modulate the secretion of progesterone.
5. After a sufficient degree of estrogenic stimulation, the pituitary LH surge is triggered, which is the proximate cause of ovulation that occurs 24 to 36 hours later. Ovulation heralds the transition to the luteal-secretory phase.
6. The estrogen level decreases through the early luteal phase from just before ovulation until the midluteal phase, when it begins to rise again as a result of corpus luteum secretion.
7. Progesterone levels rise precipitously after ovulation and can be used as a presumptive sign that ovulation has occurred.
8. Both estrogen and progesterone levels remain elevated through the lifespan of the corpus luteum and then wane with its demise, thereby setting the stage for the next cycle.

Uterus

Cyclic Changes of the Endometrium

The cyclic histologic changes in the adult human endometrium were described by Noyes, Hertig, and Rock in 1950 ([50](#)) ([Fig. 7.10](#)). These changes proceed in an orderly fashion in response to cyclic hormonal production by the ovaries ([Fig. 7.9](#)). Histologic cycling of the endometrium can best be viewed in two parts: the endometrial glands and the surrounding stroma. The superficial two-thirds of the endometrium is the zone that proliferates and is ultimately shed with each cycle if pregnancy does not occur. This cycling portion of the endometrium is known as the *decidua functionalis* and is composed of a deeply situated intermediate zone (stratum spongiosum) and a superficial compact zone (stratum compactum). The *decidua basalis* is the deepest region of the endometrium. It does not undergo significant monthly proliferation but, instead, is the source of endometrial regeneration after each menses ([51](#)).

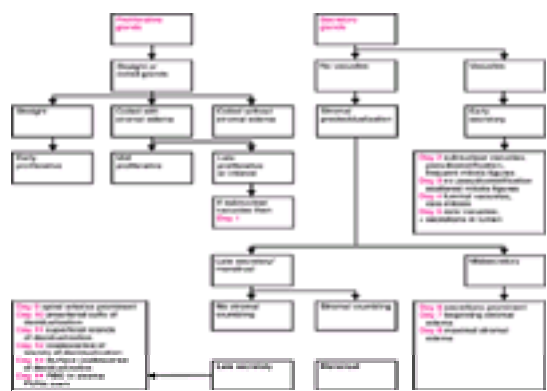

Figure 7-10 The histologic changes of the menstrual cycle. Endometrial biopsy can be used to determine the state of the endometrium corresponding to the day of the cycle.

Proliferative Phase

By convention, the first day of vaginal bleeding is called day 1 of the menstrual cycle. After menses, the decidua basalis is composed of primordial glands and dense scant stroma in its location adjacent to the myometrium. The proliferative phase is characterized by progressive mitotic growth of the decidua functionalis in preparation for implantation of the embryo in response to rising circulating levels of estrogen ([52](#)). At the beginning of the proliferative phase, the endometrium is relatively thin (1 to 2 mm). The predominant change seen during this time is evolution of the initially straight, narrow, and short endometrial glands into longer, tortuous structures ([53](#)). Histologically, these proliferating glands have multiple mitotic cells, and their organization changes from a low columnar pattern in the early proliferative period to a pseudostratified pattern before ovulation. The stroma is a dense compact layer throughout this time. Vascular structures are infrequently seen.

Secretory Phase

In the typical 28-day cycle, ovulation occurs on cycle day 14. Within 48 to 72 hours following ovulation, the onset of progesterone secretion produces a shift in histologic appearance of the endometrium to the secretory phase, so named for the clear presence of eosinophilic protein-rich secretory products in the glandular lumen. In contrast to the proliferative phase, the secretory phase of the menstrual cycle is characterized by the cellular effects of progesterone in addition to estrogen. In general, progesterone's effects are antagonistic to those of estrogen and there is a progressive decrease in the endometrial cell's estrogen receptor concentration. As a result, during the latter half of the cycle, there is an antagonism of estrogen-induced DNA synthesis and cellular mitosis ([52](#)).

During the secretory phase, the endometrial glands form characteristic periodic acid–Schiff positive–staining, glycogen-containing vacuoles. These vacuoles initially appear subnuclearly (by cycle day 16) and then progress toward the glandular lumen ([50](#)) ([Fig. 7.10](#)). The nuclei can be seen in the midportion of the cells by cycle day 17 and ultimately undergo apocrine secretion into the glandular lumen by cycle day 19 to 20. At postovulatory day 6 to 7, secretory activity of the glands is maximal and the endometrium is optimally prepared for implantation of the blastocyst.

The stroma of the secretory phase remains unchanged histologically until the seventh post-ovulatory day, when there is a progressive increase in edema. Coincident with maximal stromal edema in the late secretory phase, the spiral arteries become clearly visible and then progressively lengthen and coil during the remainder of the secretory phase. By day 24, an eosinophilic staining pattern, known as *cuffing*, is visible in the perivascular stroma. Eosinophilia then progresses to form islands in the stroma followed by areas of confluence. This staining pattern of the edematous stroma is termed *pseudodecidua* because of its similarity to the pattern that occurs in pregnancy. Approximately 2 days prior to menses, there is a dramatic increase in the number of polymorphonuclear lymphocytes that migrate from the vascular system. This leukocytic infiltration heralds the collapse of the endometrial stroma and the onset of the menstrual flow.

Menses

In the absence of implantation, glandular secretion ceases and an irregular breakdown of the decidua functionalis occurs. The result is a shedding of this layer of the endometrium, a process termed menses. It is the destruction of the corpus luteum and its production of estrogen and progesterone that is the proximate cause of the shedding. With withdrawal of sex steroids, there is a profound spiral artery vascular spasm that ultimately leads to endometrial ischemia. Simultaneously, there is a breakdown of lysosomes and a release of proteolytic enzymes, which further promote local tissue destruction. This layer of endometrium is then shed, leaving the decidua basalis as the source of subsequent endometrial growth. Prostaglandins are produced throughout the menstrual cycle and are at their highest concentration during menses ([53](#)). Prostaglandin_{2a} (PG_{2a}) is a potent vasoconstrictor, causing further arteriolar vasospasm and endometrial ischemia. Prostaglandin_{2a} also produces myometrial contractions that decrease local uterine wall blood flow and may serve to physically expel sloughing endometrial tissue from the uterus.

Dating the Endometrium

The precise nature of the histologic changes that occur in secretory endometrium relative to the LH surge allows the assessment of the “normalcy” of endometrial

development (Fig. 7.9). By knowing when a patient is chronologically postovulatory, it is possible to obtain a sample of the endometrium by endometrial biopsy and determine whether the state of the endometrium corresponds to the phase of the cycle (Fig. 7.10). Any large discrepancy (more than 2-day lag time) is termed a luteal phase defect and has been linked to both failure of implantation and early pregnancy loss (54). To perform this diagnostic test, it is first critical to determine when ovulation occurs. Once the timing of ovulation has been established, investigators have traditionally chosen 10 to 12 days postovulation as the time for biopsy. However, endometrial sampling at the time of implantation (6 to 8 days postovulation) may be more accurate (55).

Simple hematoxylin and eosin (H&E) stain evaluation is a crude, insensitive, and frequently inaccurate method of assessing endometrial receptivity. Normal implantation requires a complex set of events, many being expressed as changes within the endometrium (56). These changes include expression of specific glycoproteins and adhesion molecules, production of cytokines, and variation in tissue enzyme levels (57). As the importance of each of these factors in implantation becomes clear, it will likely become possible to subject one or more endometrial biopsy samples to a complex variety of stains, thereby assessing the development of individual markers. Such complex screening, already used in other tissue systems, will allow a more precise diagnosis of endometrial dysfunction than the current general diagnosis of luteal phase defect.

Ovarian Follicular Development

The number of oocytes peaks in the fetus at 6 to 7 million by 20 weeks of gestation (58) (Fig. 7.11). Simultaneously (and peaking at the fifth month of gestation), atresia of the oogonia occurs, rapidly followed by follicular atresia. At birth, only 1 to 2 million oocytes remain in the ovaries, and at puberty, only 300,000 of the original 6 to 7 million oocytes are available for ovulation (58,59). Of these, only 400 to 500 will ultimately be released during ovulation. By the time of menopause, the ovary will be composed primarily of dense stromal tissue with only rare interspersed oocytes remaining.

Figure 7-11 The number of oocytes in the ovary before and after birth and through menopause.

In humans, oogonial formation or mitosis does not occur postnatally. Because oocytes enter the diplotene resting stage of meiosis in the fetus and persist in this stage until ovulation, much of the deoxyribonucleic acid (DNA), proteins, and messenger ribonucleic acid (mRNA) necessary for development of the preimplantation embryo will have been synthesized by this stage. At the diplotene stage, a single layer of 8 to 10 granulosa cells surround the oogonia to form the primordial follicle. The oogonia that fail to become properly surrounded by granulosa cells undergo atresia (60).

Meiotic Arrest of Oocyte and Resumption

Meiosis (the germ cell process of reduction division) is commonly divided into four phases: prophase, metaphase, anaphase, and telophase. The prophase of meiosis I is further divided into five stages: leptotene, zygotene, pachytene, diplotene, and diakinesis.

Oogonia differ from spermatogonia in that only one final daughter cell (oocyte) forms from each precursor cell, with the excess genetic material discarded in three polar bodies. When the developing oogonia begin to enter meiotic prophase I, they are known as primary oocytes (61). This process begins at roughly 8 weeks of gestation. Only those oogonia that enter meiosis will survive the wave of atresia that sweeps the fetal ovary before birth. The oocytes arrested in prophase (in the late diplotene or "dictyate" stage) will remain so until the time of ovulation, when the process of meiosis resumes. The mechanism for this mitotic stasis is believed to be an oocyte maturation inhibitor (OMI) produced by granulosa cells (62). This inhibitor gains access to the oocyte via gap junctions connecting the oocyte and its surrounding cumulus of granulosa. With the midcycle LH surge, the gap junctions are disrupted, granulosa cells are no longer connected to the oocyte, and meiosis I is allowed to resume.

Follicular Development

Follicular development is a dynamic process that continues from menarche until menopause. The process is designed to allow the monthly recruitment of a cohort of follicles and, ultimately, to release a single mature dominant follicle during ovulation each month.

Primordial Follicles

The initial recruitment and growth of the primordial follicles is gonadotropin independent and affects a cohort over several months (63). However, the stimuli responsible for the recruitment of a specific cohort of follicles in each cycle are unknown. At the primordial follicle stage, shortly after initial recruitment, FSH assumes control of follicular differentiation and growth and allows a cohort of follicles to continue differentiation. This process signals the shift from gonadotropin-independent to gonadotropin-dependent growth. The first changes seen are growth of the oocyte and expansion of the single layer of follicular granulosa cells into a multilayer of cuboidal cells. The decline in luteal phase progesterone and inhibin production by the now-fading corpus luteum from the previous cycle allows the increase in FSH that stimulates this follicular growth (64).

Preantral Follicle

During the several days following the breakdown of the corpus luteum, growth of the cohort of follicles continues, driven by the stimulus of FSH. The enlarging oocyte then secretes a glycoprotein-rich substance, the zona pellucida, which separates it from the surrounding granulosa cells (except for the aforementioned gap junction). With transformation from a primordial to a preantral follicle, there is continued mitotic proliferation of the encompassing granulosa cells. Simultaneously, theca cells in the stroma bordering the granulosa cells proliferate. Both cell types function synergistically to produce estrogens that are secreted into the systemic circulation. At this stage of development, each of the seemingly identical cohort members must either be selected for dominance or undergo atresia. It is likely that the follicle destined to ovulate has been selected prior to this point, although the mechanism for selection remains obscure.

Two-cell Two-gonadotropin Theory

The fundamental tenet of follicular development is the two-cell two-gonadotropin theory (65,66 and 67) (Fig. 7.12). This theory states that there is a subdivision and compartmentalization of steroid hormone synthesis activity in the developing follicle. In general, most aromatase activity (for estrogen production) is in the granulosa cells (68). Aromatase activity is enhanced by FSH stimulation of specific receptors on these cells (69,70). However, granulosa cells lack several enzymes that occur earlier in the steroidogenic pathway and require androgens as a substrate for aromatization. Androgens, in turn, are synthesized primarily in response to stimulation by LH, and the theca cells possess most of the LH receptors at this stage (69,70). Therefore, a synergistic relationship must exist: LH stimulates the theca cells to produce androgens (primarily androstenedione) which, in turn, are transferred to the granulosa cells for FSH-stimulated aromatization into estrogens. These locally produced estrogens create a microenvironment within the follicle that is favorable for continued growth and nutrition (71). Both FSH and local estrogens serve to further stimulate estrogen production, FSH receptor synthesis and expression, and granulosa cell proliferation and differentiation.

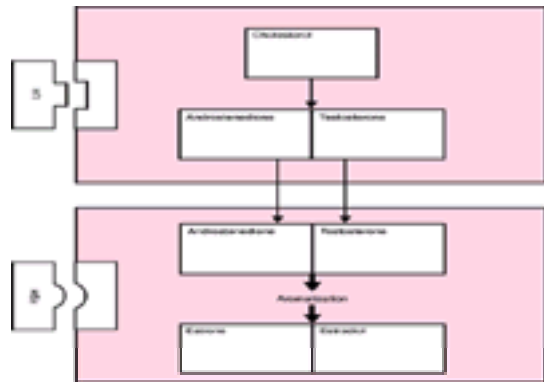

Figure 7-12 The two-cell two-gonadotropin theory of follicular development in which there is compartmentalization of steroid hormone synthesis in the developing follicle.

Androgens have two different regulatory roles in follicular development. At low concentrations (i.e., in the early preantral follicle), they serve to stimulate aromatase activity via specific receptors in granulosa cells. At higher levels of androgens, there is intense 5 α -reductase activity that converts the androgens to forms that cannot be aromatized (65,72). This androgenic microenvironment inhibits the expression of FSH receptors on the granulosa cells, thereby inhibiting aromatase activity and setting the follicle on the path to atresia (73). Meanwhile, as the peripheral estrogen level rises, it negatively feeds back on the pituitary and hypothalamus to decrease circulating FSH levels (74). Increased ovarian production of inhibin further decreases FSH production at this point.

The falling FSH level that occurs with the progression of the follicular phase represents a threat to continued follicular growth. The resulting adverse environment can be withstood only by follicles with a selective advantage for binding the diminishing FSH molecules; that is, those with the greatest number of FSH receptors. The dominant follicle, therefore, can be perceived as the one with a richly estrogenic microenvironment and the most FSH receptors (75). As it grows and develops, the follicle continues to produce estrogen, which results in further lowering of the circulating FSH and creating a more adverse environment for competing follicles. This process continues until all members of the initial cohort have suffered atresia, with the exception of the single dominant follicle. The stage is then set for ovulation.

Preovulatory Follicle

Preovulatory follicles are characterized by a fluid-filled antrum that is composed of plasma with granulosa-cell secretions. The granulosa cells at this point have further differentiated into a heterogeneous population. The oocyte remains connected to the follicle by a stalk of specialized granulosa known as the *cumulus oophorus*.

Rising estrogen levels have a negative feedback effect on FSH secretion. Conversely, LH undergoes biphasic regulation by circulating estrogens. At lower concentrations, estrogens inhibit LH secretion. At higher levels, however, estrogen enhances LH release. This stimulation requires a sustained high level of estrogen (200 pg/ml) for more than 48 hours (76). Once the rising estrogen level produces positive feedback, a substantial surge in LH secretion occurs. Concomitant to these events, the local estrogen-FSH interactions in the dominant follicle induce LH receptors on the granulosa cells. Thus, exposure to high levels of LH results in a specific response by the dominant follicle—the result is luteinization of the granulosa cells, production of progesterone, and initiation of ovulation. In general, ovulation will occur in the single mature, or Graafian, follicle 10 to 12 hours after the LH peak or 34 to 36 hours after the initial rise in midcycle LH (77,78 and 79).

The sex steroids are not the only gonadotropin regulators of follicular development. Two related granulosa cell-derived peptides have been identified that play opposing roles in pituitary feedback (80). The first of these, inhibin, is secreted in two forms: inhibin A and inhibin B. Inhibin B is secreted primarily in the follicular phase, and is stimulated by FSH (81), whereas inhibin A is mainly active in the luteal phase. Both forms act to inhibit FSH synthesis and release (82,83). The second peptide, activin, stimulates FSH release from the pituitary gland and potentiates its action in the ovary (84,85). It is likely that there are numerous other intraovarian regulators similar to inhibin and activin, each of which may play a key role in promoting the normal ovulatory process (86). Some of these include insulin-like growth factor (ILGF)-1, epidermal growth factor (EGF)/transforming growth factor (TGF)- α , TGF- β 1, b-fibroblast growth factor (FGF), IL-1, TNF- α , OMI, and renin-angiotensin.

Ovulation

The midcycle LH surge is responsible for a dramatic increase in local concentrations of prostaglandins and proteolytic enzymes in the follicular wall (87). These substances progressively weaken the follicular wall and ultimately allow a perforation to form. Ovulation most likely represents a slow extrusion of the oocyte through this opening in the follicle rather than a rupture of the follicular structure (88). In fact, direct measurements of intrafollicular pressures have been recorded and have failed to demonstrate an explosive event.

Luteal Phase

Structure of Corpus Luteum After ovulation, the remaining follicular shell is transformed into the primary regulator of the luteal phase—the corpus luteum. Membranous granulosa cells remaining in the follicle begin to take up lipids and the characteristic yellow lutein pigment for which the structure is named. These cells are active secretory structures that produce progesterone, which supports the endometrium of the luteal phase. In addition, estrogen and inhibin A are produced in significant quantities. Unlike the process that occurs in the developing follicle, the basement membrane of the corpus luteum degenerates to allow proliferating blood vessels to invade the granulosa-luteal cells in response to secretion of angiogenic factors such as vascular endothelial growth factor (89). This angiogenic response allows large amounts of luteal hormones to enter the systemic circulation.

Hormonal Function and Regulation

The hormonal changes of the luteal phase are characterized by a series of negative feedback interactions designed to lead to regression of the corpus luteum if pregnancy does not occur. Corpus luteum steroids (estradiol and progesterone) provide negative central feedback and cause a decrease in FSH and LH secretion. Continued secretion of both steroids will decrease the stimuli for subsequent follicular recruitment. Similarly, luteal secretion of inhibin also potentiates FSH withdrawal. In the ovary, local production of progesterone inhibits the further development and recruitment of additional follicles.

Continued corpus luteum function depends on continued LH production. In the absence of this stimulation, the corpus luteum will invariably regress after 12 to 16 days and form the scarlike corpora albicans (90). The exact mechanism of luteolysis, however, is unclear and most likely also involves local paracrine factors. In the absence of pregnancy, the corpus luteum regresses, and estrogen and progesterone levels wane. This, in turn, removes central inhibition on gonadotropin secretion and allows FSH and LH levels to again rise and recruit another cohort of follicles.

If pregnancy does occur, placental human chorionic gonadotropin (hCG) will mimic LH action and continually stimulate the corpus luteum to secrete progesterone. Thus, successful implantation results in hormonal support to allow continued maintenance of the corpus luteum and the endometrium. Evidence from patients undergoing oocyte donation cycles has demonstrated that continued luteal function is essential to continuation of the pregnancy until approximately 5 weeks of gestation, when sufficient progesterone is produced by the developing placenta (91). This switch in the source of regulatory progesterone production is referred to as the luteal-placental shift.

Summary of Menstrual Cycle Regulation

Following is a summary of the regulation of the menstrual cycle:

1. GnRH is produced in the arcuate nucleus of the hypothalamus and secreted in a pulsatile fashion into the portal circulation, where it travels to the anterior pituitary.

2. Ovarian follicular development moves from a period of gonadotropin independence to a phase of FSH dependence.
3. As the corpus luteum of the previous cycle fades, luteal production of progesterone and inhibin A decreases, allowing FSH levels to rise.
4. In response to FSH stimulus, the follicles grow and differentiate and secrete increasing amounts of estrogen.
5. Estrogens stimulate growth and differentiation of the functional layer of the endometrium, which prepares for implantation. Estrogens work with FSH in stimulating follicular development.
6. The two-cell two-gonadotropin theory dictates that with LH stimulation the ovarian theca cells will produce androgens that are converted by the granulosa cells into estrogens under the stimulus of FSH.
7. Rising estrogen levels negatively feed back on the pituitary gland and hypothalamus and decrease the secretion of FSH.
8. The one follicle destined to ovulate each cycle is called the dominant follicle. It has relatively more FSH receptors and produces a larger concentration of estrogens than the follicles that will undergo atresia. It is able to continue to grow despite falling FSH levels.
9. Sustained high estrogen levels cause a surge in pituitary LH secretion that triggers ovulation, progesterone production, and the shift to the secretory, or luteal, phase.
10. Luteal function is dependent on the presence of LH. Without continued LH secretion, the corpus luteum will regress after 12 to 16 days.
11. If pregnancy occurs, the embryo secretes hCG, which mimics the action of LH by sustaining the corpus luteum. The corpus luteum continues to secrete progesterone and supports the secretory endometrium, allowing the pregnancy to continue to develop.

[Approaches to Preventive Care](#)
[Guidelines for Primary and Preventive Care](#)
[Guide to Clinical Preventive Services](#)
[Guidelines for Adolescent Preventive Services](#)
[Counseling for Health Maintenance](#)
[References](#)

Although obstetrician-gynecologists traditionally focus on the management of illnesses and abnormal conditions, many provide care that is oriented toward health maintenance and prevention or early detection of disease. The value of preventive services is apparent in trends such as the reduced mortality rate from cervical cancer, in part resulting from the increased use of cervical cytology testing. Neonatal screening for phenylketonuria (PKU) and hypothyroidism are examples of effective mechanisms for prevention of mental retardation. Women often regard their gynecologist as their primary care provider; indeed, many women of reproductive age have had no other physician since childhood. In this role, some gynecologists include as a routine part of their practices screening for certain medical conditions, such as hypertension, diabetes mellitus, and thyroid disease, as well as management of those conditions in the absence of complications.

Some traditional aspects of gynecologic practice, such as family planning, can be considered preventive health care. Although hormone replacement therapy can be prescribed to relieve the relatively time-limited symptoms of menopause, it also offers long-term benefits in the prevention of osteoporosis. As primary care physicians, obstetrician-gynecologists provide ongoing care for women through all stages of their lives—from reproductive age to postmenopause. Preventive medical services encompass screening and counseling for a broad range of health behaviors and risks, including family planning, sexual practices, sexually transmitted diseases (STDs), smoking, alcohol and other drug use, diet, and exercise.

In recent years there has been increasing emphasis on women's health and gender-specific medicine. This has enabled obstetrician-gynecologists to become more knowledgeable about the pathophysiologic aspects of diseases in women and thus better equipped to manage them.

Gynecologist as Primary Care Provider

Primary preventive health care in obstetrics and gynecology has been defined as including the following elements ([1](#)):

1. The entry point to the health care system
2. Direct involvement in the patient's health care
3. Continuity in relationship between the physician and patient
4. Care managed with an awareness of the relationship of disease to the family structure
5. Dedication to long-term prevention and early detection of serious illness
6. Provision of general health care (i.e., concerned with diseases other than those of the reproductive tract)
7. Application of skill and judgment regarding consultation and referral, when required, for assurance of complete care by multiple health care providers
8. Availability on a 24-hour basis

In addition, the American College of Obstetricians and Gynecologists (ACOG) has outlined the components of primary preventive care as including the ability to ([2](#)):

1. Establish a physician-patient relationship that creates a health-promoting alliance, including helping patients to control their own health choices, to recognize the benefits of avoiding high-risk behavior, and to acquire the necessary attitudes and skills to change behaviors that place their health at risk.
2. Be familiar with the leading causes of death and morbidity within different age groups in order to incorporate a holistic approach to assessing patients' risks.
3. Apply the knowledge and skills needed to identify underlying problems, counsel patients, and educate patients, adapting to their individual needs, communication skills, age, race, sex, and socioeconomic status.
4. Encourage patient follow-up.
5. Incorporate a team approach to patient care, using the expertise of nurses, health educators, other allied health professionals, and relevant social services.

According to ACOG, primary care emphasizes health maintenance, preventive services, early detection of disease, availability of services, and continuity of care. The obstetrician-gynecologist often serves as a primary medical resource and counselor to the patient and her family for a wide range of medical conditions. However, all clinicians, regardless of the extent of their training, have limitations to their knowledge and skills and should seek consultation at appropriate times for the benefit of their patients in providing both reproductive and nonreproductive care ([3](#)).

Guidelines for primary and preventive services have been issued by a number of medical bodies ([4,5](#)): the American Academy of Family Physicians ([6](#)), the U.S. Preventive Services Task Force ([7](#)), and the American Medical Association ([8](#)). The guidelines from various organizations differ somewhat in their specifics, and a national guideline clearinghouse for evidence-based clinical practice guidelines, sponsored by the Agency for Healthcare Policy and Research, is available to provide comparisons between guidelines for a given medical condition or intervention ([9](#)). Books specific to the provision of primary health care by obstetrician-gynecologists are now available ([10,11,12,13,14,15](#) and [16](#)).

In 1998 in the United States, there were approximately 500 million visits by women to ambulatory medical care providers. Eighteen percent of the visits (76 million) were made to gynecologists ([17](#)). Forty-six percent of ambulatory visits were made by individuals between the ages of 15 and 44 years ([17](#)). The most frequently cited reason for an office visit to an obstetrician-gynecologist by women older than 15 years of age was routine prenatal examination. The second most frequently cited reason was general medical examination. For women in this age group, obstetrician-gynecologists provided more general medical examinations than general and family practitioners and internists combined. For women of reproductive age (15 to 44 years), gynecologists provided nearly 4 times as many general medical examinations than did general and family practitioners, and almost 12 times as many examinations as internists ([18](#)).

In a survey of practicing physicians who were asked to categorize themselves as a primary care physician, a specialist, or a consultant, nearly one-half of

obstetricians and gynecologists (48%) considered themselves to be primary care providers (18). Gynecologists younger than 35 years of age, those in the South Atlantic census region, and those who were paid by hospitals and medical centers were more likely to consider themselves primary care providers. In a 1995 survey of those completing their residencies, 87% of the respondents believed that obstetrics and gynecology was primary care and 85% planned to practice accordingly after residency (19). However, only one-half of residency training directors support the inclusion of 6 months of primary care in the residency education program (20).

Obstetricians and gynecologists are less likely than other primary care physicians to refer their patients. Data compiled by the National Center for Health Statistics (NCHS) indicate that gynecologists had a referral rate of 4%, general internists 7.3%, and family and general practitioners 7.3% (21).

In 1993, ACOG commissioned a Gallup poll to assess how women viewed the care provided by their obstetrician-gynecologists (22). When compared with other physicians, obstetrician-gynecologists were more likely to perform cervical cytology testing, pelvic examination, and breast examination than were other physicians. Obstetrician-gynecologists were as likely as other physicians to have checked blood pressure and referred patients for mammography. When compared with other physicians, they were slightly less likely to have checked cholesterol levels. Obstetrician-gynecologists are somewhat more likely than other physicians to have discussed family planning, preconception issues, and STDs, including human immunodeficiency virus. Other physicians were more likely to discuss medication use than were obstetrician-gynecologists. Other physicians were as likely as obstetrician-gynecologists to have discussed diet and exercise, smoking, alcohol use, hormone replacement therapy, osteoporosis, emotional problems, illegal drug use, and physical abuse (22). More than one-half of all women who reported seeing an obstetrician-gynecologist considered him or her to be their primary physician. As expected, the percentage was highest among women aged 18 to 29 years (69%) and lowest among women older than 40 years (45%) (22).

Approaches to Preventive Care

Currently in health care, there is a shift from a focus on disease to a focus on prevention. Efforts are underway to promote effective screening measures that can have a beneficial effect on public and individual health. Following is a brief description of programs developed by ACOG, the U.S. Preventive Services Task Force, and the American Medical Association to provide guidelines for preventive care.

Guidelines for Primary and Preventive Care

The initial evaluation involves a complete history, physical examination, routine and indicated laboratory studies, evaluation and counseling, appropriate immunizations, and relevant interventions. Risk factors should be identified and arrangements should be made for continuing care or referral, as needed. The leading causes of death and morbidity within different age groups are listed in [Table 8.1](#) and [Table 8.2](#) (4). Subsequent care should follow a specific schedule, yearly or as appropriate based on the patient's needs and age. The ACOG recommendations for periodic evaluation, screening, and counseling by age groups are shown in [Table 8.3](#), [Table 8.4](#), [Table 8.5](#) and [Table 8.6](#). These tables also include recommendations for patients who have high-risk factors that require targeted screening or treatment (7). High-risk factors are listed in [Table 8.7](#). Recommendations for immunizations are included in [Table 8.8](#).

Table 8.1. Leading Causes of Death by Age Group

Table 8.2. Leading Causes of Morbidity by Age Group

Table 8.3. Periodic Assessment Ages 13–18 Years

Table 8.4. Periodic Assessment Ages 19–39 Years

Table 8.5. Periodic Assessment Ages 40–64 Years

Table 8.6. Periodic Assessment Age 65 Years and Older

Table 8.7. High-risk Factors

Age 19–39 Years	Age 40–64 Years	Age 65 Years and Older
Periodic		
Tetanus-diphtheria booster vaccine between ages 11 years and 19 years	Tetanus-diphtheria booster every 10 years	Tetanus-diphtheria booster every 10 years
Hepatitis B vaccine (one series for those not previously immunized)	Hepatitis B vaccine (one series for those not previously immunized)	Hepatitis B vaccine (one series for those not previously immunized)
High-risk groups^a		
Influenza vaccine	Meningitis-mumps-rubella vaccine	Meningitis-mumps-rubella vaccine
Hepatitis A vaccine	Hepatitis A vaccine	Hepatitis A vaccine
Pneumococcal vaccine	Hepatitis B vaccine	Hepatitis B vaccine
Meningitis-mumps-rubella vaccine	Influenza vaccine	Influenza vaccine
Tetanus vaccine	Pneumococcal vaccine	Pneumococcal vaccine
	Tetanus vaccine	Tetanus vaccine

Guide to Clinical Preventive Services

The U.S. Preventive Services Task Force, commissioned in 1984, was a 20-member nongovernmental panel of experts in primary care medicine, epidemiology, and public health. Initial and subsequent reviews and recommendations are being revised and released (23). In 1976, a similar panel was convened in Canada—the Canadian Task Force on the Periodic Health Examination—which issued its report in 1979 (24). The charge of both panels was to develop recommendations for the appropriate use of preventive interventions based on a systematic review of evidence of clinical effectiveness.

The task force used several criteria for selecting conditions to evaluate, including the burden of suffering posed by a given condition, its prevalence (proportion of the population affected), and its incidence (number of new cases per year) (23). The task force reviewed only those preventive services that would be provided for asymptomatic individuals. Primary preventive measures are those that involve intervention before the disease develops, for example, quitting smoking, increasing physical activity, eating a healthy diet, quitting alcohol and other drug use, using seat belts, and receiving immunizations. Secondary preventive measures are those used to identify and treat asymptomatic persons who have risk factors or preclinical disease but in whom the disease itself has not become clinically apparent.

Examples of secondary preventive measures are well known in gynecology: screening mammography and cervical cytology testing.

The Preventive Services Task Force analyzed the effectiveness of various screening measures and tests. For screening tests, they assessed the accuracy of the test, including its sensitivity, specificity, and positive and negative predictive values. The task force also reviewed the methodologic quality of the studies. Because the design of a study influences the interpretation of the data and the weight given to its results, the U.S. Preventive Services Task Force established a hierarchy of the types of studies available to assess the effectiveness of various interventions. This hierarchy is listed in [Table 8.9](#). The strength of the task force's recommendations regarding the value of a screening or preventive intervention is based on the quality of the evidence available. In some circumstances, there is good evidence to recommend for or against an intervention, whereas in others, there is only fair or poor evidence regarding the effectiveness of an intervention. The strength of the task force's recommendations were graded according to a system used by the Canadian Task Force on the Periodic Health Examination ([24](#)) ([Table 8.10](#)).

I. Evidence obtained from at least one properly designed randomized, controlled trial.
II-1. Evidence obtained from well-designed controlled trials without randomization.
II-2. Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group.
II-3. Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled experiments (such as the results of the introduction of penicillin treatment in the 1940s) could also be regarded as this type of evidence.
III. Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

From: Canadian Task Force on the Periodic Health Examination. The periodic health examination. CMAJ 1979;81:1193-204, with permission.

Table 8.9. Quality of Evidence—U.S. Preventive Services Task Force

Strength of Recommendations
A: There is good evidence to support the recommendation that the condition be specifically considered in a periodic health examination.
B: There is fair evidence to support the recommendation that the condition be specifically considered in a periodic health examination.
C: There is insufficient evidence to recommend for or against the inclusion of the condition in a periodic health examination, but recommendations may be made on other grounds.
D: There is fair evidence to support the recommendation that the condition be excluded from consideration in a periodic health examination.
E: There is good evidence to support the recommendation that the condition be excluded from consideration in a periodic health examination.

U.S. Preventive Services Task Force. Guide to Clinical Preventive Services, 2nd ed. Baltimore: Williams & Wilkins, 1996.

Table 8.10. The Task Force Graded the *Strength of Recommendations* for or Against Preventive Interventions as Follows

The U.S. Preventive Services Task Force drew a number of conclusions based on review of the data ([7](#)).

1. Interventions that address patients' personal health practices are vitally important.
2. The clinician and patient should share decision making.
3. Clinicians should be selective in ordering tests and providing preventive services.
4. Clinicians must take every opportunity to deliver preventive services, especially to persons with limited access to care.
5. For some health problems, community-level interventions may be more effective than clinical preventive services.

The quality of clinical evidence also has been rated and published internationally by other medical groups using a rating system similar to that used by the U.S. Preventive Services Task Force ([25](#)). In one source, which is updated every 6 months and has a lag time of 5 to 9 months from search to publication, treatment effects are categorized as follows ([25](#)):

1. Beneficial
2. Likely to be beneficial
3. Trade-off between benefits and harms
4. Unknown effectiveness
5. Unlikely to be beneficial
6. Likely to be ineffective or harmful

Other international efforts to categorize the effectiveness of treatments include the Cochrane Library, which produces and publishes high-quality systematic reviews of controlled trials ([26](#)). The Cochrane Library provides searchable databases available online and through institutional purchase of licenses. Evidence-based guidelines are published in journals available in print and online, by discipline (i.e., medicine, mental health, and nursing).

Guidelines For Adolescent Preventive Services

Around the same time that clinicians were evaluating the primary health care needs of adults, clinicians who practice adolescent medicine (with backgrounds in pediatrics, internal medicine, family medicine, gynecology, nursing, psychology, nutrition, and other professions) recognized that the guidelines for adult and pediatric health services did not always fit the needs and health risks of adolescence. Neither the ACOG Guidelines for Primary Preventive Care ([4](#)) nor the U.S. Preventive Services Task Force recommendations ([7](#)) are sufficiently comprehensive or focused on this age group, although both documents include many important aspects of adolescent health care. The American Medical Association, with the assistance of a national scientific advisory board, developed the Guidelines for Adolescent Preventive Services (GAPS) in response to this perceived need for recommendations for delivering comprehensive adolescent preventive services ([8,27](#)).

Obstetrician-gynecologists typically see adolescents in crisis, to provide care for unintended pregnancies or STDs, including pelvic inflammatory disease. The need for preventing these crises is evident. The GAPS report extends the framework of services provided to adolescents. The impetus for developing GAPS was the belief that a fundamental change in the delivery of adolescent health services was necessary. Gynecologists could easily provide most, if not all, of the recommended services; annual preventive visits to a gynecologist might well lead to the prevention of gynecologic health problems. There are numerous opportunities for primary preventive care of adolescents in a gynecologist's office.

The GAPS report includes 24 recommendations ([Table 8.11](#)). These recommendations address the delivery of health care, focus on the use of health guidance to promote the health and well-being of adolescents and their families, promote the use of screening to identify conditions that occur relatively frequently in adolescents and cause significant suffering either during adolescence or later in life, and provide guidelines for immunizations for the primary prevention of specific infectious diseases ([8](#)).

Table 8.11. Guidelines for Adolescent Preventive Services

The GAPS recommendations stem from the conclusion that the current health threats to adolescents are predominantly behavioral rather than biomedical, that more of today's adolescents are involved in health behaviors with the potential for serious consequences, that today's adolescents are involved in health-risk behaviors at younger ages than previous generations, that many adolescents engage in multiple health-risk behaviors, and that most adolescents engage in at least some type of behavior that threatens their health and well-being (8). Gynecologists are in a good position to detect high-risk behaviors and to determine whether multiple risk-taking behaviors exist; for example, the early initiation of sexual activity and unsafe sexual practices are associated with substance use (28). Adolescents who are sexually active are much more likely to have used alcohol (6.3 times greater risk), 4 times more likely to have used drugs other than marijuana, and nearly 10 times more likely to have been a passenger in a motor vehicle with a driver who was using drugs than are adolescents who are not sexually active (29). Thus, by being aware of comorbidities, gynecologists can screen for these behaviors and potentially intervene before there are serious harmful health consequences.

ACOG has issued guidelines that build on the GAPS recommendations in recognition of the role that obstetrician-gynecologists potentially could play in providing preventive services for adolescents (5). These guidelines suggest an initial visit (not necessarily examination) to the obstetrician-gynecologist for health guidance, screening, and the provision of preventive health care service between the ages of 13 and 15 years (30) and subsequent annual preventive health care visits (5).

Counseling for Health Maintenance

During periodic assessments, patients should be counseled about preventive care depending on their age and risk factors. **Obesity, smoking, and alcohol abuse are associated with preventable problems that can have major long-term impacts on health.** Thus, patients should be counseled about smoking cessation and moderation in alcohol use and directed to appropriate community resources as necessary. Positive health behaviors, such as eating a healthy diet and engaging in regular exercise, should be reinforced.

Adjustments may be necessary based on the presence of risk factors and the woman's current lifestyle and condition. Efforts should focus on weight control, cardiovascular fitness, and reduction of risk factors associated with cardiovascular disease and diabetes (30,31,32 and 33).

Nutrition

Patients should be given general nutritional information and referred to other professionals if they have special needs (34). Assessment of the patient's body mass index (weight [in kilograms] divided by height [in meters] squared [kilograms per square meter]) will give valuable information about the patient's nutritional status. Patients who are 20% above or below the normal range require evaluation and counseling and should be assessed for systemic disease or an eating disorder.

Central obesity—measured as waist-to-hip ratio—is a risk factor for coronary heart disease and some forms of cancer. When the waist-to-hip ratio exceeds 0.76, there is a greater relative risk of death from cancer or cardiovascular disease in women aged 55 to 69 years.

The Food Guide Pyramid developed by the U.S. Department of Agriculture helps women choose food from five groups to provide needed nutrients (Fig. 8.1) (35). The pyramid is based on the need to eat a variety of foods to get adequate energy, protein, vitamins, minerals, and fiber. The diet portrayed is high in vegetables, fruits, and grain products.

Figure 8-1 The Food Guide Pyramid. A Guide to Daily Food Choices. This is a guide to help men and nonpregnant women choose foods that will give them the nutrients they need. Because a pregnant woman needs extra calories, she should get at least the number of servings shown in parentheses after the standard servings.

Fiber content of the diet is being studied for its potential role in the prevention of several disorders, particularly colon cancer. Currently, it is recommended that the average diet contain 20 to 30 g of fiber per day. Foods high in dietary fiber include whole-grain breads and cereals, green and yellow vegetables, citrus fruits, and some legumes.

Adequate calcium intake is important in the prevention of osteoporosis. A postmenopausal woman should ingest 1,500 mg/day. Adolescents require 1,300 mg/day. There is no evidence that moderate caffeine intake causes osteoporosis when calcium intake is inadequate. Because it is difficult to ingest an adequate amount of calcium daily in an average diet, supplements may be required.

The Centers for Disease Control and Prevention has recommended that women of reproductive age who are capable of becoming pregnant take supplemental folic acid (0.4 mg daily) to help prevent neural tube defects in their infants (36). Women who are contemplating pregnancy should be counseled about the risk of fetal neural tube defects and the role of folic acid in their prevention.

Following are some general nutritional guidelines for all women issued by the Committee on Diet and Health of the National Research Council (37):

- 1. Total fat intake should be 30% of calories or less.** Saturated fatty acid intake should be less than 10% of calories, and the intake of cholesterol should be less than 300 mg daily.
- 2. Every day, five or more servings of a combination of vegetables and fruits, especially green and yellow vegetables and citrus fruit, should be eaten.** The daily intake of starches and other complex carbohydrates should be increased by eating six or more servings of a combination of breads, cereals, and legumes.

3. Protein should be maintained at moderate levels (<1.6 g/kg of body weight).
4. Total daily intake of salt should be limited to 6 g or less.
5. Vitamin-mineral supplement intake should not exceed the recommended dietary intake per day.

Alcohol

Alcoholic beverages should be limited to less than 1 oz of absolute alcohol per day (equivalent to two cans of beer, two glasses of wine, or two average cocktails).

A simple device called the T-ACE questionnaire can be used to elicit information about alcohol use and identify problem drinkers ([Table 8.12](#)). Women should be questioned in a nonjudgmental fashion about their alcohol use and directed to counseling services as required.

Do you have a drinking problem?	
Experts in treating alcohol abuse use the T-ACE questions below to help them find out whether a person has a drinking problem. These questions can also apply to other drugs.	
T	How many drinks does it take to make you feel high (Tolerance)?
A	Have people Annoyed you by criticizing your drinking?
C	Have you ever felt you ought to Cut down on your drinking?
E	Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (Eye opener)?
If your answer to the tolerance questions is more than two drinks, give yourself a score of 2. If you answer yes to any of the other questions, give yourself a score of 1 each. If your total score is 2 or more, you may have a drinking problem.	
From Selval R, Marler SS, Aggar P. The T-ACE question: practical prenatal detection of risk-drinking. <i>Am J Obstet Gynecol</i> 1993;169:1044-5.	

Table 8.12. T-ACE Questionnaire

Exercise

Exercise can help control or prevent hypertension, diabetes mellitus, hypercholesterolemia, and cardiovascular disease. Moderate exercise along with calcium supplementation and hormone replacement therapy can help retard bone loss in postmenopausal women ([38](#)). Exercise helps promote weight loss, strength and fitness, and stress reduction.

Before beginning an exercise program, patients should be examined to ensure that exercise will not pose a risk to their health. Women should be counseled about safety guidelines for exercise. Factors that should be considered in establishing an exercise program include medical limitations and selection of activities that promote health and enhance compliance. A variety of physical activities (e.g., gardening, raking leaves, walking to work, taking the stairs) can be incorporated easily into an individual's daily routine. Emphasis should be placed on regular physical activity (e.g., 30 min/d) rather than episodic vigorous exercise, especially in sedentary individuals ([38](#)). High-impact exercise is not necessary to achieve benefits, and it may be harmful. Regular low-impact or moderate aerobic exercise has been associated with improved long-term compliance and adequate health maintenance benefits.

Cardiovascular fitness can be evaluated by measurement of heart rate during exercise. As conditioning improves, the heart rate stabilizes at a fixed level. The heart rate at which conditioning will develop is called the target heart rate ([38](#)). **The formula for calculating the target heart rate is 220 minus the patient's age times 0.75.** For example, a 50-year-old woman would target her heart rate at 119 ($220 - 50 = 170 \times 0.75 = 119$).

Smoking Cessation

Smoking is a major cause of preventable illness, and every opportunity should be taken to encourage patients who smoke to quit. The effectiveness of smoking cessation programs varies, however, and numerous approaches have been used. The American Cancer Society suggests the following five-step approach:

1. Begin by obtaining a patient history of smoking habits and assessing the patient's motivation to stop smoking.
2. Give clear advice to stop smoking, emphasizing the benefits of cessation.
3. Set a specific goal (e.g., a realistic date to stop smoking).
4. Suggest cessation strategies.
5. Arrange a visit or phone call to monitor process.

Patient education about the benefits of smoking cessation, clear advice to quit smoking, and physician support improve smoking cessation rates, although 95% of smokers who successfully quit do so on their own. Self-help materials are available from the National Cancer Institute as well as community-based support groups and local chapters of the American Cancer Society and the American Lung Association. To aid in cessation, nicotine replacement therapy may be offered in the form of chewing gum or a transdermal patch. This should be prescribed only in conjunction with, not as a replacement for, ongoing visits for counseling and support.

Gynecologists have become responsible for care that extends beyond diseases of the reproductive organs to include much of the general medical care of women. Broadening the spectrum of care places emphasis on the caring nature of the physician rather than the surgical or procedural aspects of the specialty. Early diagnosis and treatment of medical illnesses can have a major impact on a woman's health and is a key component of primary care. Although timely referral is important for complex and advanced disorders, the gynecologist initially may treat many conditions.

The gynecologist should provide screening and early intervention for certain conditions that commonly arise in the office setting or have a significant impact on women's health. Respiratory problems are the most common reasons patients seek care from a physician, so gynecologists should be aware of their pathophysiology. Cardiovascular disease has a significant impact on overall morbidity and is the main cause of death in women. Cardiovascular illness is associated with cigarette smoking, hypertension, hypercholesterolemia, and diabetes mellitus. These conditions are responsive to screening, behavior modification, and control to lower risk factors. A major cause of morbidity for women is thyroid disease; because of the interaction of hormones and the overall effect on the endocrine system, thyroid disease can be of special significance in women.

Respiratory Infections

Infections of the respiratory system can range from the common cold to life-threatening illness. Those who have risk factors should be counseled about preventive measures. Vaccines against flu and pneumonia should be offered as indicated (see Chapter 8, [Table 8.7](#)).

Sinusitis

A problem frequently encountered in women is self-diagnosed "sinus problems" ([1](#)). Many medical problems—headaches, dental pain, postnasal drainage, halitosis, and dyspepsia—may be related to sinus conditions. The sinuses are not an isolated organ, and diseases of the sinuses are often related to conditions that affect other portions of the respiratory system (i.e., the nose, bronchial tree, and lung) ([2](#)). The entire respiratory system may be infected by one particular virus or pathogen (the sinobronchial or sinopulmonary syndrome); however, the most prominent symptoms are usually produced in one anatomic area. Therefore, during the evaluation of complaints attributable to sinusitis, the presence of other infections should be investigated.

Exposure to multiple infectious and chemical agents or reaction to nervous, physical, emotional, or hormonal stimuli may cause an inflammatory response in the respiratory system ([3](#)). Systemic diseases such as connective tissue syndromes and malnutrition may contribute to chronic sinusitis. Environmental factors in the workplace and geographic conditions (e.g., cold and damp weather) may aggravate or accelerate the development of sinusitis. Factors contributing to the development of sinus disease include atmospheric pollutants, allergy, tobacco smoke, skeletal deformities, dental conditions, barotrauma from scuba diving or airline travel, and neoplasms.

Most infections begin with a viral agent in the nose or nasopharynx that causes inflammation that blocks the draining ostia. The location of the symptoms varies by anatomic site: maxillary sinus over the cheeks, ethmoid sinus across the nose, frontal sinus in the supraorbital area and sphenoid sinus to the vertex of the head. Viral agents impede the sweeping motion of cilia in the sinus and, in combination with edema from inflammation, lead to superinfection with bacteria. Common bacterial agents infecting sinuses are *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Staphylococcus aureus*, and a-hemolytic streptococcus species. Gram-negative organisms are usually limited to compromised hosts in intensive care units. Chronic sinusitis develops from either inadequate drainage or compromised local defense mechanisms. The flora in chronic disease is usually polymicrobial, with mixed infections consisting of aerobic and anaerobic organisms.

Sinus ailments frequently occur in middle-aged individuals. Acute infection is usually located in the maxillary and frontal sinuses. Classically, infection in the maxillary sinus is due to obstruction of the ostia found in the medial wall of the nose. Fever, malaise, a vague headache, and pain in the maxillary teeth are early symptoms. Complaints of "fullness" in the face or exploding pressure behind the eyes are elicited. Pressure and percussion over the malar areas results in complaints of severe pain. Purulent exudates in the middle meatus of the nose or in the nasopharynx are commonly observed. **The five clinical findings of maxillary toothache, poor response to nasal decongestants, abnormal transillumination, a colored nasal discharge established by history or a colored nasal discharge on examination are the most useful clinical findings. When four or more features are present the likelihood of sinusitis is high, and when none is present sinusitis is highly unlikely** ([4](#)). Initial episodes of sinusitis do not require imaging studies, but when persistent infections occur, studies and referral are indicated. Therapy is usually empiric. Unless samples are obtained by direct needle drainage, cultures are of no value because it is impossible to avoid contamination by oropharyngeal flora.

Broad antibiotic therapy is necessary to cover common aerobes and anaerobes but should be limited to patients with acute pain and purulent discharge. For acute, uncomplicated sinus infections *amoxicillin* (500 mg 3 times a day) or *trimethoprim-sulfamethoxazole* (one tablet twice daily) remain the treatments of choice. *Amoxicillin* is inexpensive, penetrates the sinus tissues well, and can be discontinued and another antibiotic substituted if symptoms have not improved in 48 to 72 hours. If b-lactam resistance is likely, *amoxicillin-clavulanic acid* (875 mg twice daily), or *azithromycin* (5-day course once a day) may be used. Other second-line drugs include *cefuroxime* (250 mg twice daily), *ciprofloxacin* (500 mg twice daily), *clarithromycin* (500 mg twice daily), *levofloxacin* (500 mg once a day), and *loracarbef* (400

mg twice daily). The usual treatment course is 14 days, and patients should be informed that a relapse may occur if the full course of treatment is not completed. Systemic decongestants containing *pseudoephedrine* are useful in shrinking the obstructive ostia and promoting sinus drainage and ventilation. Topical decongestants should be used for no longer than 13 days, because prolonged use may lead to rebound vasodilation and worsening of symptoms. Mucolytic agents such as *guaifenesin* may help thin sinus secretions and promote drainage. Antihistamines should be avoided in acute sinusitis because their drying effects may lead to thickened secretions and poor drainage of the sinuses. Symptomatic therapies should include facial hot packs and analgesics. Improvement in symptoms should be apparent within 48 hours, but 10 days of therapy may be necessary for complete resolution. If symptoms do not respond, other classes of antibiotics should be used based on presumed microbial resistance. In difficult cases, referral to an otolaryngologist for sinus irrigation may be necessary.

Chronic sinusitis may result from repeated infections with inadequate drainage. The interval between infections becomes progressively shorter until there are no remissions. Symptoms are recurrent pain in the malar area or chronic postnasal drip. Chronic sinusitis is associated with chronic cough and laryngitis with intermittent acute infections. In the preantibiotic era, chronic sinusitis was the result of repeated acute sinusitis with incomplete resolution, whereas allergy currently is receiving greater attention as a possible cause. Surface ciliated epithelia are injured, resulting in impaired mucus removal. A vicious cycle of incomplete resolution of infection followed by reinfection and ending with the emergence of opportunistic organisms occurs. Swelling and edema of the mucosa, in conjunction with hypersecretion of mucus, lead to ductal obstruction and infection. Treatment is directed at the underlying etiology, either allergy control or aggressive management of infections. Resistant cases will require computed tomography (CT) and endoscopic surgery with polyp removal. Nasoantral window formation is radical surgery usually reserved for advanced conditions that do not respond to other forms of therapy.

Untreated, sinus infections may have serious consequences such as orbital cellulitis leading to orbital abscess, subperiosteal abscess formation of the facial bones, cavernous sinus thrombosis, and acute meningitis. Brain and dural abscesses are rare and usually are caused by direct spread of pathogens from a sinus. At present, CT scanning is the most accurate diagnostic tool. Aggressive surgical approaches used with broad-spectrum antibiotics are necessary for adequate drainage.

Otitis Media

Otitis media remains primarily a disease of children but may affect adults. Serous otitis media is usually secondary to a concurrent viral infection of the upper respiratory tract. In most cases, diagnosis reveals fluid behind the tympanic membrane. Therapy involves treatment of symptoms with antihistamines, decongestants, and glucocorticoids, but little data exist supporting use of these medications. Acute otitis media is usually caused by a bacterial infection; *Streptococcus pneumoniae* and *Haemophilus influenzae* are the pathogens most often involved. Symptoms include acute purulent otorrhea, fever, hearing loss, and leukocytosis (5). Physical examination of the ear will reveal a red, bulging, or perforated membrane. Indicated treatment is broad-spectrum antibiotics such as *amoxicillin-clavulanic acid*, *cefuroxime*, and *trimethoprim-sulfamethoxazole*. The role of antihistamines in treatment of otitis media is unclear.

Bronchitis

Acute bronchitis is an inflammatory condition of the tracheobronchial tree, most often caused by a viral infection and occurring in winter. Common cold viruses (rhinovirus and coronavirus), adenovirus, influenza virus and *Mycoplasma pneumoniae* (a nonviral pathogen) are the most common pathogens. Bacterial infections are less common and may occur as secondary pathogens. Cough, hoarseness, and fever are the usual initial symptoms. During the first 3 to 4 days, the symptoms of rhinitis and sore throat are prominent; however, coughing may last as long as 3 weeks. Unfortunately, the prolonged nature of these infections result in use of antibiotics to "clear up the infection." Sputum production is common and may be prolonged in cigarette smokers. Most serious bacterial infections occur in cigarette smokers because of damage to the lining of the upper respiratory tree and changes in the host flora.

Physical examination will demonstrate a variety of upper airway sounds, usually coarse rhonchi. Rales are usually not auscultated, and signs of consolidation and alveolar involvement are absent. During auscultation of the chest, signs of pneumonia such as fine rales, decreased breath sounds, and euphonia ("E to A changes") should be sought. If the findings of the physical examination are uncertain or if the patient's condition appears toxic, chest radiography should be performed to detect the presence of parenchymal disease. Paradoxically, as the initial acute syndrome subsides, sputum production may become more purulent. Sputum cultures are of limited value because of the polymicrobial nature of infections. In uncomplicated cases, the goal of treatment is symptomatic relief, whereas use of antibiotics is reserved for patients who have chest radiographic findings consistent with pneumonia. Cough is usually the most aggravating symptom and may be treated with antitussive preparations containing either dextromethorphan or codeine. The efficacy of expectorants has not been proved.

Chronic bronchitis is defined as the presence of a productive cough with excessive secretions for at least 3 months in a year for 2 consecutive years. Prevalence has been estimated to be between 10% to 25% of the adult population. In the past, incidence has been lower in women than men, but as the prevalence of cigarette smoking in women has increased, so has the incidence of bronchitis in women. Chronic bronchitis is usually classified as a form of chronic obstructive pulmonary disease (COPD). Other causes include chronic infections and environmental pathogens found in dust. The cardinal manifestation of disease is an incessant cough, usually in the morning, with expectoration of sputum. Because of frequent exacerbations and hospitalizations required, and the complexity of medical management, these patients should be referred to an internist for treatment.

Pneumonia

Pneumonia is defined as inflammation of the distal lung that includes terminal airways, alveolar spaces, and the interstitium. Pneumonia may have multiple causes, including viral and bacterial infections or aspiration. Aspiration pneumonia is usually the result of depressed awareness commonly associated with use of drugs, alcohol, or anesthesia. Viral pneumonias are caused by multiple infectious agents including influenza A or B, parainfluenza virus, or respiratory syncytial virus. Most viral syndromes are spread by aerosolization associated with coughing, sneezing, and even conversation. Incubation time is short, requiring only 1 to 3 days prior to the acute onset of fever, chills, headache, fatigue, and myalgia. Symptom intensity is directly related to intensity of the host febrile reaction. Pneumonia develops in only 1% of patients who have a viral syndrome, but mortality rates may reach 30% in immunocompromised individuals and the elderly. An additional risk is the development of secondary bacterial pneumonias after the initial viral insult. These infections are more common in elderly patients and may explain the high fatality rate associated with them in this group (6). Staphylococcal pneumonias, most commonly arising from a previous viral infection, are extremely lethal regardless of the patient's age. The best approach to viral pneumonia is prevention by immunization. Influenza and pneumonia immunization should be offered as indicated (see Chapter 8, Table 8.7). In epidemics, *amantadine* has been used to treat individuals who have not been vaccinated. Treatment is supportive with administration of antipyretics and fluids.

Bacterial pneumonia is classified as either nosocomial or community acquired. The classification determines the prognosis and choice of antibiotic therapy in many cases. Risk factors that contribute to mortality are chronic cardiopulmonary diseases, alcoholism, diabetes mellitus, renal failure, malignancy, and malnutrition. Prognostic features associated with poor outcome include greater than two-lobe involvement, respiratory rate greater than 30 breaths/minute on arrival in the health care center, severe hypoxemia (<60 mm Hg breathing room air), hypoalbuminemia, and septicemia (7). Pneumonia is a common cause of adult respiratory distress syndrome (ARDS), which has a mortality rate of between 50% to 70% (8).

Signs and symptoms of pneumonia vary depending on the infecting organism and the patient's immune status (9). In typical pneumonias, the patient appears toxic with high fever, rigors, productive cough, chills, or pleuritic chest pain. Chest radiographs will often disclose infiltrates. The following agents, listed in decreasing order, cause two-thirds of all bacterial pneumonias: *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Klebsiella pneumoniae*, gram-negative organisms, and anaerobic bacteria. Atypical pneumonias are more insidious in onset; moderate fever is present without the characteristic rigors and chills. Additional symptoms include a nonproductive cough, headache, myalgias, and mild leukocytosis. Chest radiographic examination reveals a bronchopneumonia with a diffuse interstitial pattern ("bat wing distribution"); characteristically, the patient does not appear to be as ill as the radiographic findings suggest. Common causes of atypical pneumonia include viruses, *Mycoplasma pneumoniae*, *Legionella pneumophila*, *Chlamydia pneumoniae* (also called the TWAR agent), and other rare agents.

A strong index of suspicion is required to establish a diagnosis, especially in elderly and immunocompromised individuals, because of altered response mechanisms. This is even true with so-called *typical agents*. Subtle clues in the elderly include changes in mentation, confusion, and exacerbation of other illnesses. The febrile response may be entirely absent. Even in high-risk groups, an increased respiratory rate of greater than 25 breaths per minute remains the most reliable sign. In high-risk patients mortality is strongly correlated with the inability to mount normal defenses to the symptoms of fever, chills, and tachycardia.

Laboratory studies helpful in identifying community-acquired pneumonia are sputum Gram stain, sputum culture, and blood culture. An adequate sputum collection (defined as more than 25 neutrophils with less than 10 epithelial cells per low-powered field on microscopic examination) may be difficult to obtain. The assistance of respiratory therapists should be sought to obtain induced sputum. *Legionella pneumoniae* requires different laboratory techniques such as direct fluorescent antibody

staining of organisms in the sputum or indirect serologic tests using enzyme-linked immunosorbent assay (ELISA) technology. *Mycoplasma pneumoniae* infection should be suspected in the presence of positive cold agglutinin findings and the appropriate clinical symptoms.

Therapy should be directed toward the responsible or most likely pathogen but, in many cases of pneumonia, the exact cause cannot be determined and empiric therapy should be initiated. Pneumonia that occurs without coexisting conditions such as heart disease, lung disease, renal insufficiency, liver disease, or other comorbid medical illnesses in patients who are ≥ 60 years of age should be treated on an outpatient basis with a macrolide such as *erythromycin* (500 mg four times a day). *Clarithromycin* (500 mg twice daily) or *azithromycin* (500 mg on day 1, followed by 250 mg once a day for 4 weeks) is preferred for smokers or those who are intolerant to *erythromycin*. *Doxycycline* (100 mg twice daily) may be used for patients who are allergic or intolerant to macrolides. Patients who have coexisting conditions, are ≥ 60 years of age, or both should be treated on an outpatient basis with a second-generation *cephalosporin* or β -lactam- β -lactamase inhibitor, like *amoxicillin-clavulanic acid*, with or without a macrolide if legionellosis is a concern.

The same protocol for outpatient therapy may be used for hospitalized patients except that a third-generation cephalosporin may be used (10). Hospitalization is usually necessary in patients who are very ill, elderly, or immunocompromised. Oxygen therapy and hydration, in addition to antibiotic therapy, should be initiated. The use of chest physiotherapy should be reserved for patients who have copious sputum or who have an ineffective cough. Patients may be switched to oral antibiotics when they are able to eat and drink, have negative blood cultures, a temperature $< 38^{\circ}\text{C}$, a respiratory rate of ≤ 24 breaths per minute and a pulse rate of ≤ 100 beats per minute. Patients may be discharged when they fulfill the aforementioned criteria and their white blood cell count is 12×10^9 per liter, comorbid illnesses are stable, oxygen saturation is $> 90\%$ on room air, or the patient has COPD with $\text{P O}_2 > 60$ mm Hg and $\text{PCO}_2 < 45$ mm Hg (11).

The pneumococcal vaccine should be given to women at high risk for pneumonia. All adults 65 years or older and people with special health problems such as heart or lung disease, alcoholism, kidney failure, diabetes mellitus, human immunodeficiency virus (HIV) infection, or certain types of cancer should be immunized (see Chapter 8, Table 8.7). Repeat vaccination is recommended 5 years after the first dose in high-risk groups. The vaccine is active against 23 types of pneumococcal strains and most people develop protection within 2 to 3 weeks of receiving the immunization.

The influenza vaccine should be given every fall to the following high-risk groups: individuals 50 years of age or older, individuals with serious long-term health problems like heart disease, lung disease, kidney disease, diabetes mellitus, immunosuppression secondary to long-term steroid or cancer therapy (see Chapter 8, Table 8.7), women who will be in their third trimester of pregnancy during the flu season (November through April), and anyone coming into close contact with people at risk of serious influenza, such as physicians, nurses, and family members. The best time for vaccination is October to mid-November. Antiviral agents should not be used as a substitute for vaccination but can be a useful adjunct. The four agents approved for use in the United States are *amantadine*, *rimantadine*, *zanamivir*, and *oseltamivir*. These medications should be given within 2 days of the onset of symptoms to shorten the duration of uncomplicated illness caused by influenza (12).

Cardiovascular Disease

The risk factors for coronary artery disease are presented in Table 9.1. Central to treating cardiovascular disease is the control of contributing diseases and risk factors (Table 9.2). Aerobic exercise protects against cardiovascular disease (13). Additional aspects of prevention of myocardial disease, renal disease, and stroke include control of hypertension, identification and control of diabetes mellitus and obesity, and control of dietary fats, especially cholesterol, in susceptible individuals (Fig. 9.1). The presence or absence of target-organ damage shown in Table 9.3 also determines the risk for coronary artery disease in hypertensive patients.

Age > 60
Diabetes mellitus
Smoking
Dyslipidemia
Gender (men and postmenopausal women)
Family history of cardiovascular disease (men < 55 y; women < 55 y)

Adapted from The Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI, Bethesda, MD: National Institutes of Health, National Heart, Lung, and Blood Institute; 1997; NIH publication 99-4081).

Table 9.1. Major Risk Factors for Coronary Artery Disease

Weight reduction if overweight
Limit alcohol use to less than 1 ounce of absolute alcohol per day (2 beers, 10 ounces of wine, 2 ounces of 100-proof whiskey)
Regular aerobic exercise (30–45 minutes fast walking 3 times/week)
Decrease salt intake to less than 2.4 grams per day
Stop cigarette smoking
Reduce dietary saturated fat and cholesterol
Maintain adequate intake of calcium, potassium, and magnesium
If diabetic, control glucose

Table 9.3. Target-organ Damage and Clinical Cardiovascular Disease

Hypertension

The relationship between hypertension and cardiovascular events such as stroke, coronary artery disease, congestive heart disease, and renal disease is well known. More than 50 million people in the United States have hypertension and it is found in 15% of the population between the ages of 18 and 74 years. The incidence increases with age and varies with race. After age 50, women have a higher incidence of hypertension than males; however, this may be a confounding variable related to the overall mortality of men at an earlier age (14). Over 60% of those 60 years and older can be classified as hypertensive (15). The contribution of hypertension to overall cardiovascular morbidity and mortality in women has been thought to be less important than in males, but this may reflect the relative absence of research done with women. Recognition and treatment of hypertension may decrease the development of renal and cardiac disease.

Epidemiology

The incidence of hypertension is twice as high in African Americans than in whites. Geographic variations are present: there is a higher prevalence of hypertension and stroke in the southeastern United States, regardless of race (16). One multicenter study confirmed that there is an increased incidence of hypertension, not only in African Americans, but also in those with lower levels of education (17). Preventive measures can be most effective in those at highest risk, such as African American women and individuals from the lowest socioeconomic levels (17). The influence of genetic predisposition is poorly understood. Studies of women have been limited to those that determine side effects of medication and the impact of certain medications on long-term lipid status (14).

Classically, hypertension is defined as blood pressure levels higher than 140/90 when measured on two separate occasions. However, therapy may be indicated only for individuals at high risk. Individuals at low risk, such as white women with no other risk factors, may benefit from lifestyle modification only (17). Elevation of systolic blood pressure in middle-aged and elderly patients was once considered innocuous; however, recent studies suggest that control of systolic blood pressure is more important than control of diastolic blood pressure (18). Life insurance risk tables indicate that when blood pressure is controlled to lower than 140/90, normal survival occurs over a 10- to 20-year follow-up period, regardless of gender. **Recommendations for treatment of hypertension are based on sustained blood pressure levels higher than 140/90.**

Most individuals (>95%) with hypertension have primary or essential hypertension (cause unknown), whereas less than 5% have secondary hypertension resulting from another disorder. Key factors should be determined in the history and physical examination. The presence of prior elevated readings, previous use of antihypertensive agents, a family history of death from cardiovascular disease prior to age 55, and excessive alcohol and sodium use constitute important historical information. Lifestyle modification is increasingly important in the therapy of hypertension; thus, a detailed history of diet and physical activity should be obtained (19). Baseline laboratory evaluations to rule out reversible causes of hypertension (secondary hypertension) are listed in [Table 9.4](#). Diagnosis and management are based on the classification of blood pressure readings in [Table 9.5](#). In addition, patients are stratified into three different risk groups for therapeutic decision making ([Table 9.6](#)).

Urinalysis
Complete blood count
Potassium, sodium, creatinine
Fasting glucose
Total cholesterol, high-density lipoprotein cholesterol
12-lead electrocardiogram

*If any of the above are abnormal, consultation or referral to an internist is indicated.
Adapted from *The Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure* (JNC VI). Bethesda, MD: National Institutes of Health, National Heart, Lung, and Blood Institute; 1997. NIH publication 99-4086.

Table 9.4. Laboratory Tests and Procedures Recommended in the Evaluation of Uncomplicated Hypertension^a

Category	Systolic BP (mm Hg)	Diastolic BP (mm Hg)
Optimal	<120	<80
Normal	<130	<85
High normal	130-139	85-89
Hypertension	—	—
Stage 1	140-159	90-99
Stage 2	160-179	100-109
Stage 3	≥180	≥110

BP, blood pressure.

rates and higher serum creatinine levels. Control of hypertension with concurrent renal insufficiency is difficult and is probably best handled by an internist or nephrologist. Thiazides and loop diuretics should not be used concurrently because they cause profound diuresis, which may lead to renal impairment. Concurrent use of nonsteroidal antiinflammatory drugs (NSAIDs) limits the effectiveness of thiazides. Other side effects, which further limit the usefulness of thiazide diuretics, include hyperuricemia, which may contribute to acute gout attacks, glucose intolerance, and hyperlipidemias (29). The metabolic side effects of these drugs have limited their popularity recently.

Adrenergic Inhibitors

b-Blockers have been used extensively for years as antihypertensive agents. The mechanism of action is decreasing cardiac output and plasma renin activity with some increase in total peripheral resistance. As a class, they are an excellent source of first-line therapy, especially for migraine sufferers. The original formulation, *propranolol*, was highly lipid soluble, which contributed to bothersome side effects such as depression, sleep disturbances (nightmares in the elderly), and constipation in higher doses. Formulations such as *atenolol* are water soluble, are b₁ selective, and have fewer side effects. At higher doses, however, b₂ effects emerge. Despite speculation that b₁-selective agents may be safe in asthmatics, they should never be used in these patients. Additional advantages of water-soluble agents are longer half-lives and reduced dosing schedules, which improve compliance. Metabolic changes, similar to those of thiazide diuretics, have reduced the popularity of these drugs. These side effects include an increase in triglyceride levels, a decrease in high-density lipoprotein (HDL) cholesterol levels, and blunting of adrenergic release in response to hypoglycemia. These metabolic problems far outweigh the benefits in patients with diabetes mellitus (30). NSAIDs may also decrease the effectiveness of b-blockers. Additional contraindications are COPD, sick sinus syndrome, or any bradyarrhythmia. A popular use of b-blockers is for treatment of angina and myocardial infarctions. If these drugs are acutely withdrawn, however, a rebound phenomenon of ischemia may occur, leading to acute myocardial infarction. b-Blockers continue to be useful, despite these potential problems, especially to counteract reflex tachycardia common with smooth muscle-relaxing drugs.

a₁-Adrenergic drugs became popular in males because they have minimal effects on potency and a unique relationship to lipids. Interestingly, they may contribute to stress urinary incontinence in women as a result of altered urethral tone (31). As single agents, they decrease total cholesterol and low-density lipoprotein (LDL) cholesterol while increasing HDL cholesterol levels, in contrast to the metabolic effects of b-blockers. Mode of action is to promote vascular relaxation by blocking postganglionic norepinephrine vasoconstriction in the peripheral vascular smooth muscle. *Prazosin* and *doxazosin* are currently the most popular preparations available in this class. A serious side effect of these drugs, most commonly described in the elderly, is called the *first-dose effect*. In susceptible individuals, severe orthostasis was reported when therapy was initiated, but it subsided after several days. In combination with diuretics, hypotension may be further exacerbated. Therapy should begin with small bedtime doses followed by incremental increases. Other side effects, which may limit usefulness in some patients, include tachycardia, weakness, dizziness, and mild fluid retention.

Angiotensin-converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors (ACE inhibitors) have rapidly become a first-line drug in the treatment of hypertension. Their rapid rise in popularity is due to the introduction of new formulations that allow for once- or twice-daily dosing with a good therapeutic response. There are relatively few side effects; chronic cough is the most worrisome and is the most common cause of discontinuing therapy for this group of drugs. Other side effects are occasional first-dose hypotension and blood dyscrasias. Occasionally patients will suffer from rashes, loss of taste, fatigue, or headaches. Because use is strictly contraindicated during pregnancy, other agents should be considered for women who could become pregnant. ACE inhibitors can be used in combination with other agents, including diuretics, calcium-channel antagonists, and b-blockers. In contrast to b-blockers, these medications can be used in patients with asthma, COPD, depression, and diabetes or peripheral vascular disease. For unknown reasons, they are less effective in African Americans unless a diuretic is used concomitantly. Combined with diuretics, the effectiveness of both drugs increases, but hypovolemia may result. If renal failure is present, hyperkalemia may result from potassium supplementation and altered tubular metabolism. Any NSAID, including *aspirin*, may decrease the antihypertensive effectiveness.

Angiotensin Receptor Antagonists

Angiotensin receptor antagonists such as *losartan* and *valsartan* are drugs that interfere with the binding of angiotensin-II to AT-I receptors. They are as effective as ACE inhibitors in lowering blood pressure without causing the side effect of coughing. Their efficacy in protecting the heart and kidney, similar to ACE inhibitors, remains to be established.

Calcium-channel Blockers

Calcium-channel blockers have been a major therapeutic breakthrough for patients with coronary artery disease and have been found to be effective in patients with hypertension and peripheral vascular disease. The mechanism of action is to block calcium movement across smooth muscle, therefore promoting vessel wall relaxation. Calcium-channel blockers are especially useful in treating concurrent hypertension and coronary artery disease. Additionally, these drugs have been shown to be particularly effective in the elderly and African Americans. Side effects noted include headache, dizziness, constipation, and peripheral edema. The introduction of long-acting calcium-channel blockers has made these preparations more amenable for use in hypertension. Heart failure or conduction disturbances are relative contraindications for use of these drugs.

Direct Vasodilators

Hydralazine is a potent vasodilator used for years in obstetrics for severe hypertension associated with preeclampsia and eclampsia. The mechanism of action is direct relaxation of vascular smooth muscle, primarily arterial. Major side effects include headaches, tachycardia, and fluid (sodium) retention that may result in paradoxical hypertension. Several combinations have been used to counter the side effects and enhance antihypertensive effects. Diuretics may be added to reverse fluid retention caused by sodium retention. When used in combination with b-blockers, tachycardia and headaches may be controlled without compromising the objective of lowering blood pressure. Drug-induced lupus erythematosus has been widely stated as a potential side effect but is rare in normal therapeutic doses of 25 to 50 mg three times per day. *Minoxidil* is another extremely potent drug in this class, but it is of limited use to the gynecologist due to its side effects in women (beard growth). Because of *minoxidil's* potency, only experienced practitioners should use it.

Central-acting Agents

Central-acting agents (*methyldopa* and *clonidine*) have long been used in obstetrics. The mechanism of action is to inhibit the sympathetic nervous system, resulting in peripheral vascular relaxation. The popularity of this group of drugs has been limited by side effects such as taste disorders and dry mouth, as well as the need for frequent dosing (except for the transdermal form of clonidine). Sudden withdrawal of clonidine may precipitate a hypertensive crisis and induce angina. The clonidine withdrawal syndrome is more likely with concomitant use of b-blockers. Compliance is always a major issue in patient care, and side effects can have a major impact. With the introduction of new classes of drugs with improved efficacy and reduced side effects, the use of medications in this class is expected to decline.

Monitoring Therapy

For patients with slightly elevated blood pressure who are being managed with lifestyle modification, blood pressure readings should be monitored frequently by a professional nurse, the patient, or medical office staff at 1- to 2-week intervals. If the patient has other diseases (i.e., cardiovascular or renal), therapy should be initiated earlier and should be directed to the target organ. If lifestyle modification alone is successful, close monitoring is necessary at 3- to 6-month intervals. When lifestyle modification is unsuccessful, blood pressure medication should be administered to decrease target organ disease.

When beginning therapy, concurrent medical conditions that can be treated with a common agent should be considered. Gender, as a consideration in choosing an antihypertensive agent, has been found unimportant. Concurrent diseases that are important include (a) migraine headaches, for which b-blockers or calcium-channel blockers may be the best choice, (b) diabetes mellitus, for which ACE inhibitors should be used, and (c) patients who have had myocardial infarctions who should receive b-blockers because they reduce the risk for sudden death and recurrent myocardial infarctions. In addition, African Americans are noted to respond better to a combination of diuretics and calcium-channel blockers.

Once antihypertensive medications are initiated, monitoring should be frequent. Selected agents and dosages for therapy are found in [Table 9.7](#) and are not meant to be all-inclusive. Patients capable of home blood pressure monitoring should be encouraged to measure blood pressure at the same time twice weekly ([32](#)) and maintain a log for physician review of effectiveness of therapy. Once medications are begun, a return appointment should be scheduled in 2 to 4 weeks to monitor effectiveness and side effects. Where possible, single agents (monotherapy) should be used to improve compliance. Monotherapy should control 50% to 60% of patients with mild-to-moderate hypertension. If initial doses are ineffective, then a higher dose should be used prior to changing agents. If resistance to therapy continues, then a different class may be started or a second drug should be added.

Medication (Class)	Normal Daily Dosage (mg/day) and Interval	Dispensing Unit (mg)
ACE Inhibitors		
Enalapril	5-40 (qd, bid)	2.5, 5, 10, 20
Lisinopril	10-50 (qd, bid)	2.5, 5, 10, 20, 30, 40
Calcium channel blockers		
Verapamil, sustained release	120-480 (qd)	120, 180, 240, 360
Diltiazem, sustained release	120-360 (bid)	60, 90, 120
β-Blockers		
Propranolol	1-30 (qd)	1, 2, 5, 10
Mixed α- and β-Blockers		
Labetalol	200-800 (bid)	100, 200, 300
Diuretics		
Hydrochlorothiazide	12.5-50 (qd)	25, 50
Furosemide (potassium sparing)	30-120 (qd)	50, 100
β-Blockers		
Propranolol (lipid soluble)	50-150 (qd)	40, 80, 120, 160
Atenolol (water soluble)	50-100 (qd)	50, 100
Angiotensin receptor antagonists		
Losartan	25-100 (qd)	25, 50, 100

Table 9.7. Selected Medications and Dosage for Control of Essential Hypertension

If intolerable side effects develop, a different class of medications should be started and monitored. In the past, step therapy was used, starting with thiazides, followed by the addition of β -blockers, and finally followed by vasodilator drugs. The newer drugs (ACE inhibitors, postadrenergic ganglionic blockers, and calcium-channel blockers) are more potent, have longer half-lives, and may be used as single agents. Patients whose blood pressure is difficult to control with monotherapy should be considered for referral. Causes of resistance to therapy include diseases and secondary causes of hypertension missed during the initial evaluation, unrecognized early end-stage disease, and poor compliance. Patients with evidence of target-organ disease should also be considered for transfer or referral to the appropriate specialist for more intensive diagnostic workup and therapy.

Cholesterol

It has been stated that cholesterol is the most highly decorated small molecule in biology ([33](#)). The dietary influence of cholesterol on atherosclerosis and its relationship to hypertension and cardiovascular events (myocardial infarction and stroke) has been widely debated in both the scientific and lay communities ([34](#)). The controversy centers on the influence of dietary cholesterol in risk assessment and prevention of cardiovascular disease ([35](#)). Many assume that all cholesterol and fat in the diet have negative health consequences. Furthermore, cholesterol metabolism is complex and our understanding in some cases is extrapolated from animal models. The role of cholesterol testing (who, when, and at what age) is hotly debated among health care professionals. Cholesterol testing is fraught with multiple variables that affect results. The purpose of the following discussion is to identify patients at risk for complications of hypercholesterolemia and better understand overall metabolism and therapy.

Terms and Definitions

Exclusively LDL and HDL cholesterol do not determine cholesterol metabolism, despite popular discussion. Cholesterol is usually found in an esterized form with various proteins and glycerides that characterize the stage of metabolism. The following components are important lipid particles in cholesterol metabolism.

Chylomicrons These are large lipoprotein particles that consist of dietary triglycerides and cholesterol. Chylomicrons are secreted in the intestinal lumen, absorbed in the lymph, and then passed into general circulation. In adipose tissue and skeletal muscle, they adhere to binding sites on the capillary wall and are metabolized for energy production.

Lipoprotein Particle A lipoprotein particle is made from three major components. The core consists of nonpolar lipids (triglycerides and cholesterol esters) that are present in varying amounts, depending on which stage of the metabolic pathway they are found. Surrounding the nonpolar core is a surface coat of phospholipids that is made of apoproteins and structural proteins.

Apoprotein Attached to all lipoprotein particles is an apoprotein. This is a specific recognition protein exposed at the surface of a lipoprotein particle. Apoproteins have specific receptors and demarcate the stage of cholesterol metabolism. Certain apoproteins are associated with specific types of cholesterol. For example, apoprotein A-I and apoprotein A-II are associated with HDL cholesterol, the so-called *scavenger cholesterol*. Apoprotein C-II has additional activity as a cofactor for lipoprotein lipase.

Lipoprotein Class Lipoprotein particles are separated into five classes that are dependent on physical characteristics. Lipoprotein classes are determined by the separation of lipids in an electrophoretic field; however, *in vivo* they are in a continuum. The various cholesterol metabolites are separated by density. As lipoprotein particles are metabolized and lipids are removed for energy production, they become denser. Additionally, attached apoproteins are modified as cholesterol moves from the so-called *exogenous pathway* (dietary) to the *endogenous pathway* (postabsorption and metabolized by the liver).

Subdivisions of the lipoprotein classes are described below and summarized in [Fig. 9.3](#).

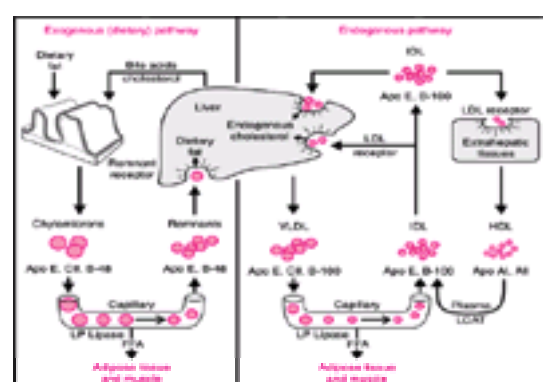

Figure 9.3 Metabolic pathways for lipid metabolism.

Prehepatic Metabolites

Chylomicrons and Remnants These metabolites are composed of major lipids and apoproteins of the A, B-48, C, and E classes. Their density is 1.006 g/ml. As expected, these are large particles made up of dietary cholesterol molecules that are absorbed with triglycerides.

Posthepatic Metabolites

Very-low-density Lipoprotein These metabolites are transient remnants found after initial liver metabolism and comprise only 10% to 15% of cholesterol particles. Very-low-density lipoproteins (VLDLs) consist of endogenously synthesized triglycerides with a density of 1.006 g/ml. The diameter is considerably smaller than that of the chylomicrons, ranging from 300 to 800 nm.

Intermediate-density Lipoprotein (IDL) The major lipids in this group consist of cholesterol esters that are posthepatic remnants but are derived from dietary sources. Associated apoproteins are B-100, C-III, and E. Apoprotein B-48 is lost after the initial hepatic metabolism and B-100 is substituted. Apoprotein E, which is a liver recognition apoprotein, is found only in VLDLs and intermediate-density lipoproteins (IDL). IDL metabolites are transient lipoproteins and are measured only in certain pathologic conditions. The density is 1.019 g/ml with a diameter of 250 nm—a very significant drop in diameter from 800 nm found in the VLDL.

LDL Cholesterol The major lipid in this group is the cholesterol ester and is associated with B-100 apoprotein. LDL cholesterol accounts for approximately 60% to 70% of total cholesterol. Elevated levels of LDL cholesterol have been associated with increased rates of myocardial infarction in women over 65 years of age. There is a structural class called LDL(a') that is associated with myocardial infarction. Several families have been described with structurally abnormal B-100 apoprotein and are at high risk for myocardial infarction due to lipid buildup and premature atherosclerosis (36). Density ranges from 1.019 to 1.063, with a diameter of 180 to 280 nm.

HDL Cholesterol This is composed of cholesterol esters with apoproteins A-I and A-II. These particles account for 20% to 30% of total cholesterol and are the densest, with a weight of 1.063 to 1.120 g/ml. The diameter of this group of proteins is 50 to 120 nm.

Metabolism

Cholesterol metabolism is divided into two pathways. The first pathway is the exogenous pathway derived from dietary sources. The second pathway is called the endogenous pathway or the lipid transport pathway. Individual variations exist in the ability to metabolize cholesterol, with patients classified as normals, hyporesponders, and hyperresponders (37). Hyporesponders may be given cholesterol-loaded diets with no effect on serum cholesterol measurements. The hyperresponder, in contrast, has high serum cholesterol levels, regardless of dietary intake. Explanations of differences are well described in animal models but not in humans.

Once a meal is eaten, cholesterol is transported as dietary fat. The average American diet contains approximately 100 grams of triglyceride and approximately 1 gram of cholesterol daily. Dietary fats are saponified in the intestinal lumen by pancreatic lipases and synthesized into chylomicrons that are first absorbed by active transport into intestinal lymph and then into the general circulation. Capillaries in the adipose tissue and skeletal muscle are able to incorporate triglycerides and fats by the action of lipoprotein lipase. As schematically depicted in Fig. 9.3, metabolic utilization may occur during either phase of metabolism (e.g., dietary or endogenous). During absorption and synthesis of chylomicrons, *apoproteins* are incorporated. Apoprotein C-II is important as a cofactor to activate lipoprotein lipase, which enzymatically liberates fatty acids (for energy) and monoglycerides. These fatty acids may enter endothelial, adipose, or muscle cells, where they are either oxidized into active metabolic products or reesterified to triglycerides.

Triglycerides are found in the core lipoprotein particles and are removed through the capillary endothelium and the chylomicron. Predominant apoproteins are B-48 or B-100 and E apoproteins. When chylomicron synthesis occurs in the intestine, the primary B apoprotein is B-48; upon leaving adipose cells, muscle cells, or the liver the second B apoprotein, or B-100, is substituted. Abnormal forms of B-100 are associated with premature cardiovascular disease and are currently used as genetic markers in research laboratories (38). Another apoprotein added during cellular metabolism is apoprotein E. Apoprotein E plays an important role in liver recognition of chylomicron remnants. Theories suggest that hypo- and hyperresponders to dietary cholesterol may be secondary to the liver's ability to recognize and metabolize apoprotein E (39). In the animal model, populations with large numbers of liver receptors for apoprotein E easily metabolize cholesterol and are labeled hyporesponders. Individuals with a reduced number of apoprotein E receptors are unable to metabolize cholesterol as readily, which increases the number of lipid particles in their blood. These individuals are labeled hyperresponders. Despite dietary cholesterol modification, these individuals continue to have high serum cholesterol levels.

After metabolic degradation of dietary chylomicrons, apoprotein substitution occurs and liver metabolism of cholesterol esters begins. Lipid transport is now in the endogenous pathway. Carbohydrates are synthesized to fatty acids and esterified with glycerol to form triglycerides. These newly formed triglycerides are not of dietary origin and are placed in the core of VLDLs. VLDL particles are relatively large and carry 5 to 10 times more triglyceride than cholesterol esters with apoprotein B-100. Hypertriglyceridemia is an independent risk factor for cardiovascular disease (40). The relationship between hypertriglyceridemia and cardiovascular disease is well known but poorly defined.

VLDL particles are transported to tissue capillaries, where they are broken down to usable fuels, monoglycerides, and fatty acids. Apoproteins C and E are still present within this lipoprotein particle. After metabolic enzymatic degradation in the peripheral tissues, the IDLs remain. IDLs are either catabolized in the liver by binding to LDL receptors or are modified in the peripheral tissues. As noted above, they are associated with apoprotein E receptors, the liver recognition receptors. During the transformation from IDL to LDL cholesterol, all apoproteins are removed, except apoprotein B-100. The LDL cholesterol, or the so-called *high-risk cholesterol*, is found in high circulating levels.

Despite the negative connotation of LDL cholesterol in cardiovascular research, it is a very important cellular metabolite that is a precursor for adrenocortical cells, lymphocytes, and renal cells. LDL receptors on cell surfaces allow for LDL cholesterol incorporation into cellular metabolism. In target cells, these lipid particles are hydrolyzed to form cholesterol for use in membrane synthesis and as precursors for steroid hormones (such as estrogen and progesterone). Once the cell has incorporated the necessary cholesterol, the cell surface receptor reforms limiting further absorption. The liver uses the LDL cholesterol for bile acids synthesis and free cholesterol, which is secreted into the bile. In the normal human, 70% to 80% of LDL is removed from the plasma each day and secreted in the bile by utilization of the LDL receptor pathway.

The final metabolic pathway is the transformation of HDL cholesterol in extrahepatic tissue. HDL cholesterol carries the plasma enzyme lecithin cholesterol acyltransferase (LCAT). LCAT allows HDL cholesterol to resynthesize lipids to VLDL cholesterol and recycle the lipid cascade. The fate of newly synthesized VLDL cholesterol is the same as absorbed VLDL and it eventually becomes LDL cholesterol. HDL cholesterol acts as a "scavenger" and therefore reverses the deposit of cholesterol into tissues. There is good evidence that HDL cholesterol is responsible for the reversal of atherosclerotic changes in vessels, hence the term *the good cholesterol*. (41,42).

Hyperlipoproteinemia

When cholesterol is measured, various fractions are reported. Plasma cholesterol or total cholesterol consists of cholesterol and unesterified cholesterol fractions. If triglycerides are analyzed in conjunction with cholesterol, then assumptions can be made concerning which metabolic pathway may be abnormal. The elevation of both total cholesterol and triglyceride levels signifies a problem with chylomicrons and VLDL synthesis. If the triglyceride-to-cholesterol ratio is greater than 5:1, then the predominant fractions are chylomicrons and VLDL. When the triglycerides-to-cholesterol ratio is less than 5:1, then the problems exist in the VLDL and LDL fractions. Establishing a "normal population" and then setting various limits at the 10th and 90th percentiles define hyperlipoproteinemias. A recent standard for women sets the 80th percentile for cholesterol at 240 mg/dl and the 50th percentile at 200 mg/dl (Table 9.8). Researchers continue to argue that populations vary and may have different cutoff limits depending on the amount of fat versus vegetable and fiber consumption within the diet (43).

Initial Classification	
Total cholesterol	
<200 mg/dL	Desirable blood cholesterol
200-239 mg/dL	Borderline high blood cholesterol
≥240 mg/dL	High blood cholesterol
HDL cholesterol	
<35 mg/dL	Low HDL cholesterol
Triglycerides	
<100 mg/dL	Normal
200-400 mg/dL	Borderline high
400-1000 mg/dL	High
>1000 mg/dL	Very high

HDL, high-density lipoprotein.

Table 9.8. Initial Classification Based on the Total Cholesterol and HDL Cholesterol Levels

Laboratory Testing

The consensus of most researchers is that office laboratory analyses of total cholesterol are virtually worthless as an accurate measure of cholesterol. The measurement techniques are extremely variable. In well-controlled studies, it has been shown that the variation in readings is large (44). Therefore, despite their popularity, they are totally inadequate for either screening or monitoring treatment of patients with hypercholesterolemia.

There are multiple environmental causes of variation in cholesterol measurements (45). Major sources of variation within individuals include diet, obesity, smoking, ethanol intake, and the effects of exercise. Other clinical conditions that affect cholesterol measurements include hypothyroidism, diabetes mellitus, acute or recent myocardial infarction, and recent weight changes. Other variables include the fasting state, position while the sample is drawn, and the use and duration of venous occlusion. Anticoagulants and storage and shipping conditions also can alter lipoprotein measurements (46).

Intraperson variation has been well described. If a single individual has total cholesterol measured 4 times during the day, the variation is 2.5%. If retested within 1 month, on a twice-weekly basis, the coefficient of variation increases to 4.8%. Monthly measurements over 1 year may result in a variation as high as 6.1%. Therefore, for accurate standardization, at least two and preferably four specimens taken 1 month apart should be collected in the same dietary state in order for a lipid value to be considered accurate.

Age and sex contribute to variations in total cholesterol measurements. Before age 50, women have lower lipid values than men; after age 50, lipid values increase. Exogenous oral conjugated estrogens are thought to contribute to this effect. The genetic basis for interperson variability is thought to be mediated by apolipoprotein receptors.

Seasonal variation also occurs. In December or January, lipid samples taken were found to be approximately 2.5% higher than those measured in June or July. LDL cholesterol and total cholesterol were higher, with no significant variation found for HDL cholesterol. The index population was found to weigh approximately 6% more in December and January than in June or July, which may account for the differences.

The effect of diet and obesity has been well studied. Some researchers felt this effect may be related to hypo- and hyperresponder status. However, weight reduction in an obese individual generally affects the triglyceride level, which may decrease as much as 40%. Total cholesterol and LDL cholesterol levels decrease less than 10% with diet changes; however, HDL cholesterol levels increase approximately 10%. Weight gain negates any benefit from prior weight loss. Therefore, accuracy of lipid measurements depends on the stability of the patient's weight.

Alcohol and cigarette smoking are well-known modifiers of cholesterol levels. Moderate sustained alcohol intake is noted to increase HDL cholesterol and decrease LDL cholesterol levels; however, there is a complementary increase in triglyceride levels. Alcohol has a protective effect when taken in moderation (defined as approximately 2 ounces of absolute alcohol per day), but this effect is negated with higher quantities. The increase in HDL cholesterol levels is in the HDL₃ fraction, important in the scavenger mechanism of removing LDL cholesterol. Smoking has the opposite effect, by increasing LDL cholesterol and triglyceride levels and decreasing HDL cholesterol levels. The HDL₃ fraction decreases with cigarette smoking. The critical number of cigarettes smoked is 15 to 20 per day, regardless of sex. Caffeine has a mixed effect on lipoprotein measurements but should be avoided in the 12 hours prior to blood collection.

Exercise is an important variable in overall risk management for heart disease. Federal agencies have recognized that moderate levels of exercise are as important in overall cardiovascular health as control of hypertension and cessation of cigarette smoking. Strenuous exercise lowers the concentrations of triglycerides and LDL and increases HDL in the serum. To obtain accurate measurements, vigorous exercise should not be performed within 12 hours of obtaining blood samples.

Because of the diurnal variation of blood triglyceride levels, blood samples should be collected in the morning after a 12-hour fast. Excessive quantities of water should not be consumed before the blood is drawn. The patient should be sitting quietly for approximately 15 minutes prior to the blood draw. Patients who were placed in the supine position for 30 minutes and then required to stand for 30 minutes had a 9% increase in total cholesterol, LDL cholesterol, and VLDL cholesterol fractions, while the HDL cholesterol increased by 10% and triglyceride levels increased by 12%. Additionally, if the tourniquet time is more than 5 minutes, causing vascular stasis, all measurements increase by 10% to 15%. After even 2 minutes of venous occlusion, serum cholesterol increases can be 2% to 5%. Therefore, collection of the cholesterol sample should be done first if multiple blood samples are required. Finger-stick samples are approximately 8.5% lower for all component measurements than venous blood due to contamination from interstitial and lymph fluids.

Collection tube anticoagulants may have a profound effect on lipoproteins. The total cholesterol level has been observed to change depending on the anticoagulant used: ethylenediaminetetraacetic acid (EDTA) increases measurements by 3%, oxalate increases by 9%, citrate increases by 14%, and fluoride by 18%. EDTA is considered the standard anticoagulant for cholesterol measurement. If cholesterol measurements cannot be run in a reasonable time, the samples may be stored at 0°C for up to 4 days, at -20°C for 6 months, or at -50° to -80°C indefinitely. Specimens transported by mail should be placed on dry ice.

One of the most important aspects of overall standardization of lipoprotein measurements is the laboratory used. Currently, laboratory levels should be within ±5% of CDC standards for lipoprotein measurements. Approximately 80% of laboratories in one study met this criteria (47). Therefore, to accurately assess cholesterol values, the clinician should be knowledgeable about the laboratory used. It may be useful to consult with the clinical pathologist of a hospital to determine if the laboratory complies with CDC standards for cholesterol and lipoprotein measurements.

Disease States and Medication Effects

Certain disease states and medications have an impact on cholesterol measurements. As noted previously, diuretics and propranolol increase triglyceride and decrease HDL cholesterol levels. Diuretics may also increase total cholesterol levels. Patients with diabetes mellitus, especially those with poor control, may have very high levels of triglycerides, LDL cholesterol, and decreased HDL cholesterol. This may explain why they are prone to cardiovascular diseases. Diabetics under "tight" control generally have improved lipoprotein levels.

Pregnancy is associated with decreased total serum cholesterol in the first trimester with continuous increases of all fractions over the second and third trimesters (48). The LDL and triglyceride concentrations are the lipoproteins most affected by pregnancy. Limited studies have been done on standardization of lipid levels in pregnancy. Because of the short span, interventions would be of little clinical significance. Lastly, patients with hypothyroidism are also noted to have increased levels of total cholesterol and LDL cholesterol.

Management

Once hyperlipidemia is confirmed on at least two separate occasions, secondary causes should be diagnosed or excluded by taking a detailed medical and drug history, measuring serum creatinine and fasting glucose levels, and performing thyroid and liver function tests. For obese patients, diet and weight loss is the first

level of therapy. [Figure 9.4](#) shows a suggested algorithm for cholesterol control based on the LDL level. Cholesterol- and fat-lowering diets abound in most bookstores and allow the patient to choose a diet she will best follow. The role of exercise and cigarette cessation should be stressed to all patients. Patients with family history of cardiovascular disease (history of premature coronary artery problems and strokes) should be tested and started on conservative programs when they are in their twenties. After 3 to 6 months, if the LDL cholesterol level remains above 160 mg/dl, or above 130 mg/dl with risk factors, medical therapy should be initiated. Since the second report of the Adult Treatment Panel of the National Cholesterol Education Program (NCEP ATP II) was published in 1993, evidence from recent clinical trials has suggested a lower treatment threshold for patients with established coronary artery disease.

Figure 9.4 Treatment decisions based on the LDL cholesterol level. (Adapted from the Second Report of the National Cholesterol Education Program (NCEP) Expert Panel on the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. *JAMA* 1993;269:3015–3023.)

The bile acid-binding resins cholestyramine and colestipol were the mainstay of therapy for years but are associated with constipation, bloating, nausea, and heartburn. These agents also may interfere with the absorption of many drugs, which has limited their usefulness. *Nicotinic acid* (500 mg 3 times a day) decreases triglyceride, LDL, and lipoprotein(a) levels and increases HDL levels more than any other drug. However, flushing, pruritus, and gastrointestinal distress are a few of the adverse effects of nicotinic acid. Starting at a low dose and pretreating with *aspirin* (325 mg) or *ibuprofen* (200 mg) can minimize the facial flushing. Fibric acid derivatives like clofibrate and gemfibrozil are used mainly to lower triglycerides and increase HDL but may increase LDL levels in some patients. The 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors (“statins”) include *atorvastatin*, *fluvastatin*, *lovastatin*, *pravastatin*, and *simvastatin*. These medicines inhibit HMG-CoA reductase, the enzyme that catalyzes the rate-limiting step in cholesterol synthesis. Several clinical trials have shown that *pravastatin*, *simvastatin*, and *lovastatin* have a beneficial effect in cardiovascular disease. Statins are generally better tolerated than other lipid-lowering drugs, but severe myalgias, muscle weakness with increases in creatine phosphokinase levels, and rarely rhabdomyolysis leading to renal failure have been reported. Symptomatic hepatitis is rare, but serum glutamic oxaloacetic transaminases should be measured 6 and 12 weeks after initiation of therapy, and semiannually once therapeutic levels are reached. The usual daily starting doses for the statin drugs are the following: *atorvastatin* (10 mg), *fluvastatin* (20 mg), *lovastatin* (20 mg), *pravastatin* (20 mg), and *simvastatin* (20 mg) (49).

Diabetes Mellitus

Diabetes mellitus (DM) is a chronic disorder of altered carbohydrate, protein, and fat metabolism from a deficiency in the secretion or function of insulin. The disease is defined by either fasting hyperglycemia or elevated plasma glucose levels after an oral glucose tolerance test (OGTT). The major complications of DM are primarily vascular and metabolic complications. Only 50% of an estimated 13 million Americans with DM have been diagnosed. The prevalence of DM is higher in women and certain ethnic groups, although a background rate in the general population is 2.5% (50). Risk factors for DM are (a) age greater than 45 years, (b) adiposity or obesity, (c) a family history of diabetes, (d) race and ethnicity, (e) hypertension (140/90 or greater), (f) HDL cholesterol less than or equal to 35 mg/dl with or without a triglyceride level greater than or equal to 250 mg/dl, and (g) history of gestational diabetes or delivery of baby over 9 pounds. Lifestyle may be the most important variable for type 2 diabetes, as discussed below. Major complications of DM include blindness, renal disease, gangrene of an extremity, heart disease, and stroke. Diabetes is one of the four major risk factors for cardiovascular disease (51).

Classification

In January of 1999, the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus published a report revising the system that had been in use since 1979 (52). The goal of the revision is to provide guidelines for nomenclature and testing that may reduce diagnostic confusion and improve patient well-being (Table 9.9). The terms insulin-dependent diabetes mellitus (IDDM) and non-insulin-dependent diabetes mellitus (NIDDM) should be eliminated to reduce confusion regarding the meaning of each of these categories. These terms should be replaced by the designations of type 1 and type 2 diabetes mellitus.

1. Type 1 diabetes (characterized by pancreatic destruction leading to insulin deficiency)
A. Idiopathic
B. Insulin-mediated
2. Type 2 diabetes (a combination of insulin resistance and some degree of inadequate insulin secretion)
3. Other types of diabetes
A. Impaired glucose tolerance (IGT)
B. Endocrinopathies (Cushing's syndrome, acromegaly, pheochromocytoma, hyperaldosteronism)
C. Drug- or chemical-induced
D. Diseases of the exocrine pancreas (pancreatitis, neoplasia)
E. Infections
F. Genetic defects of β -cell function and insulin action
G. Gestational diabetes mellitus

Adapted from: The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. *Diabetes Care* 2000;23:44-54E.

Table 9.9. Classification of Diabetes Mellitus

Type 1 Diabetes Mellitus

The major metabolic disturbance of type 1 diabetes is the absence of insulin from destruction of β cells in the pancreas. Insulin is necessary for glucose metabolism and cellular respiration. When insulin is absent, ketosis results. The cause of type 1 diabetes is unknown; however, data suggest an autoimmune factor from either a viral infection or toxic components in the environment. Studies in the past decade have shown a correlation between many autoimmune diseases and the human leukocyte antigens (HLA).

Insulin-sensitive tissues (muscle, liver, and fat) fail to metabolize glucose efficiently in the absence of insulin. In uncontrolled type 1 diabetes, additional excess of counterregulatory hormones (cortisol, catecholamines, and glucagon) contributes to further metabolic dysfunction. In the absence of adequate amounts of insulin, increasing breakdown products of muscle (amino acid proteolysis), fat (fatty acid lipolysis), and glycogen (glucose glycogenolysis) are recognized. Additionally, there is an increase in glucose production from noncarbohydrate precursors from gluconeogenesis and ketogenesis in the liver. If not promptly treated, severe metabolic decompensation (i.e., diabetic ketoacidosis [DKA]) will occur and may lead to death.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus is a heterogeneous form of diabetes that commonly occurs in older age groups (>40 years), and is more frequently noted to have familial tendency than type 1 diabetes. In contrast to an absence of insulin that occurs with type 1 diabetes, altered metabolism of insulin occurs in type 2

diabetes, resulting in insulin resistance. This condition is characterized by impaired glucose uptake in target tissues. A compensatory increase in insulin secretion results, with higher-than-normal circulating insulin levels (53). Obesity is present in 85% of affected patients. The cause of type 2 diabetes is unknown, but defects in both the secretion and action of insulin are suspected.

Many patients diagnosed with type 2 diabetes at an early age eventually exhaust endogenous pancreatic insulin and require injected insulin. When under severe stress, such as infection or surgery, they may develop DKA, or a hyperglycemic hyperosmolar nonketotic state (HHNS). Risk factors for type 2 diabetes include ethnicity, obesity, strong family history of DM, sedentary lifestyle, impaired glucose tolerance, upper body adiposity, history of gestational diabetes, and hyperinsulinemia. The presence of risk factors strongly influences the development of type 2 diabetes in susceptible populations.

Diagnosis

Three methods are available to diagnose diabetes mellitus in nonpregnant adults:

1. A single fasting blood glucose greater than or equal to 126 mg/dl on two separate occasions;
2. A random blood glucose equal to or above 200 mg/dl in an individual with classic signs and symptoms of diabetes (polydipsia, polyuria, polyphagia, and weight loss); and
3. A 2-hour OGTT (fasting sample, 60- and 120-minute samples) after a 75-gram load of glucose.

A 2-hour OGTT should not be performed if the first two criteria are present.

Diagnostic criteria for impaired glucose intolerance (IGT) testing are a fasting glucose \geq 110 mg/dl but <126 mg/dl.

The 2-hour OGTT should be performed under the following conditions:

1. A 10-hour fast precedes morning testing.
2. The patient should sit throughout the procedure.
3. No smoking is permitted during the test interval.
4. Caffeinated beverages should not be consumed.
5. More than 150 grams of carbohydrates should be ingested for 3 days prior to the test.
6. No drugs should be taken prior to the test.
7. The patient should not be bedridden or under stress.

Patients should be considered for diabetes mellitus testing if the following factors are present:

- Age \geq 45 years (repeat at 3-year intervals)
- Classic signs and symptoms of diabetes (i.e., polyuria, polydipsia, polyphagia, and weight loss)
- Ethnic groups at high risk (Pacific Islanders, Native Americans, African Americans, Hispanic Americans, Asian Americans)
- Obesity
- First-degree relative with diabetes
- Gestational diabetes or birth of a baby over 9 pounds
- Hypertension (\geq 140/90)
- HDL cholesterol levels \leq 35 mg/dl or triglyceride level \geq 250 mg/dl
- Impaired glucose tolerance based on previous testing

Assessment of Glycemic Control

The only acceptable method for assessment of glycemic control is by determination of blood glucose by the direct enzymatic method and not by urine values. Urine values have been proven not to reflect current blood values. In the past decade multiple adequate techniques using test strips and meters have been introduced. These machines work well but reflect whole blood determinations, not serum values. Upgrades of testing strips (in which blood does not need to be wiped away) and glucometers with memory storage have made home glucose monitoring more reliable. Urine tapes to test for ketones are useful and quick methods for assessing ketosis. If the urine is consistently positive for ketones and blood glucose values remain above 300 mg/dl, the patient should seek medical advice. Physician treatment guidelines are in [Table 9.10](#) and patient guidelines in [Table 9.11](#). A 10-year multicenter study for diabetes control and complication trial (DCCT) performed under the auspices of the National Institutes of Health (NIH) showed a marked reduction (40% to 50%) in complications of neuropathy, retinopathy, and nephropathy when patients with type 1 diabetes mellitus received intensive therapy (accomplished by a team approach) as compared with those who received standard therapy.

Standard diagnosis and therapy of diabetes mellitus (DM).

The oral glucose tolerance test (OGTT) is not recommended for routine clinical use because of its higher cost, time requirements, and limited reproducibility.

Multiple abnormal laboratory values to meet several criteria (fasting and random glucose values, to name signs and symptoms and complications, and to meet tests for average risk tests).

These patients are at high risk with appropriate dietary, exercise, and social interventions.

Standard criteria with history, evidence for blood or urinary ketones, symptoms, or other laboratory abnormalities.

If asymptomatic or presymptomatic, refer to a neurologist.

Standard criteria of hemoglobin A1c (HbA1c) or glycosylated hemoglobin (GHb) as a standard.

Check test and results at least 1 year.

Patients to use finger stick blood glucose for daily diabetic control.

Monitor chronic glucose control by HbA1c every 3 to 6 months in the office.

Initial general health examinations should consist of a complete history and physical examination and the following laboratory tests: CBC, uric acid, cholesterol, electrolyte panel, serum urea nitrogen, creatinine, liver function tests, urine for microalbuminuria and ECG (starting at age 40 or earlier, repeat yearly).

Small hypoglycemic agents or drugs that do not cause hypoglycemia may be considered if fasting blood glucose is not controlled by diet and exercise, if the patient has low body weight, or if the patient is unable to tolerate insulin or oral hypoglycemic agents.

If the HbA1c is \geq 7.0% or the postprandial glucose is \geq 200 mg/dl, consider the oral hypoglycemic agents, insulin, or both.

If the fasting serum glucose is \geq 126 mg/dl consistently on two occasions, or over 200 mg/dl consistently on one occasion, or if the patient has symptoms of hyperglycemia, or if the patient has microalbuminuria, or if the patient has retinopathy, or if the patient has nephropathy, or if the patient has neuropathy, or if the patient has other complications of diabetes mellitus, refer to a specialist.

Table 9.10. Physician Guidelines in the Therapy of Diabetes Mellitus

- Initiate an ADA reducing diet (50% CHO, 30% fat, 20% protein, high fiber) with three meals a day.
- Maintain ideal body weight or reduce weight by 5% to 15% in 3 months if obese.
- Modify risk factors (smoking, exercise, fat intake).
- Check fasting blood glucose by finger stick daily for 2 months. If FBG declines, no other therapy is needed. If FBG does not decline or increases, use of an oral hypoglycemic agent may be considered.

ADA, American Diabetes Association; CHO, carbohydrate; FBG, fasting blood glucose. Adapted from The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. Diabetes Care 2000;23:56-542.

Table 9.11. Patient Guidelines for Treatment of Type 2 Diabetes

Treatment of Type 2 Diabetes Mellitus

Diet is the most important component of diabetes mellitus management and usually the hardest way to achieve control. Three major strategies are used: weight loss, low fat diet (<30% of calories from fat), and physical exercise. Obese patients should reduce their weight to ideal body weight. Metabolic advantages of weight reduction are improved lipid profile and improved glucose control secondary to increased insulin sensitivity and decreased insulin resistance. The greater the weight loss, the greater the improvement in lipid disorders. Physical exercise promotes weight loss and improves insulin sensitivity and dyslipidemia in those who are in high-risk groups for cardiovascular and microvascular diseases (54).

Oral hypoglycemic agents (OHAs) are recommended for many type 2 diabetic patients (55). First- and second-generation sulfonylureas are currently the only agents approved by the FDA. Other classes of drugs like biguanides, thiazolidinediones, and α -glucosidase inhibitors have recently been introduced which have different effects in patients with type 2 diabetes than sulfonylureas. Currently available sulfonylurea formulations and biguanides are listed in Table 9.12. The mode of action of sulfonylureas is based on two different mechanisms, (a) enhanced insulin secretion from the pancreas, and (b) an extrapancreatic effect which is poorly understood. Endogenous insulin secretion (as measured by C peptide) is necessary for OHAs to work. Additionally, if the fasting blood glucose in a patient on an adequate diabetic diet is greater than 250 mg/dl, there is little effect. OHAs fail to control glucose in 3% to 5% of patients annually. Frequent evaluation to monitor control (every 3 months) is important. If glucose levels cannot be controlled with oral hypoglycemic agents like sulfonylureas, then *insulin*, *metformin* (a biguanide), or an α -glucosidase inhibitor should be started and referral should be considered because of the increased rate of complications experienced by this group.

OHA	Trade Name	Daily Dose	Duration of Action (hrs)
Tolbutamide	Orinase	750 mg-3.0 g in divided doses	6-12
Tolazamide	Tolinase	200-1000 mg in divided doses	12-24
Acetohexamide	Dymelor	250-1500 mg in a single dose	12-24
Chlorpropamide	Diabinese	100-500 mg in a single dose	up to 60
Glyburide	Micronase, DiaBeta	2.5-20 mg variable dose	10-24
Gliclazide	Glucotal	2.5-40 mg variable dose	3-8
Metformin	Glucophage	500 mg-2.5 grams in 2 or 3 divided doses	6-12

OHA, oral hypoglycemic agent.

Table 9.12. Commonly Used Oral Hypoglycemic Agents

Thyroid Diseases

Thyroid disorders are more common in women and some families, although the exact inheritance is unknown (56). In geriatric populations, the incidence may be as high as 5% (57). Unfortunately, the laboratory diagnosis of thyroid disease can be difficult because of altered hormonal states such as pregnancy and exogenous hormones. Thyroid hormones act in target tissues by binding to nuclear receptors, which induce changes in gene expression (58). Extrathyroidal conversion of thyroxine (T_4) to triiodothyronine (T_3) takes place in target tissue. T_3 binds the nuclear receptor with higher affinity than T_4 , which makes T_3 more biologically active. Pituitary thyroid-stimulating hormone (TSH) and hypothalamic thyrotropin-releasing hormone (TRH) regulate hormone production and thyroid growth by normal feedback physiology. Thyroid-stimulating immunoglobulins (TSIs), once known as long-acting thyroid stimulator (LATS), bind to the TSH receptor that results in hyperthyroid Graves' disease.

Plasma proteins bind over 99% of circulating T_4 and T_3 , predominately to thyroxine-binding globulin (TBG), and the remaining 1% of thyroid hormones are free. Free levels of thyroid hormones remain constant despite physiologic or pharmacologic alterations. Regardless of total serum rotein levels, active thyroid hormone remains stable. In healthy women, transitions from puberty to menopause do not alter free thyroid hormone concentrations. Excess endogenous or exogenous sources of estrogen increase TBG plasma concentration by decreasing hepatic clearance. Androgens (especially testosterone) and corticosteroids have the opposite effect by increasing hepatic TBG clearance.

Thyroid function tests may be misleading in women receiving exogenous sources of estrogen because of altered binding characteristics. In euthyroid individuals, elevations of thyroid hormone concentrations arise from three mechanisms, (a) increased protein binding because of altered albumin and estrogen states, (b) decreased peripheral conversion of T_4 to T_3 , or (c) rarely occurring congenital tissue resistance to thyroid hormones. The most common alteration in laboratory findings is due to altered estrogen states (hormonal replacement therapy, pregnancy), which complicate interpretation of thyroid function studies. Most laboratories compensate by reporting a free T_4 index or a "T₇" which mathematically corrects for physiologic alterations. If a question arises, consultation with the clinical pathologist should be sought.

Hypothyroidism

Overt hypothyroidism occurs in 2% of women, and at least an additional 5% develop subclinical hypothyroidism. This is especially true in the elderly in whom many of the signs and symptoms are subtle. The principal cause of hypothyroidism is autoimmune thyroiditis (Hashimoto's thyroiditis). A familial predisposition is observed in many cases, but the specific genetic or environmental trigger is unknown. The incidence of autoimmune thyroiditis increases with age, affecting up to 15% of women over 65 years of age. Many have subclinical hypothyroidism that is defined as an elevated serum TSH concentration with a normal serum free T_4 level.

Thyroid replacement therapy usually reverses this condition. Autoimmune thyroiditis may be associated with other endocrine (e.g., type 1 diabetes, primary ovarian failure, adrenal insufficiency, and hypoparathyroidism) and nonendocrine disorders (e.g., vitiligo and pernicious anemia) (59). Therefore, when autoimmune diseases are present, there should be a high degree of suspicion for concurrent thyroid disorders. Iatrogenic causes of hypothyroidism occur after surgical removal or radioactive iodine therapy for hyperthyroidism or thyroid cancer. Forty years ago, radiation was used to treat acne and other dermatologic disorders; these patients have an increased risk of thyroid cancer and require close monitoring. Hypothyroidism rarely occurs secondary to pituitary or hypothalamic diseases from TSH or TRH deficiency but must be considered if symptoms occur after neurosurgical procedures.

Clinical Features

Manifestations of hypothyroidism include a broad range of signs and symptoms including fatigue, lethargy, cold intolerance, nightmares, dry skin, hair loss, constipation, periorbital carotene deposition (causing a yellow discoloration), carpal tunnel syndrome, and weight gain (usually less than 5 to 10 kg). Menstrual dysfunction is common, either as menorrhagia or amenorrhea. Infertility may arise from anovulation, but exogenous thyroid hormone is not useful for women who are anovulatory and euthyroid. Empiric use of thyroid extract, common many years ago, should be discouraged. Common neuropsychiatric symptoms that may be early signs of hypothyroidism include depression, irritability, impaired memory, and dementia in the elderly.

Hypothyroidism is not a cause of premenstrual syndrome (PMS), but worsening PMS may be a subtle manifestation of hypothyroidism (60). Hypothyroidism may cause precocious or delayed puberty. Hyperprolactinemia and galactorrhea are unusual manifestations of hypothyroidism; however, assessment of thyroid function should be considered. A TSH level should be obtained in cases of amenorrhea, galactorrhea, and hyperprolactinemia to distinguish primary hypothyroidism from a prolactin-secreting pituitary adenoma.

Diagnosis

Hypothyroidism should always be confirmed with laboratory studies. Primary hypothyroidism is characterized by the combination of an elevated serum TSH with a low serum free T_4 or free T_4 index. Autoimmune thyroiditis can be confirmed by the presence of serum antithyroid peroxidase (formerly referred to as antimicrosomal) antibodies. Central hypothyroidism, although rare, is distinguished by a low or low-normal serum free T_4 with either a low or inappropriately normal serum TSH concentration.

Therapy

L-thyroxine (T₄) is the treatment of choice for hypothyroidism and is available as levothyroxine (Synthroid or Levothroid) (61). The mode of action is by conversion of T₄ to T₃ in peripheral tissues. A parenteral formulation is available but seldom needed because of the long half-life (7 days) of oral preparations. Absorption may be poor when taken in combination with aluminum hydroxide (common in antacids), cholestyramine, ferrous sulfate, or sucralfate because of binding or chelation. The usual T₄ requirement is weight-related (approximately 1.6 µg/kg) but decreases for the elderly. Normal daily dosage is 0.1 to 0.15 mg, but should be adjusted to maintain TSH levels within the normal range.

In the early 1980s, many clinicians thought that by increasing the serum T₄ to mildly elevated levels that conversion of T₄ to T₃ would be enhanced. Subsequent data has proven that even with a mild increase of T₄ there was associated cortical bone loss and atrial fibrillation, particularly in older women (62). A low initial T₄ dose (0.025 mg/day) should be initiated in patients with known or suspected coronary artery disease. Rapid replacement may worsen angina and, in some cases, induce myocardial infarction.

Hyperthyroidism

Hyperthyroidism affects 2% of women during their lifetimes, most often during their childbearing years. Graves' disease represents the most common disorder; it is associated with orbital inflammation causing the classic exophthalmos associated with the disease, and a characteristic dermopathy, pretibial myxedema. The cause of Graves' disease in genetically susceptible women is unknown. Autonomously functioning benign thyroid neoplasias are less common causes of hyperthyroidism and are associated with toxic adenomas and toxic multinodular goiters. Transient thyrotoxicosis may be the result of unregulated glandular release of thyroid hormone in postpartum (painless, silent, or lymphocytic) thyroiditis and subacute (painful) thyroiditis. Other rare causes of thyroid overactivity include: human chorionic gonadotropin (hCG)-secreting choriocarcinoma, TSH-secreting pituitary adenoma, and struma ovarii. Factitious ingestion or iatrogenic overprescribing should be considered in patients with eating disorders.

Clinical Features

Symptoms of thyrotoxicosis include fatigue, diarrhea, heat intolerance, palpitations, dyspnea, nervousness, and weight loss. In young patients there may be paradoxical weight gain from an increased appetite. Thyrotoxicosis may cause vomiting in pregnant women that may be confused with hyperemesis gravidarum (63). Tachycardia, lid lag, tremor, proximal muscle weakness, and warm, moist skin are classic physical findings on examination. The most dramatic physical changes are ophthalmologic and include lid retraction, periorbital edema, and proptosis. These eye findings, however, occur in less than one-third of women. In elderly adults, symptoms are often more subtle with presentations of unexplained weight loss, atrial fibrillation, or new-onset angina pectoris (64). Menstrual abnormalities span from regular menses to light flow, to anovulatory menses and associated infertility. Goiter is common in younger women with Graves' disease but may be absent in older women. Toxic nodular goiter is associated with nonhomogeneous glandular enlargement, while in subacute thyroiditis the gland is tender, hard, and enlarged.

Diagnosis

Most thyrotoxic patients have elevated total and free T₄ and T₃ (measured by radioimmuno assay [RIA]) concentrations. In thyrotoxicosis, serum TSH concentrations are virtually undetectable, even with very sensitive assays (sensitivity measured to 0.1 units). Sensitive serum TSH measurements may aid in the diagnosis of hyperthyroidism. Radioiodine uptake scans are useful in the differential diagnosis of established hyperthyroidism. Scans with homogeneous uptake of radioactive iodine are suggestive of Graves' disease, while those with a heterogeneous tracer uptake are suggestive of a diagnosis of toxic nodular goiter. In distinction, thyroiditis and medication-induced thyrotoxicosis are associated with diminished glandular radioisotope concentration.

Therapy

Antithyroid medications, either *propylthiouracil (PTU)* (50 to 300 mg every 6 to 8 hours) or *methimazole* (10 to 30 mg per day) are initial therapies used. After metabolic control is obtained, definitive therapy is obtained by thyroid ablation with radioiodine. This results in permanent hypothyroidism. Both antithyroid drugs block thyroid hormone biosynthesis and may have additional immunosuppressive effects on the gland. The primary difference in oral medications is that PTU partially inhibits extrathyroidal T₄-to-T₃ conversion, while methimazole does not. However, methimazole has a longer half-life and permits single-daily dosing that may encourage compliance. Euthyroidism is typically restored in 3 to 10 weeks, and treatment with oral antithyroid agents is continued for 6 to 24 months, unless total ablation with radioiodine or surgical resection is performed. Surgery has become less popular, because it is invasive and may result in inadvertent parathyroid removal that commits the patient to lifelong calcium therapy.

The relapse rate with oral antithyroid medications is 50% over a lifetime. Lifelong follow-up is important when medical therapy is used solely because of the high relapse rate. Both medications have infrequent (5%) minor side effects that include fever, rash, or arthralgias. Major toxicity is rare (<1%) and includes hepatitis, vasculitis, and agranulocytosis. Agranulocytosis is not predictable by periodic complete blood counts; therefore, patients who have sore throats or fevers should stop the medication and call their physicians immediately.

Therapy with iodine-131 provides a permanent cure of hyperthyroidism in 70% to 80% of patients. The principal drawback to radioactive iodine therapy is the high rate of postablative hypothyroidism, which occurs in at least 50% of patients immediately posttherapy, with additional cases developing at a rate of 2% to 3% per year.

Based on the assumption that hypothyroidism will develop, patients should be given lifetime thyroid replacement. β -Adrenergic blocking agents such as propranolol are useful adjunctive therapy for control of sympathomimetic symptoms such as tachycardia (65). An additional benefit of β -blockers is the blocking of peripheral conversion of T₄ to T₃. In rare cases of thyroid storm, PTU, β -blockers, glucocorticoids, and high-dose iodine preparations (SSKI, or intravenous sodium iodide) should be started immediately, and referral to an intensive care unit is advisable.

Thyroid Nodules and Cancer

Thyroid nodules are common and found on physical examination in up to 5% of patients. Nodules may be demonstrated ultrasonographically in as many as 30% of unselected patients. Most nodules, when discovered, are asymptomatic and benign; however, malignancy and hyperthyroidism must be excluded. Irradiation in childhood, regardless of dose, is associated with a higher risk of malignancy. Virtually all nodules require histologic evaluation. In the past decade, this is accomplished by fine-needle aspiration (FNA) biopsy rather than open surgical biopsy. Thyroid function tests should be performed prior to FNA, and if the results are abnormal the underlying disease should be treated. In many cases, the nodule will regress during therapy and eliminate the need for FNA. Nodules that persist after treatment should undergo biopsy. Because most nodules are "cold" on scanning, it is more cost effective to proceed with tissue sampling rather than scanning. Biopsy is successful and provides a diagnosis in 95% of cases; however, in the 5% without diagnosis, surgical biopsy is necessary. Only 20% of surgical biopsies of an "indeterminate aspiration" are found to be malignant (66).

Papillary thyroid carcinoma is the most common malignancy, found in 75% of cases. Patients who are less than 50 years of age with a primary tumor of less than 4 centimeters when discovered, even with associated cervical lymph node metastasis, usually are cured. Anaplastic tumors in the elderly have a poor prognosis and progress rapidly despite therapy. Radioiodine therapy or surgical ablation are the most common methods of therapy. After therapy, the patient should be placed on lifetime suppression and monitored by assessment of TBG levels.

The history of contraception is a long one; however, the voluntary control of fertility is even more important in modern society ([1](#)). With each woman expected to have no more than one or two children, most of the reproductive years are spent trying to avoid pregnancy. Effective control of reproduction is essential to a woman's ability to accomplish her individual goals. From a larger perspective, the rapid growth of the human population in this century threatens the survival of all. At its present rate, the population of the world will double in 47 years and that of many of the poorer countries of the world will double in about 20 years ([2](#)) ([Fig. 10.1](#)). For the individual and for the planet, reproductive health requires careful use of effective means to prevent both pregnancy and sexually transmitted diseases (STDs) ([3](#)).

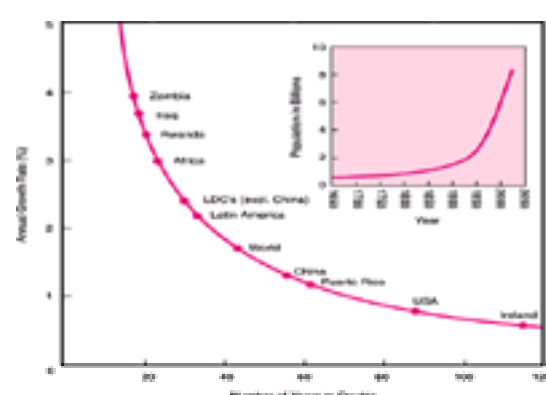

Figure 10.1 Doubling time at different rates of population growth, with representative countries, and world population growth curve. (From Hatcher RA, Trussell J, Stewart F, et al. *Contraceptive technology*. 17th ed. New York: Ardent Media, 1998:768, with permission.)

From puberty until menopause, women are faced with concerns about childbearing or its avoidance: the only options are sexual abstinence, contraception, or pregnancy. The contraceptive choices made by American couples in 1995, when the last national fertility survey was conducted by the U.S. government from a large national probability sample, are shown in [Table 10.1](#) ([4](#)). For couples older than 35 years of age, sterilization is the number one choice. For younger couples, oral contraceptives (OCs) are the most used method, and the condom ranks second. Although use of contraception is high, a significant proportion of sexually active couples do not use contraception: 5.2% in the 1995 National Fertility Survey ([4](#)). The percentage of women using no contraception is highest among the youngest group (i.e., adolescents).

Table 10.1. Percentage Distribution of Contraceptive Users Aged 15–44 Years, by Current Method, 1982–1995

It is estimated that 49% of births in the United States in 1994 were unintended, and that by 45 years of age, 43% of women will have at least one induced abortion (5). Abortion is an obvious indicator of unplanned pregnancy. Abortion ratios by age group indicate that the use of abortion is greatest for the youngest women and least for women in their late 20s and early 30s (Fig. 10.2). Use increases again as women become older. Young people are much more likely to experience contraceptive failure because their fertility is greater than that of older women and because they are more likely to have intercourse without contraception. The effect of age on pregnancy rates with different contraceptive methods is shown in Figure 10.3.

Efficacy of Contraception

Factors affecting whether pregnancy will occur include the fecundity of both partners, the timing of intercourse in relation to the time of ovulation, the method of contraception used, the intrinsic effectiveness of the contraceptive method, and the correct use of the method. It is impossible to assess the effectiveness of a contraceptive method in isolation from the other factors. The best way to assess effectiveness is long-term evaluation of a group of sexually active women using a particular method for a specified period to observe how frequently pregnancy occurs. **A pregnancy rate per 100 women per year can be calculated using the Pearl formula (dividing the number of pregnancies by the total number of months contributed by all couples, and then multiplying the quotient by 1,200).** With most methods, pregnancy rates decrease with time as the more fertile or less careful couples become pregnant and drop out. More accurate information is provided by the life-table method, which calculates the probability of pregnancy in successive months, which are then added over a given interval. Problems relate to which pregnancies are counted: those occurring among all couples or those in women the investigators deem to have used the method correctly. Because of this complexity, rates of pregnancy with different methods are best calculated by reporting two different rates derived from multiple studies (i.e., the lowest rate) and the usual rate as shown in Table 10.2.

Method	Percentage of pregnancies		Percentage of women continuing use at the end of the first year
	Continuing use at the end of the first year	Continuing use at the end of the first year	
Injectable	0.1	0.1	99.9

Safety

Some contraceptive methods have associated health risks; areas of concern are listed in Table 10.3. All of the methods are safer than the alternative (pregnancy with

birth), with the possible exception of OC use by cigarette smokers older than 35 years of age (6). Most methods provide noncontraceptive health benefits in addition to contraception. Oral contraceptives reduce the risk for ovarian and endometrial cancer and ectopic pregnancy. Barrier methods and spermicides provide some protection against STDs, cervical cancer, and tubal infertility.

Method	Advantages	Disadvantages	Side Effects	Contraindications
Coitus interruptus	Available, free	Requires perfect use	None	None
Calendar	Available, free	Requires perfect use	None	None
Periodic abstinence	Available, free	Requires perfect use	None	None
Cervical cap	Available, free	Requires perfect use	None	None
Diaphragm	Available, free	Requires perfect use	None	None

Contraceptive pill	Highly effective, long-acting	Requires daily use	None	None

Table 10.3. Overview of Contraceptive Methods

Cost

Some methods, such as intrauterine devices (IUDs) and subdermal implants, require an expensive initial investment but provide prolonged protection for a low annual cost. The results of a complex cost analysis based on the cost of the method plus the cost of pregnancy if the method fails are shown in Table 10.4. Sterilization and the long-acting methods are least expensive over the long term (7).

Method	Cost (\$)	Cost Multiple (SP)
Vasectomy	55	1.0
Tubal ligation	118	2.14
Intrauterine device	150	2.71
Norgplant	202	3.66
Degameresprogesterone acetate	395	7.19
Oral contraceptives	455	8.27
Condoms	275	14.08
Diaphragm	1147	20.81

*For every \$1.00 spent on vasectomy, the amount shown would be spent on the method indicated.
From Ashok T, Arnold DL, Macfield M. Cost effectiveness of levonorgestrel subdermal implants: comparison with other contraceptive methods available in the United States. J Reprod Med 1990;39:291-298, with permission.

Table 10.4. Cost per Patient per Year of Contraceptive Methods

Nonhormonal Methods

Coitus Interruptus

Coitus interruptus is withdrawal of the penis from the vagina before ejaculation. This method, along with induced abortion and late marriage, is believed to account for most of the decline in fertility of preindustrial Europe (8). Coitus interruptus remains a very important means of fertility control in the Third World. This method has obvious advantages: immediate availability and no cost. Theoretically, the risk for STDs should be reduced, although this has not been studied. The Oxford Study reported a failure rate of 6.7 per 100 woman-years for this method (9). The penis must be completely withdrawn both from the vagina and from the external genitalia because pregnancy has occurred from ejaculation on the female external genitalia without penetration.

Lactation Amenorrhea

Ovulation is suppressed during lactation. The suckling of the infant elevates prolactin levels and reduces gonadotropin-releasing hormone (GnRH) from the hypothalamus, reducing luteinizing hormone (LH) release so that follicular maturation is inhibited (10). The duration of this suppression is variable and is influenced by the frequency and duration of nursing, length of time since birth, and probably by the mother's nutritional status. Even with continued nursing, ovulation eventually returns but is unlikely before 6 months, especially if the woman is amenorrheic and is fully breast feeding with no supplemental foods given to the infant (11). If pregnancy is to be delayed, another method of contraception should be used from 6 months after birth, when menstruation resumes, or when supplemental feeding is instituted. The risk for breast cancer may be reduced in women who have lactated, but whether this apparent benefit exists independent of early first pregnancy is not clear.

Combination OCs are generally not advised during lactation because they reduce the amount of milk produced by some women, although they can be used once milk production is established. Hormonal methods without estrogen can be used. These include progestin-only OCs, implants, and injectable contraception, none of which decreases milk production. Barrier methods, spermicides, and IUDs are also good options for nursing mothers (12).

Periodic Abstinence or Natural Family Planning

With periodic abstinence methods, couples attempt to avoid intercourse during the fertile period around the time of ovulation. A variety of methods are available: the calendar method, the mucus method (Billings or ovulation method), and the symptothermal method, which is a combination of the first two methods. The calendar method is the least effective. With the mucus method, the woman attempts to predict the fertile period by feeling the cervical mucus with her fingers. Under estrogen influence, the mucus increases in quantity and becomes progressively more slippery and elastic until a peak day is reached. Thereafter, the mucus becomes scant and dry under the influence of progesterone until onset of the next menses. Intercourse may be allowed during the "dry days" immediately after menses until mucus is detected. Thereafter, the couple must abstain until the fourth day after the "peak" day.

In the symptothermal method, the first day of abstinence is predicted either from the calendar, by subtracting 21 from the length of the shortest menstrual cycle in the preceding 6 months, or the first day mucus is detected, whichever comes first. The end of the fertile period is predicted by use of basal body temperature. The woman takes her temperature every morning and resumes intercourse 3 days after the thermal shift, the rise in body temperature that signals that the corpus luteum is producing progesterone and that ovulation has occurred.

Efficacy

The ovulation method was evaluated by the World Health Organization in a five-country study. Women who successfully completed three monthly cycles of teaching were then enrolled in a 13-cycle efficacy study. Trussell and Grummer-Strawn calculated a 3.1% probability of pregnancy in 1 year for the small proportion of couples who used the method perfectly and 86.4% probability of pregnancy for the rest (13). Because sperm may survive several days in the female genital tract, even a week's abstinence around the time of actual ovulation offers no guarantee against pregnancy. Also, ovulation can occur even in the absence of menstruation. Pregnancies have occurred after a single act of coitus 7 days before apparent ovulation indicated by basal body temperature. Vaginal infections increase vaginal discharge, complicating the use of the method.

Accurate advance prediction of the time of ovulation would greatly facilitate both the use and efficacy of periodic abstinence. Devices that combine an electronic thermometer with small computers are being explored in an effort to improve the accuracy of basal body temperature as a predictor of the fertile phase (14). Home monitoring of estrogen provides 4 or more days' warning before ovulation and allows intercourse to be resumed 1 to 3 days after ovulation (15). Another approach is the identification of microcrystals in saliva as an indication of approaching ovulation (16).

Risks

Conceptions resulting from intercourse remote from the time of ovulation more often lead to spontaneous abortion than conceptions from midcycle intercourse (17). However, malformations are not more common (18).

Condoms

In the 1700s, condoms made of animal intestine were used by the aristocracy of Europe, but condoms were not widely available until the vulcanization of rubber in the 1840s (1). Modern condoms are usually made of latex rubber, although condoms made from animal intestine are still sold and are preferred by some who feel they afford better sensation. The condom captures and holds the seminal fluid, thus preventing its deposition in the vagina. Until recently, condoms in the United States were made with a relatively thick wall (0.065 to 0.085 mm) to prevent breakage. Japanese condoms as thin as 0.02 mm are now available in the United States (2). Condoms prelubricated with the spermicide nonoxynol-9 are more effective than condoms without spermicide (19). The risk for condom breakage is about 3% (20) and is related to friction. Water-based lubricants may reduce the risk for breakage. Petroleum-based products such as mineral oil must be avoided because even brief exposure to condoms markedly reduces their strength (21).

Sexually Transmitted Diseases

Latex condoms and other barrier methods reduce the risk for STDs. Gonorrhea, ureaplasma, and pelvic inflammatory disease (PID) and its sequelae (tubal infertility) are reduced with consistent use of barrier methods (22,23). A comparison of infertile women and postpartum women showed a 40% reduction in infertility with use of condoms or the diaphragm. The greatest benefit was noted with a combination of the barrier method and a spermicide (24).

Tested *in vitro*, *Chlamydia trachomatis*, herpes virus type 2, human immunodeficiency virus (HIV), and hepatitis B did not penetrate latex condoms but did cross through condoms made from animal intestine (25). Additional protection is provided by the addition of the spermicide *nonoxynol-9* (26). Follow-up of sexual partners of HIV-infected individuals has shown considerable protection when condoms are used (27). Consistent condom use provides more protection than inconsistent use (28). Studies of HIV-negative, high-risk women who used both condoms and spermicidal suppositories of *nonoxynol-9* demonstrated a high degree of protection from HIV seroconversion during follow-up (29). Vaginal spermicide should be used in addition to condoms when prevention of infection is of prime concern. Condoms also offer some protection from cervical neoplasia. In one study, the relative risk for severe dysplasia among users of condoms or diaphragms was 0.4 at 5 to 9 years of use and only 0.2 when the barriers had been used for 10 years or more, which is a 60% to 80% reduction (30). Another study compared women with invasive cervical cancer to controls. The relative risk for invasive cervical cancer was 0.4 when those who had used condoms or diaphragms were compared with those who had never used them (31).

Latex allergy could lead to life-threatening anaphylaxis in either partner from latex condoms. Blank has suggested that *nonoxynol-9* used with latex condoms could increase risk for sensitization by leaching a latex protein from the condom (32). Nonlatex condoms of polyurethane and *Tactylon* are now available and should be offered to couples who have a history suggestive of latex allergy.

Female Condom

Vaginal pouches made of polyurethane are now available for use by women. Efficacy trials have not matched historical trials with other barrier methods, but no randomized trial of the new method has been published. Initial U.S. trials showed a pregnancy rate of 15% in 6 months; however, reanalysis suggests that with perfect use, the pregnancy rate may be only 2.6%. This rate is comparable to perfect use of the diaphragm and cervical cap, the other female barrier methods (33). Colposcopic studies of women using the female condom demonstrate no signs of trauma, and the bacterial flora is not changed (34).

Vaginal Spermicides

Vaginal spermicides combine a spermicidal chemical, either *nonoxynol-9* or *octoxynol*, with a base of cream, jelly, aerosol foam, foaming tablet, film, or suppository. Spermicides are nonionic surface-active detergents that immobilize sperm. In simulated intercourse under laboratory conditions, aerosol foams provided rapid dispersal throughout the vagina and offered the best protection. Jellies and melting suppositories provided poor distribution (35). Spermicides alone appear considerably less effective than condoms or a diaphragm with spermicide. *Nonoxynol-9* is known to reduce the risk for bacterial vaginosis and other STDs, including HIV (36).

Concerns have been raised about possible teratogenicity of spermicides. *Nonoxynol-9* is not absorbed from the human vagina, however (37), and several large studies have found no greater risk for miscarriage, birth defects, or low birth weight in spermicide users than in other women (38,39).

Nonoxynol-9 is toxic to the lactobacilli that normally colonize the vagina. Women who use spermicides regularly have increased vaginal colonization with the bacterium *Escherichia coli* and may be predisposed to *E. coli* bacteriuria after intercourse (40).

Vaginal Barriers

At the beginning of the 20th century, four types of vaginal barriers were used in Europe: vaginal diaphragm, cervical cap, vault cap, and vimule (Fig. 10.4). All of these barriers are still made and sold in England. Vaginal diaphragms and cervical caps are used in the United States. When used consistently, vaginal barriers can be highly effective. They are safe and, as condoms, they have the noncontraceptive benefit of relative protection from STDs, tubal infertility, and cervical neoplasia.

Figure 10.4 Vaginal barriers (left to right): Prentiff cavity rim cervical cap, plastic cap, vault cap, vimule, and vaginal diaphragm. (From Copeland LJ. *Textbook of gynecology* Philadelphia: WB Saunders, 1993:159, with permission.)

Diaphragm

The diaphragm consists of a circular spring covered with fine latex rubber (Fig. 10.5). There are several types of diaphragm, as determined by the spring rim: coil, flat,

or arcing. Coil-spring and flat-spring diaphragms become a flat oval when compressed for insertion. Arcing diaphragms form an arc or half moon when compressed; they are easiest to insert correctly. The practitioner must not only fit the diaphragm for the patient, but also instruct her in its insertion and verify by examination that she can insert it correctly to cover the cervix and upper vagina. Spermicide is always prescribed for use with the diaphragm; however, whether this practice is necessary is not well studied. In a small trial, women using the diaphragm without spermicide had a higher (19.3 per 100 woman-years) but statistically not significant risk for pregnancy than those who used the diaphragm with spermicide (12.3 per 100 woman-years) (41). Conversely, a different study found that women who wore the diaphragm constantly, removing, washing, and reinserting the diaphragm daily without using a spermicide, had lower pregnancy rates than women who used the diaphragm in the conventional fashion, with a spermicide, only when needed (42). Proper fitting and proper use are key to its effectiveness.

Figure 10.5 Wide-seal diaphragm. (From Copeland LJ. *Textbook of gynecology* Philadelphia: WB Saunders, 1993:162, with permission.)

Fitting Diaphragms

Fitting of a diaphragm should be performed as follows:

1. **To fit a diaphragm properly, a vaginal examination should first be performed.** With the first and second fingers in the posterior fornix, the thumb of the examining hand is placed against the first finger to mark where the first finger touches the pubic bone. The distance from the tip of the middle finger to the tip of the thumb is the diameter of the diaphragm that should first be tried.
2. **A set of test diaphragms of various sizes is used, and the test diaphragm is inserted and checked by palpation.** The diaphragm should open easily in the vagina and fill the fornices without pressure. The largest diaphragm that fits comfortably should be selected. A size 65, 70, or 75 diaphragm will fit most women.
3. **The patient should practice insertion and should be reexamined to confirm proper position of the device.** About 1 teaspoon of water-soluble spermicidal jelly or cream is placed in the cavity of the dome. The diaphragm is inserted with the dome downward so that the cervix will sit in a pool of the spermicide.
4. **The diaphragm can be inserted several hours before intercourse. If intercourse is repeated, additional spermicidal jelly should be inserted into the vagina without removing the diaphragm. The diaphragm should be left in place at least 6 hours after intercourse to allow for immobilization of sperm.** It is then removed, washed with soap and water, allowed to dry, and stored away from heat. It should not be dusted with talc because genital exposure to talc may predispose to ovarian cancer.

Risks

Diaphragm use, especially prolonged use during multiple acts of intercourse, appears to increase the risk for bladder infections. Risk for cystitis increases with the numbers of days the diaphragm is used in a week (relative risk, 1.42, 2.83, and 5.68 for use 1, 3, or 5 days in a week) (43). A smaller-sized, wide-seal diaphragm or a cervical cap can be used if recurrent cystitis is a problem, although the problem may relate not only to mechanical obstruction but also to alterations in vaginal flora produced by the spermicide. An epidemiologic study comparing cases of toxic shock with controls found no increased risk from diaphragm use (44).

Cervical Caps

The cap is much smaller than the diaphragm, does not contain a spring in the rim, and covers only the cervix. Caps are used with spermicide, but the contribution of the spermicide to the efficacy is not known. Studies of the efficacy of cervical caps have revealed a range of results. The Prentiff cap has a pregnancy rate of 8 per 100 woman-years with the cap left in place for as long as 5 days at a time (45). A multicenter study of 3,433 women found a first-year pregnancy rate of 11.3 per 100 women. Women whose pattern of use was described as "near perfect" had a first-year pregnancy rate of 6.1 per 100, half that of the overall rate (46). The pregnancy rate increased when the cap was worn for more than 72 hours at a time. Dislodgment of the cap during intercourse or at other times was reported by 27.5% of the users after 3 months of use; dislodgment and accidental pregnancy were the main reasons that women discontinued use of the cap. By 1 year, 49% of women discontinued use or were lost to follow-up. In randomized trials, the cervical cap was as effective as the diaphragm overall, but the failure rates with "perfect use" were considerably higher for the cap than for the diaphragm (47). Parous women using the cap had more failures than nulliparous women. A new version of the cervical cap made of silicone rubber is being studied. It looks like a sailor's hat with the dome covering the cervix and the brim fitting into the vaginal fornices (48). It is made in three sizes—24-, 28-, and 32-mm diameter—and can be expected to be reusable for 2 to 3 years. It is used with spermicide and is left in place as long as 48 hours.

Fitting Cervical Caps

The Prentiff cavity rim cervical cap is available in the United States in sizes 22, 25, 28, and 31 (internal diameter of the rim in millimeters). A cervical cap should be fitted as follows:

1. **The cervical size is estimated by inspection and palpation.** Nulliparous women usually require a size 22, whereas parous women generally are fitted with a size 25.
2. **The cap is inserted by compressing it between finger and thumb and placing it through the introitus, dome outward.** It is then pushed gently upward to fit over the cervix. The dome is indented with the examiner's finger to create suction against the cervix. The dome should remain compressed for several seconds, indicating a good fit, and gentle lateral pressure on the rim should not dislodge the cap. The smallest Prentiff cap (22 mm) is too large for many nulliparous women, and a good fit may not be obtained.
3. **Before use, the cap is one-third filled with spermicidal jelly or cream.** It can be left in place as long as 72 hours. The patient is instructed to check for dislodgment of the cap after intercourse, and use of an additional contraceptive method such as a condom is advised until it is clear that the cap will not be dislodged.

Risks

In one large trial, negative cervical cytology progressed to dysplasia in 4% of cap wearers and in 2% of diaphragm wearers (49). Other studies have not found this effect (46); in contrast, Koch found cap wearers to be protected from dysplasia compared with controls using other methods (45). The results of cervical cytology appeared to improve during use (48). Cap use has not been associated with cystitis (45,46). Toxic shock has not been reported, even in large series (46).

Intrauterine Devices

IUDs are very important worldwide but play a minor role in contraception for the U.S. population because of a fear of infection that is no longer justified in most populations. The high-dose copper IUD sold in the United States (*TCU380*, or *ParaGard*) provides safe, long-term contraception with effectiveness equivalent to tubal sterilization. Two IUDs are now in use in the United States, and a third has been approved by the U.S. Food and Drug Administration (FDA). These IUDs are the *copper T380A (ParaGard)*, the progesterone-releasing T (*Progestasert*), and the *levonorgestrel*-releasing T (*Mirena*). The copper T380A has bands of copper on the cross arms of the T in addition to copper wire around the stem, providing a total surface area of 380 mm of copper, almost double the surface area of copper of earlier copper devices (Fig. 10.6). The *copper T380A* is approved for up to 10 years of continuous use. The *Progestasert* must be replaced every year. The *Mirena* (Fig. 10.7)

10.7) is approved in the United States for 5 years, although studies through 7 years show no loss of efficacy (49).

Figure 10.6 Copper T380AA (ParaGard) intrauterine device. (Courtesy of Gynopharma, Inc.)

Figure 10.7 Mirena intrauterine device (levonorgestrel T).

Mechanism of Action

IUDs cause the formation of “biologic foam” within the uterine cavity that contains strands of fibrin, phagocytic cells, and proteolytic enzymes. Copper IUDs continuously release a small amount of the metal, producing an even greater inflammatory response. All IUDs stimulate the formation of prostaglandins within the uterus, consistent with both smooth muscle contraction and inflammation. Scanning electron microscopy studies of the endometrium of women wearing IUDs show alterations in the surface morphology of cells, especially of the microvilli of ciliated cells (51). There are major alterations in the composition of proteins within the uterine cavity, and new proteins and proteinase inhibitors are found in washings from the uterus (52). The altered intrauterine environment interferes with sperm passage through the uterus, preventing fertilization. The natural progesterone in the *Progestasert* induces endometrial atrophy. The levonorgestrel in the *Mirena* is much more potent than natural progesterone. Blood levels of the hormone are about half that seen with the levonorgestrel subdermal implant (*Norplant*) and are sufficient to block ovulation in many women (49).

The IUD is not an abortifacient. The contraceptive effectiveness does not depend on interference with implantation, although this phenomenon also occurs and is the basis for using copper IUDs for emergency contraception. Sperm can be obtained by laparoscopy in washings from the fallopian tubes of control women at midcycle, whereas no sperm are present in the tubal washings from women wearing IUDs (53). Ova flushed from the tubes at tubal sterilization showed no evidence of fertilization in women wearing IUDs (54), and studies of serum b-human chorionic gonadotropin do not indicate pregnancy in women wearing IUDs (55).

Effectiveness

The *copper T380A* and the *levonorgestrel T* have remarkably low pregnancy rates, less than 0.2 per 100 woman-years. Total pregnancies over a 7-year period were only 1.1 per 100 for the *levonorgestrel T* and 1.4 for the *copper T380A* in a comparative study (49). Twelve-year data on the *copper T380A* showed a cumulative pregnancy rate of only 1.9 per 100 women (56). The *Progestasert* has a higher failure rate, about three pregnancies per 100 women per year.

Benefits

Modern IUDs provide excellent contraception, independent of coitus, without continued effort by the user. During use, both the *ParaGard* and the *Mirena* IUDs protect against ectopic pregnancy. The *Progestasert* and *Mirena*, by releasing progesterone or levonorgestrel, reduced menstrual bleeding and cramping. The *Mirena* has been used extensively to treat heavy menstrual bleeding and is used in Europe and the United Kingdom as an alternative to hysterectomy for menorrhagia (57).

Risks

Infection The *Women's Health Study* (58) found the *Dalkon Shiela* device (now withdrawn from the market) to increase the risk for PID by eightfold when women hospitalized for PID were compared with control women hospitalized for other illnesses. In contrast, risk from the other IUDs was markedly less: relative risk for PID was 2.2 for the *Progestasert*, 1.9 for the *Copper 7*, 1.3 for the *Saf-T-Coil*, and 1.2 for the *Lippes Loop* (58). Increased risk was detectable only within 4 months of insertion of the IUD. A still larger, prospective World Health Organization study revealed that PID increased only during the first 20 days after insertion. Thereafter, the rate of diagnosis of PID was about 1.6 cases per 1,000 women per year, the same as in the general population (59).

Exposure to sexually transmitted pathogens is a more important determinant of PID than the wearing of an IUD. In the *Women's Health Study*, women who were currently married or cohabiting and who said they had only one sexual partner in the past 6 months had no increase in PID (58). In contrast, previously married or single women had marginal increase in risk, even though they had only one partner in the previous 6 months (60). The only pelvic infection that has been unequivocally related to IUD use is actinomycosis (61). It appears that PID with actinomycosis has been reported only in women wearing an IUD. Rates of colonization with actinomycosis increase with duration of use for plastic devices but appear to be much less for copper-releasing IUDs.

Pelvic Inflammatory Disease When PID is suspected in an IUD-wearing woman, the IUD should be immediately removed, appropriate cultures should be obtained, and high-dose antibiotic therapy should be started. Pelvic abscess should be suspected and ruled out by ultrasound examination.

Ectopic Pregnancy If pregnancy occurs in an IUD wearer, it will be ectopic in about 5% of cases. This is because the fallopian tubes are less well protected against pregnancy than the uterus. Compared with women using no contraception, however, women wearing either the *copper T380A* or the *levonorgestrel T* have an 80% to 90% reduction in the risk for ectopic pregnancy (49), which is a greater reduction than that seen for users of barrier methods. Women using OCs have a 90% reduced risk (62). In contrast, the *Progestasert* increases risk slightly, probably because the progesterone affects tubal motility and does not inhibit ovulation (63). One study reported an increased risk for ectopic pregnancy among past users of older IUDs, but it did not include the current higher-dose copper IUD (*ParaGard*) or the *levonorgestrel T* (*Mirena*) (64).

Fertility Case-control studies of infertile women in the United States have revealed that a history of IUD use is associated with a twofold increase in the risk for infertility associated with tubal factors. The risk applies to methods other than the copper IUD, for which there is no increased risk (65,66 and 67). Risk was not increased among women who reported only one sexual partner (65). The Oxford Study found that women gave birth just as promptly after IUD removal as they did after discontinuing use of the diaphragm (68). Exposure to sexually transmitted pathogens confers risk for infertility. Modern IUDs confer a small increased risk for

infertility (67).

Clinical Management

Contraindications to IUD use include pregnancy, a history of PID, undiagnosed genital bleeding, uterine anomalies, and large fibroid tumors. Chronic immune suppression should be considered a contraindication. Women with such conditions are considered to be at greater risk for PID; in addition, the effectiveness of the IUD may be compromised. A number of pregnancies have occurred in renal transplant recipients soon after IUD insertion. Copper allergy and Wilson's disease are contraindications to the use of copper IUDs.

Insertion

At the initial visit, the patient's history is obtained; a physical examination, cervical culture for *Neisseria gonorrhoeae*, and a test for chlamydia are performed; detailed counseling regarding risks and alternatives is also provided. The patient should avoid intercourse until returning for insertion of the device at a second visit. Premedication with oral prostaglandin inhibitors such as *ibuprofen* is strongly advised. Antibiotic prophylaxis has not been found beneficial, probably because the risk for pelvic infection with IUD insertion is so low. A large randomized trial of 1,985 patients receiving either oral azithromycin or placebo found no difference in rates of IUD removal during the first 90 days after insertion and no difference in rate of salpingitis (69). These women were screened for STDs only by self-history. The IUD is usually inserted during menses in order to be sure the patient is not pregnant, but it can be inserted at any time in the cycle if the patient is already using effective contraception (70).

The technique of insertion is as follows:

1. **The cervix is exposed with a speculum.** The vaginal vault and cervix are cleansed with a bacteriocidal solution, such as an iodine-containing solution.
2. **The uterine cavity should be measured with a uterine sound.** The depth of the cavity should measure at least 6 cm from the external os. A smaller uterus is not likely to tolerate currently available IUDs.
3. **A paracervical block** with 10 mL of 1% *lidocaine* mixed with *atropine* (5 mg) can be used to avoid vasovagal syncope and minimize discomfort. In some women, serious cardiac arrhythmia can occur with cervical stimulation and can be avoided by these measures.
4. **Use of a tenaculum for insertion is mandatory to prevent perforation.** The cervix is grasped with a tenaculum and gently pulled downward to straighten the angle between the cervical canal and the uterine cavity. The IUD, previously loaded into its inserter, is then gently introduced through the cervical canal.
5. **With the *ParaGard* and the *Progestasert*, the outer sheath of the inserter is withdrawn a short distance to release the arms of the T and is then gently pushed inward again to elevate the now-opened T against the fundus (71).** The outer sheath and the inner stylet of the inserter are withdrawn, and the strings are cut to project about 2 cm from the external cervical os.
6. **With the *Mirena* IUD, insertion is somewhat different. The inserter tube loaded with the IUD is introduced into the uterus until the preset sliding flange on the inserter is 1.5 to 2 cm from the external os of the cervix.** The arms of the T device are then released upward into the uterine cavity, and the inserter is pushed up under them to elevate the IUD up against the uterine fundus.

Intrauterine Devices in Pregnancy

A woman with an IUD in place who has amenorrhea should have a pregnancy test and pelvic examination. If an intrauterine pregnancy is diagnosed and the IUD strings are visible, the IUD should be removed as soon as possible in order to prevent later septic abortion, premature rupture of the membranes, and premature birth (72). When the strings of the IUD are not visible, an ultrasound examination should be performed to localize the IUD and determine whether expulsion has occurred. If the IUD is present, there are three options for management:

1. Therapeutic abortion
2. Ultrasound-guided intrauterine removal of the IUD
3. Continuation of the pregnancy with the device left in place

If the patient wishes to continue the pregnancy, ultrasound evaluation of the location of the IUD is advised (73). If the IUD is not in a fundal location, ultrasound-guided removal using small alligator forceps is advised. If the location is fundal, the IUD should be left in place. If pregnancy continues with an IUD in place, the patient must be warned of the symptoms of intrauterine infection and should be cautioned to seek care promptly for fever or flulike symptoms, abdominal cramping, or bleeding. At the earliest sign of infection, high-dose intravenous antibiotic therapy should be given and the pregnancy evacuated promptly.

Duration of Use

Annual rates of pregnancy, expulsions, and medical removals decrease with each year of use (74,75). Therefore, a woman who has had no problem by year 5, for example, is very unlikely to experience problems in the subsequent years. As noted, the *Progestasert* should be replaced at the end of 1 year, but the *copper T380A* is approved for 10 years and the *levonorgestrel T* for 5 years. Actinomyces can be detected by cervical cytology. Should actinomyces-like particles be found, removal of the IUD and treatment with oral penicillin is recommended.

Choice of Devices

Of the three IUDs approved in the United States, the *copper T380A* and *levonorgestrel T* are preferred. They provide protection for many years, have remarkably low pregnancy rates, and reduce risk for ectopic pregnancy substantially. The *Progestasert* must be replaced annually, theoretically exposing the patient to some risk for infection with each insertion, and increasing cost markedly. It is less effective and increases the risk for ectopic pregnancy slightly. Both the *Progestasert* and *Mirena* IUDs reduce the amount of menstrual bleeding and dysmenorrhea. The *copper T380A* can be expected to increase menstrual bleeding.

Hormonal Contraception

Hormonal contraceptives are female sex steroids, synthetic estrogen and synthetic progesterone (progestin), or progestin only. They can be administered in the form of OCs, implants, and injectables.

The most widely used hormonal contraceptive is the combination OC. Combination OCs can be monophasic, with the same dose of estrogen and progestin administered each day, or multiphasic, in which varying doses of steroids are given through a 21-day cycle. Typically, they are administered for 21 days beginning on the Sunday after a menstrual period, then discontinued for 7 days to allow for withdrawal bleeding that mimics the normal menstrual cycle. The 28-day version provides placebo tablets for the last 7 days of the cycle so the user simply takes one pill a day and starts a new pack as soon as the first pack is completed. Progestin-only formulations contain no estrogen. These are taken every day without interruption. Other forms of hormonal contraception include injectable progestins and estrogen-progestin combinations, subdermal implants releasing progestin, and the experimental vaginal rings that release either estrogen-progestin or progestin alone.

Silastic rings worn in the vagina release steroid hormones that are absorbed at a constant rate, allowing contraception with blood levels of steroids well below the peak levels that are seen with OCs. Rings containing levonorgestrel or combinations of levonorgestrel and estrogens are being studied (76).

Steroid Hormone Action

Sex steroids were originally defined by their biologic activity. They are characterized by their affinity for specific estrogen, progesterone, or androgen receptors as well as by their biologic effects in different systems (74). Steroids are rapidly absorbed in the gut but go directly into the liver through the portal circulation, where they are rapidly metabolized and inactivated. Therefore, large doses of steroids are required when they are administered orally. The addition of the ethinyl group to carbon-17 of the steroid molecule hinders degradation by the liver enzyme 17-hydroxysteroid dehydrogenase.

Progestins

Progestins are synthetic compounds that mimic the effect of natural progesterone but differ from it structurally ([Fig. 10.8](#)). There are three classes: the estranes and gonanes, which are 19-nor progestins and are structurally similar to testosterone but lacking a carbon at position 19, and the pregnane or 17-acetoxy compounds, which are structurally similar to progesterone. Only the estrane and gonane compounds are used in oral contraceptives in the United States, but *medroxyprogesterone acetate* (*Provera*), one of the pregnane compounds, is the major injectable progestin. The progestins differ from each other in their affinities for estrogen, androgen, and progesterone receptors; their ability to inhibit ovulation; and their ability to substitute for progesterone and antagonize estrogen. Some are directly bound to the receptor (levonorgestrel, norethindrone), whereas others require bioactivation as, for example, desogestrel, which is converted in the body to its active metabolite, 3-keto-desogestrel. The 17-acetoxy progestins (e.g., *medroxyprogesterone acetate*) are bound by the progesterone receptor. *Norgestrel* exists as two stereoisomers, identified as dextronorgestrel and levonorgestrel. Only levonorgestrel is biologically active. Three newer progestins (*norgestimate*, *desogestrel*, and *gestodene*) are viewed as more “selective” than the other 19-nor progestins, in that they have little or no androgenic effect at doses that inhibit ovulation([78](#)). The FDA has approved norgestimate- and desogestrel-containing OCs, and *gestodene* is available in Europe. *Gestodene* is a derivative of levonorgestrel that is more potent than the other preparations (i.e., very little of it is required for antifertility effects). Androgenic potency is considered undesirable because of the adverse effect of androgen and androgenic progestins on lipid and glucose metabolism. Androgenic progestins reduce levels of circulating high-density lipoprotein (HDL), elevate low-density lipoprotein (LDL), and adversely effect glucose tolerance in a dose-dependent fashion ([79](#)).

Figure 10.8 Progestins of interest for contraception. (From Copeland LJ, Jarrell JF. *Textbook of gynecology*. 2nd ed. Philadelphia: WB Saunders, 2000:303, with permission.)

Estrogens

In the United States, OCs contain either of two estrogens: *mestranol* or *ethinyl estradiol* (*EE*). *Mestranol* is *EE* with an extra methyl group. It requires bioactivation in the liver, where the methyl group is cleaved, releasing the active agent, *EE*. **OCs with 35 mg of *EE* provide the same blood levels of hormone as do OCs containing 50 mg of *mestranol*** ([80](#)).

Antifertility Effects

Combination Oral Contraceptives

Ovulation can be inhibited by oral estrogen or by oral progestin alone, but large doses are required. Pharmacologic synergism is exhibited when the two hormones are combined and ovulation is suppressed at a much lower dose of each agent. Combination OCs suppress basal follicle-stimulating hormone (FSH) and LH. Oral contraceptives diminish the ability of the pituitary gland to synthesize gonadotropins when it is stimulated by the hypothalamic gonadotropin-releasing hormone (GnRH) ([81](#)). Ovarian follicles do not mature, little estradiol is produced, and there is no midcycle LH surge. Ovulation does not occur, the corpus luteum does not form, and progesterone is not produced. This blockade of ovulation is dose related. Newer low-dose OCs do not provide as dense a block and allow somewhat higher base-line FSH and LH levels than higher-dose formulations ([82](#)). This makes ovulation somewhat more likely to occur if pills are missed or if the patient takes another medication that interferes with OC action.

Progestin-only Preparations

The mode of action of progestin-only contraceptives depends very much on the dose of the compound ([83](#)). At low blood levels of progestin, ovulation will occur part of the time. With the progestin-only “minipill,” which supplies 0.3 mg of *norethindrone* per day (*Micronor*), 40% of cycles are ovulatory, 25% have inadequate luteal function, 18% have follicular maturation without ovulation, and 18% have complete suppression of follicle development. At moderate blood levels of progestin, normal basal levels of FSH and LH are present, and some follicle maturation may occur. Estradiol production is present, and the surge of estradiol that would normally trigger pituitary release of LH occurs; there is no answering LH surge, however, and hence no ovulation. At higher blood levels of progestin, basal FSH is reduced, and there is less follicular activity, less estradiol production, and no LH surge.

Hormonal Implants

With the subdermal implant that releases *levonorgestrel* (*Norplant*), there is some follicular maturation and estrogen production, but LH peak levels are low and ovulation is often inhibited. In the first year of use, ovulation is believed to occur in about 20% of cycles. The proportion of ovulatory cycles increases with time, probably as a result of the decline in hormone release. By the fourth year of use, 41% of cycles are ovulatory. The mechanisms of contraception with low-dose progestins are believed to include effects on the cervical mucus, endometrium, and tubal motility. The scant, dry cervical mucus in women using these preparations inhibits sperm migration into the upper tract. Progestins decrease nuclear estrogen receptor levels, decrease progesterone receptors, and induce activity of the enzyme 17-hydroxysteroid dehydrogenase that metabolizes natural estradiol 17b ([84](#)).

The sustained release offered by contraceptive implants allows for highly effective contraception at relatively low blood levels of the steroid. [Figure 10.9](#) depicts expected steroid blood levels with implants, injectables, and oral contraceptives. An additional mechanism for contraception has been discovered with the antiprogestone *mefipristone* (*RU486*). In the normal cycle, there is a small amount of progesterone production from the follicle just before ovulation. This progesterone appears essential to ovulation, because if the antiprogestone is given before ovulation, it can be delayed for several days ([84,85](#)).

Figure 10.9 Schematic representation of the expected pharmacokinetic profiles of progestogens administered in different formulations. (From Landgren BM. Mechanism of action of gestagens. *Int J Gynecol Obstet* 1990;32:95–110, with permission.)

Oral Contraceptives

When used consistently, combination OCs have pregnancy rates as low as two to three per 1,000 women per year. Progestin-only OCs are less effective, with best results of three to four pregnancies per 100 woman-years. Both methods have the potential for user error; therefore, there may be a 10-fold difference between the best results and results in typical users for pregnancy prevention. Injectable progestins and implants are much less subject to user error. The difference between the best results and results in typical users is small and is comparable to pregnancy rates after tubal sterilization ([Table 10.2](#)).

Metabolic Effects and Safety

Venous Thrombosis Older studies linked OC use to venous thrombosis and embolism, cerebral vascular accidents, and heart attack ([86,87](#)). More recent studies have found a much lower risk ([88](#)). Rereading of the older literature on venous thrombosis reveals that absolute risk was strongly determined by other very obvious predisposing causes of thrombosis that are now considered contraindications to OC use: previous thrombosis, preexisting vascular disease, coronary artery disease, leukemia, cancer, and serious trauma ([89](#)).

Normally, the coagulation system maintains a dynamic balance of procoagulant and anticoagulant systems in the blood. Estrogens affect both systems in a dose-related fashion. For most women, fibrinolysis (anticoagulation) is increased as much as coagulation, maintaining the dynamic balance at increased levels of production and destruction of fibrinogen ([90,91](#)) ([Fig. 10.10](#)). Current low-dose OCs have less measurable effect on the coagulation system, and fibrinolytic factors increase at the same rate as procoagulant factors ([92,93](#)). The lower estrogen dose (30 to 35 mg *EE*) reduces the risk for a thromboembolic event when compared with higher-dose (50 mg estrogen) OCs ([94](#)) ([Table 10.5](#)). Theoretically, thrombosis risk should be still less with current OCs containing only 20 mg of *EE*, but this has not been demonstrated. Smokers taking low-dose OCs demonstrate more marked activation of the coagulation system than nonsmokers—shortening of the prothrombin time, increased fibrinogen levels, and decreased antithrombin III—but also have increased fibrinolysis as measured by plasminogen activity ([94](#)).

Figure 10.10 Dynamic balance of hemostasis. (From Winkler UH, Buhler K, Schlinder AE. The dynamic balance of hemostasis: implications for the risk of oral contraceptive use. In: Runnebaum B, Rabe T, Kissel L, eds. *Female contraception and male fertility regulation*. Advances in Gynecological and Obstetric Research Series. Confort, England: Parthenon Publishing Group, 1991:85–92, with permission.)

Estrogen (dose)	Rate/10,000 person years	Relative Risk (all cases)	Relative Risk (proven diagnosis)
<50 µg	4.2	1.0	1.0 ^a
50 µg	7.0	1.5	2.0 (0.0–4.0)
>50 µg	10.0	1.7	3.2 (2.4–4.3)

^a Base line risk used to calculate risk for higher doses. From Cersman BS, Piper JM, Tamita DM, et al. Oral contraceptive dose and the risk of deep venous thrombosis. *Am J Epidemiol* 1991;133:33–37, with permission.

Table 10.5. Oral Contraceptive Estrogen Dose and Risk for Deep Vein Thrombosis

The absolute risk for thrombosis in OC users taking pills containing 30 to 35 mg *EE* is 3 per 10,000 per year, compared with 1 per 10,000 reproductive-aged women not using OCs and 6 per 10,000 in pregnancy ([95](#)). Thrombosis risk is apparent by 4 months after starting estrogen-containing OCs and does not increase further with continued use. Risk is highest during the first year of use ([96](#)).

Thrombophilia Changes in the coagulation system are detectable in all women, even those taking lower-dose OCs; however, some are genetically predisposed to thrombosis when challenged by pregnancy or administration of exogenous estrogen. Bloemenkamp and colleagues studied hemostatic variables in women given low-dose OCs who had previous thrombosis with OCs and compared them with women with no thrombosis ([97](#)). Women known to have inherited thrombophilic disorders were excluded. Both groups of women had significant changes in clotting factors: increased factor VII, factor VIII, and protein C, and a decrease in antithrombin, activated protein C sensitivity ratio, and protein S. However, the women with a history of thrombosis who were taking OCs had more pronounced changes. They were “high hemostatic responders” when exposed to OCs. Women with inherited deficiencies of antithrombin III, protein C, or protein S are at very high risk for thrombosis with pregnancy or estrogen therapy, but they make up a very small proportion of potential OC users. A much more common variation has been identified, factor V Leiden. This genetic variation exists in 3% to 5% of the white population. It codes for a one amino acid mutation in the factor V protein, inhibiting cleavage of the protein by activated protein C, an essential step in maintaining the balance between coagulation and fibrinolysis ([98](#)). A study of risk for a first thromboembolic episode among women using OCs found it to be 2.2 per 10,000 woman-years for women without the factor V mutation and 27.7 per 10,000 woman-years for women with the mutation ([99](#)). In women homozygous or heterozygous for factor V Leiden who do not use OCs, the risk is estimated to be 4.9 per 10,000 woman-years. The effect of estrogen dose was not examined. Cigarette smoking did not affect this risk. There are pronounced ethnic differences in the presence of this mutation. The Leiden allele is found in 5% of whites but is rare in Africans, Asians, Amerindians, Eskimos, and Polynesians ([100](#)). A similar mutation is found in the prothrombin gene at position 20210 and is described as prothrombin G20210A. It is found in 3% of a European population and is also strongly associated with venous thrombosis in women taking OCs ([101](#)).

Pregnancy is an even greater challenge for women with inherited defects of anticoagulation ([102](#)). A woman who sustains a venous event while using OCs should be evaluated thoroughly after she has recovered. Assessment should include measurement of antithrombin III, protein C, and protein S levels, resistance to activated protein C, genetic testing for factor V Leiden mutation and the prothrombin G20210A mutation, and testing for antiphospholipid antibody. It should not be assumed that OCs are the unique cause of the thrombotic episode.

Vandenbroucke and colleagues have explored the issue of routine screening for factor V Leiden ([103](#)). They conclude that routine screening of OC patients is not justified because effective contraception would be denied to 5% of white women, while preventing only a small number of fatal pulmonary emboli. Furthermore, if pregnant women were screened and those who screened positive were then treated with heparin, the number of cases of fatal bleeding might equal or exceed the number of fatal pulmonary emboli ([104](#)). Screening based on personal or family history of deep vein thrombosis before starting OCs or at the first antenatal visit was considered worthwhile.

Several studies have found a modest increased risk for venous thrombosis when users of OCs containing newer agents (i.e., *progestins*, *desogestrel*, or *gestodene*) were compared with users of older progestins ([105](#)). Physiologically, this was hard to understand because the estrogen and its dose are the same, and a 1993 review of *desogestrel*-containing OCs had found only minimal changes in coagulation and fibrinolysis ([106](#)). Lewis and colleagues have concluded that the biases “attrition of

susceptibles” and “adverse selection” explain the apparent increase in thrombosis. Most cases of venous thrombosis attributable to OCs occur during the initial months of use (107). Hence, comparing new users to women already taking OCs for some time without incident will demonstrate an apparent increase with the new product that is artificial. Also, physicians may presume that newer drugs are safer, and prescribe them selectively for women with risk factors. Analysis of data from a large European study of thrombosis with different OCs has shown that apparent risk for thrombosis was lowest with the first low-dose pills introduced and highest with those recently introduced, even though the newest pill had the lowest estrogen dose (105) (Fig. 10.11).

Figure 10.11 Risk ratios of oral contraceptives for thrombosis by year of market introduction for women aged 25 to 44 years. LNG, levonorgestrel with 30 mg ethinyl estradiol; GES, gestodene with 30 mg ethinyl estradiol; NORG, norgestimate with 35 mg of ethinyl estradiol; DES20, desogestrel with 20 mg of ethinyl estradiol. (From Lewis MA, Heinemann LAJ, MacRae KD, et al. The increased risk of venous thrombosis and the use of third generation progestagens: role of bias in observational research. *Contraception* 1996;54:5–13, with permission.)

Ischemic Heart Disease Ischemic heart disease and stroke were the major causes of death blamed on OC use in the past. It is now known that the principal determinants of risk are advancing age and cigarette smoking (108). With the higher-dose OCs used in the 1980s, smoking had a profound effect on risk. Women smoking 25 or more cigarettes per day had a 30-fold increased risk for myocardial infarction if they used OCs, compared with nonsmokers not using OCs (109) (Fig. 10.12). Use of OCs is now much safer because most women are taking low-dose pills and because physicians prescribe selectively, excluding women with major cardiovascular risk factors. A very large U.S. study confirms the safety of OCs as currently prescribed. A total of 187 women aged 15 to 44 years with confirmed myocardial infarction were identified during 3.6 million woman-years of observation in the Kaiser Permanente Medical Care Program in California between 1991 and 1994. This is a rate of 3.2 per 100,000 woman-years (110). Nearly all current users took OCs with less than 50 mg of EE. After adjusting for age, illness, smoking, ethnicity, and body mass index, risk for myocardial infarction was not increased [odds ratio (OR), 1.14; 95% confidence interval (CI), 0.27 to 4.72]. Of heart attack victims, 61% were smokers; only 7.7% were current OC users. In a later study, the same investigators pooled results from the California study with a similar study from Washington State. The results were the same. Current users of low-dose OCs had no increased risk for myocardial infarction, after adjustment for major risk factors and sociodemographic factors (111). That past use of OCs does not increase risk for myocardial infarction later has already been clearly established (112).

Figure 10.12 Risk for myocardial infarction in women younger than 50 years of age: effect of oral contraceptives and smoking. (From Rosenberg L, Kaufman DW, Helmrich SP, et al. Myocardial infarction and cigarette smoking in women younger than 50 years of age. *JAMA* 1985;253:2965–2969, with permission.)

One study of so-called third-generation OCs found that women using OCs containing the new progestins desogestrel or gestodene are less likely to have myocardial infarction than women who use OCs with similar estrogen doses (113). Myocardial infarction risk was strongly increased among smokers, even after adjustment for OC use, but smokers who used OCs with the new progestins were less likely to have myocardial infarction than smokers who used the older OCs (113). These findings are biologically plausible based on the beneficial effect on lipids of OCs containing the new progestins.

Oral Contraceptives and Stroke In the 1970s, OC use appeared to be linked to risk for both hemorrhagic and thrombotic stroke, but these studies failed to take into consideration preexisting risk factors (114). Although a rare form of cerebrovascular insufficiency, moyamoya disease, is clearly linked to OC use (115), new information shows no risk for women who are otherwise healthy and who use currently available low-dose pills. Petitti and colleagues identified all Kaiser Permanente Medical Care Program patients aged 15 to 44 years who sustained fatal or nonfatal stroke in California from 1991 to 1994 (116). Hypertension, diabetes, obesity, current cigarette smoking, and black race were strongly associated with stroke risk, but neither current nor past OC use was associated with stroke in this study. A World Health Organization (WHO) study of cases from 1989 to 1993 from 17 countries in Europe and the developing world included women on higher-dose OCs as well as low-dose OCs. European women using low-dose OCs had no increased risk for either type of stroke, thrombotic or hemorrhagic. Those on higher-dose OCs did have measurable risk (117,118). Women in developing countries had an apparent modest increase in risk, but this finding was attributed to undetected existing risk factors. Another study from Europe found less stroke risk from low-dose pills than from older higher-dose pills, and that risk was less if the patient's blood pressure was checked before starting OCs. The authors concluded that a small risk from low-dose OCs could be controlled if women with hypertension were not given OCs (119).

Smokers and women with hypertension and diabetes are clearly at increased risk for cardiovascular disease whether or not they use oral contraceptives. The important question is whether risk is further increased if they use low-dose OCs, and if so, by how much. The World Health Organization study described previously provides some insight: Smokers taking OCs had 7 times the risk for ischemic (thrombotic) stroke when compared with smokers who did not use OCs, and hypertensive women had 10-fold increased risk if they took OCs, but a 5-fold risk if they did not (117). Similarly, Lidegaard reported from Denmark that diabetic women had a 5-fold increase risk for stroke, which increased to 10-fold if they took OCs (120). Unfortunately, Lidegaard's data were not limited to low-estrogen OCs. The data suggest that although risk is primarily determined by the predisposing condition—hypertension, diabetes, or cigarette smoking—the risk can be magnified by OC use, even when the OCs are low dose. The current U.S. practice of limiting OC use by women older than 35 years of age to nonsmokers without other vascular disease risk factors is prudent.

Blood Pressure Oral contraceptives have a dose-related effect on blood pressure. With the older high-dose pills, as many as 5% of patients could be expected to have blood pressure levels of higher than 140/90 mm Hg. The mechanism is believed to be an estrogen-induced increase in renin substrate in susceptible individuals. Current low-dose pills have minimal blood pressure effects, but surveillance of blood pressure is still advised to detect the occasional idiosyncratic response.

Glucose Metabolism Oral estrogen alone has no adverse effect on glucose metabolism, but progestins exhibit insulin antagonism (121). Older OC formulations with higher doses of progestins produced abnormal glucose tolerance tests with elevated insulin levels in the average patient. The effect on glucose metabolism, similar to the effect on lipids, is related to androgenic potency of the progestin and to its dose (7972).

Lipid Metabolism Higher-dose OCs could have significant adverse effects on lipids (122). Androgens and estrogens have competing effects on hepatic lipase, a liver enzyme critical to lipid metabolism. Estrogens depress LDL and elevate HDL, which are changes that can be expected to reduce the risk for atherosclerosis (123). Androgens and androgenic progestins can antagonize these beneficial changes, reducing HDL and elevating LDL levels. Estrogens elevate triglyceride levels. Low-dose formulations have minimal adverse effect on lipids (124), and the newer formulations (with desogestrel and norgestimate as the progestin) produce potentially beneficial changes by elevating HDL and lowering LDL (79) (Fig. 10.13). Although average values of a large group show only small lipid changes with current OCs, an occasional patient may have exaggerated effects. Women whose lipid values are higher than the mean before treatment are more likely to experience abnormalities during treatment (124).

Figure 10.13 Percentage differences in HDL and LDL cholesterol levels and in the incremental area for insulin in response to the oral glucose tolerance test (OGTT) between women taking one of seven combination oral contraceptives and those not taking oral contraceptives. The T bars indicate 1 standard deviation, and the double daggers ($p < 0.05$) indicate significant differences between users and nonusers in the mean values for the principal metabolic variables. EE, ethinyl estradiol; LG, levonorgestrel; NE, norethindrone; DG, desogestrel. (From **Godsland IF, Crook D, Simpson R, et al.** The effects of different formulations of oral contraceptive agents on lipid and carbohydrate metabolism. *N Engl J Med* 1990;323:1375–1382, with permission.)

Other Metabolic Effects Oral contraceptives can produce changes in a broad variety of proteins synthesized by the liver. The estrogen in OCs increases circulating-thyroid-binding globulin, thereby affecting tests of thyroid function that are based on binding, increasing total thyroxine (T_4), and decreasing triiodothyronine (T_3) resin uptake. The results of actual thyroid function tests, as measured by free T_4 and radioiodine tests, are normal (125).

Oral Contraceptives and Neoplasia

Endometrial Cancer and Ovarian Cancer Combination OCs reduce the risk for subsequent endometrial cancer and ovarian cancer (126,127). A recent study found that as little as 1 year of OC use was protective (OR, 0.57; 95% CI, 0.87 to 1.03), and continued use reduced risk by 7% per year. Benefit persisted for 15 years after last use, with little diminution (128). A 50% reduction in ovarian cancer risk was observed for women who took OCs for 3 to 4 years, and an 80% reduction was seen with 10 or more years of use. There was some benefit from as little as 3 to 11 months of use. The benefit continues for at least 15 years since last use, and it does not diminish even at 15 years from use (126). National vital statistics data from England support these observations. Ovarian cancer mortality is declining in England and Wales in women younger than 55 years of age, and this decline has been attributed to OC use (129). Use of OCs after 1980, when low-dose pills predominated, provides protection equivalent to older, higher-dose OCs (130).

Two years of OC use reduces the risk for subsequent endometrial cancer by 40%, and 4 or more years of use reduces the risk by 60% (127).

Cervical Cancer There may be a weak association between OC use and squamous cancer of the cervix. Important risk factors are early sexual intercourse and exposure to human papillomavirus (131). Women who have used OCs typically started sexual relations at younger ages than women who have not used OCs and, in some studies, report having had more partners. These factors also increase one's chance of acquiring human papillomavirus (HPV), the most important risk factor for cervical cancer. Because barrier contraceptives reduce the risk for cervical cancer, use of alternative choices for contraception can compound the difficulty in establishing an association with OC use alone. The presence of HPV types 16 or 18 is associated with a 50-fold increase in risk for preneoplastic lesions of the cervix (132). **If a woman already has HPV, OC use does not further increase her risk for cervical neoplasia, but among women who are HPV negative, OC use doubles the risk of having such a lesion.** This apparent adverse effect could be explained entirely by OC users being less likely to use barrier contraception.

Adenocarcinomas of the cervix are rare, but they are not as easily detected as other lesions by screening cervical cytology, and the incidence appears to be increasing. A 1994 study found a doubling of risk for adenocarcinoma with OC use that increased with duration of use, reaching a relative risk of 4.4 if total use of OCs exceeded 12 years (133). The results of this study were adjusted for history of genital warts, number of sexual partners, and age at first intercourse. Because adenocarcinoma of the cervix is rare, absolute risk is low. If this apparent association were real, the cumulative risk of long-term OC use to 55 years of age would be about 1 in 1,000 patients (134).

Use of OCs is, at most, a minor factor in causation of cervical cancer; however, women who have used OCs should have annual Papanicolaou (Pap) tests. To reduce risk, women who are not in mutually monogamous relationships should be advised to use barrier methods in addition to hormonal contraception.

Breast Cancer There is a large volume of conflicting literature on the relationship between OC use and breast cancer. Generally, no increase in overall risk is found from OC use, but some studies have found that risk may increase in women who used OCs before their first term pregnancy (135) or who used OCs for many years, who are nulligravid, who are young at the time of diagnosis, and who continue using OCs in their 40s (136). A large British study found a small but statistically stable increase in breast cancer diagnosed before 36 years of age among OC users, but that risk was less for OCs with less than 50 mg of estrogen. Progestin-only OCs appeared to have a protective effect. Significantly, OC users who developed breast cancer were more likely to be diagnosed in early stages and were less likely to have lymph node involvement than were controls (136). Women with a family history of breast cancer were not found to have increased risk with OC use in one study (137). Some of the findings are difficult to interpret; for example, risk does not increase with prolonged exposure. This finding would not be expected if OCs were truly causal (137).

The best information to date comes from a metaanalysis of 54 studies of breast cancer and hormonal contraceptives. The Collaborative Group on Hormonal Factors in Breast Cancer reanalyzed data on 53,297 women with breast cancer and 100,239 controls from 25 countries, representing about 90% of the epidemiologic data available worldwide (138). Current use of OCs was associated with a very small but statistically stable 24% increased risk [relative risk (RR), 1.24; 95% CI, 1.15 to 1.33]. The risk fell rapidly after discontinuation, to 16% 1 to 4 years after stopping and to 7% 5 to 9 years after stopping. Risk disappeared 10 years after cessation (RR, 1.01; 95% CI, 0.96 to 1.05). Breast cancers diagnosed while women were taking OCs were less advanced clinically than those in women who had never used OCs. Results did not differ in any important way by ethnic group, reproductive history, or family history. There was a greater risk in women who started OC use before 20 years of age relative to women who started OCs later, but because breast cancer is so rare before 20 years of age, there was no increase in actual numbers of breast cancer cases among women who started use of OCs at a young age. A term pregnancy also causes a short-term increase in breast cancer risk, thought to be from the growth-enhancing effects of estrogen, but there is a longer-term reduction in risk, perhaps the result of pregnancy-induced terminal differentiation of breast cells (139). The effects of OCs may be the same and may promote growth of existing cancers, leading to their presentation and diagnosis at an earlier age, rather than actually causing cancers to form. Most breast cancers are seen after 50 years of age, and only now are large numbers of women with OC exposure entering this age group. At present the risk, if it is increased, is small, and is not present 10 years after cessation of use. Reassurance is provided by a 1999 Swedish study that compared 3,016 women aged 50 to 74 years who had invasive breast cancer with 3,263 controls of the same age. No relation between past use of OCs and breast cancer was found (140).

In the Collaborative Group's study, oral contraceptive use by women with a first-degree relative who had breast cancer did not increase risk regardless of the duration of use before first-term pregnancy (138). In contrast, a recent historical cohort study of 426 families with breast cancer found that sisters and daughters of women with breast cancer had a threefold increase risk for breast cancer if they had used OCs before 1975. Granddaughters and nieces or women who married into the families

had no increased risk. There were too few cases among women who used the lower-dose OCs available after 1975 to determine whether there is risk (141).

Liver Tumors OCs have been implicated as a cause of benign adenomas of the liver. These hormonally responsive tumors can cause fatal hemorrhage. They usually regress when OC use is discontinued; risk is related to prolonged use (142). There is a strong correlation between OC use and hepatocellular adenoma. Fortunately, the tumors are rare; about 30 cases per 1,000,000 users per year have been predicted with older formulations. Presumably, newer low-dose products pose less risk. A link to hepatic carcinoma has been proposed, but a large study from six countries in Europe found no association between use of OCs and subsequent liver cancer (143).

Health Benefits of Oral Contraceptives

OCs have important health benefits (Table 10.6). As noted earlier, OC use produces strong and lasting reduced risk for endometrial and ovarian cancer. In addition, protection has been found for women with known hereditary ovarian cancer. Any past use of OCs conferred a 50% reduction in ovarian cancer risk when women with this history who took OCs were compared with their sisters as controls (OR, 0.5; 95% CI, 0.3 to 0.8). Protection increased with increasing duration of use (144). The mechanism of action of OCs in the prevention of ovarian cancer is unknown but may involve selective induction of apoptosis (programmed cell death). Macaques treated with *EE* plus *levonorgestrel* or *levonorgestrel* alone showed an increase in the proportion of ovarian epithelial cells in apoptosis in comparison with animals fed a diet containing no hormones (145).

Clearly established benefits
Reduced ovarian cancer
Reduced endometrial cancer
Reduced ectopic pregnancy
Reduced benign breast disease
Reduced functional ovarian cysts
Reduced uterine fibroids
Less dysmenorrhea
Less anemia
Regular menstrual cycle
Reduced pelvic inflammatory disease
Reduced risk of colon cancer
Less clearly established benefits
Fewer new cases of rheumatoid arthritis
Less osteoporosis
Less osteoarthritis
Less atherosclerosis

From Stubblefield PC. Health benefits of oral contraceptives. In: *Pharm 1996*, 29(Suppl 3):113-138, with permission.

Table 10.6. Noncontraceptive Benefits of Oral Contraception

Chlamydial colonization of the cervix appears more likely in OC users than in nonusers but, despite this, there is a 40% to 50% reduction in risk for chlamydial PID (146). Combination OCs confer marked reduction in risk for ectopic pregnancy, although the progestin-only OCs appear to increase risk.

Other documented benefits of OC use include a significant reduction in the need for biopsies for benign breast disease and surgery for ovarian cysts. Use of OCs also helps relieve dysmenorrhea and associated anemia from menstrual blood loss (147). All combination OCs offer some protection from functional ovarian cysts, but multiphasic preparations offer less protection than other forms of combination OCs (148). If progestin-only OCs are truly protective against breast cancer, the *levonorgestrel* implants also could be expected to confer this benefit.

There is growing evidence that OC use is also protective against colon cancer. A case-control study in Italy comparing women with colon cancer with controls found a 37% reduction in colon cancer and a 34% reduction in rectal cancer (colon cancer OR, 0.63, 95% CI 0.45 to 0.87; rectal cancer OR, 0.66, 95% CI 0.43 to 1.01). Longer use produced more protection against colon cancer (149). Results of the U.S. Nurses Health Study also disclosed some degree of protection. Women who had used OCs for 96 months or more had a 40% lower risk for colorectal cancer (RR, 0.60; 95% CI, 1.15 to 2.14) (150). The mechanism of protection has not been identified.

Fertility after OC Use After discontinuing OCs, return of ovulatory cycles may be delayed for a few months. Women who have amenorrhea more than 6 months after discontinuation of OCs should undergo a full evaluation because of the risk for prolactin-producing pituitary tumors. This risk is not related to OC use but rather to the probability that the slow-growing tumor was already present and produced menstrual irregularity, prompting the patient to take OCs (151).

Sexuality In a study that recorded all episodes of female-initiated sexual behavior throughout the menstrual cycle, an increase in sexual activity at the time of ovulation was noted. This increase was not present in women who were taking OCs (152).

Teratogenicity A metaanalysis of 12 prospective studies, including 6,102 women who used OCs and 85,167 women who did not, revealed no increase in overall risk for malformation, congenital heart defects, or limb reduction defects with the use of OCs (153). Progestins have been used to prevent miscarriage. A large study compared women showing signs of threatened abortion who were treated with progestins (primarily medroxyprogesterone acetate) with women who were not treated. The rate of malformation was the same among the 1,146 exposed infants as among the 1,608 unexposed infants (154). Conversely, estrogens taken in high doses in pregnancy can induce vaginal cancer in exposed female offspring *in utero*.

Interaction of Oral Contraceptives with Other Drugs

Some drugs reduce the effectiveness of oral contraceptives (e.g., rifampin); conversely, OCs can augment or reduce the effectiveness of other drugs (e.g., benzodiazepines). Phenytoin, phenobarbital, and rifampin induce synthesis of cytochrome P450 enzymes in the liver and reduce plasma levels of *EE* in women taking OCs, which may cause contraceptive failure (155). The antifungal agents *griseofulvin*, *ketoconazole*, and *itraconazole* also induce these hepatic enzymes and may reduce OC efficacy (156). *Ampicillin* and *tetracycline* have been implicated in numerous case reports of OC failure. They kill gut bacteria (primarily clostridia) that are responsible for hydrolysis of steroid glucuronides in the intestine, which allows reabsorption of the steroid through the enterohepatic circulation. In human studies, however, it has not been possible to demonstrate reduced plasma levels of *EE*. Although women taking OCs who will be treated with antibiotics are commonly advised to use condoms as well, controlled studies of OC users have found no difference in pregnancy rates with exposure to penicillins, cephalosporins, and tetracyclines (157).

Certain drugs actually appear to increase plasma levels of contraceptive steroids. Ascorbic acid (vitamin C) and *acetaminophen* may elevate plasma *EE*.

An example of OCs affecting the metabolism of other drugs is seen with *diazepam* and related compounds. OCs reduce the metabolic clearance and increase the half-life of those benzodiazepines that are metabolized primarily by oxidation: *chlordiazepoxide*, *alprazolam*, *diazepam*, and *nitrazepam*. *Caffeine* and *theophylline* are metabolized in the liver by two of the P450 isozymes, and their clearance is also reduced in OC users. *Cyclosporine* is hydroxylated by another of the P450 isozymes, and its plasma concentrations are increased by OCs. Plasma levels of some analgesic drugs are decreased in OC users. *Salicylic acid* and *morphine* clearances are enhanced by OC use; therefore, higher doses could be needed for adequate therapeutic effect. Clearance of *ethanol* may be reduced in OC users (158).

Oral Contraceptives and Clinical Chemistry Alterations

Oral contraceptives have the potential to alter a number of clinical laboratory tests as a result of estrogen-induced changes in hepatic synthesis; however, a large study comparing OC users to pregnant and nonpregnant controls found minimal changes (158). Hormone users took a variety of OCs containing 50 to 100 mg of estrogen, higher doses than are used today. Compared with nonpregnant women who were not using OCs, the OC users had an increase in T₄ that is explained by increased circulating thyroid-binding protein, no change in creatinine, a slight reduction in mean fasting glucose values, a reduction in total bilirubin, a modest reduction in serum glutamic oxaloacetic transaminase, a decrease in alkaline phosphatase, and no change in globulin.

Choice of Oral Contraceptives

The oral contraceptives currently available in the United States are listed in [Table 10.7](#). With the introduction of OCs containing the new progestins, new preparations with 20 mg of *EE*, new variations of multiphasic preparations, plus branded generic formulations of older OCs, an array of choices are possible.

Table 10.7. Composition of Oral Contraceptives in Current Use in the United States, 2001

The lowest-dose OCs all contain the same amount of the same estrogen, 20 mg of *EE*. However, the progestins differ: *norethindrone acetate*, *levonorgestrel*, *desogestrel*, or *norgestimate* ([Table 10.7](#)). The first 20-mg *EE* OC (*LoEstrin 1-20*) contained 1 mg *norethindrone acetate*. A comparison of this OC to a triphasic OC with 35 mg of *EE* and *norgestimate* (NGM) (*Ortho Tri-Cylen*) found considerable more breakthrough bleeding and spotting and more episodes of missed menses with the 20-mg *norethindrone acetate/EE* than with the higher-estrogen OC containing *norgestimate*. There was no difference in compliance, discontinuation rates, or adverse events ([159](#)). In a three-way trial, the 35-mg NGM/*EE* triphasic OC (*Ortho Tri-Cylen*) was compared with two new 20-mg *EE* pills, one containing 100 mg of *levonorgestrel* (*Allose*), the other containing 150 mg *desogestrel*, followed by 2 hormone-free days then 5 days of 10 mg *EE* per day (*Mircette*) ([160](#)). Contraceptive efficacy was not significantly different. Women starting on OCs had more breakthrough bleeding and bleeding in the second half of the cycle with *Allose* than with the other two OCs in the first two cycles, but thereafter there was little difference, except that *Mircette* users had more breakthrough bleeding in cycle 4. Women taking *Tri-Cylen* consistently experienced more frequent estrogenic side effects of bloating, breast tenderness, and nausea than did women on either 20-mg *EE* OC. These authors concluded that for the specific OCs evaluated, changing to the lowest estrogen dose was beneficial.

For the average patient, the first choice of preparation for contraceptive purposes is a low-estrogen OC (20 to 35 mg of *EE*) or a very low-estrogen OC (20 mg *EE*).

1. Breakthrough bleeding and spotting are common at first and generally improve with time. If the problem persists, it may be relieved by changing from a multiphasic to monophasic version at the same estrogen level.
2. If bleeding remains a problem, a temporary increase in estrogen should be tried: 20 mg of *EE* daily for 7 days while continuing the OC ([161](#)).

Side effects—nausea, breast tenderness, mood changes, and weight gain—are less common with current formulations than with previous OCs and usually resolve after the first few cycles.

1. If symptoms persist, the lowest-dose highly effective formulations could be tried: those containing only 20 mg of *EE*.
2. In patients who have persistent breast tenderness, the type of OC could be changed to one with more progestin activity, for example, the 20- to 30-mg *EE* pills that contain *levonorgestrel*. High-potency progestin OCs produce fewer breast symptoms ([162](#)).
3. Nausea is generally related to the estrogen component, and changing to the 20-mg *EE* preparation may be beneficial.

Injectable Hormonal Contraceptives

Depomedroxyprogesterone Acetate

Depomedroxyprogesterone acetate (*DMPA*), a suspension of microcrystals of a synthetic progestin, was approved for contraception in 1992. A single 150-mg intramuscular dose will suppress ovulation in most women for 14 weeks or longer ([163](#)). The regimen of 150 mg every 3 months is highly effective, producing pregnancy rates of about 0.3 per 100 women per year. Probably because of the high blood levels of the progestin, efficacy appears not to be reduced by administration of other drugs and is not dependent on the patient's weight. Women treated with *DMPA* experience disruption of the menstrual cycle and have initial spotting and bleeding at irregular intervals. Eventually, total amenorrhea develops in most women who take *DMPA*; with continued administration, amenorrhea develops in 50% of women by 1 year and in 80% by 3 years ([Fig. 10.14](#)). Persistent irregular bleeding is treated by adding low-dose estrogen temporarily; for example, conjugated estrogens, 1.25 mg per day, can be given for 10 to 21 days at a time. *DMPA* persists in the body for several months in women who have used it for long-term contraception, and return to fertility may be delayed. In a large study, however, 70% of former users desiring pregnancy conceived within 12 months, and 90% conceived within 24 months ([164](#)).

Figure 10.14 Bleeding pattern and duration of use of depomedroxyprogesterone acetate (DMPA): percentage of women who have bleeding, spotting, or amenorrhea while taking DMPA 150 mg every 3 months. (From Schwallie PC, Assenzo JR. Contraceptive use-efficacy study utilizing *medroxyprogesterone acetate* administered as an intramuscular injection once every 90 days. *Fertil Steril* 1973;24:331–339, with permission.)

Safety

Long-term users of *DMPA* may have lower bone density than nonusers, probably reflecting reduced estrogen levels; however, this effect has not been associated with increased fractures ([165](#)). Other investigators have not detected bone loss during 3 years or more of *DMPA* use ([166](#)). A small study comparing *DMPA* to implant or OC users found that *DMPA* blocked the usual rapid increase in bone density normally seen in adolescents ([167](#)). This may suggest that *DMPA* may be less desirable for young adolescents. The effect of *DMPA* on plasma lipids has been inconsistent; in general, *DMPA* users appear to have reduced total cholesterol and triglycerides, slight reduction in HDL cholesterol, and no change or slight increase in LDL cholesterol, all of which are consistent with a reduction in circulating estrogen levels. In some studies, the decrease in HDL and increase in LDL are statistically significant, although the values remain within normal ranges ([168](#)). The use of *DMPA* has not been associated with myocardial infarction. Glucose tolerance tests disclose a small elevation of glucose in *DMPA* users. There is no change in hemostatic parameters, with the exception that antithrombin III levels are sometimes found to be reduced with chronic therapy ([168](#)). *DMPA* has not been linked to thrombotic episodes in women of reproductive age. However, thrombotic episodes have occurred in elderly women with advanced cancer who were treated with a

variety of agents, including *DMPA* and *tamoxifen* (169,170). Such patients are at high risk for thrombosis regardless of the use of *DMPA*. Women taking *DMPA* appear to experience a weight gain of 2 to 3 pounds more than nonusers over several years. Its use has not been associated with teratogenesis. It is safe for use by lactating women and, as with other progestin-only hormonal methods, appears to increase milk production. *DMPA* has not been associated with affective disorders or mood changes, although the data are limited (171,172).

Benefits

DMPA appears to have many of the noncontraceptive benefits of combination oral contraceptives. Decreases in anemia, PID, ectopic pregnancy, and endometrial cancer have been reported (173). No association between *DMPA* and cervical cancer has been demonstrated (174). Ovarian cancer has been found to be unrelated to the use of *DMPA* (175). The risk for breast cancer diagnosis during the first 4 years of use appears to be slightly increased, but there is no relation to long-term use and no overall increase in breast cancer risk; hence, any causal relationship between *DMPA* and breast cancer is unlikely (176).

Once-a-Month Injectable

A once-a-month injectable containing only 25 mg of *DMPA* in combination with 5 mg of the long-acting estrogen, estradiol cypionate, has recently become available in the United States after extensive use in developing countries. Originally developed by the World Health Organization, it is described as *CycloFem* or *CycloProvera* in the literature, and is marketed in the United States as *Lunelle* (177). Given once a month, this combination produces excellent contraceptive effects. Monthly withdrawal bleeding is like a normal menses, leading to high continuation rates (178).

Subdermal Implants

The *levonorgestrel* implant (*Norplant*) consists of six rods, each measuring 34 mm in length and 2.4 mm in outside diameter and containing 36 mg of the progestin *levonorgestrel* (179,180,181,182,183,184,185 and 186). About 80 mg/d is released during the first 6 to 12 months after insertion. The release rate then gradually declines to 30 to 35 mg/d. Blood levels of the steroid are about 0.35 ng/mL at 6 months and remain above 0.25 ng/mL for 5 years. Plasma levels less than 0.20 ng/mL result in higher pregnancy rates. The level of progestin present for implant users produces very effective contraception; the total number of pregnancies over 5 years is only 1 in 100 (180). The progestin blocks the LH surge necessary for ovulation, so that over 5 years, only about one third of cycles are ovulatory. In response to the progestin, the cervical mucus becomes scant and thick and does not allow sperm penetration. An older, thicker-walled version of the implants was studied in the United States and had less contraceptive efficacy for women weighing 70 kg or more. Current devices have a pliable, less dense wall, and the release rate of *levonorgestrel* is 15% higher than with earlier versions, so that weight is less of a problem (Table 10.8). Some advise that in obese women, the implants should be replaced after 3 years in order to maintain a high level of pregnancy protection.

Weight at insertion (kg)	No. of Patients	Total	Pliable Tubing	Rigid Tubing
<50	552	0.2	0	0.3
50-59	1,041	3.5	2.0	4.3
60-69	585	3.5	1.5	4.5
>70	309	7.6	2.4	9.3
Total	2,489	3.5	1.6	4.9

From Dansey PD. Hormonal implants: contraception for a new century. *Am J Obstet Gynecol* 1994;170:1536-1543, with permission.

Table 10.8. Pregnancy Rates with Norplant: Gross Cumulative Pregnancy Rates at 5 Years by Patient's Weight and Type of Tubing

A two-rod version of *Norplant*, *Norplant II*, has undergone extensive testing. It is as effective as *Norplant* and is easier to insert and remove (185). Single-rod systems containing a new progestin, 3-keto-desogestrel (*Implanon*) are in the final phase of U.S. trials. In preliminary studies, *Implanon* appeared to be even more effective than *Norplant* (186). It is intended for 3 years of use.

Bleeding Patterns

The implant produces endometrial atrophy. The normal menstrual cycle is disrupted, resulting in a range of possible bleeding patterns, from reasonably regular monthly bleeding, to frequent spotting and almost daily bleeding, to complete amenorrhea. The bleeding pattern changes over time and eventually tends to become more like a normal menstrual pattern. Women who have monthly bleeding are more likely to be ovulating and should be evaluated for pregnancy if they become amenorrheic. Irregular bleeding and spotting can be treated with low-dose oral estrogen, low-dose oral *levonorgestrel*, or *ibuprofen* (179). Implants have no adverse effect on lactation and can be used by lactating women. Their effects are immediately reversed by removing the implants, and the return to fertility is generally prompt.

Metabolic Effects

Implants do not alter glucose metabolism. There are minimal lipid changes. Total cholesterol and triglycerides are reduced, and there is either no change or minimal decrease in HDL, but the same ratio of total cholesterol to HDL is maintained. Therefore, it is very unlikely that implants promote development of atherosclerosis (180). Implants have no adverse effect on bone density. A cross-sectional comparison of long-term implant users with IUD-wearing women found no differences in bone density as assessed by dual-energy x-ray absorptiometry (181).

Adverse Events and Side Effects

Irregular bleeding and headache are the main reasons given for discontinuing use of implants. Side effects that are occasionally reported include acne, weight gain or loss, mastalgia, mood change, depression, hyperpigmentation over the implants, hirsutism, and galactorrhea. Symptomatic functional cysts occasionally occur. These usually resolve spontaneously over a few weeks without surgery. If pregnancy occurs, the probability of it being ectopic is increased compared with conceptions in other women; however, because pregnancy is so rare in women using implants, the total rate of ectopic pregnancies (0.28 per 1,000 woman-years) is well below that of the U.S. population (180). Serious side effects resulting in hospitalization or disability reported to the FDA from 1991 to 1993 included 24 women with infection at the implantation site, 14 with difficulties in removing the capsules, 14 with stroke, 3 with thrombotic thrombocytopenic purpura, 6 with thrombocytopenia, and 29 with pseudotumor cerebri (182). The rate of occurrence of these illnesses did not exceed that expected in women in the reproductive years, and no causal connection was implied. The hospitalizations from problems of insertion and removal can be totally prevented by using proper technique with these procedures (183).

Insertion

Implants are inserted just beneath the skin of the inner surface of the upper arm using a 10-gauge trocar as an inserter. Insertion is readily accomplished in a few minutes with local anesthesia. It is important to place the trocar just beneath the skin, inserted parallel to the skin, all the way to the second mark on the trocar before loading the rod for insertion. In this way, the rods are inserted without tension and will not migrate. Difficult removals generally are the result of poor insertion technique. Removal of implants can be time consuming. The end of the rod should be manipulated into a small incision in the skin, using a scalpel to nick the fibrous sheath that forms around the rod and then pushing it out with finger pressure (183). With the Emory technique, a somewhat longer (10-mm) incision is used, and hemostat forceps are used to disrupt the fibrous capsule around the ends of all of the implants before removal with an instrument (180). With the "U" technique, an incision is made over the midportion of the middle implant, and a special grasping forceps developed for vasectomy procedures is advanced subcutaneously to grasp the midportion of each rod and extract it (184).

Emergency Contraception

Implantation of the fertilized ovum is believed to occur on the sixth day after fertilization. This interval provides an opportunity to prevent pregnancy even after fertilization occurs. This can be accomplished using hormonal agents singly or in combination, or IUDs.

Estrogens

High-dose estrogen taken within 72 hours of coitus prevents pregnancy. The mechanism of action of postcoital estrogen use may involve altered tubal motility, interference with corpus luteum function mediated by prostaglandins, or alteration of the endometrium. In an analysis of more than 3,000 women treated after coitus with 5 mg of *EE* daily for 5 days, the pregnancy rate was 0.15% (187).

Estrogen and Progestin in Combination

High-dose estrogen has largely replaced the combination of *EE* 0.200 mg and *levonorgestrel* 2 mg (2 *Ovral* tablets followed by 2 more tablets 12 hours later), as first described by Yuzpe (188). The average pregnancy rate with this method is 1.8%, but it is 1.2% if treatment is started within 12 hours of intercourse (189). Nausea and vomiting are common with both regimens, and an antiemetic is usually prescribed. A comparable dosing of *EE* and *levonorgestrel* is provided by taking 4 tablets of *LoOvral*, *Nordette*, *Levlen*, *Triphasil*, or *TriLevlen*, or 5 tablets of *Allose*, instead of 2 tablets of *Ovral*. A kit containing four tablets, each containing 50 mg of *EE* and 250 mg of *levonorgestrel*, is marketed in the United States under the name *Preven* specifically for emergency contraception.

Levonorgestrel Alone

A new and better alternative for emergency contraception is using *levonorgestrel* alone, 0.75 mg initially, followed by another 0.75 mg 12 hours later. This preparation is sold in the United States as Plan B. The World Health Organization carried out a randomized trial with 1998 women assigned to the Yuzpe method or to *levonorgestrel* alone, started within 72 hours of intercourse. The pregnancy rate was 3.2% with the Yuzpe method, and only 1.1% with *levonorgestrel* alone (RR for pregnancy, 0.32; 95% CI, 0.18 to 0.70). Nausea and vomiting occurred much less frequently with *levonorgestrel* alone (23.1% versus 50.5%, and 5.6% versus 18.8%) (190). The efficacy of both methods declines as time increases since intercourse. Even after 49 to 72 hours, however, the pregnancy rate with the *levonorgestrel* treatment was only 2.7%, and it is likely that considerable efficacy would be found beyond 72 hours (Fig. 10.15). Because of greater efficacy and less nausea, *levonorgestrel* used alone appears to be the best hormonal method for emergency contraception currently available in the United States.

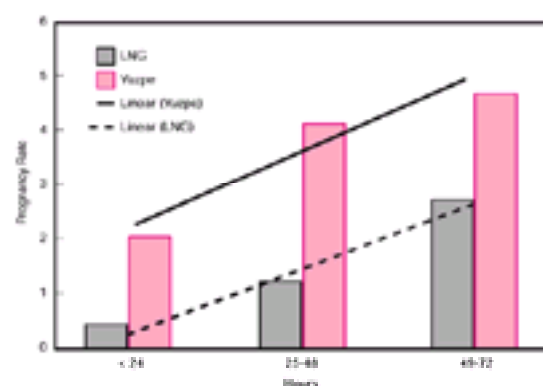

Figure 10.15 Emergency contraception: pregnancy rates by treatment group and time since unprotected coitus. LNG is levonorgestrel, 0.75 mg × 2. Yuzpe method is ethinyl estradiol, 0.100 mg plus levonorgestrel 0.50 mg × 2, 12 hours later. [From Anon. Randomized controlled trial of levonorgestrel versus the Yuzpe regimen of combined oral contraceptives for emergency contraception. Task Force on Postovulatory Methods of Fertility Regulation. *Lancet* 1998;352:430 (modified from Table 3), with permission.]

Copper Intrauterine Device

Postcoital insertion of a copper IUD within 72 hours appears to be even more effective than steroids (191). In 879 patients treated with an IUD, only one pregnancy occurred (187). No pregnancies occurred during the first month after insertion of copper IUDs as long as 7 days after coitus. It is likely that the *levonorgestrel* IUD would also work for this purpose, but there are as yet no studies of its use after coitus.

Danazol

A weak androgen, danazol has also been used for emergency contraception. The pregnancy rate was 2% among 998 women (187). In general, the oral contraceptive preparations are more desirable because they are less costly and have fewer side effects.

Mifepristone

The antiprogestone *mifepristone* (*RU486*) is also highly effective for postcoital contraception and appears to have no significant side effects. A three-way trial of the Yuzpe method—*danazol*, 600 mg repeated after 12 hours, and *mifepristone*, 600 mg as a single dose, yielded pregnancy rates of 2.62, 4.66, and 0%, respectively (192). Much lower doses of *mifepristone* have been studied. Doses as low as 10 mg are effective (193). *Mifepristone* is also highly effective in inducing menstruation when taken on day 27 of the menstrual cycle, well beyond the 72-hour window usually considered for postcoital contraception. Of 62 women treated in this fashion, only 1 conceived (187).

Contraception for Women with Chronic Illness

Women with chronic illness may present special problems that should be considered in the choice of a method of contraception. The illness may make pregnancy more complicated and dangerous for these women, thus making effective contraception all the more important. Some common conditions and considerations about contraception are listed in Table 10.9.

Psychiatric disorders
<ul style="list-style-type: none"> • Avoid combination, progestin, ethinyl, and copper IUD in general. • Use of barrier methods should be encouraged by dominant sex partner.
Contraception disorders
<ul style="list-style-type: none"> • Menorrhagic disorders: CCI may be indicated to prevent hemorrhagic ovarian cysts and a decreased hematocrit. • Amenorrhea disorders: avoid estrogen-containing CCI.
Endocrine disorders
<ul style="list-style-type: none"> • May use low-dose CCI if lipid abnormality successfully managed by diet or drug therapy. • Use should be avoided in untreated or poorly controlled diabetes. • Avoid CCI if hyperandrogenism is present. • Avoid high androgen CCI, and CCI are acceptable.
Hypertension
<ul style="list-style-type: none"> • The woman with no other risk factors with well-controlled hypertension may use low-dose CCI. • CCI are contraindicated in women with poorly controlled hypertension. • CCI are contraindicated in women with poorly controlled hypertension. • Avoid CCI if hypertension is present. • Avoid high androgen CCI, and progestin-only CCI are good alternatives.
Diabetes
<ul style="list-style-type: none"> • Women with diabetes without vascular disease may use low-dose CCI. • CCI are contraindicated in women with vascular disease. • Avoid CCI if hypertension is present. • Avoid high androgen CCI, and progestin-only CCI are good alternatives.
Headache
<ul style="list-style-type: none"> • Avoid high androgen CCI, and progestin-only CCI are good alternatives. • Avoid high androgen CCI, and progestin-only CCI are good alternatives.
Smoking
<ul style="list-style-type: none"> • CCI are contraindicated in women with current or former smoking. • CCI are contraindicated in women with current or former smoking.

Table 10.9. Contraception for Women with Chronic Illness

Hormonal Contraception for Men

The same negative feedback of sex steroids that can block ovulation in women will also suppress spermatogenesis in men, but it will produce loss of libido and potentially extinguish sexual performance. Replacement testosterone therapy restores libido and performance without restoring spermatogenesis. The principle was first demonstrated in 1974 using oral estrogen and methyl testosterone (194). Testosterone alone suppresses pituitary release of LH and FSH to very low levels and depresses or abolishes spermatogenesis, whereas the testosterone in systemic circulation maintains normal sexual behavior and body habitus. Weekly doses of 200 mg achieved azoospermia in only 40% to 70% of white men; the rest became oligospermic (195). Pregnancy has occurred in partners of androgen-treated oligospermic men with sperm counts as low as 3 million/mL (196). Asian men may be treated more effectively than white men. In a study of seven Indonesian men, 100 mg of testosterone weekly produced azoospermia in all of them (197). Combinations of DMPA and androgen have been widely studied but also fail to achieve 100% sperm suppression in white men (198). Current interest is in using GnRH analogues to suppress spermatogenesis, with long-acting androgens used for replacement. One of these regimens will likely prove clinically useful, but at present, costs are high, and long-term safety remains to be established. Adverse lipid changes have been noted with DMPA and androgen combinations, raising concern about vascular disease with prolonged use. Liver cancer is a concern with long-term androgen therapy (199).

Sterilization

Surgical sterilization is the most common method of fertility control used by couples in the United States (4). Laparoscopic techniques for women and vasectomy for men are safe and readily available throughout the United States. The mean age at sterilization is 30 years. Age younger than 30 years when sterilized and divorce and remarriage are predictors of sterilization regret, which may lead to a request for reversal of sterilization (200).

Female Sterilization

Hysterectomy is no longer considered for sterilization because morbidity and mortality are too high in comparison with tubal sterilization. Four procedures are common in the United States.

1. Tubal sterilization at the time of laparotomy for a cesarean delivery or other abdominal operation
2. Postpartum minilaparotomy soon after vaginal delivery
3. Interval minilaparotomy
4. Laparoscopy

Vaginal tubal sterilization, which has been associated with occasional pelvic abscess, is rarely performed in the United States.

Postpartum tubal sterilization at the time of cesarean delivery adds no risk, other than a slight prolongation of operating time; however, cesarean birth has more risk than vaginal birth, and planned sterilization should not influence the decision to perform a cesarean delivery. Sterilization is no more likely to fail if done with a cesarean delivery than at other times (201).

Postpartum minilaparotomy can be performed in the immediate postpartum state. The uterus is enlarged, and the fallopian tubes lie in the midabdomen, easily accessible through a small, 3- to 4-cm subumbilical incision.

Interval minilaparotomy, first described by Uchida (202), was rediscovered and popularized in the early 1970s in response to the increased demand for sterilization procedures as a simpler alternative to laparoscopy. In the nongravid state, the uterus and tubes lie deep in the pelvis. A short transverse suprapubic incision is made, and the uterus and tubes are then elevated upward, just beneath the incision by use of a uterine-elevating probe placed into the uterine cavity through the vagina. Interval minilaparotomy is usually performed as an outpatient procedure and can be accomplished readily with local anesthesia and conscious sedation.

Surgical Technique

The tubal lesion usually elected is the Pomeroy or modified Pomeroy technique (Fig. 10.16). In the classic Pomeroy procedure, a loop of tube is excised after ligating the base of the loop with a single absorbable suture. A modification of the procedure is excision of the midportion of the tube after ligation of the segment with two separate absorbable sutures. This modified procedure has several names: *partial salpingectomy*, *Parkland Hospital technique*, *separate sutures technique*, and *modified Pomeroy*. In the Madlener technique, now abandoned because of too many failures, a loop of tube is crushed by cross-clamping its base, ligated with permanent suture, and then excised. Pomeroy and partial salpingectomy procedures have failure rates of 1 to 4 per 1,000 cases (201). In contrast, pregnancy is almost unheard of after tubal sterilization by the Irving or Uchida methods (201,202). In the Irving method, the midportion of the tube is excised, and the proximal stump of each tube is turned back and led into a small stab wound in the wall of the uterus and sutured in place, creating a blind loop (203). With the Uchida method, a saline-epinephrine solution (1:1,000) is injected beneath the mucosa of the midportion of the tube, separating the mucosa from the underlying tube. The mucosa is incised along the antimesenteric border of the tube, and a tubal segment is excised under traction so that the ligated proximal stump will retract beneath the mucosa when released. The mucosa is then closed with sutures, burying the proximal stump and separating it from the distal stump. In Uchida's personal series of more than 20,000 cases, there were no pregnancies (202).

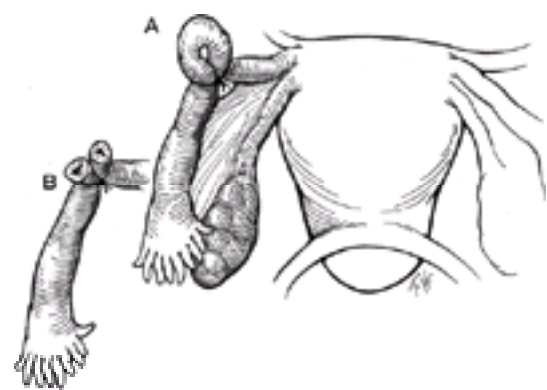

Figure 10.16 Pomeroy technique for tubal sterilization.

Laparoscopy

In the standard laparoscopy technique, the abdomen is inflated with a gas (carbon dioxide or nitrous oxide) through a special needle inserted at the lower margin of the umbilicus (204). A hollow sheath containing a pointed trocar is then pushed through the abdominal wall at the same location; the trocar is removed; and the laparoscope is inserted into the abdominal cavity through the sheath to visualize the pelvic organs. A second, smaller trocar is inserted in the suprapubic region to allow the insertion of special grasping forceps. Alternatively, an operating laparoscope that has a channel for the instruments can be used; thus, the procedure can be performed through a single small incision. Laparoscopic sterilization is usually performed in the hospital under general anesthesia but can be performed under local anesthesia with conscious sedation. Overnight hospitalization for laparoscopy is rarely needed.

Open Laparoscopy Standard laparoscopy carries with it a small but definite risk for injury to major blood vessels with insertion of the sharp trocar. With the alternative technique of open laparoscopy, neither needle nor sharp trocar is used; instead, the peritoneal cavity is opened directly through an incision at the lower edge of the umbilicus (205). A special funnel-shaped sleeve, the Hasson cannula, is then inserted, and the laparoscope is introduced through it.

Techniques of Laparoscopic Sterilization Sterilization is accomplished by any of four techniques: bipolar electrical coagulation, application of a small Silastic

rubber band (Falope ring) (206), the plastic and metal Hulka clip (204), or the Filshie clip (207). The Filshie clip is new to the United States, although it has been used extensively in the United Kingdom and Canada (208). It is a hinged device made of titanium with a liner of silicone rubber tubing. In the bipolar electrocoagulation technique, the midisthmic portion of the tube and adjacent mesosalpinx are grasped with special bipolar forceps, and radiofrequency electric current is applied to three adjacent areas, coagulating 3 cm of tube (Fig. 10.17). The tube alone is then recoagulated in the same places. The radiofrequency generator must deliver at least 25 watts into a 100-ohm resistance at the probe tips to ensure coagulation of the complete thickness of the fallopian tube and not just the outer layer; otherwise, the sterilization will fail (209). To apply the Falope ring, the midisthmic portion of the tube is grasped, with tongs advanced through a cylindrical probe that has the ring stretched around it. A loop of tube is pulled back into the probe, and the outer cylinder is advanced, releasing the Silastic ring around the base of the loop of tube, producing ischemic necrosis (Fig. 10.18). If the tube cannot be pulled easily into the applicator, the operator should stop and change to electrical coagulation rather than persist and risk lacerating the tube with the Falope ring applicator. The banded tube must be inspected at close range through the laparoscope to demonstrate that the full thickness of the tube has been pulled through the Falope ring. The Hulka clip is also placed across the midisthmus, ensuring that the applicator is at right angles to the tube and that the tube is completely contained within the clip before the clip is closed. The Filshie clip (Fig. 10.19) is also placed at right angles across the midisthmus, taking care that the anvil of the posterior jaw can be visualized through the mesosalpinx beyond the tube to ensure that the complete thickness of the tube is completely within the jaws of the clip before it is closed.

TABLE cellSpacing=0 cellPadding=0 align=left border=0 hspace="10" vspace="5">

Figure 10.17 Technique for bipolar electrocoagulation tubal sterilization.

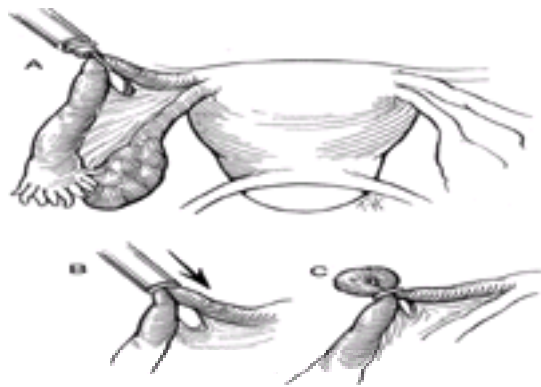

Figure 10.18 Placement of the Falope ring for tubal sterilization.

Figure 10.19 Filshie clip for tubal sterilization.

The electric and band or clip techniques each have advantages and disadvantages. Bipolar coagulation can be used with any fallopian tube. The Falope ring and Hulka and Filshie clips cannot be applied if the tube is thickened from previous salpingitis. There is more pain during the first several hours after Falope ring application. This can be prevented by bathing the tubes with a few milliliters of 2% lidocaine just before ring placement. Failures of the Falope ring or the clips generally result from misapplication, and pregnancy, if it occurs, is usually intrauterine. After bipolar sterilization, pregnancy may result from tuboperitoneal fistula and is ectopic in more than 50% of cases. If inadequate electrical energy is used, a thin band of fallopian tube remains that contains the intact lumen and allows intrauterine pregnancy to occur. Thermocoagulation, the use of heat probes rather than electrical current, is employed extensively in Germany for laparoscopic tubal sterilization but has had little use in the United States.

Risks of Tubal Sterilization

Tubal sterilization is remarkably safe. In 1983, the total complication rate in a large series from several institutions was 1.7 per 100 (210). Complications were increased by use of general anesthesia, previous pelvic or abdominal surgery, history of PID, obesity, and diabetes mellitus. The most common significant complication was unintended laparotomy for sterilization after intraabdominal adhesions were found. In another series, 2,827 laparoscopic sterilizations were performed with the Silastic band using local anesthesia and intravenous sedation. Only four cases could not be completed (a technical failure rate of 0.14%), and laparotomy was not needed (211). Rarely, salpingitis can occur as a complication of the surgery. This occurs more often with electric coagulation than nonelectric techniques. From 1977 until 1981, there were four deaths per 100,000 procedures in the United States, less than the risk of one pregnancy; almost half of the deaths were from complications of general anesthesia, usually related to the use of mask ventilation (212). The last U.S. national study was of sterilizations performed in 1979 to 1980. There were a total of 9 to 10 deaths per 100,000 sterilizations, but only 1 to 2 per 100,000 were attributed to the sterilization procedure alone (213). When general anesthesia is used for laparoscopy, endotracheal intubation is mandatory because the pneumoperitoneum increases the risk for aspiration. International data from the Association for Voluntary Surgical Contraception show a similar record of safety from Third World programs: 4.7 deaths per 100,000 female sterilizations and 0.5 per 100,000 vasectomies (214).

Family Health International has reported large randomized multicenter trials of the different means for tubal sterilization. The Filshie and Hulka clips were compared in two trials. A total of 2,126 women were studied, of which 878 had either clip placed by minilaparotomy and 1,248 had either clip placed by laparoscopy, and were then evaluated at up to 24 months (215). Pregnancy rates were 1.1 per 1,000 women with the Filshie clip and 6.9 per 1,000 with the Hulka clip at 12 months, a difference in rates that was close to statistically significant ($p = 0.06$). This same group compared the Filshie clip to the Silastic tubal ring in a similar study with a total of 2,746 women, of which 915 had the devices placed at minilaparotomy and 1,831 had laparoscopy (216). Pregnancy rates at 12 months were the same for the Filshie clip and the tubal ring: 1.7 per 1,000 women. The ring was judged more difficult to apply, but three women spontaneously expelled the Filshie clip during the 12 months of

follow-up.

Benefits of Tubal Sterilization

In addition to providing excellent contraception, tubal ligation is associated with reduced risk for ovarian cancer that persists for as long as 20 years after surgery ([217](#)).

Sterilization Failure

Many “failures” occur during the first month after laparoscopy and are the result of a pregnancy already begun when the sterilization was performed. Contraception should be continued until the day of surgery, and a sensitive pregnancy test should be routinely performed on the day of surgery. Because implantation does not occur until 6 days after conception, however, a woman could conceive just before her surgery and there would be no way to detect it. Scheduling sterilization early in the menstrual cycle obviates the problem but adds to the logistic difficulty. Another cause of failure is the presence of anatomic abnormalities, usually adhesions surrounding and obscuring one or both tubes. An experienced laparoscopic surgeon with proper instruments can usually lyse the adhesions, restore normal anatomic relations, and positively identify the tube. In some circumstances, however, successful sterilization will not be possible by laparoscopy, and the surgeon must know before surgery whether the patient is prepared to undergo laparotomy, if necessary, to accomplish sterilization.

Most studies of sterilization failure are short term. The Centers for Disease Control and Prevention's Collaborative Review of Sterilization (CREST) reported on a cohort of 10,685 women sterilized between 1978 and 1986 at any of 16 participating centers in the United States who were followed from 8 to 14 years ([218](#)). The true failure rates for 10 years obtained by the life-table method are given in [Table 10.10](#). Pregnancies resulting from sterilization during the luteal phase of the cycle in which the surgery was performed were excluded. Thirty-three percent of all remaining pregnancies were ectopic. The most effective methods at 10 years were unipolar coagulation at laparoscopy and postpartum partial salpingectomy, generally a modified Pomeroy procedure. Bipolar tubal coagulation and the Hulka-Clemens clip were least effective. Younger women had higher risk for failure, as would be expected because of their greater fecundity.

Method	
Unipolar coagulation	7.5
Postpartum partial salpingectomy	7.5
Silastic band (Filshie or Yoon)	17.7
Interval partial salpingectomy	20.1
Bipolar coagulation	24.0
Hulka-Clemens clip	36.5
Total all methods	18.5

From Petrossian HL, Xia Z, Hughes JM, et al. The risk of pregnancy after tubal sterilization: findings from the U.S. Collaborative Review of Sterilization. *Am J Obstet Gynecol* 1996;174:1164 (Table II) (194), with permission.

Table 10.10. Ten-year Life-table Cumulative Probability of Pregnancy per 1,000 Procedures with Different Methods of Tubal Sterilization, United States, 1978–1986.

Over the years since the CREST study began, sterilization by unipolar electrosurgery was abandoned because of risk for bowel burns and was replaced with bipolar electrosurgery or the nonelectric methods (tubal ring, Hulka-Clemens clip, and more recently, the Filshie clip). An important later analysis of the CREST data found that bipolar sterilization could have a very low long-term failure rate if an adequate portion of the tube is coagulated. CREST study subjects who were sterilized with bipolar electrosurgery in 1985 to 1987 had lower failure rates than those sterilized earlier (1978 to 1985). The important difference was in the technique of application of the electric energy to the tubes. Women whose bipolar procedure involved coagulation at three sites or more had low 5-year failure rates (3.2 per 1,000 procedures), whereas women who had fewer than three sites of tubal coagulation had a 5-year failure rate of 12.9 per 1,000 ($p = 0.01$) ([219](#)).

Reversal of Sterilization

Reversal of sterilization is more successful after mechanical occlusion than after electrocoagulation because the latter method destroys much more of the tube. With modern microsurgical techniques and an isthmus-to-isthmus anastomosis, pregnancy follows in about 75% of cases ([220](#)). A substantial risk for ectopic pregnancy exists after reversal.

Late Sequelae of Tubal Sterilization

Increased menstrual irregularity and pain have been attributed to previous tubal sterilization. In patients who underwent the older laparoscopy technique with unipolar electrical destruction of a major portion of the tube, these concerns may be warranted ([221](#)). Study of the problem is complicated by the facts that many women develop these symptoms even though they have not had tubal surgery, and OCs reduce pain and create an artificially normal menstrual cycle. Therefore, women who discontinued OC use concurrent with tubal sterilization will experience more dysmenorrhea, which is entirely unrelated to the sterilization. The best answer presently available also comes from the CREST study ([222](#)). A total of 9,514 women who had undergone tubal sterilization were compared with 573 women whose partners had undergone vasectomy. Both groups were followed up to 5 years with annual standardized telephone interviews. Women who had undergone tubal sterilization were no more likely to report persistent changes in intermenstrual bleeding or length of the menstrual cycle than women whose partners had vasectomy. The sterilized women, in fact, reported decreases in days of bleeding, amount of bleeding, and menstrual pain but were slightly more likely to report cycle irregularity (OR, 1.6; 95% CI, 1.1 to 2.3). Hence, this study found no evidence to support the existence of a posttubal ligation syndrome.

Vasectomy

Vasectomy, excision of a portion of the vas deferens, is readily accomplished with local anesthesia in an office setting. It does not decrease sexual performance ([223](#)). The basic technique is to palpate the vas through the scrotum, grasp it with fingers or atraumatic forceps, make a small incision over the vas, and pull a loop of the vas into the incision. A small segment is removed, and then a needle electrode is used to coagulate the lumen of both ends. Improved techniques include the no-scalpel vasectomy, in which the pointed end of the forceps is used to puncture the skin over the vas. This small variation reduces the chance of bleeding and avoids the need to suture the incision. Another variation is the open-ended vasectomy, in which only the abdominal end of the severed vas is coagulated while the testicular end is left open. This is believed to prevent congestive epididymitis ([224](#)).

Reversibility

Vasectomy must be regarded as a permanent means of sterilization; however, with microsurgical techniques, vasovasostomy will result in pregnancy about half the time. The longer the interval since vasectomy, the poorer the chance of reversal.

Safety

Operative complications include scrotal hematomas, wound infection, and epididymitis, but serious sequelae are rare. There have been no reports of deaths from vasectomy in the United States in many years, and the death rate in a large Third World series was only 0.5 per 100,000. Studies of vasectomized monkeys showed accelerated atherosclerosis, but several large-scale human studies have found no connection between vasectomy and vascular disease ([225,226](#)). Concerns about long-term safety recurred with the report of a possible association between prostate cancer and vasectomy ([227](#)). Prostate cancer is largely a disease of the Western world and is strongly linked to dietary animal fat, family history, and race ([228](#)). In the West, it is more common in men of African American ancestry and rare in men of Asian descent. Recent studies are reassuring. A large multiethnic case-control study from the United States and Canada compared 1,642 men with prostate cancer

to 1,636 controls and found no overall association (OR, 1.1; 95% CI, 0.83 to 1.3) (229). Older reports may reflect bias, perhaps that higher-status men, with diets higher in animal fat, were more likely than lower-status men to choose vasectomy.

Abortion

Given the desire in developed countries to limit families to one or two children and the efficacy of contraception in general use, it is extremely likely that any normal couple will experience at least one unwanted pregnancy at some time during their reproductive years. In Third World countries, desired family size is larger, but access to effective contraception is limited. As a result, abortion is common. Worldwide, about 26 to 31 million legal abortions and an estimated 10 to 22 million clandestine abortions are performed every year (230). Where abortion is legal, it is generally reasonably safe; where it is illegal, complications are common, and about 150,000 women die every year from these complications (231). Societies cannot prevent abortion, but they can determine whether it will be illegal and dangerous or legal and safe. Many countries in which abortion is completely illegal have very high rates of clandestine abortion. Abortion rates in representative countries are given in Table 10.11 (232).

Table 10.11. Rates of Induced Abortion in Representative Countries, 1985–1991 per 1,000 Women Aged 15–44 Years

Death from illegal abortion was once common in the United States. In the 1940s, more than 1,000 women died each year of complications from abortion (233). In 1992, the last year for which complete data are available, there were 17 deaths from spontaneous abortion, 10 deaths from legally induced abortion, and no deaths from illegal abortion (abortion induced by a nonprofessional) in the entire United States. (234). The American Medical Association's Council on Scientific Affairs has reviewed the impact of legal abortion and attributes the decline in deaths during this century to the introduction of antibiotics to treat sepsis; the widespread use of effective contraception beginning in the 1960s, which reduced the number of unwanted pregnancies; and, more recently, the shift from illegal to legal abortion (235). Much of the continued decline in non-abortion-related maternal mortality of recent years can be attributed to choice of legal abortion by women at high risk for pregnancy mortality. The United States has a serious problem with teenage pregnancy. Without legal abortion, there would be almost twice as many teenage births each year.

The number of abortions reported each year in the United States—1,186,039 in 1997 according to the Centers for Disease Control and Prevention—has been decreasing since 1990. In 1997, the national abortion ratio was 306 abortions for every 1,000 live births, and the national abortion rate was 20 per 1,000 women aged 15 to 44 years (236). Most women who obtain abortions are unmarried (79% in 1997), and the ratio of abortions to live births is 9 times higher for unmarried women than for married women. Use of abortion varies markedly with age. In 1997, 20% of women obtaining abortions were 19 years of age or younger, and 51.8% were 24 years of age or younger. In 1997, the last year for which detailed information is available, the abortion ratio for women younger than 15 years of age was 729 per 1,000 live births, almost as many abortions as births (Fig. 10.2). The lowest abortion ratio, 161 per 1,000 live births, is for women aged 30 to 34 years. Legal abortion rates and ratios reached their highest in the early 1980s as they replaced illegal abortions, and both have declined since, especially for the youngest women (Fig. 10.20) (16).

Figure 10.20 Abortion ratios, by age group and by year, United States, 1974–1997. Ratio equals induced abortions per 1,000 live births. [From Koonin LM, Strauss LT, Chrisman CE, et al. Abortion surveillance, 1997. *MMWR Morb Mortal Wkly Rep* 2000;49(SS-11):14, with permission.]

Regardless of personal feelings about the ethics of interrupting pregnancy, health professionals have a duty to know the medical facts about abortion and to share them with their patients (237). Providers are not required to perform abortions against their ethical principles, but they have a duty to help patients assess pregnancy risks and to make appropriate referrals.

Safety Issues

The risk for death from legal abortion was 0.7 per 100,000 induced abortions in 1996 (234). In contrast, total maternal mortality is about 7 or 8 per 100,000 live births. The risk for death from legal abortion before 16 weeks is 10-fold less than that from continuing the pregnancy to delivery. As shown in Table 10.12, the risk for death increases with gestational age (238). For individual women with high-risk conditions (e.g., cyanotic heart disease), even late abortion is a safer alternative to birth. Because of the availability of low-cost, out-of-hospital first-trimester abortion, 88% of legal abortions are performed during the first trimester (before 13 weeks of amenorrhea), when abortion is the safest (238). The type of procedure is another determinant of risk. First-trimester abortions are virtually all performed by vacuum curettage; however, in the midtrimester, a variety of techniques can be used. Risk for death from abortion by the various techniques at different gestational ages is given in Table 10.13. The data clearly show the greater safety of instrumental evacuation of the uterus [dilation and evacuation (D & E)] performed in the early midtrimester. Another determinant of risk is anesthesia. Use of general anesthesia increases the risk for perforation of the uterus, visceral injury, hemorrhage, hysterectomy, and death (239). The preferred alternative is paracervical block with local anesthetic, augmented with conscious sedation when needed.

Weeks of Gestation	Deaths	Abortions	Rate ^a	Relative Risk

Table 10.13. Death to Case Rates for Legal Abortions by Type of Procedure and Weeks of Gestation, United States, 1974–1987

Techniques for Abortion

Most abortions are performed by vacuum curettage. Early procedures (5 to 7 weeks from beginning of last normal menses) can be readily performed in an office setting using simple instruments: a 5- to 6-mm flexible plastic cannula and a modified 50-mL plastic syringe as vacuum source (240). After 7 weeks, somewhat larger rigid plastic cannulas (8 to 12 mm in diameter) are generally used, depending on gestational age, with an electric pump as the vacuum source. Most abortions in the United States are performed outside of hospitals, usually in freestanding specialty clinics, at a cost far below that of hospital services. General anesthesia is unnecessary. Adequate pain relief is provided by infiltrating the cervix with local anesthetic, augmented with intravenous sedatives and analgesics for conscious sedation (241).

Medical Means for Abortion

Mifepristone (RU486), an analogue of the progestin *norethindrone*, has strong affinity for the progesterone receptor but acts as an antagonist, blocking the effect of natural progesterone. Given alone, the drug was moderately effective in causing abortion of early pregnancy; however, the combination of *mifepristone* with a low dose of prostaglandin proved very effective. In a series of almost 17,000 cases, 600 mg of *mifepristone* orally followed in 36 to 48 hours by either *sulprostone* or *gemeprost* produced complete abortion in 95% of cases (242). The only significant complications of this method to date have been three myocardial infarctions, with one death. All three myocardial infarctions occurred in women older than 35 years of age who were heavy smokers and occurred at the time of administration of *sulprostone*, a prostaglandin E₂ analogue (243). No myocardial infarctions have occurred with the prostaglandin E₁ analogue *gemeprost*. *Misoprostol*, another prostaglandin E₁ analogue, seems to have fewer side effects and a greater margin of safety than *sulprostone*. It is very effective when combined with *mifepristone* and is the prostaglandin used with *mifepristone* in the United States (244).

The 600-mg dose of *mifepristone* used initially is actually far more than needed. Several investigators have shown that a 200-mg dose is equally effective (245,246,247 and 248). Initially, *misoprostol* was given orally, but the vaginal route of administration is more effective, probably because it provides sustained blood levels of the drug over several hours (249). The combination of 200 mg *mifepristone* orally followed by 800 mg of vaginal *misoprostol* produced complete abortion in 98% of women treated, after up to 63 days of amenorrhea, and appears to be the regimen of choice (246). *Misoprostol* can be given 1 to 3 days after the *mifepristone* with no loss of efficacy (248). Initially, patients returned to the clinics to receive *misoprostol* and remained on site for several hours. Half or more expel the pregnancy within 4 to 5 hours after *misoprostol* is given. However, it has been shown that patients may safely be given the *misoprostol* for self-administration at home (250).

Methotrexate and Misoprostol

The antifolate *methotrexate* provides another medical approach to pregnancy termination. Widely used to treat ectopic pregnancies without surgery (251), it can also be used with intrauterine gestations. *Methotrexate*, 50 mg/M² given intramuscularly, followed by *misoprostol*, 800 mg inserted vaginally, produced abortion in six pregnancies up to 56 days from the last menstrual period (252). *Methotrexate* used alone without the *misoprostol* is also successful, although bleeding does not begin until an average of 24 days after treatment (253). In a large multicenter trial, 53% of patients aborted after the first dose of *misoprostol* and an additional 15% after the second dose. A total of 92% had successful abortion by 35 days after the initial *methotrexate* injection (254). The *methotrexate-misoprostol* regimen takes longer than *mifepristone-methotrexate* and is not as effective, but it is much less expensive. *Methotrexate* is usually given as an intramuscular injection, but a 50-mg oral dose is equally effective (255).

Second-trimester Abortion

Most legal abortions are performed before 13 menstrual weeks. Abortions performed after 13 weeks include those done because of fetal defects, medical or psychiatric illness that had not manifested earlier in pregnancy, and changed social circumstances, such as abandonment by the spouse. Young age is the single greatest factor determining the need for late abortion. In 1997, 24.9% of abortions for women younger than 15 years of age were midtrimester, whereas 16.8% of abortions for women 15 to 19 years of age and only 9.3% of abortions for women 30 to 34 years of age were performed after 12 weeks of gestation (236). These proportions have changed little in a decade.

Dilation and Evacuation

D & E is the most commonly used method of midtrimester abortion in the United States (236). Typically, the cervix is prepared by insertion of hygroscopic dilators, stems of the seaweed *Laminaria japonicum* (laminaria). Placed in the cervical canal as small sticks, these devices take up water from the cervix and swell, triggering dilation. When these are removed the following day, sufficient cervical dilation is accomplished to allow insertion of strong forceps and a large-bore vacuum cannula to extract the fetus and placenta (256,257). Ultrasound guidance during the procedure is helpful (258). For more advanced procedures, sequential insertion of laminaria over 2 or more days is practiced, in order to achieve a greater degree of cervical dilation (259). At the end of the midtrimester, procedures that combine serial multiple laminaria dilation of the cervix with intrafetal injection of digoxin, induction of labor, and assisted expulsion of the fetus are used (260).

Labor-induction Methods

Hypertonic Solutions Amnioinfusion of hypertonic saline is historically important as one of the oldest labor-induction methods for abortion. Saline has serious

hazards: cardiovascular collapse, pulmonary and cerebral edema, and renal failure occur if the solution is injected intravenously. All patients are at risk for serious disseminated intravascular coagulopathy (261). However, attention to proper technique for amnioinfusion, with the saline instilled by gravity flow through connecting tubing from a single-dose bottle under ultrasound guidance, reduces the frequency of such mishaps. Hypertonic urea is safer than saline. It is combined with low doses of prostaglandin to increase efficacy and shorten the interval from injection to abortion.

Prostaglandins Prostaglandins, oxygenated metabolites of C²⁰ carboxylic acid, are found naturally in most biologic tissues, where they act as modulators of cell function. They act through specific receptors of the G-protein family that are coupled to a variety of intracellular signal mechanisms, which may stimulate or inhibit adenylyl cyclase, or phosphatidylinositol (262). Prostaglandins of the E and F series can cause uterine contraction at any stage of gestation. These agents can be given by intraamniotic infusion, by intramuscular injection, or by vaginal suppository. The 15 methyl analogues of prostaglandin F_{2a} (*carboprost*) and prostaglandin E₂ (*dinoprostone*) are highly effective but frequently produce side effects of vomiting and diarrhea. Vaginal *misoprostol* (200 mg every 2 hours) has been shown to be as effective as *dinoprostol* suppositories (20 mg every 3 hours) in patients with fetal death or intact pregnancy at 12 to 22 weeks of gestation (263). In this study, patients with a living fetus were treated with ultrasound-guided intracardiac injection of potassium chloride to ensure fetal death before administration of misoprostol. *Misoprostol*-treated patients experienced fewer side effects of fever, uterine pain, vomiting, and diarrhea. *Misoprostol* was much less expensive and easier to administer. A comparison of 200-, 400-, and 600-mg doses of misoprostol at 12-hour intervals produced rates of abortion of 70.6%, 82%, and 96%, respectively, within 48 hours; however, the side effects of vomiting, diarrhea, and fever increased with increasing dose (264). Doses as high as 400 mg vaginally every 3 hours have been used (265), but caution is needed because there is risk for uterine rupture with higher doses used in the later midtrimester. More investigation is needed to determine the ideal dosage; one regimen is 400 mg of *misoprostol* at 6-hour intervals.

There is also interest in midtrimester abortion induced with combinations of *mifepristone* and *misoprostol*. Pretreatment with mifepristone would undoubtedly increase the effect of *misoprostol*, reducing the necessary dose of the second drug. A French protocol used 600 mg of *mifepristone*, followed at 26 hours with placement of laminaria into the cervix, after which *misoprostol* was administered. The method was highly effective, with very short time intervals from the onset of *misoprostol* administration to abortion; however, one case of uterine rupture occurred in a patient with a uterine scar (266).

About one third of patients treated with 20-mg doses of *dinoprostone* have a temperature elevation of 1°C or more. This phenomenon is not seen with *carboprost tromethamine*, which slightly reduced body temperature. The effect of *misoprostol* on body temperature is dose related; generally, there is no effect at 200 mg given every 12 hours, but the effect increases as the dose increases and intervals are shortened.

Transient fetal survival can be a problem with all prostaglandin methods used in the midtrimester. To prevent this problem, and to shorten the interval to abortion and avoid failed abortion, many centers use a fetal intracardiac injection of potassium chloride (3 mL of a 2-mmol solution) or 1.5 mg of *digoxin*. Others perform amniocentesis and inject a small volume of intraamniotic hypertonic saline (60 mL of a 23% solution).

Retained placenta is common with all prostaglandin abortions. Instrumental extraction is necessary in about half of cases.

Oxytocin in very high doses is as effective as *dinoprostone* at 17 to 24 weeks of pregnancy (267). Patients initially receive an infusion of 50 units of *oxytocin* in 500 mL of 5% dextrose and normal saline over 3 hours, 1 hour of no *oxytocin*, followed by a 100-unit, 500-mL solution over 3 hours, another hour of rest, and then a 150-unit, 500-mL solution over 3 hours, alternating 3 hours of *oxytocin* with 1 hour of rest. The *oxytocin* is increased by 50 units in each successive period until a final concentration of 300 units per 500 mL has been reached.

Complications The labor-induction methods share common hazards: failure of the primary procedure to produce abortion within a reasonable time, incomplete abortion, retained placenta, hemorrhage, infection, and embolic phenomena. Failed abortion can lead to serious infection and continued blood loss. If fetal expulsion has not occurred after 24 to 36 hours, consideration should be given to a D & E procedure.

Selective Reduction

Multifetal pregnancies are at risk for extremely premature birth, with major neonatal complications resulting. To prevent this, selective reduction of higher-order multiple gestation to twins is often practiced. In a series of 463 pregnancies treated with ultrasound-guided fetal intracardiac injection of potassium chloride (0.2 to 0.4 mL of a 2-mmol solution in the first trimester, 0.5 to 3.0 mL in the second trimester), 83% of the surviving fetuses delivered at 33 weeks or later (268). Another indication for selective reduction is one anomalous fetus of a multifetal gestation. A 1999 series reported 402 patients treated as described for this indication (269). Rates of pregnancy loss after the procedure by gestational age at the time of procedure were 5.4% at 9 to 12 weeks, 8.7% at 13 to 18 weeks, 6.8% at 19 to 24 weeks, and 9.1% at 25 weeks or more. No maternal coagulopathy occurred, and no ischemic damages or coagulopathies were seen in the surviving neonates. Selective induction should not be attempted with monoamniotic twins or with twin-twin transfusion syndrome because of the possibility of embolic phenomena and infarction in the surviving twin. Maternal serum α -fetoprotein remains elevated into the second trimester after first-trimester procedures.

Induced Abortion and Subsequent Reproduction

Legal abortion, as currently practiced in the United States, has no measurable adverse effect on later reproduction (270). Even two or more induced abortions have no detectable adverse effect (271). Abortion as practiced in the United States is not associated with low birth weight, premature birth, or increased perinatal loss (272). Concerns about infertility as a result of induced abortion are unfounded, except for the rare severe complication managed by hysterectomy (273). The lack of adverse effects on later pregnancy probably reflects the safety of current abortion technology in the United States.

The Future

Contraceptive development is extremely slow in the United States because of the legal climate, the great cost of meeting regulatory requirements, and the low priority given this area by the medical community. On the international scene, a number of new approaches to contraception are in development. The two-rod version of *Norplant* (*Norplant II*) should soon be available. *Levonorgestrel* in a biodegradable rod of *caprolactone* that does not require removal is currently being tested, as is the single-rod implant releasing *3-keto-desogestrel*.

The *GyneFix*, a frameless copper IUD now available in Europe, consists of a surgical suture with small copper cylinders crimped to it. The knot on the proximal end of the suture is pushed 1 cm into the uterine wall with a special inserter. Comparative trials have found it more effective than the *copper T380A* and to have fewer expulsions and fewer removals for pain and bleeding (274). It is of considerable interest for these reasons and also because of excellent retention after postpartum insertion.

Silastic vaginal rings releasing either progestin or progestin-estrogen combinations have been studied for years and are now undergoing field trials in a number of countries. A patch for transdermal release of estrogen and progestin for contraception is being tested in the United States. Both of these methods for steroid delivery have the advantage of greater ease of compliance for the user. There is great interest in developing compounds that could be used as a vaginal contraceptive and that would be protective against HIV. One such compound is a phenyl phosphate derivative of *zidovudine*. It has both spermicidal and antiretroviral activity and has proved nontoxic in short-term trials in mice (275).

Current methods of tubal sterilization require abdominal surgery. To meet the coming demand for vast numbers of sterilizations worldwide, easier means must be devised. Considerable effort has gone into developing transuterine methods of female sterilization that would avoid the need to open the abdominal cavity to gain access to the fallopian tubes. Hysteroscopy with tubal cannulation and electrofulguration or the injection of Silastic that forms in place into tubal plugs have been explored and largely abandoned (276). A simpler option is placement of quinine pellets in the uterus through an IUD inserter. It has been known for years that intrauterine quinine can produce sclerosis of the proximal fallopian tube. This method has recently been rediscovered and is being seriously explored. A pellet containing 252 mg of quinine is inserted into the uterus during the proliferative phase of the cycle and again 1 month later. In a large trial, the 1-year pregnancy rate for 9,461 women who received two doses was 2.63 per 100 woman-years. The rate of ectopic pregnancy was 0.89 per 1,000 woman-years (277).

Immunologic contraception-sterilization has been pursued for many years. Talwar and colleagues in India have worked for many years toward vaccination against human chorionic gonadotropin (hCG) and have performed trials in humans (278). Another area of interest is in vaccinating men or women against specific sperm

antigens and the zona pellucida (279).

Chinese researchers have developed a method of percutaneous occlusion of the vas that has been used in more than 100,000 men, is effective, and appears to be reversible. Polyurethane elastomer is injected into the vas, where it solidifies and forms a plug, providing an effective block to sperm. The plugs are removed using local anesthesia, and fertility returns in most cases after as long as 4 years with the plugs *in situ* (280). *Gossypol*, an extract of cottonseed, was evaluated in China as a male contraceptive but abandoned because of problems with hypokalemia in users. When *gossypol* was reevaluated in a multinational study, hypokalemia was not a problem. Of 134 men treated, 65% had sperm counts less than 1 million/mL. About half of men followed more than 1 year after treatment recovered to a normal sperm count. *Gossypol* may be an alternative to vasectomy (281).

Chapter 11 Sexuality, Sexual Dysfunction, and Sexual Assault

David A. Baram

[Sexuality](#)
[Sexual Practices](#)
[The Sexual Response Cycle](#)
[Factors Affecting Sexual Response](#)
[Sexual Dysfunction](#)
[Sexual Assault](#)
[Childhood Sexual Abuse](#)
[Rape](#)
[References](#)

Sexuality is an important and integral part of every woman's life. Questions and concerns about sexuality span a woman's entire lifetime, from questions about puberty to concerns about change in sexual function with menopause and aging. The obstetrician-gynecologist, as a primary health care provider for women, should include a sexual history as a routine part of a woman's periodic health assessment.

Concerns about sexuality and sexual dysfunction are common in the general population. Surveys have found that almost two thirds of the women questioned had concerns about their sexuality ([1,2,3,4](#) and [5](#)). One third of women lacked interest in sex, 20% said sex was not always pleasurable, 15% experienced pain with intercourse, up to 50% experienced difficulty becoming aroused, 50% noted difficulty reaching orgasm, and up to 25% were unable to experience orgasm.

In addition, obstetrician-gynecologists should routinely inquire about a history of childhood sexual abuse or adult sexual assault because these experiences are common and often have a lasting and profound effect on a woman's mental and sexual function as well as her general health and well-being. One of eight American women will be forcibly raped during her lifetime ([6](#)), and nearly half of women in the United States report some type of contact sexual victimization ([7](#)). Fifty percent of American women report uninvited sexual attention in the workplace ([7](#)).

Despite the importance of these issues to their health care, many women find it difficult to talk to their physicians about sexual concerns, and many physicians are uncomfortable discussing sexual issues with their patients ([8](#)). In a recent survey, 71% of adults said they thought their doctor would dismiss any concerns about sexual problems they might bring up, and 68% said they were afraid that discussing sexuality would embarrass their physician ([9](#)). **Surveys of primary care physicians reveal that fewer than half ask their new patients about sexual practices and concerns and that many physicians make incorrect assumptions about their patients' sexual activity based on marital status, profession, age, race, or socioeconomic status** ([10,11](#)).

Sexuality

Physicians may be concerned that patients will be offended by questions about their sexual practices or may believe that little useful information will be gained by asking patients about sexual concerns or a history of sexual assault. In addition, some physicians may have anxiety about their perceived inability to treat sexual concerns, may believe that they have too little time to obtain a sexual history, may be distressed by their patient's history of sexually related violence, or may experience personal discomfort when discussing sexual matters with their patients ([12](#)). However, surveys of patients reveal that they expect their physician to be able to address sex-related concerns and believe it is appropriate for questions about sexuality to be included as a routine part of the gynecologic history ([8](#)). Not asking about sexuality suggests to the patient that sexuality is not important and is not to be discussed. Furthermore, not discussing sexual abuse implies that sexual assault has no long-term consequences.

Physicians will feel more comfortable talking to their patients about sex if they have an understanding of the normal sexual response and know how to approach the evaluation and treatment of common sexual dysfunctions. **Asking about sexual concerns gives physicians an opportunity to educate patients about the risk for sexually transmitted infections (STIs), counsel patients about safe sex practices, evaluate patients' needs for contraception, and dispel sexual myths and misconceptions. Furthermore, patients are given permission to address sexual issues in a professional, confidential, and nonjudgmental setting** ([13](#)). Even if patients are initially uncomfortable discussing these sensitive and private issues, they know that their physician will be receptive if they want to discuss sexual concerns in the future.

When taking a sexual history, it is important to allow patients to feel comfortable and safe ([14](#)). The physician's personal values and potential biases should be left out of the discussion. Physicians should use a private location for the interview and let the patient know that the conversation will be confidential. Good listening skills and attention to nonverbal cues are helpful. It is important to use straightforward language that the patient can understand and acknowledge that many people find it difficult to discuss sensitive and intimate issues. Most sexual concerns can be resolved by providing factual information, reassurance, and appropriate medical intervention. Only a few open-ended questions are required to elicit a basic sexual history from patients. These questions should be a part of the medical history taken during a routine examination and can be obtained in either a face-to-face interview or in a written history the patient completes before seeing the physician ([12,15](#)):

"Are you currently sexually active?" "With men, women, or both?"
"Are you or your partner having any sexual difficulties?"
"Has there been any change in your sexual activity?"
"Have you ever experienced any unwanted or harmful touching or sexual activity?"

If a positive response is elicited by any of these questions, further evaluation of the patient may be warranted. Follow-up questions might include:

"Are you having difficulty initiating a sexual encounter or becoming aroused when you want to be sexual?"
"Do you experience as much arousal as you would like?"
"Do you experience vaginal dryness during intercourse?"
"Do you have orgasms when you want to?"
"Are you satisfied with your sexual relationship?"
"Do you have pain with intercourse?"
"Has this difficulty always been present, or is it new to you?"
"Have you had this difficulty with all of your partners or just with the current one?"
"Is the difficulty always there or just some of the time?"
"Does anything make it better or worse?"

“How much of a concern is this for you and your partner?”
“Do you have any idea what may have caused your sexual difficulty?”
“Have you received any treatment for this difficulty?”
“What are your expectations and goals for treatment?”

Further inquiries about specific sexual dysfunction or the sequelae of sexual abuse can be addressed when appropriate, and the patient can be referred for psychological counseling or sex therapy when necessary (16).

Sexual Practices

Two recent comprehensive surveys provide an interesting and useful description of the sexual behavior of Americans (2,3,17). Sexual activity among adolescents in the United States has increased significantly during the past 20 years. The average age for first intercourse in both men and women is 16 years. By 19 years of age, 66% to 75% of women and 79% to 86% of men will have had intercourse. Most young men and women have multiple, serial sexual partners. They use condoms infrequently and inconsistently, thus exposing themselves to STIs and unintended pregnancy. A survey of American men and women between the ages of 18 and 59 years revealed the following findings (2):

- Most men and women are satisfied with their sex lives, even those who rarely have sex. Among married men and women, 87% reported that they were satisfied with their sexual relationship.
- Sexual dysfunction was reported in 43% of women and was more likely in women with poor physical and emotional health, unmarried women, younger women, uneducated women, women who had experienced sexual victimization, women who were sexually inexperienced, and women with negative experiences in prior sexual relationships (3).
- Women have sex with a partner from a few times per month (47%), to 2 to 3 times per week (32%), to 4 or more times per week (7%). Twelve percent of women have sex a few times per year, and 3% have never been sexually active.
- The most appealing sexual activity for both men and women is vaginal intercourse. Watching their partner undress and receiving and giving oral sex were also considered very pleasurable.
- Most Americans are monogamous. Of married men and women, 75% and 85%, respectively, said they had never been unfaithful.
- There may be fewer homosexuals than previously believed—2.7% of men and 1.3% of women had a homosexual partner in the past year. Since puberty, 7.1% of men and 3.8% of women had same-gender sexual partners.
- Twenty-two percent of women said they had been forced to do something sexual, usually by someone they loved, but only 3% of men admitted to forcing themselves on a woman. Perhaps men and women have different ideas about what constitutes sexual coercion.

The Sexual Response Cycle

The sexual response cycle in women is mediated by the complex interplay of psychological, environmental, and physiologic (hormonal, vascular, muscular, and neurologic) factors. The initial phase of the sexual response cycle is interest and desire, followed by the four successive phases originally described by Masters and Johnson (18): arousal, plateau, orgasm, and resolution. There is wide variability in the way women respond sexually, and each phase can be affected by aging, illness, medication, alcohol, illicit drugs, and relationship factors.

An attempt has been made to redefine the linear progression of sexual response described by Masters and Johnson. The Basson model postulates that the sexual cycle in women is cyclical rather than linear and that arousal and desire are interchangeable (19,20). In this model, the starting point for sexuality is the desire for intimacy and closeness rather than a need for physical sexual release. Many women are satisfied with an intimate encounter that does not necessarily include intercourse or orgasm.

For most women, the clitoris is the most sexually sensitive part of their anatomy, and stimulation of the clitoris produces the greatest sexual arousal and the most intense orgasms. Other sexually sensitive areas are the nipples, breasts, labia, and, to a lesser extent, the vagina. Although the lower third of the vagina is responsive to touch, the upper two thirds of the vagina is sensitive primarily to pressure.

There has been speculation about the existence of a *G spot* (named after Ernest Graefenberg, who first described it in 1944), an area of the vagina located anteriorly midway between the symphysis pubis and the cervix that is believed to be exquisitely sensitive to deep pressure. This area, believed to be similar to the male prostate, has been described as glandular tissue capable of secreting prostatic acid phosphatase into the urethra, sometimes in such copious amounts that women seem to ejaculate during orgasm. However, analysis of the fluid “ejaculate” has proved that it is probably urine, not prostatic fluid. It is not uncommon for women who are normally continent to leak urine during orgasm. These women should be reassured that this is a common phenomenon and does not require medical intervention.

Desire Phase

Sexual desire is the motivation and the inclination to be sexual. It is a “subjective feeling state” that may be triggered by both internal (fantasy) and external (an interested partner) sexual cues and is dependent on adequate neuroendocrine functioning (20). The sensation of desire is under the influence of dopamine-sensitive excitatory centers located in the limbic system. Testosterone is responsible for desire and arousal in both men and women. Drive is the biologic component of desire and is characterized by sexual thoughts, erotic interest in others, genital tingling, and seeking out of sexual activity (20). Desire is influenced by sexual orientation, preferences, psychological mindset, beliefs and values, expectations, willingness to behave sexually, and environmental setting.

Arousal (Excitement) Phase

The arousal (excitement) phase is mediated by the parasympathetic nervous system and is characterized by erotic feelings and the appearance of vaginal lubrication. Sexual arousal increases blood flow to the vagina, and the resulting vasocongestion and changes in capillary permeability create a condition that increases the capillary filtration fraction. The filtered capillary fluid transudates between the intercellular spaces of the vaginal epithelium, causing droplets of fluid to form on the walls of the vagina. In addition to feelings of sexual tension, sexually excited women experience tachycardia, rapid breathing, an elevation in blood pressure, a generalized feeling of warmth, breast engorgement, generalized muscle tension (myotonia), nipple erection, mottling of the skin, and a maculopapular erythematous rash (“sex flush”) over the chest and breasts. During this phase, the clitoris and labia become swollen; the vagina lengthens, distends, and dilates; and the uterus elevates out of the pelvis (18,20).

During the latter stages of arousal, sexual tension and erotic feelings intensify, and vasocongestion reaches maximum intensity (plateau). The skin becomes more mottled, the breasts become more engorged, and the nipples become more erect. The labia become more swollen and turn dark red, and the lower third of the vagina swells and thickens to form the “orgasmic platform” (18,20). The clitoris becomes more swollen and elevates to lie nearer the symphysis pubis. The uterus elevates fully out of the pelvis. With adequate sexual stimulation, women reach the point of orgasmic inevitability (threshold point).

Orgasm Phase

Orgasm is a myotonic response mediated by the sympathetic nervous system. It is experienced as a sudden release of the tension that has built up during the arousal. Orgasm is the most intensely pleasurable of the sexual sensations. It consists of multiple (3 to 15) 0.8-second reflex rhythmic contractions of the muscles (pubococcygeal) surrounding the vagina, perineum, anus, and orgasmic platform. Uterine contractions are also experienced by many women during orgasm (18). Thus, some women describe the sensation of an orgasm as different after hysterectomy. Many women who are orgasmic prefer to have orgasms before intercourse, during the time when clitoral stimulation is most intense. Unlike men, who are relatively unresponsive to sexual stimulation after orgasm (refractory period), women are potentially multiorgasmic and capable of experiencing more than one orgasm during a single sexual cycle. Thus, they can experience orgasms both before and during intercourse if adequate clitoral stimulation is provided.

Resolution Phase

Following the sudden release of sexual tension brought about by orgasm, women experience a feeling of relaxation and well-being. The physiologic

changes that took place during arousal are reversed, and the body returns to a resting state. Complete uterine descent, detumescence of the clitoris and orgasmic platform, and decongestion of the vagina and labia takes about 5 to 10 minutes.

Factors Affecting Sexual Response

Aging

Aging and the cessation of ovarian function accompanying menopause have a significant effect on the sexual response cycle of women. **Sexual desire and the frequency of intercourse decrease gradually as women age, although women retain interest in sex and continue to have the potential for sexual pleasure for their entire lives.** The need for closeness, love, and intimacy does not change with age. The way women function sexually as they grow older is largely dependent on health status, partner availability, and how frequently they had sex and how much they enjoyed sex when they were younger (21). Results of a study of healthy men and women aged 80 to 101 years living in retirement communities indicated that these elderly people were still very sexually active (22). Sexual touching and caressing, followed by masturbation and then intercourse, were the most common sexual activities in this population.

Anatomic changes that accompany aging are noted in Table 11.1. These changes predispose women to more frequent episodes of vulvovaginitis and urinary tract infections that, along with decreased vaginal lubrication, may cause dyspareunia. The effects of aging on sexual physiology are noted in Table 11.2. Women who remain coitally active after menopause have less vulvar and vaginal atrophy than abstinent women (23). Illnesses that accompany aging may also have an impact on sexual function. Arteriosclerosis may decrease vaginal blood flow and cause decreased arousal, lubrication, and orgasmic intensity. Chronic obstructive pulmonary disease may cause lowered testosterone levels, impairing sexual desire. Pain from an arthritic hip may make it difficult for a woman to find a comfortable position for intercourse.

Reduced pubic hair
Loss of fat and subcutaneous tissue from the mons pubis
Reduced vaginal size
Thinning of vaginal walls
Decreased elasticity of vaginal walls
Shrinkage of the labia minora
Thinning of the labia minora
Decreased clitoral sensitivity
Decreased clitoral size
Reduced uterine size
Cervical atrophy
Reduced ovary size and weight
Reduced perineal muscle tone
Thinner orgasmic platform
Breast atrophy
Decreased breast engorgement during arousal
Sensory changes in the nipple and areola

Table 11.1. Anatomic Changes of Aging

Decreased sexual desire
Increased time required to become sexually aroused
Longer time needed to lubricate
Production of less vaginal lubrication
Less intense orgasms
Increased need for stimulation to become orgasmic
No change in the ability to have orgasms
Less likely to be multiorgasmic

Table 11.2. Sexual Physiology—Effects of Aging

Several psychosocial factors may influence an older woman's sexual activity. Older women may lack a sexual partner, or their partner may develop erectile dysfunction. The couple may have had an unsatisfactory sexual relationship earlier in life and may not be able to negotiate the changes and possible sexual dysfunctions that can come with aging. Couples may find that they can no longer function sexually as they did in the past and are unable to make the transition or adapt to a new (noncoital) way of lovemaking. Other factors include privacy issues (such as living in a nursing home), reluctance to masturbate, and the negative attitudes of society toward sexuality in older women (23). Aging men and women may experience performance anxiety as they enter into new relationships (24,25 and 26). As women age, many tend to be less fit. Improved physical fitness is positively related to the frequency of sexual intimacy, which in turn is related to longevity (26). Suggestions for aging patients might include taking a warm bath before lovemaking to loosen stiff joints, making love in the morning when the couple is less fatigued, and experimenting with oral or manual sexual stimulation to orgasm without having intercourse.

Management of sexual difficulties in older women should include estrogen or testosterone supplementation (27,28 and 29). Local or systemic estrogen supplementation can alleviate vaginal dryness, urinary tract symptoms, and dyspareunia. Estrogen replacement restores vaginal cells, decreases pH, and increases vaginal blood flow, thus alleviating vaginal dryness, urinary tract symptoms, and dyspareunia. Estrogen replacement also seems to benefit sexual desire, sexual fantasy, arousal, sexual enjoyment, and orgasmic frequency in postmenopausal women (27). In addition, estrogen supplementation improves insomnia, hot flashes, and other menopausal symptoms (e.g., sense of well-being) that may interfere with sexual function. The addition of progesterone to the hormone replacement therapy regimen partially opposes the beneficial effects of estrogen by decreasing vaginal blood flow (27). Estrogen supplementation also decreases free testosterone levels by nearly 50% by increasing levels of sex hormone-binding globulin, thus decreasing free testosterone levels (29,31).

Testosterone levels gradually decrease in women as they age (29). Testosterone supplementation, either alone or in combination with estrogen, has been demonstrated to improve libido, arousal, sexual responsiveness, frequency of sexual fantasies and dreams, clitoral sensitivity, and frequency of orgasm in women who are testosterone deficient (<30 ng/mL) from surgical or natural menopause. In addition, restoration of normal testosterone levels can benefit muscle tone, physical energy, mood, sense of well-being, and genital atrophy not responsive to estrogen supplementation (27,32). Side effects of testosterone include acne, hirsutism, deepening of the voice, clitoromegaly, hepatotoxicity, alopecia, and undesirable changes in lipoprotein levels. Patients taking androgens should be prescribed the lowest effective dose of medication and carefully monitored for side effects.

Sildenafil, effective for treating erectile dysfunction in men, has been investigated for the treatment of sexual dysfunction in women (33,34). One study demonstrated the effectiveness of sildenafil in reversing female sexual dysfunction induced by selective serotonin reuptake inhibitors (SSRIs) (34). Another study failed to demonstrate any improvement in sexual function in postmenopausal women but did note improvement in vaginal lubrication and clitoral sensitivity. The effectiveness of sildenafil and other recently developed pharmacologic agents in the treatment of sexual dysfunction in women has yet to be documented.

The sexual expectations of the aging patient and her partner and an assessment of their current level of sexual functioning should also be evaluated. Myths they may have heard about sexuality in the elderly should be dispelled. If the couple is interested in retaining sexual function, they should be instructed in alternative forms of sexual expression and ways of alleviating discomfort. However, aging patients may have difficulty changing their sexual expectations and ways of making love. They may not easily adapt to change and may resist reevaluating long-held sexual beliefs, attitudes, behavior, and gender roles.

Drugs

A variety of prescription and nonprescription medications, including alcohol and illicit drugs, can alter the normal sexual response (35,36,37,38 and 39) (Table 11.3).

The patient's use of these drugs should be assessed as part of the medical history, and adjustments in dosage or formulation may be suggested, if appropriate. With some medications, like the SSRIs, it may be appropriate to suggest a short medication holiday to allow for temporary return of sexual function.

Antihypertensives
Thiazide diuretics
Antidepressants
Lithium
Antipsychotics
Anticholinergics
Beta-blockers
Neuroleptics
Enoxacin
Hallucinogens
Amphetamines
Cocaine
Oral contraceptives
Anticoagulants
Chemotherapy
Diuretics
Digoxin
Insulin

Table 11.3. Drugs that Can Interfere with Sexual Functioning

Illness

Both acute (e.g., myocardial infarction) and chronic (e.g., chronic renal disease or arthritis) illnesses can create depression, a distorted body image, physical discomfort, and disturbances in the hormonal, vascular, and neurologic integrity needed for sexual functioning (40). Neurologic disorders that impair sexual functioning include multiple sclerosis, alcoholic neuropathy, and spinal cord injury. Endocrine and metabolic disorders, such as diabetes mellitus, hyperprolactinemia, testosterone deficiency, estrogen deficiency states, and hypothyroidism can affect the sexual response.

Infertility evaluation and treatment can have a significant effect on a woman's body image and feelings of self-worth and self-esteem. Infertility may cause her to feel depressed, helpless, hopeless, unattractive, and sexually undesirable. The loss of sexual spontaneity, a goal-directed approach to sex, and the need for scheduled intercourse may lead to sexual dysfunction and relationship difficulties (41).

Breast cancer diagnosis and treatment can affect sexuality (42,43). However, most women cope well with the stress of treatment and do not develop major psychiatric disorders or significant sexual dysfunction. A number of studies have compared women who undergo mastectomies with women who have conservative surgery (lumpectomy) with breast conservation. These studies have revealed little difference between the two groups in postoperative marital satisfaction, psychological adjustment, frequency of sex, or incidence of sexual dysfunction. The frequency of breast stimulation with sexual activity does decrease after mastectomy (18), and many men and women avoid looking at the surgical scar. Women who undergo lumpectomy have more positive feelings about their bodies, especially their appearance in the nude, than do women who have mastectomies (44). The strongest predictor of postcancer sexual satisfaction is not the extent of the surgery but rather the woman's overall psychological health, relationship satisfaction, and precancer level of sexual functioning (45). Interestingly, many women report that their physicians did not discuss the impact of breast surgery on sexuality before their operations took place.

Common gynecologic procedures, performed for either benign or malignant conditions, can significantly affect a woman's body image, feelings of self-worth and self-esteem, and psychosexual function (46,47 and 48). In premenopausal women, an oophorectomy can have a deleterious effect on sexual desire and feelings of sexual arousal.

Concern about sexual functioning following hysterectomy is often the most common preoperative anxiety experienced by patients (49). **A number of studies have shown that abdominal hysterectomy does not have an adverse effect on sexual functioning if the vagina is not shortened excessively and if the ovaries are preserved (50,51).** Many women report a decrease in dyspareunia, an increase in frequency and strength of orgasms, and an increase in libido and frequency of intercourse following hysterectomy for benign disease (49). Some gynecologists prefer to perform supracervical hysterectomies in an effort to preserve full sexual function; however, there are inadequate data to support that this practice is effective for this purpose.

Women who undergo surgery for gynecologic cancer experience more sexual dysfunction (inhibited sexual desire, decreased arousal, dyspareunia, and anorgasmia) and are less sexually active than healthy women of the same age (52,53). Dyspareunia may be related to a decrease in vaginal lubrication secondary to surgical menopause or to vaginal shortening and scarring from radiation therapy. Some patients, especially those with cervical cancer, may worry that resumption of sexual activity may provoke a recurrence of their disease (54). Among patients with gynecologic cancer, sexual activity following treatment does not seem related to the type of cancer or the stage of the disease.

Physicians should discuss sexual concerns with the patient and her partner before surgery, attempt to dispel myths and misconceptions, and continue to offer counseling to patients after treatment. Specific technical advice (the use of water-based lubricating jelly, noncoital sexual activity for patients with severe dyspareunia, the use of vaginal dilators, and Kegel exercises) should also be provided. Women who function well sexually before surgery and have a positive self-image will be better able to cope with the sexual difficulties caused by gynecologic cancer treatment than women with poor precancer sexual adjustment (53).

The physical, emotional, and economic stresses of pregnancy often affect a couple's sexual and marital relationship (55,56,57 and 58). Sexual attitudes and behavior during pregnancy are influenced by sexual value systems, folklore (taboos), religious beliefs, physical changes, and arbitrary medical restrictions. In a pregnancy uncomplicated by preterm labor, antepartum bleeding, or an incompetent cervix, there is no evidence that intercourse increases the risk for pregnancy complications.

Pregnancy-related alterations in sexual response include breast tenderness, a feeling of fullness in the labia and vagina, possible bleeding from the cervix with intercourse, and uterine contractions with orgasm (56,57). Pregnant women may find it difficult to feel sexual when they perceive themselves as unattractive or when they are fatigued, nauseated, or uncomfortable. Both partners may be afraid that intercourse may precipitate preterm labor, rupture the membranes, or harm the fetus. Increasing abdominal size may make the couple's usual positions for lovemaking awkward and uncomfortable.

Most women and men experience a longitudinal decrease in sexual desire, frequency of orgasm, sexual satisfaction, and frequency of intercourse as pregnancy progresses. Sexual satisfaction in pregnancy is closely correlated with feeling happy about the pregnancy, feeling attractive, and experiencing orgasm with lovemaking. Toward the end of the third trimester, there is a significant increase in physical discomfort and concerns about labor and delivery and the health of the child. At this time, many couples decrease sexual activity or become abstinent. However, the need for closeness, emotional support, and nurturing during late pregnancy can continue to be met with touching, caressing, holding, and noncoital lovemaking.

After delivery, many women experience fatigue, weakness, vaginal bleeding and discharge, perineal discomfort, hemorrhoids, sore breasts, and decreased vaginal lubrication and dyspareunia secondary to decreased estrogen levels. Women may be hesitant to resume having intercourse because of lack of sexual desire, fear of vaginal injury or infection, physical discomfort, fear of waking the baby, decreased sense of attractiveness, change in body image, or postpartum depression. Compared with women who bottle feed, women who breast feed are more likely to experience decreased sexual desire and dyspareunia as a result of lower testosterone and estrogen levels. Although many couples begin to have intercourse 6 to 8 weeks after delivery, many couples may wait as long as a year to resume their pregnancy level of intimacy.

Physicians can help their patients by acknowledging and discussing the normal fluctuations in sexual desire and frequency of intercourse that occur during and after pregnancy. Couples should be encouraged to continue their usual patterns of lovemaking during pregnancy as long they are emotionally and physically comfortable and there are no contraindications to intercourse.

Sexual Dysfunction

Types of sexual dysfunctions include (59,60):

1. Sexual desire disorders (hypoactive or inhibited sexual desire and sexual aversion)
2. Sexual arousal disorders
3. Orgasmic disorders
4. Sexual pain disorders (vaginismus, dyspareunia, and noncoital sexual pain)
5. Sexual disorders resulting from general medical conditions and substance abuse

Each disorder can be further classified as either ([59](#)):

1. Lifelong or acquired (after a period of normal sexual functioning)
2. Generalized (i.e., not limited to a specific partner or situation) or situational
3. Caused by psychological or medical factors

When evaluating patients with sexual dysfunction, it is important to obtain the following information ([60,61](#) and [62](#)):

1. A specific description of the dysfunction and an analysis of current sexual functioning
2. When the dysfunction began and how it progressed over time
3. Any precipitating factors
4. The patient's theory about what caused the dysfunction
5. What effect the dysfunction has had on her relationship
6. Past treatment and outcomes
7. Expectations and goals for treatment
8. Understanding of sexual physiology and sexual behavior
9. Any myths or misinformation

Although many physicians have some anxiety about discussing sexual issues with their patients and believe that they lack the basic skills to provide sexual counseling, most sexual concerns can be treated by the general gynecologist. **The PLISSIT model is a useful sexual counseling and therapy method consisting of four levels of therapeutic intervention** ([63](#)). Using the first three levels of this model, 80% to 90% of sexual concerns can be addressed ([61](#)). The PLISSIT model is as follows:

1. **Permission** validates the patient's feelings and gives her permission to address her sexual concerns.
2. **Limited Information** provides the patient with information about sexual physiology and behavior.
3. **Specific Suggestions** involve specific reeducation regarding the patient's sexual attitudes and practices.
4. Referral for **Intensive Therapy** is reserved for those patients who do not respond to the first three levels of intervention and who may require intensive individual or couple therapy.

As an example of a specific suggestion, a woman with primary anorgasmia is first given permission to look at her genitalia and touch her clitoris. She is then given limited information about genital anatomy and the physiology of the sexual response. Specific suggestions are then offered about using fantasy and directed masturbation, encouraging her to make use of self-help books ([64](#)). Patients who have been sexually abused or who have significant anxiety or depression, sexual aversion, or significant marital dysfunction should be referred to a therapist who specializes in these areas.

Hypoactive Sexual Desire Disorder

Hypoactive sexual desire disorder (HSDD) is a recurrent deficiency or absence of sexual fantasies or thoughts or desire for sexual activity causing marked distress and interpersonal difficulty ([65,66](#)). Patients with HSDD have little interest in seeking sexual stimuli but often retain the ability to become sexually aroused and experience orgasm if they are approached sexually by their partner. This disorder usually develops in adulthood, often after a period of adequate sexual interest and functioning. HSDD is the most common sexual dysfunction in both women and men and is the most difficult to treat ([67,68](#)). It often is accompanied by another sexual disorder, such as dyspareunia or anorgasmia. Some individuals may experience sexual aversion, a complete avoidance of all sexual activity with a partner ([59](#)).

Physiologic causes of HSDD include medications ([Table 11.3](#)), chronic medical illnesses, depression, stress, substance abuse, aging, and hormonal alterations ([36,69](#)). Serum testosterone and prolactin levels should be evaluated in any patient presenting with the recent onset of HSDD because elevated prolactin levels (from a pituitary adenoma) or low testosterone levels (sometimes following natural or surgical menopause) could be responsible. Some postmenopausal patients who experience dyspareunia secondary to vaginal atrophy may avoid intercourse. This condition will resolve with systemic or vaginal estrogen replacement therapy. Some women with HSDD benefit from testosterone supplementation.

Individual causes of HSDD include religious orthodoxy, anhedonic or obsessive-compulsive personality (these patients may lack the capacity for play and find it difficult to display emotion and let themselves go), masked sexual deviation (e.g., transvestism), fear of pregnancy or STIs, and object choice issues (i.e., the patient may be a homosexual trying to function sexually in a heterosexual relationship).

Some individuals experience an unconscious and involuntary suppression of sexual desire and actively avoid sexual situations. They may suppress their desire by evoking negative thoughts or by allowing spontaneously emerging negative thoughts to intrude when they have a sexual opportunity (antifantasies) ([65](#)). Sexual desire can also be inhibited by performance anxiety, negative body image, chronic stress, low self-esteem, depression, the anticipation of an unpleasant sexual experience, fear of intimacy, or residual guilt about sex and pleasure. Women who have been sexually abused as children or sexually assaulted as adults may experience sexual avoidance or aversion. Some patients may fear loss of control over their sexual feelings and, therefore, may suppress them completely. If a patient is experiencing another form of sexual dysfunction, such as dyspareunia or anorgasmia, she may also be experiencing HSDD ([65](#)).

The way a couple functions sexually is often a good barometer of how things are going in the rest of the relationship. Therefore, whenever a woman presents with sexual concerns or sexual dysfunction, it is important to inquire about the relationship in general. If significant relationship problems exist in addition to sexual concerns, the couple should be referred for counseling. Relationship causes of HSDD include lack of sexual attraction for the partner (due to factors such as poor hygiene), poor lovemaking skills, sexual inexperience of one or both partners, marital conflict, lack of commitment, or discomfort with physical closeness owing to distrust of the partner or a sense of vulnerability. Some couples experience sexual difficulties because of differences in feelings regarding how close one partner would like to be to the other. One partner may want to be very close, whereas the other desires more distance ([70](#)). Couples may be sexually incompatible, with one partner making sexual demands the other is unable or unwilling to accommodate. Couples may have difficulty with the timing or the way they initiate sexual activity, or they may have incompatible or very different levels of sexual desire ([71](#)). Spouse abuse, financial problems, concerns about children, and marital power and control issues can significantly affect the way a couple functions sexually. It is difficult for anyone to feel sexual if they feel unloved or are depressed, overwhelmed with career and household responsibilities, unhappy about their relationship, or afraid of or angry with their partner.

Treatment of patients with HSDD may require both individual therapy and relationship counseling. Insight-oriented psychotherapy may allow the patient to identify the negative feelings that inhibit her erotic impulses and to gain insight into the underlying causes of her low sexual desire ([69](#)). Individual "homework" assignments include identifying erotic feelings, body awareness exercises, reading about human sexuality and sexual techniques, and fantasy training ([72](#)). In addition, the couple may benefit from learning how to perform structured sexual exercises known as *sensate focus exercises* ([73](#)). These behavior-modification exercises are designed to reduce sexual anxiety and to provide the couple with a nondemanding, nonthreatening, and reassuring environment in which they can address performance anxiety, sexual communication issues, and lack of sexual experience and knowledge.

Meeting with a couple for a few sessions to assess their sexual knowledge, attitudes, and practices is often beneficial. Many of the sexual problems couples encounter are due to a knowledge or experience deficit, sexual misconceptions, or the inability of the couple to communicate about what they would like to give and to receive in the sexual part of their relationship. Brief counseling and education by the obstetrician-gynecologist regarding the sexual response cycle and encouragement to communicate openly and honestly are often all that is needed to help couples achieve a fulfilling sexual relationship.

Arousal phase disorders, in which women experience sexual desire and orgasm but lack vaginal lubrication and other signs of sexual stimulation, are relatively rare.

Lack of lubrication may lead to dyspareunia and eventually may impair a woman's subjective sense of arousal and pleasure. These women may benefit from the use of intravaginal lubricants, estrogen replacement therapy, or both.

Orgasmic Dysfunction

Orgasmic dysfunction in women is characterized by persistent or recurrent delay in or absence of orgasm following a normal sexual excitement phase, resulting in distress or interpersonal difficulty. Orgasmic dysfunction is more prevalent in younger and less sexually experienced women. Primary (lifelong) anorgasmia is found in about 5% to 10% of women (68) and is more common than secondary (acquired) anorgasmia. Some women develop secondary anorgasmia owing to relationship problems, depression, substance abuse, prescription medication (e.g., fluoxetine, SSRIs), chronic medical illness (e.g., diabetes), estrogen deficiency, or neurologic disorders (e.g., multiple sclerosis) (59). Many women who are orgasmic with masturbation and during noncoital sex may be distressed because they are not orgasmic during intercourse, do not have multiple orgasms or an orgasm with every sexual encounter, or do not have an orgasm at the same time as their partner. Surveys of sexual behavior demonstrate, however, that most couples do not experience orgasm simultaneously and that many women are more likely to be orgasmic during foreplay, when they receive more direct and intense clitoral stimulation, than during intercourse (68).

The most common psychological cause of anorgasmia is obsessive self-observation and monitoring during the arousal phase, often accompanied by anxiety and distracting, negative, and self-defeating thoughts (74,75). A woman with orgasmic dysfunction may be so busy monitoring her own and her partner's response and so concerned about "failing" that she is unable to relax enough to allow her natural reflexes to take over and trigger an orgasm (69,76). Masters and Johnson call this form of performance anxiety "spectatoring" (73). Inhibited orgasm may be related to a history of sexual abuse, negative feelings toward sexuality, relationship problems, an inattentive partner, ineffective sexual technique, low self-esteem, poor body image, or fear of losing control (75).

Numerous programs have been proposed for the treatment of orgasmic dysfunction (75). Approaches include evaluation and treatment of medical and psychiatric disorders (including substance abuse), sex education, communication and sexual skills training, marital therapy, group therapy, erotic fantasy, and counseling to reduce sexual anxiety and performance anxiety.

The most effective treatment for primary anorgasmia is employing a program of directed masturbation accompanied by erotic fantasy. Success rates of 80% to 90% have been reported using this technique (76). Several excellent self-help books are available to help women learn how to become orgasmic through masturbation (64,77). These self-help books instruct women how to increase their self-awareness by exploring their genital area in a nondemanding way. Once a woman has identified the most sensitive and pleasurable parts of her body, she can manually stimulate her clitoris and other erogenous areas while incorporating erotic fantasy until she reaches orgasm. A vibrator may be useful if the patient is unable to have an orgasm without one. Once the patient has experienced orgasm through masturbation, she may want to teach the technique to her partner, showing him how and where she likes to be touched during lovemaking. Manual stimulation of the clitoris by the woman or her partner while having intercourse (the bridge technique) may help women become orgasmic during intercourse.

Sexual Pain Disorder

Vaginismus

Vaginismus is the recurrent or persistent involuntary contraction of the perineal muscles surrounding the outer third of the vagina when vaginal penetration with a penis, finger, tampon, or speculum is attempted (59). Vaginismus is an involuntary reflex precipitated by real or imagined attempts at vaginal penetration. It can be global, in which the woman is unable to place anything inside her vagina, or situational, in which she is able to use a tampon and can tolerate a pelvic examination but cannot have intercourse. Many women with vaginismus have normal sexual desire, experience vaginal lubrication, and are orgasmic but are unable to have intercourse. Vaginismus can be primary, in which the woman has never been able to have intercourse, or secondary, which is often due to acquired dyspareunia. Some couples may cope with this difficulty for years before they seek help. They usually seek treatment because they desire children or decide they would like to consummate their relationship. Vaginismus is relatively rare, affecting about 1% of women (68).

Vaginismus can be a conditioned response to an unpleasant experience such as past sexual trauma or abuse, a painful first pelvic examination, or a painful first attempt at intercourse. It may occur secondary to religious orthodoxy, negative sexual upbringing, or sexual orientation concerns (78,79). Many women with vaginismus have an extreme fear of penetration and misconceptions about their anatomy and about the size of their vagina. They may believe that their vagina is too small to accommodate a tampon or penis and that great physical harm will result from placing anything inside the vagina.

Although medical conditions are rarely the cause of vaginismus, conditions such as endometriosis, chronic pelvic inflammatory disease, partially imperforate hymen, and vaginal stenosis must be ruled out by a careful pelvic examination. The pelvic examination, which should be performed, if possible, in the presence of the woman's partner, allows the physician to help educate the couple about normal female anatomy and may help dispel misconceptions about the size of the introitus and vagina. Providing the patient with a mirror to observe the examination is helpful. Because the etiology of vaginismus is usually psychophysiologic, patients with this condition should not have surgery to "enlarge" their introitus unless they have a partially imperforate hymen or other valid indication for surgery.

Treatment of vaginismus is directed toward extinguishing the conditioned involuntary vaginal spasm. This can be accomplished by the following:

1. Help the woman become more familiar with her anatomy and more comfortable with her sexuality.
2. Teach her techniques to help her relax when she anticipates vaginal penetration.
3. Instruct her in the use of Kegel exercises in order to gain control over the muscles surrounding her introitus.
4. Instruct her how to use graduated rubber dilators (fingers can also be used as dilators).

The protocol for use of the dilators is explained to the patient while she is in the office, but the actual placement of the dilators is done by the patient when she is at home. It is important for the patient to maintain total control over the use of the dilators and to use them in an environment that is comfortable and safe. The dilators should be covered with a warm, water-soluble lubricant. She should initially try to place the dilators (or her finger) in her vagina when she is alone and relaxed. If she is unable to relax enough to place the smallest dilator in her vagina, she may be able to reduce her anxiety by learning relaxation or self-hypnosis techniques. Medications, such as *propranolol* or *alprazolam*, may also help reduce anxiety. Once the patient has been able to place the smallest dilator in her vagina, she can progressively insert the larger dilators, practicing Kegel exercises while the dilators are in place. When she is comfortable inserting the larger dilators, she can teach her partner how to place the dilators in her vagina while she maintains control over how quickly and deeply the dilators are placed. She may then be ready to proceed to intercourse. Again, this must be under her control, with her sitting or kneeling over her partner and inserting his penis herself. Most couples (90%) who follow this protocol are successful and able to have intercourse.

Dyspareunia

Dyspareunia ("difficult mating") is genital pain that occurs before, during, or after intercourse in the absence of vaginismus. The repeated experience of pain during intercourse can cause marked distress, anxiety, and interpersonal difficulties, leading to anticipation of a negative sexual experience and eventually to sexual avoidance (59). As with other forms of sexual dysfunction, dyspareunia can be generalized or situational, lifelong or acquired. Secondary dyspareunia occurs, on the average, about 10 years after the onset of sexual activity. **Dyspareunia is one of the most common sexual dysfunctions seen by gynecologists and is estimated to affect about two thirds of women during their lifetime** (80,81). Women with dyspareunia usually discuss the pain with their sexual partner, but fewer than half of these women consult a physician. Because dyspareunia is a psychophysiologic condition, both psychological and physical factors must be considered in patient assessment. Many women with dyspareunia report more physical symptoms, psychological distress, and relationship issues than women who do not have pain during intercourse (82).

A careful history should be directed toward a complete chronology of the discomfort, an assessment of the impact of the dyspareunia on the patient and her partner, and any prior attempts to treat the condition (78,79 and 80). The patient should be asked about the specific location of the pain, when in the course of lovemaking the pain occurs, how long the pain lasts, the nature and quality of the pain, what factors relieve or aggravate the discomfort, and the severity of the pain. It is useful to ask the patient her theory about how the pain began and to assess her expectations and goals for treatment. Patients should be carefully asked about a history of childhood sexual or physical abuse or adult sexual assault because these situations may be associated with dyspareunia. Patients who are anxious about sexuality because of sexual misconceptions, guilt, fear of pregnancy or STIs, or prior unpleasant sexual experiences may be unable to relax during lovemaking, leading to

impaired arousal and lubrication.

During the physical examination, attempts should be made to identify any organic factors contributing to the discomfort. Physiologic changes that take place during sexual arousal may account for pain that is present during intercourse but absent at other times, such as during a routine pelvic examination. Examples are Bartholin gland cysts, which swell during intercourse, and adhesive bands that form between portions of the hymenal ring only during arousal (78).

Causes of pain on stimulation of the external genitalia include chronic vulvitis and clitoral irritation and hypersensitivity. Pain at the introitus caused by penile entry can be caused by a rigid hymenal ring; scar tissue in an episiotomy repair; a müllerian abnormality; and vaginitis caused by one of the many common vaginal pathogens, such as *Candida*, *Trichomonas*, or *Gardnerella* species, or by irritation from over-the-counter vaginal sprays, douches, or contraceptive devices. Other causes include Bartholin gland inflammation, radiation vaginitis, infection with human papillomavirus, urethral syndrome, cystitis, vaginal trauma, chronic constipation, or proctitis. Vaginal infection is the most common cause of successfully treated dyspareunia (81). Another common cause of dyspareunia is friction due to inadequate sexual arousal. This situation can be resolved by counseling the couple to spend more time with foreplay, ensuring that the woman has adequate lubrication before intercourse. Use of a water-soluble lubricant (e.g., *Astroglide*) is also helpful. Vaginal atrophy resulting from hypoestrogenic states (menopause and lactation) can be treated with systemic or vaginal estrogen replacement.

Vulvar vestibulitis syndrome is a constellation of symptoms consisting of severe pain or burning on touching the vestibule and attempting vaginal entry (83). Women with vulvar vestibulitis report difficulty with sexual arousal, decreased lubrication, dyspareunia, and negative emotions during sexual encounters (84,85). On examination, diffuse or focal vulvar erythema is noted around the orifices of Bartholin, Skene, periurethral, or vestibular glands. This syndrome may be caused by an infection (subclinical human papillomavirus, bacterial vaginosis, or chronic candidiasis), irritants (soaps, detergents, douches, vaginal sprays), or altered vaginal pH secondary to a decrease in lactobacilli. Vulvar vestibulitis may be secondary to treatment of human papillomavirus with podophyllin, trichloroacetic acid, or laser.

The treatment of vulvar vestibulitis syndrome is empirical because the cause is unknown (83). A comprehensive multimodality approach may be necessary, as outlined in Chapter 14. Associated infections should be treated, vulvovaginal irritants should be eliminated, and surgery (vestibulectomy with vaginal advancement) should be reserved for patients with severe dyspareunia who have not responded to conservative management (83).

Causes of midvaginal pain include a congenitally shortened vagina, interstitial cystitis, and urethritis. Pain with orgasm may be associated with uterine contractions. Dyspareunia with deep vaginal penetration can be associated with inadequate vaginal lengthening and lubrication secondary to inadequate sexual arousal, chronic pelvic inflammatory disease, endometriosis, a fixed retroverted uterus, a pelvic mass, an enlarged uterus as a result of myomas or adenomyosis, inflammatory bowel disease, irritable bowel syndrome, or pelvic relaxation (80).

Psychological factors contributing to dyspareunia include:

1. *Developmental factors* (e.g., an upbringing that invested sex with guilt and shame)
2. *Traumatic factors* (e.g., childhood sexual abuse or other sexual assault)
3. *Relationship factors* (e.g., anger or resentment toward a sexual partner)

Lazarus uses the mnemonic BASIC ID to describe his multimodal approach to the assessment of dyspareunia (84). This approach addresses the issues noted in Table 11.4.

Behavior: Faulty technique
Affect: Guilt, anger, fear, and shame
Sensation: Where is the pain?
Imagery: Do intrusive thoughts or negative images disrupt sexual enjoyment?
Cognition: Are there dysfunctional beliefs or misinformation that play a role in undermining sexual participation?
Interpersonal: How do the partners communicate and relate in both sexual and nonsexual settings?
Drugs: Is the patient on any medication that would diminish vaginal lubrication?

Table 11.4. Assessment of Dyspareunia

Sexual Assault

Sexual assault of children and adult women has reached epidemic proportions in the United States and is the fastest growing, most frequently committed, and most underreported crime (86,87 and 88). Sexual assault is a crime of violence and aggression, not passion, and encompasses a continuum of sexual activity that ranges from sexual coercion to contact abuse (unwanted kissing, touching, or fondling) to forcible rape. In a survey of female family practice patients, 47% reported some type of contact sexual victimization during their lifetime. Twenty-five percent reported attempted rape, and 13% had been forcibly raped, many as children (7,89). Among battered women, about 35% experience marital rape as an element of their repetitive abuse. Spousal rape is infrequently reported because of fear of retribution and economic dependency (90). **The terms *sexual abuse survivor* and *assault survivor* are preferable to *victim*.**

Childhood Sexual Abuse

Childhood sexual abuse has a profound and potentially lifelong effect on the survivor. Although most cases of childhood sexual abuse are not reported by the survivor or her family, it is estimated that as many as one third of adult women were sexually abused as children. Childhood sexual abuse is often accompanied by another type of household dysfunction, such as physical abuse, violence against other family members, or substance abuse by parental figures (88). Younger children are more often exposed to genital fondling or noncontact abuse (exhibitionism, forced observation of masturbation, or posing in child pornography), and children older than 10 years of age are more likely to be forced to have intercourse or oral sex (91). As children age, they are more likely to experience sexual abuse outside the home and more likely to be victimized by strangers. As adolescents, women survivors of childhood sexual abuse are at risk for early unplanned pregnancy, STIs, prostitution, antisocial behavior, running away from home, lying, stealing, eating disorders, and multiple somatic symptoms. These women are more likely to engage in health risk behaviors such as smoking, substance abuse, and early sexual activity with multiple partners (92). They may be less likely to use contraception. Survivors often avoid pelvic examinations and are less likely to have Papanicolaou (Pap) tests because of the association between vaginal examinations and pain. They often receive inadequate prenatal care and are more likely than women who have not been abused to experience suicidal ideation and depression and to deliver smaller and less mature babies (88).

Obstetrician-gynecologists can assist their sexual assault patients by validating their feelings and concerns and giving them control over their examination. It is important to ask the patient for permission to perform the examination, give her the opportunity to have an advocate in the room with her, and let her know that she has the right to stop the examination at any time (88).

Survivors may be unable to trust or establish rapport with adults. Some women blame themselves for the abuse and come to believe that they are not entitled to assistance from others. Thus, they risk continuing to enter abusive relationships. Women survivors of childhood sexual abuse often develop feelings of powerlessness and helplessness and may become chronically depressed. There is a high incidence of self-destructive behavior, including suicide and deliberate self-harm, such as cutting or burning themselves (88,93,94). The most extreme mental health symptoms in assault survivors are associated with the onset of abuse at an early age, frequent abuse over a long period, use of force, or abuse by a parent. Survivors are also at risk for becoming victimized again later in life (95). Fifty percent of women who report being abused as children are abused again as adults. Women who are sexually abused as children carry the effects of abuse into adulthood. As adults, they have the same level of physical symptoms and psychological distress as women who do not report childhood sexual abuse but are currently experiencing sexual

or physical abuse ([96](#)).

Women who have been sexually abused as children or sexually assaulted as adults often experience sexual dysfunction and difficulty with intimate relationships and parenting ([97](#)). Chronic sexual concerns may include fear of intimate relationships, lack of sexual enjoyment, difficulty with desire and arousal, and anorgasmia. Compared with women who have not been sexually assaulted, they are more likely to experience depression, suicide attempts, chronic anxiety, anger, substance abuse problems, dissociative personality disorder, borderline personality disorder, fatigue, low self-esteem, feelings of guilt and self-blame, and sleep disturbance ([96,98,99](#)). They often experience social isolation, phobias, feelings of vulnerability, fear, humiliation, grief, and loss of control ([6,100](#)). Survivors of sexual assault represent a disproportionate number of patients with chronic headaches and chronic pelvic pain (they have a lower pain threshold) and are more likely to have somatic symptoms that do not respond to routine medical treatment ([99,101](#)). Women with common gynecologic symptoms, such as dysmenorrhea, menorrhagia, and sexual dysfunction, are much more likely to have a history of sexual assault ([102](#)). If they have been forced to perform oral sex, they may have a dental phobia and avoid preventive dental care.

Survivors may develop posttraumatic stress disorder (PTSD), defined as development of characteristic symptoms following a psychologically traumatic event outside of normal human experience. Symptoms of PTSD include blunting of affect, denial of symptoms, intrusive reexperiencing of the incident, avoidance of stimuli associated with the assault, and intense psychological distress and agitation in response to reminders of the event ([86,93](#)). Women affected by PTSD are more likely to commit suicide. The cognitive sequelae include flashbacks, nightmares, disturbances in perception, memory loss, and dissociative experiences ([103](#)). These women may not be able to tolerate pelvic examinations and may avoid seeking routine gynecologic care because these examinations may remind them of the sexual abuse they experienced as children. However, they are more likely to use the medical care system for nongynecologic concerns ([104](#)). Women with PTSD are at greater risk for being overweight and having gastrointestinal disturbances ([92](#)).

Rape

Although the legal definition of sexual assault may vary from state to state, most definitions of rape include:

1. The use of physical force, deception, intimidation, or the threat of bodily harm
2. Lack of consent or inability to give consent because the survivor is very young or very old, impaired by alcohol or drug use, unconsciousness, or mentally or physically impaired
3. Oral, vaginal, or rectal penetration with a penis, finger, or object

The National Women's Study provides the best statistics available about the incidence of forcible rape in the United States ([6](#)). This study revealed that 13%, or one of eight adult women, are survivors of at least one completed rape during their lifetime. Of the women they surveyed, 0.7% had been raped during the past year, equaling an estimated 683,000 adult women who were raped during a 12-month period. Of the women surveyed, 39% were raped more than once. Most disturbing, however, is the finding that most rapes occurred during childhood and adolescence; 29% of all forcible rapes occurred when the survivor was younger than 11 years of age, and 32% occurred between the ages of 11 and 17 years. Indeed, "rape in America is a tragedy of youth" ([6](#)). Twenty-two percent of rapes occurred between the ages of 18 and 24 years, 7% between the ages of 25 and 29 years, and only 6% occurred when the survivor was older than 30 years of age.

There are many myths about rape. Perhaps the most common is that women are raped by strangers. In fact, only about 20% to 25% of women are raped by someone they do not know. Most women are raped by a relative or acquaintance (9% by husbands or ex-husbands, 11% by fathers or stepfathers, 10% by boyfriends or ex-boyfriends, 16% by other relatives, and 29% by other nonrelatives) ([6](#)). Although acquaintance rape may seem to be less traumatic than stranger rape, survivors of acquaintance rape often take longer to recover. Another common misconception about rape is that most survivors sustain serious physical injury. Seventy percent of rape survivors report no physical injury, and only 4% sustain serious injury. Serious injury is rare, although almost half of the rape survivors report being fearful of serious injury or death during the assault ([6](#)). The most common injuries from a sexual assault are vaginal lacerations resulting in bleeding and pain. Intraperitoneal extension of a vaginal laceration or damage to the anal mucosa is rare ([105](#)). Common nongenital injuries in survivors include cuts, bruises, scratches, broken bones and teeth, and knife or gunshot wounds ([106](#)). About 0.1% of sexual assaults result in death. Common causes of death during a sexual assault include mechanical asphyxiation, trauma, lacerations, drowning, and gunshot wounds ([105](#)).

There are at least four types of rapists ([107](#)):

1. **Opportunist rapists (30%) exhibit no anger toward the women they assault and usually use little or no force.** These rapes are impulsive and may occur in the context of an existing relationship ("date" or acquaintance rape). The highest incidence of acquaintance rape is among women in the twelfth grade of high school and in the first year of college ([108](#)). Up to half of college women report date rape. Many of these women may have been unable to give consent because of impairment by alcohol or rohypnol, the "date rape drug." Date rape may have even greater psychological consequences than rape by a stranger because it involves a violation of trust ([105](#)).
2. **Anger rapists (40%) usually batter the survivor and use more physical force than is necessary to overpower her.** This type of sexual assault is episodic, impulsive, and spontaneous. An anger rapist often physically assaults his victim, sexually assaults her, and forces her to perform degrading acts. The rapist is angry or depressed and is often seeking retribution—for perceived wrongs or injustices he imagines have been done to him by others, especially women. He may victimize the very young or the very old.
3. **Power rapists (25%) do not intend to physically harm their victim but rather to possess or control her in order to gain sexual gratification.** However, a power rapist may use force or the threat of force to overcome his victim. These assaults are premeditated and repetitive, and they may increase in aggression over time. The rapist is usually anxious and may give orders to his victim, ask her personal questions, or inquire about her response during the assault. This assault may occur over an extended period while the victim is held captive. These rapists are insecure about their virility and are trying to compensate for their feelings of inadequacy and low self-esteem.
4. **Sadistic rapists (5%) become sexually excited by inflicting pain on their victim.** These rapists may have a thought disorder and often exhibit other forms of psychopathology. This type of assault is calculated and planned. The victim is often a stranger. The rape may involve bondage, torture, or bizarre acts and may occur over an extended period of time. The survivor often suffers both genital and nongenital injuries and may be murdered or mutilated. Other rapists may act out of impulse, as when they encounter a victim during the course of another crime such as burglary. Some rapists believe they are entitled to their victim, as in acquaintance rape or father-daughter incest ([86](#)). A consistent finding among all types of rapists is a lack of empathy for the survivor.

Even when sexual assaults are reported (only 16% of rapes are ever reported to the police), few rapists are arrested, and even fewer are brought to trial and convicted. Fewer than 1% of rapists ever serve a prison term ([107](#)). Many women do not report the assault to the police because they are concerned about their name being disclosed by the news media, fear retaliation from the perpetrator, are afraid they will not be believed, or do not trust the judicial process.

Only 17% of rape survivors seek medical attention after an assault. Many rape survivors do not inform their physicians about the assault and may never volunteer information about the assault unless they are directly asked. Therefore, when obtaining a medical history, physicians should routinely ask, "Has anyone ever forced you to have sexual relations when you did not want to?"

Effects of Rape

Following sexual assault, women have many concerns, including pregnancy, STIs (including human immunodeficiency virus [HIV] infection), being blamed for the assault, having their name made public, and having their family and friends find out about the assault. The initial reactions to sexual assault may be shock, numbness, withdrawal, and possibly denial. It is difficult to predict how any assaulted individual will react. Despite their recent trauma, women presenting for medical care may appear calm and detached.

The *rape trauma syndrome* is a constellation of physical and psychological symptoms, including fear, helplessness, disbelief, shock, guilt, humiliation, embarrassment, anger, and self-blame. The acute, or disorganization, phase of the syndrome lasts from days to weeks. Survivors may experience intrusive memories of the assault, blunting of affect, and hypersensitivity to environmental stimuli. They are anxious, do not feel safe, have difficulty sleeping and eating, and experience nightmares and a variety of somatic symptoms ([86,109,110](#)). They may fear that their assailant will return to retaliate or rape them again.

In the weeks to months following the sexual assault, survivors often return to normal activities and routines. They may appear to have dealt successfully with the assault, but they may be repressing strong feelings of anger, fear, guilt, and embarrassment. In the months following the assault, survivors begin the process of integration and resolution. During this phase, they begin to accept the assault as part of their life experience, and somatic and emotional symptoms may decrease

progressively in severity. However, the sequelae of rape are often persistent and long-lasting (93). Over the long-term, survivors may have difficulty with work and with family relationships. Disruption of existing relationships is not uncommon. Nearly half of the survivors lose their jobs or are forced to quit in the year following the rape, and half change their place of residency (100).

Examination and Treatment

The responsibilities of physicians providing immediate treatment for sexual assault survivors are listed in [Table 11.5](#). **Because of the legal ramifications, consent must be obtained from the patient before obtaining the history, performing the physical examination, and collecting evidence. Documentation of the handling of specimens is especially important, and the “chain of evidence” for collected material must be carefully maintained. Everyone who handles the evidence must sign for it and hand it directly to the next person in the chain. The patient should be interviewed in a quiet and supportive environment by an examiner who is objective and nonjudgmental. Support personnel and patient advocates, such as family, friends, or, if available, a counselor from a rape crisis service, should be encouraged to accompany the patient. It is important not to leave the survivor alone and to give her as much control as possible over the examination.** In order to provide useful forensic information, the examination should be performed as soon as possible after the incident occurred.

1. Obtaining an accurate gynecologic history, including a recording of the sexual assault
2. Assessing, documenting, and treating physical injuries
3. Obtaining appropriate cultures (including samples for forensic tests), treating any existing infection, and providing prophylaxis for sexually transmitted diseases
4. Providing therapy to prevent unwanted pregnancy
5. Providing counseling for the patient and her partner and/or family
6. Arranging for follow-up medical care and counseling
7. Reporting to legal authorities as required by state law

Table 11.5. Physician Responsibilities in Treating Sexual Assault Survivors

The history should include the following information:

1. A general medical history and a gynecologic history, including last menstrual period, prior pregnancies, past gynecologic infections, tetanus status, history of liver disease, thrombosis or hypertension (possible contraindications to pregnancy prophylaxis with estrogens), contraceptive use, prior sexual assault, and last voluntary intercourse before the assault.
2. It is important to ascertain whether the survivor bathed, douched, used a tampon, urinated, defecated, brushed her teeth, or changed her clothes after the assault.
3. A detailed description of the sexual assault should be obtained, including the date and time of the assault, number of assailants, use of weapons, threats, and restraints, and any physical injuries that may have occurred.
4. A detailed description of the type of sexual contact must be obtained, including whether vaginal, oral, or anal contact or penetration occurred, whether the assailant used a condom, and whether there were other possible sites of ejaculation, such as the hands, clothes, or hair of the survivor.
5. The emotional state of the survivor should be observed and recorded.

The survivor should undress while standing on clean examination table paper in order to catch any hair or fibers falling from her clothing. All of her clothing should be placed in individually labeled paper bags, sealed, and given to the proper authorities. Wet or damp clothing should be air dried before packaging. During the physical examination, the degree of injury to the survivor should be assessed, and any injuries should be documented for use as evidence. The nature, size, and location of all injuries should be carefully documented, using photographs or drawings if possible. Nongenital injuries occur in 20% to 50% of all rapes (111). The most common injuries are bruises and abrasions of the head, neck, and arms (86) and genital injuries accompanied by bleeding and pain. The most common genital findings are erythema and small tears of the vulva, perineum, and introitus. There may be bleeding, mucosal tears, erythema, or a hematoma noted around the rectum if penetration has occurred. Identification of small lacerations of the genitalia or rectum may be aided by colposcopy or by staining with toluidine blue (112). Bite marks are not uncommon and frequently are found on the breasts or genitalia. Foreign bodies may be found in the vagina, rectum, or urethra. If oral penetration has taken place, injuries of the mouth and pharynx may occur (113).

Evidence must be properly collected for legal purposes as follows:

1. Examination of the patient with a Wood light may help identify semen, which will fluoresce blue-green to orange. Areas of fluorescence should be swabbed with a cotton-tipped applicator moistened with sterile water. Swabs of the vagina, mouth, and rectum may be obtained to test for the presence of sperm or semen.
2. A Pap test may also be useful to document the presence of sperm.
3. A sample of the vaginal secretions should be obtained for examination for motile sperm, semen, or pathogens. Motile sperm in the vagina indicate ejaculation within 6 hours. Nonmotile sperm can be found in the cervical mucus for as long as 1 week. If ejaculation has occurred in the mouth, seminal fluid will be rapidly destroyed by salivary enzymes (105).
4. Vaginal secretions should also be collected to test for the presence of seminal contents, including acid phosphatase, p30 protein (specific to the prostate), seminal vesicle-specific antigen, and ABO antigens, and for DNA fingerprinting (88).
5. The survivor's pubic hair should be combed over a sheet of paper in an attempt to obtain pubic hair from the assailant.
6. Fingernail scrapings from the survivor should be collected and evaluated for evidence of the assailant's blood, hair, or skin. This evidence may also be used for DNA fingerprinting.
7. Saliva should be collected from the survivor to document whether she is a secretor of major blood group antigens (80% of the population are secretors). If the patient is not a secretor and blood group antigens are found in vaginal washings, the antigens are probably from the semen of the assailant (88). Laboratory tests that should be performed on all sexual assault survivors are listed in [Table 11.6](#).

Cultures of the cervix, mouth, and rectum for:
<i>Neisseria gonorrhoeae</i>
<i>Chlamydia trachomatis</i>
Herpes simplex
Serologic test for syphilis
Wet prep for trichomonas
Hepatitis B surface antigen
Human immunodeficiency virus antibody
Pregnancy test

Table 11.6. Laboratory Studies in the Evaluation of Sexually Assaulted Adults

Treatment of sexual assault survivors should be directed to prevention of possible pregnancy and provision of prophylactic treatment for STIs. About 5% of fertile rape survivors will become pregnant as a result of the rape (114). Options include (a) awaiting the next expected menses; (b) repeating the serum pregnancy test in 1 to 2 weeks; and (c) using emergency (postcoital) contraception. If the patient desires emergency contraception, a preexisting pregnancy can usually be ruled

out by performing a sensitive human chorionic gonadotropin assay. Pregnancy prophylaxis can be provided by several different regimens ([115](#)) (see also [Chapter 10](#)):

1. Immediate administration of two tablets of a combination oral contraceptive (each containing 50 µg of *ethinyl estradiol* and 0.5 mg *norgestrel*, i.e., *Ovral* birth control pills) followed by two more tablets 12 hours later
2. Four tablets of a combination birth control pill containing 35 µg of *ethinyl estradiol* and a progesterone followed by four more tablets 12 hours later
3. Administration of one tablet containing 0.75 mg of *levonorgestrel* followed by a second tablet 12 hours later (Plan B)
4. Placement of a copper-containing intrauterine device
5. *Mifepristone* as a single 600-mg dose

These regimens are highly effective if administered within 72 hours after the sexual assault. Some investigators believe that emergency contraception can be effective up to 5 days after unprotected intercourse ([88](#)). However, the sooner the medications are taken, the more effective they are. Some patients experience nausea and vomiting when given postcoital contraception; these symptoms can be controlled with an antiemetic agent such as promethazine (12.5 mg every 4 to 6 mins). Emergency contraception has a small failure rate and potential teratogenicity, which should be discussed with the patient ([116](#)). Most women who take emergency contraception experience their next menstrual period within 3 days of the expected date.

The risk for acquiring an STI from a rape is difficult to assess because the prevalence of preexisting STIs is high (43%) in rape survivors ([117,118](#)). However, it is estimated that the risk for acquiring STIs from a sexual assault is as follows: gonorrhea, 6% to 12%; trichomonas, 12%; chlamydia, 2% to 12%; syphilis, 5%.

1. Because it is difficult to differentiate between a preexisting STI and a newly contracted STI attributable to a sexual assault, prophylaxis for STIs should be offered to all survivors. This is especially important because most sexual assault patients do not return for follow-up appointments ([110](#)). STI prophylaxis should cover infections with *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, trichomonas, and incubating syphilis. Current recommendations include ([118,119](#)):
 - a. *Ceftriaxone*, 250 mg intramuscularly (if the patient is allergic to cephalosporins, *spectinomycin*, 2 g intramuscularly, or *ciprofloxacin*, 500 mg orally, may be used), PLUS:
 - b. A single dose of 2 gm of *metronidazole* orally, PLUS:
 - c. A single dose of 1 gm of *azithromycin* orally or 100 mg of *doxycycline* orally twice a day for 7 days (if the patient is pregnant at the time of the assault, *erythromycin* may be substituted for *doxycycline*)
2. Hepatitis B vaccination should be offered if the sexual assault survivor has experienced vaginal, oral, or anal penetration. Hepatitis B is 20 times more infectious than HIV during intercourse ([88](#)). Vaccination is recommended at the time of the initial evaluation. Subsequent doses are provided 1 month and 6 months after the first dose is administered. It is not necessary to treat the patient with hepatitis B immune globulin (HBIG) ([119](#)).
3. Tetanus prophylaxis (5 mL intramuscularly) should also be administered if indicated.
4. If prophylactic treatment for gonorrhea, chlamydia, and trichomonas is not given, the patient should return for repeat testing in 2 weeks. If the initial test results were negative, repeat serologic tests for syphilis, hepatitis B, and HIV should be performed at 6, 12, and 24 weeks after the assault.
5. HIV conversion through sexual assault, although reported, is low and similar to conversion from occupational exposure (<0.1%). The probability of transmission depends on the type of assault, presence of trauma, site of ejaculation, HIV viral load in the ejaculate, and presence of a concomitant STI in the patient ([111](#)). At present, no recommendation can be made regarding the use of antiretroviral prophylaxis for HIV in sexual assault survivors. Factors to consider when discussing HIV prophylaxis with patients include the likelihood of exposure to the virus, the risks and benefits of treatment, the interval between the sexual assault and the initiation of therapy, and the patient's desire to be treated. Patients should be aware that the efficacy of prophylactic treatment for HIV is unknown and that they will have to be carefully monitored if they initiate treatment with antiretroviral medication.
6. Ongoing supportive counseling for the patient should be arranged, and the patient should be referred to a sexual assault center or a therapist who specializes in the treatment of sexual assault survivors.

Psychiatric problems are a central or complicating factor in most outpatient visits ([1,2](#)). Psychiatric diagnoses are extremely common and account for considerable morbidity and mortality in the general population ([3](#)). Despite this, however, psychiatric disorders are often undiagnosed or misdiagnosed in the medical setting ([4,5,6](#) and [7](#)). Clinical depression affects up to one-fourth of women during their lives ([8,9](#) and [10](#)), but an estimated 80% of the cases are neither diagnosed nor treated ([11](#)). More than one-half of the patients who commit suicide have seen a nonpsychiatric physician during the previous 3 months ([12](#)).

Many gynecologists feel uncomfortable diagnosing and treating psychiatric illnesses for a variety of reasons. The practice of gynecology has many demands, and the care of these patients requires a commitment. Patients with psychological problems can evoke negative reactions in physicians ([Table 12.1](#)). In the past, gynecologists have found it difficult to use psychiatric diagnostic systems that were based on theories of unconscious motivation and conflict. New systems for the diagnosis of psychiatric disorders are reliable and valid and can be systematically applied, and treatments are specific and effective ([8](#)). By incorporating these management strategies into practice, gynecologists can play a major role in improving the health and well-being of their patients.

1. Social stigma attached to psychiatric diagnoses, patients, and practitioners.
2. Belief that individuals with psychiatric disorders are weak, unreluctant, manipulative, or defective.
3. Belief that the criteria for psychiatric diagnoses are intuitive rather than empirical.
4. Belief that psychiatric treatments are ineffective and unsupported by medical evidence.
5. Fear that patients with psychiatric problems will demand and consume inordinate and limitless time from a medical practice.
6. Precipitation in others, including doctors, of feelings that are complementary to the strong and unpleasant emotions experienced by patients with psychiatric disorders.
7. Gynecologists' own uncertainty about their skills at psychiatric diagnosis, referral, and treatment.
8. Failure to view psychiatric problems as legitimate grounds for medical attention.

Table 12.1. Practitioners' Negative Reactions Toward Patients with Psychiatric Problems

In the past, psychiatric diagnosis was based partially on hypotheses about a patient's unconscious psychological conflicts (13). Current psychiatric diagnosis, as codified in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM IV), produced and published by the American Psychiatric Association, is based on empirical, valid, and reliable evidence (8). Use of the DSM IV yields reliability comparable to that of diagnostic systems in other areas of medicine. DSM IV diagnoses are also strongly correlated with response to treatment. The criteria in DSM IV are the basis for the diagnostic entities described in this chapter. A new edition, DSM IV TR, differs only in the text explaining some of the diagnoses, and not in the diagnostic criteria themselves (9). DSM IV PC is a special edition designed for the primary care provider. This volume is organized by initial signs and symptoms rather than psychiatric categories and uses algorithms and decision trees to facilitate the diagnostic process. Accurate diagnosis is absolutely critical to successful management, whether provided by the gynecologist or through referral to a mental health expert.

Approach to the Patient

Although diagnostic criteria list signs and symptoms, the interaction with a patient should not be reduced to a series of rapid-fire questions and answers. **A wealth of valuable information can be obtained from the patient's spontaneous description of her concerns and from her responses to the physician's open-ended questions.** A patient who is encouraged to speak for several minutes before being asked to respond to specific questions will reveal information that is useful, even vital, to her care: a thought disorder, a predominant mood, abnormally high anxiety, a personality style or disorder, and attitudes towards her diagnosis and treatment. Such information may emerge only much later, or not at all, in a question-and-answer format (15,18). It is critical that the gynecologist neither jumps to diagnostic conclusions nor proceeds directly to therapeutic interventions. One study revealed that many primary care physicians, feeling that they had too little time or training to assess psychological symptoms, tended to minimize verbal interactions with patients and to rely on the prescription of psychotropic medications (14). It is not necessary, however, for the physician and the other patients awaiting care to be held hostage by the overly talkative patient. The clinician can tell the patient with multiple, detailed complaints how much time is available for the current appointment, invite her to focus on her most pressing problem, and offer a future appointment to continue the account.

Psychiatric Referral

Many gynecologists consider referral to a mental health professional, particularly a psychiatrist, to be a delicate matter. The first question is when to refer. Most mild psychiatric disorders are treated by nonpsychiatric physicians (17). Most antidepressants and anxiolytics are prescribed by nonpsychiatric physicians. At the same time, however, most cases of psychiatric disorder are overlooked, misdiagnosed, or mistreated in primary care practice. The following factors determine the decision to refer:

- The nature and severity of the patient's disorder
- The expertise of the gynecologist
- The time available in the gynecologic practice
- The patient's preference
- The gynecologist's degree of comfort with the patient and the disorder
- The availability of mental health professionals.

Patients who are suicidal, homicidal, or acutely psychotic should be seen by a psychiatrist. Patients should also be referred for evaluation when the psychiatric diagnosis is not clear and when they fail to respond to initial treatment. For many patients, the gynecologist can resume the responsibility for ongoing care after an initial or periodic assessment by a psychiatrist.

How to Refer?

Some clinicians fear that patients will be insulted, alienated, or alarmed by a psychiatric referral. Techniques that decrease the discomfort of the gynecologist and patient and enhance the likelihood of a successful referral are discussed below (19). The referral should be explained on the basis of the patient's own signs, symptoms, and distress. For a patient suffering from clinical depression, this might be her difficulty sleeping, her loss of appetite, or her lack of energy. For a patient with an anxiety disorder, it might be her palpitations, shortness of breath, or nervousness. For a patient with mild Alzheimer's disease, it might be forgetfulness or frightening episodes, in which she finds herself in a neighborhood she does not recognize. The advent of treatments that may slow the dementing process makes these referrals easier as well.

When somatizing (psychosomatic) disorder is suspected, the gynecologist should emphasize the difficulty of living with symptoms without definitive diagnosis and treatment, rather than the physician's hypothesis that the symptoms have a psychological basis:

1. "It is very stressful to be suffering while we can't pinpoint the problem. I would like you to see one of our staff who specializes in helping people cope with these difficult situations."
2. "It must be difficult to function when you have been so sickly all your life, have seen so many doctors, have had so many diagnostic tests and medical treatments, and still don't have an answer or feel well."

It is counterproductive to convey the idea that, because the diagnostic process has not revealed a specific disorder, the problem must be "in the patient's head." It is never possible to rule out an organic cause with absolute certainty.

Many physicians fear that questioning patients about suicide or homicide will provoke these behaviors. The opposite is the case (12). An open discussion of impulses to hurt oneself or someone else helps the patient to regain control, recognize the need for mental health care, or agree to emergency interventions such as psychiatric hospitalization, while avoiding the subject intensifies the patient's feelings of isolation. The management of suicidality is addressed in the section on mood disorders.

The possibility of psychosis need not be avoided, either. Most psychotic patients have had previous experience with psychiatric referral. Their psychotic symptoms are often distressing, and they can generally discuss hallucinations and delusions quite matter-of-factly. The rare patient who comes to a gynecologist with a first episode of acute psychosis is likely to be frightened by her symptoms and willing to accept expert consultation.

Despite increasing public sophistication about mental illnesses and psychiatric care, some patients believe that any mention of mental health intervention implies either that they are "crazy" or that the referring physician is convinced that their physical symptoms are imaginary or feigned. The gynecologist may wish to state explicitly that this is not the case. Again, making the real reason for the referral clear and founded in signs and symptoms obvious to the patient will nearly always allay anxiety over a psychiatric referral.

It is not acceptable to refer a patient to a psychiatrist without informing and asking her in advance unless she is acutely psychotic, functionally incompetent, or in the throes of a suicidal or homicidal emergency. Even under those circumstances, it is highly preferable to be straightforward. A referral that begins with an unexpected clinical encounter with a psychiatrist is unfair to the psychiatrist and the patient and is unlikely to result in a satisfactory collaboration. In order to address any concern a patient may have that a mental health referral is an indication of the gynecologist's disdain or disinterest, and in the interest of good patient care in general, the referring gynecologist should make it clear to the patient that he or she will remain involved in her care. The mental health professional should be introduced as an integral member of the health care team, and the gynecologist should ask the patient to call after the mental health appointment to report on how it went and to make a follow-up appointment with the gynecologist.

Where to Refer: Which Mental Health Professional?

Mental disorders are treated by social workers, psychologists, members of the clergy (often the first to be consulted), and various kinds of counselors as well as by psychiatrists. The distinctions among mental health professionals are not generally well known or understood by the lay public. The criteria for membership in each profession can vary from place to place and institution to institution. Social workers and psychologists can be educated at the bachelor's, master's, or doctoral level. In some states, licensure is required; generally, social workers require a master's degree and psychologists a doctoral degree, as well as supervised clinical experience, to qualify. The category of counselor includes a wide variety of practitioners, including marriage counselors, pastoral counselors, school counselors, family

counselors, and others. The training of social workers may focus on social policy, institutional work, the psychosocial aspects of medical illness, or individual psychotherapy.

Practitioners of all these disciplines may or may not be trained in psychotherapy. For symptoms not meeting criteria for a major psychiatric disorder, in a patient who is able to eat, sleep, and carry out her duties, supportive psychotherapy provided by a trained mental health professional may suffice. Doctoral-level psychologists and neuropsychologists can also perform testing that can be diagnostically helpful, especially in identifying and localizing brain pathology and in defining intelligence levels. Undiagnosed cognitive deficits may contribute to noncompliance with gynecologic care as well as other problems. Trained social workers are often knowledgeable about community resources for patients and their families and about the impact of gynecologic diseases and treatments on them. Self-help or professionally led therapy groups can be helpful for patients reacting to gynecologic problems such as infertility or malignancy. Participation in a supportive group lengthens the survival time and improves the quality of life for some patients with cancer ([20,21,22,23,24](#) and [25](#)).

Psychiatrists are the only medically trained mental health professionals. They are particularly important with diagnostic dilemmas, especially when there is a question of psychological or behavioral manifestations of medical illness and pharmacologic treatment, and when a medical understanding of the gynecologic condition and treatment is necessary for clinical care. Of all mental health professionals, only psychiatrists can prescribe psychoactive medications and other biologic interventions as well as psychotherapies. Psychiatrists treat the most seriously ill patients and take responsibility for psychiatric emergencies.

In light of frequent occurrence of psychiatric problems in gynecologic practice, it is worthwhile for the gynecologist to develop an ongoing relationship with one or more local mental health professionals. The state psychiatric society may have a list of subspecialists in "consultation liaison" psychiatry. The availability of familiar and trusted resources enhances the likelihood that problems will be identified and addressed. It is also important to keep up-to-date information on local suicide prevention and other kinds of hot lines and resources for battered women and for mothers who may pose a danger to their children.

Specific Disorders

Whenever a patient's thinking, emotions, or behaviors cause concern, the gynecologist should first consider a nonpsychiatric medical disorder and a reaction to prescribed or illicit drugs. Psychiatric disorders frequently coexist with these conditions as well.

Mood Disorders

Definitions and Diagnostic Criteria

Mood is the emotional coloration of a person's experience. Mood may be pathologically elevated (mania) or lowered (depression) or may alternate between the two (bipolar or manic-depressive disorder) ([26](#)). Mood disorders are frequently confused with the inevitable ups and downs of everyday life, such as the reactions to difficult situations, including gynecologic conditions. Because of this confusion, both patients and their loved ones become frustrated when well-meaning attempts to reason with them, distract them, or do thoughtful things for them fail to influence their protractedly disturbed moods.

Mania

Mania is characterized by:

1. Elevated mood, with euphoria or without irritability
2. Grandiosity
3. Pressured, speeded-up speech, and physical activity
4. Increased energy
5. Decreased sleep
6. Reckless and potentially damaging behaviors, such as wild expenditures and promiscuity.

Mania can be acute or subacute (hypomania). Hypomania can produce self-confidence, ebullience, energy, and productivity that are the envy of others, and the patient is very reluctant to relinquish this mood for treatment and return to normal. It can therefore be particularly difficult to arrest the condition before it progresses to full-blown mania. Acute mania is a life-threatening condition; without treatment, patients literally exhaust themselves with frantic activity in the absence of adequate nutrition and rest.

Depression

The overall lifetime prevalence of affective disorders is 8.3%; the 6-month prevalence is 5.8%. During the reproductive years, depression is 2 to 3 times more common in women than in men ([27,28](#) and [29](#)). The highest incidence of depression is in the age group of 25 to 44 years, but depression occurs in every age group, from toddlers to the aged. Women have a lifetime risk of 10% to 25% and a point prevalence of 5% to 9% ([30,31](#) and [32](#)). Depression is the single most common reason for psychiatric hospitalization in the United States. As many as 15% of individuals with severe depressive disorders are successful in committing suicide. Depression is a recurrent disorder; of those who experience a major depressive episode, 50% have a second one. Of these, 70% have a third, and the incidence continues to increase with each subsequent episode. It is difficult to know whether the incidence of depression has increased over the years recently; diagnostic criteria in the past were vague and very different from those used in DSM III and IV. There is no evidence that employment outside the home increases women's vulnerability to depression, although the need to carry out multiple roles in the absence of adequate social support can be stressful ([33,34,35](#) and [36](#)).

Depression is characterized by:

1. Sad mood or irritability
2. Hopelessness
3. Helplessness
4. Decreased ability to concentrate
5. Decreased energy
6. Interference with sleep, generally with early awakening, inability to return to sleep, and failure to feel rested; in atypical cases, with increased sleep
7. Decreased appetite and weight; in atypical cases, increased food intake
8. Withdrawal from social relationships
9. Inability to enjoy previously gratifying activities
10. Loss of libido
11. Guilt
12. Psychomotor retardation or agitation
13. Thoughts of death or suicide.

The patient who has five or more of the signs and symptoms of depression for most of each day for weeks or more has a clinical depression. Depression may be acute or chronic (dysthymic disorder). Depression can be caused by genetic, neurophysiologic, and environmental factors. Trauma in early life plays a role. Serotonin is a major mediator. Changes appear on magnetic resonance imaging, and are reversed with effective treatment or spontaneous recovery. The average duration of a major depressive episode is approximately 9 months.

Depression may be precipitated by an adverse life event such as an interpersonal loss, economic reversal, or serious illness ([37,38](#)). When there is an identifiable precipitant, there is a danger that the depression will be written off as the inevitable reaction to the event rather than considered properly as a complication, like infection or pneumonia, requiring active treatment. When a patient's symptoms meet criteria for the diagnosis, treating the depression will make her much more able to cope with the precipitating situation. Co-occurring gynecologic or other medical illness can cause signs and symptoms similar to those of depression—loss of energy, sleep, and appetite—but does not cause guilt, hopelessness, or helplessness ([16](#)).

Gynecologic Issues

The incidence of depression peaks, and the gender difference prevails, during the reproductive years, which has provoked study of both psychosocial and biologic factors. There may be a subgroup of women who are vulnerable, not to absolute circulating hormone levels, but to hormonal changes. These women experience severe premenstrual mood symptoms, postpartum depression and, possibly, depression in association with hormonal influences such as hormonal contraceptive methods, menopause, and hormone treatments.

Premenstrual Syndrome

Depending on the methodology used to gather the data, many women, perhaps a majority, experience mood and behavioral changes associated with the menstrual cycle, and many women seek care for self-diagnosed PMS, or premenstrual syndrome. **Perhaps 3% to 5% of menstruating women suffer from symptoms so marked that they qualify for a diagnosis of premenstrual dysphoric disorder (PMDD).** These categories have been the subject of many debates. In the United States, the prevalence of attitudes linking the menstrual cycle to adverse mood and behavioral changes is so high that it skews women's perceptions, the way they report symptoms to researchers, and the factors to which they attribute negative feelings. No specific hormone levels or markers are associated with premenstrual symptoms (39).

Most women who seek care for PMS have symptoms not related to the timing of the menstrual cycle (40,41). Therefore careful assessment is essential. Before the diagnosis of PMS or PMDD can be determined, a woman must record symptom ratings daily for at least two full cycles. Records of emotions and behaviors should be kept separate from menstrual records to avoid confounding patients' perceptions. At the same time, the patient must be screened for other psychiatric disorders, including depression, personality disorders, and domestic abuse.

While the evaluation proceeds, the clinician can recommend a number of lifestyle changes that have proved effective in milder cases. These include:

- Elimination of caffeine from the diet
- Smoking cessation
- Regular exercise
- Regular meals and a nutritious diet
- Adequate sleep
- Stress reduction.

Stress reduction can be accomplished by reducing or delegating responsibilities, insofar as that is possible, and devoting part of every day to relaxation techniques such as yoga. Still, many women experience stresses they cannot reduce: responsibility for the care of children and aging relatives, running a household, and employment often must be balanced.

The selective *serotonin reuptake inhibitors (SSRIs)* have proven effective for PMDD in clinical trials. As of this writing, fluoxetine has received U.S. Food and Drug Administration (FDA) approval for this indication, and other SSRIs are in the midst of the approval process (42,43,44 and 45). Although SSRIs and all other antidepressants require about 2 weeks of daily administration to achieve therapeutic effect, it appears that fluoxetine is effective for PMDD when taken in the usual daily doses for just the 1 to 2 weeks preceding menstruation. The medication has been packaged for this specific indication and dosage regimen. It is thought that the mode of action of SSRIs when used in this fashion is different from that which alleviates major depression. Other medications used for the treatment of PMS are shown in Table 12.2.

Medication	Indications	Advantages	Disadvantages	Notes
Fluoxetine	PMS, PMDD	Effective for PMS/PMDD, FDA approved	Requires 2 weeks of daily administration	Used for 1-2 weeks preceding menstruation
Other SSRIs	PMS, PMDD	Effective for PMS/PMDD	Requires 2 weeks of daily administration	Not FDA approved for PMS/PMDD
Other antidepressants	PMS, PMDD	Effective for PMS/PMDD	Requires 2 weeks of daily administration	Not FDA approved for PMS/PMDD

Table 12.2. Scientific Basis of Selected Medications Used to Treat PMS

Other Reproductive Events

Infertility is described by most women undergoing treatment as the most stressful event of their lives. Each unsuccessful treatment is experienced as the loss of a hoped-for pregnancy. The loss of a fetus or newborn induces grief, which entails some of the same symptoms as depression. Patients should not be pressed to "put the loss behind them" or expected to be "over it" within several months. Some feelings of sadness may persist for years. However, their sleep, appetite, and other vital functions and behaviors should begin to improve after a few weeks (37). Depression can complicate grief and should be treated. There is no evidence that induced abortion increases the incidence of clinical depression.

Peripartum Depression

The incidence of depression does not decrease during pregnancy and increases to approximately 10% postpartum. It must be distinguished from the transitory, self-limited, and very common "baby blues." Mild cases can be managed with psychotherapy. Moderate-to-severe cases may require antidepressant medications. Although no agent can be declared perfectly safe for use during pregnancy and lactation, the older SSRI agents have been well studied, yielding little or no evidence of adverse effects on the fetus or nursing infant (46,47). Medication should not be stopped arbitrarily, nor breast feeding prohibited.

Menopause

Although menopause was assumed for many years to be associated with an increased incidence of depression, this assumption has not been borne out in empirical studies. Whereas some patients are upset by their loss of fertility, others find menopause liberating (48,49). Patients who have suffered PMS or postpartum depression may, however, be vulnerable. Patients with depression at the time of menopause should be assessed for psychosocial precipitants and domestic abuse.

Depression in elderly patients can cause a pseudodementia, characterized by decreased activity and interest and what appears to be forgetfulness. Unlike patients with organically based dementia, these patients report memory loss rather than trying to compensate and cover up for it.

Approach to the Patient

The severity of depression is determined by the patient's emotional pain and the degree of interference with her normal functioning. Depression is an agonizingly painful but readily diagnosable and treatable disease (3). Nevertheless, it shares the stigma of all psychiatric disorders. Patients and their families often attribute the signs and symptoms of depression to life circumstances or to a medical condition, either diagnosed or undiagnosed. The persistence of symptoms in the face of a pleasant life situation or the failure of the patient to respond to attempts at cheering, such as changes of scene, often exacerbate suffering by provoking guilt

in the patient and frustration in her significant others. Patients are more likely to report low energy and general malaise than depressed mood. Even patients with moderately severe depression can continue to function and can appear not only normal, but cheerful. The only way to rule out depression is by following the diagnostic criteria (26).

Management

Both antidepressant medication and psychotherapy are effective treatments for depression. There is evidence that a combination of the two produces the best outcomes. There are many forms of psychotherapy. Those that have been specifically studied for efficacy in the treatment of depression are cognitive-behavioral therapy and interpersonal therapy. These forms of therapy are focused on present thoughts, feelings, relationships, and behaviors. They proceed for a set number of sessions, usually no more than 16 weekly sessions, in a prescribed, predetermined direction (50). Supportive and psychodynamic psychotherapy are less clearly defined and studied modalities that also may be of help.

It is especially important for the patient to have ample opportunity to work out her feelings about having a psychiatric disorder, understand how it has affected her life, and feel comfortable about taking any medication prescribed. Patients often attribute depression to weakness or laziness, and they often confuse antidepressants with stimulants and other psychoactive drugs. It is useful to provide the patient with written material about depression so that she can review it and explain the diagnosis to her family and friends.

The types and characteristics of antidepressants are in Table 12.3. All of these agents have comparable therapeutic efficacy and all require at least 2 to 4 weeks to take full effect. It is not yet possible to identify which patients will respond best to which medications; responses vary on an individual basis, even within the same class of medications. The choice of antidepressant, therefore, is based on side effects, dosage schedule, cost, and familiarity of the physician (Table 12.4). Patients tend to respond to medications that have worked for them in the past and to those that have worked for depressed family members. It is essential to continue active management until the patient has not only responded but has returned to her premorbid level of mood and function. If she does not recover completely, she should be referred to a psychiatrist (51).

Drug	Therapeutic Range (mg/L)	Approximate Therapeutic Range (mg/L)	Approximate Half-life (hr)
Tricyclic antidepressants			
Amitriptyline	100-200	100-200	10-20
Imipramine	100-200	100-200	10-20
Nortriptyline	100-200	100-200	10-20
Proprietary	100-200	100-200	10-20
MAO inhibitors			
Phenelzine	100-200	100-200	10-20
Tranylcypromine	100-200	100-200	10-20
SSRIs			
Fluoxetine	100-200	100-200	10-20
Paroxetine	100-200	100-200	10-20
Escitalopram	100-200	100-200	10-20
Atypical antidepressants			
Bupropion	100-200	100-200	10-20
Venlafaxine	100-200	100-200	10-20

Table 12.3. Pharmacology of Antidepressant Medications

Drug	Central Nervous System				Weight Gain (mg/d)
	Anticholinergic	Sedative	Stimulant	Cardiovascular	
Amitriptyline	++	++	0	++	0
Imipramine	++	++	0	++	0
Nortriptyline	+	+	0	+	0
Proprietary	++	++	0	++	0
Phenelzine	0	0	0	0	0
Tranylcypromine	0	0	0	0	0
Fluoxetine	0	0	0	0	0
Paroxetine	0	0	0	0	0
Escitalopram	0	0	0	0	0
Bupropion	0	0	0	0	0
Venlafaxine	0	0	0	0	0

Table 12.4. Side-Effect Profiles of Antidepressant Medications

Tricyclic antidepressants are the oldest and least expensive antidepressants. They all have significant anticholinergic side effects that may be problematic in medically ill and elderly patients. They are associated with some slowing of intracardiac conduction, but this side effect can be tolerated and managed in all but a few patients, and can be therapeutic for those with hyperconductibility. Tricyclic antidepressants should be taken in divided doses through the day, although bedtime dosing may help patients who have difficulty sleeping. Some tricyclics, such as *nortriptyline*, have “therapeutic windows”—blood levels above or below which they are not effective—that must be monitored. The average dose for tricyclics is 225 mg/day in divided doses. The most important drawback of tricyclics is their lethality in overdose, especially because they are used with patients already at risk for suicide. In the rare event that they must be used by a potentially suicidal patient, the patient must be given only a few pills at a time.

Monoamine oxidase (MAO) inhibitors are especially effective for atypical depression. They require dietary restrictions and can be used only in patients who are able to understand and comply with those restrictions in order to avoid hypertensive crises. **SSRIs** pose few risks of medical or suicidal complications. Side effects include anxiety, tremor, headache, and gastrointestinal upset (either diarrhea or constipation), and usually abate within a few days of the onset of treatment. A more serious side effect is loss of libido and interference with orgasm (52). Patients may be reluctant to report this side effect, but it may be the reason they discontinue treatment. Some women are willing to accept this side effect because it is an acceptable price to pay for recovery and because depression interferes with their sexual functioning anyway. Female patients are frequently concerned about weight gain. In one study, it appeared that a weight gain of 5 to 7 pounds may be expected. It is difficult to know, however, whether the weight gain is a result of the medication alone or whether it results from improved appetite associated with recovery from depression. This concern should be brought into the open; patients may be advised to watch their diets carefully while taking the medication.

SSRIs are administered in a once-a-day regimen, with little need for dosage adjustments in most cases. It is important to continue treatment until the patient is fully recovered. SSRIs have long half-lives, so occasional missed doses do not constitute a problem. There is an SSRI withdrawal syndrome, however, and patients should be cautioned not to discontinue their medication without consulting the physician, and only then by gradually decreasing the dose. SSRIs are considerably more expensive than tricyclic antidepressants. They were not initially tested in older women, but several are under consideration by the FDA for administration to this age group (53).

Atypical Agents

Medications considered atypical include *venlafaxine* (54,55 and 56), *lithium* salts, and anticonvulsants, which are effective mood stabilizers used for bipolar disorders (57,58), and *bupropion*.

Bupropion must be taken twice a day. It lowers the seizure threshold significantly more than other antidepressants. It is used, under a special trade name, for smoking cessation, and thus is particularly useful for depressed smokers. *Bupropion* seems to cause fewer sexual side effects than the SSRIs and may decrease these side effects when added to an SSRI regimen.

Suicide

The most critical issue in the assessment and referral of depressed patients is the possibility of suicide. Risk factors for suicide include:

- Depression
- Recent losses
- Previous suicide attempts, even if seemingly not serious
- Impulsivity
- Concurrent alcohol or substance abuse
- Current or past physical or sexual abuse
- Family history of suicide
- A plan to commit suicide
- The means to carry out the plan.

Women attempt suicide more frequently than men, but men complete the act more frequently than women (59,60). This is probably due, at least in the past, to men's use of more drastic or irreversible means, such as firearms, while women tend to overdose and can be treated if discovered.

The association between unsuccessful past self-destructive behavior and successful suicide is counterintuitive. It would seem that someone who had repeatedly made suicidal gestures is more interested in the responses of others than in ending her life. However, past attempts or gestures increase the risk of completed suicide, and expressed suicidality in such patients cannot be dismissed. Most people who commit suicide have consulted a nonpsychiatric physician within the prior month. All clinicians must be prepared to discuss the possibility of suicide with their patients.

Inquiry about suicidal ideation and behavior is an inherent part of every mental status examination and is mandatory for every patient with past or current depression or evidence of self-destructive behavior. It follows from discussion of difficulties in the patient's life or mood, or the physician can open the subject by mentioning that almost everyone has thoughts of death at one time or another. Most patients will immediately volunteer that they have had such thoughts and that they have no intention of acting on them. They will often add the reasons: they have too much to look forward to, it is against their religion, it would hurt their family.

It is important to distinguish between the wish to be dead and the intention to kill oneself. In the context of a trusting doctor-patient relationship, patients will nearly always tell the truth about their feelings. A patient in a painful life situation—a chronic, painful, or terminal medical condition, the birth of a severely damaged child, or a grievous loss—may express a wish to die, and even refuse recommended medical care, but emphatically disavow any intention of actively harming herself.

If the patient has previously engaged in self-destructive behavior impulsively, without a plan or warning, it is wise to consult a psychiatrist. If a patient is actively contemplating suicide, she must see a psychiatrist immediately. Other mental health professionals may be helpful but are less likely to have dealt extensively with and assumed responsibility for suicidal patients, to be able to determine whether the patient should be hospitalized, and to have admitting privileges. Until she is in the physical presence of a psychiatrist, or in a safe environment such as a hospital emergency room, a suicidal patient should be observed and protected at all times—every second—whether she is in the consulting room or the bathroom. The staff member assigned to remain with her may not leave to make a telephone call, go to the bathroom, or get a cup of coffee. Family members may offer to monitor the patient, and can sometimes be effective, but the health care professional is responsible for ensuring that they understand these necessities. It is better to risk inconvenience and possible embarrassment to both the gynecologist and the patient than to risk a fatal outcome. Once suicide is a possibility, only a psychiatrist can make the decision that a patient is safe (33).

Psychiatric referral can also be useful in less dramatic cases: when the gynecologist lacks experience or is overloaded with other needy patients, when a first trial of treatment is unsuccessful or there is uncertainty about the diagnosis when domestic violence or substance abuse may be present, and when the depression is recurrent.

Anxiety Disorders

Diagnosis

Anxiety is a sense of dread without objective cause for fear, accompanied by the usual physical concomitants of fear. Although every human being has anxious feelings from time to time, anxiety disorders are anxiety to the point of pathology: genuine painful, disabling diseases. The anxiety disorders include generalized anxiety disorder, panic disorder, agoraphobia, specific phobias, obsessive-compulsive disorder, and posttraumatic stress disorder (61,62).

Generalized anxiety disorder is a condition in which anxiety pervades every aspect of a patient's life. She suffers from restlessness, easy fatigability, difficulty concentrating, irritability, muscle tension, and sleep disturbances. Whereas depressed patients fall asleep more or less normally and then awaken earlier than intended, anxious patients have difficulty falling asleep.

Panic disorder is characterized by panic attacks: acute periods, generally lasting about 15 minutes, with intense fear and at least four of the following symptoms:

- Palpitations
- Diaphoresis
- Trembling
- Shortness of breath
- A choking sensation
- Chest discomfort
- Gastrointestinal distress
- Lightheadedness
- A sense of unreality
- Fear of going crazy or dying
- Paresthesias
- Chills or hot flushes.

The attacks can recur without specific precipitating events. The patient is preoccupied with them and makes behavioral changes she hopes will avert future attacks: avoiding specific situations, assuring herself there is an escape route from certain situations, or refusing to be alone.

The symptoms of panic attacks are often confused with the symptoms of cardiac or pulmonary disease. They lead to many fruitless trips to the emergency department and to costly, even invasive, medical investigations. A careful history can establish the correct diagnosis in most cases.

Agoraphobia is the avoidance of situations in which the patient fears she may be trapped, such as the center of a row in the theater or driving over a bridge. She fears that such a situation will trigger a panic attack. Agoraphobia and panic disorder can occur separately or together.

Specific phobias are irrational fears of certain objects or situations, although the patient recognizes that the object or situation poses no real danger. Of particular concern in gynecology are fear of needles and fear of vomiting. Social phobia causes the patient to fear and avoid situations in which the patient fears she will be observed by others in a humiliating light. Patients may alter their lives to avoid these anxieties, interfering with their interpersonal relationships and their ability to carry out their responsibilities, or they may manage to carry on despite considerable psychological pain.

Obsessive-compulsive disorder is characterized by obsessions: recurrent impulses, images, or thoughts that the patient recognizes as her own, dislikes, and cannot control, or compulsions: intrusive, repetitive behaviors that the patient feels she must perform in order to prevent some dire consequence. The disorder can be mild or totally crippling; in one-half of the cases it becomes chronic. This disorder is classified as an anxiety disorder because the obsessions are anxiety-provoking, and the compulsions are performed in order to avoid overwhelming anxiety.

Posttraumatic stress disorder (PTSD) is the result of exposure to an event that threatens the life or safety of the patient or others. At the time of the trauma, the patient experiences horror, terror, or a sense of helplessness. Afterward, the patient may lose conscious memory of all or part of the event, avoid situations reminiscent of it, and become acutely distressed when she cannot avoid them. She feels numb and detached, without a sense of the future. She is hyperarousable and irritable and experiences difficulty sleeping and concentrating. She reexperiences the event in nightmares, flashbacks, and intrusive thoughts.

Epidemiology

Panic disorder without agoraphobia is twice as common in women as it is in men; panic disorder with agoraphobia is 3 times more common in women. Onset is generally in young adulthood, often following a stressful event. The lifetime prevalence is 1.5% to 3.5%; the 1-year prevalence is 1% to 2%. A substantial percentage of patients experience depressive episodes as well. Phobias are somewhat more common in women, depending on the object of the phobia. The 1-year prevalence is 9%, and the lifetime prevalence is 10% to 11%. Obsessive-compulsive disorder is equally common in women and men, with evidence of familial transmission. Prevalences are 2.5% for lifetime and 1.5% to 2.1% for 1 year. Posttraumatic stress disorder has a lifetime prevalence of 1% to 14%; victims of violence (including child abuse and wife battering) and war are at increased risk.

Assessment

Given the relationship between anxiety disorders and traumatic experiences, the presence of signs and symptoms of anxiety disorders should trigger inquiries about abuse. It is important to know how long the patient has suffered from the disorder, what previous attempts have been made to diagnose and treat it, and the effect it has had on her psychological development, life choices, lifestyle, and relationships. In some cases, the entire family will have organized their schedules and activities around the patient's symptoms and limitations; they may not volunteer this information.

Management

Treatment should not be limited to anti-anxiety medications. Managing, even tolerating, patient anxiety is an anxiety-provoking process; anxiety is contagious, and raises the specter of unlimited demands on the gynecologist's time and energy. Prescribing medication is a familiar and comfortable, if not optimal, way to end a medical interview. The overprescription of benzodiazepines has become a cause for medical and media concern. It is useful to defer the administration of anxiolytics until the impact of the physician's support and interest can be assessed (63). Treatment should address the effects on the patient's life and family as well as the signs and symptoms of the specific disease (64).

Benzodiazepines are most useful in acute situations. Use can quickly become chronic, with escalating dosages, diminishing therapeutic effects, and increasing demands on the physician. So many women are taking benzodiazepines, and taking them for granted, that they forget to include them in their medical histories. Patients admitted to the hospital may suffer unrecognized withdrawal symptoms, complicating their treatment, or may continue to take medications from a personal supply without informing the medical staff. For chronic anxiety and many cases of acute anxiety, there are highly effective and safer approaches.

It is important to ascertain the source of anxiety or obsessiveness. Many patients and their families are anxious because of misinformation or misunderstanding about a medical problem or treatment. Few patients can absorb all the information about significant gynecologic conditions at a single visit, but most feel that asking questions will burden the physician or make them look stupid. Patients also suffer anxiety when there is disagreement among family members or medical staff about the diagnosis or recommended treatment. Many patients dread certain aspects of care, sometimes on the basis of past experience or outdated information. A simple explanation or alteration in procedure can alleviate the anxiety. For example, a reassuring family member or friend can be allowed to stay with the patient during a diagnostic test, sedation can be administered orally or by inhalation before an intravenous line is inserted, or the patient can be allowed control over her own analgesia.

Behavioral interventions are extremely useful in managing anxiety without problematic side effects. They include hypnosis, desensitization, and relaxation techniques (65,66,67,68 and 69). Whereas the use of prescribed medications fosters the patient's dependence, these techniques provide her with tools to cope with her own anxiety. Specialists in behavioral medicine, usually psychologists, are expert in these techniques. Interested gynecologists can master some of them as well.

It is easy to be trapped into a cat-and-mouse game with an anxious and needy patient. Faced with an obsessional or anxious, talkative, and needy patient in the midst of bedside rounds, clinic, or office hours, the clinician can develop a pattern of avoidance, sometimes alternating with overindulgence stemming from feelings of guilt. This kind of behavior results in sporadic, unpredictable reinforcement of the patient's symptoms and demands for attention and is very likely to increase them. Attempting to escape by appearing distracted or harassed, or yielding with despair to the destruction of the day's schedule and the care of other patients, simply heightens the patient's anxiety.

It is preferable to develop a prospective approach. Gynecologists tend to underrate the power of their personal interactions with patients and their own ability to structure and limit those interactions appropriately. The patient should be informed of the time available and asked to focus on her most important problem, with other problems to be discussed at future, scheduled appointments. Instead of scheduling appointments and returning telephone calls grudgingly, in response to patient demands, the gynecologist should inform the patient that her condition requires regular, brief, scheduled visits. If she has been contacting the office more often than visits can reasonably be scheduled, she should be asked to call between visits, at prearranged times, to advise the staff of her progress. There are useful self-help groups for patients with various psychiatric conditions, and their families. Groups focused on victimization can validate patients' experiences and pain and help them build new lives, but they can also interfere with their motivation to find other ways to identify themselves and obtain gratification.

Medication does have a place in the management of anxiety disorders (70,71 and 72). [Table 12.5](#) describes many of these agents. Sertraline recently received FDA approval for the treatment of PTSD, and other selective serotonin reuptake inhibitors are effective for other anxiety disorders as well. Benzodiazepines are effective when taken for acute anxiety or during relatively brief, time-limited (several days) stressful situations. The specific agent should be chosen on the basis of onset of action and half-life. The patient must be admonished to avoid concomitant use of alcohol and to exercise extreme care about driving or engaging in other activities requiring attention, concentration, and coordination.

Classification	Trade Name	Site of Action	Half-life	Action Long-acting	Comments
Benzodiazepines					Modulation of benzodiazepines is indicated for anxiolysis, sedation, hypnotic, and anti-convulsant. Modulation of benzodiazepines is enhanced by alcohol.
Alprazolam	Xanax	Intermediate	Intermediate	No	Phenylpiperazine nucleus or nucleus with piperazine nucleus.
Chlorazepate	Tranxene	Intermediate	Intermediate	No	
Clonazepam	Rovatin	Long	Long	No	
Clobazam	Onfi	Short	Short	No	
Clonazepam	Rovatin	Short	Long	No	Half-life increased 3 or 4 times in elderly patients.
Lorazepam	Ativan	Intermediate	Intermediate	No	Phenylpiperazine nucleus or nucleus with piperazine nucleus.
Clonazepam	Rovatin	Long	Intermediate	No	Phenylpiperazine nucleus or nucleus with piperazine nucleus.
Flurazepam	Rothenam	Long	Short	No	
Midazolam	ProSom	—	—	—	Not effective in acute dyspnea. With caution, use risk of dependence or tolerance.

Table 12.5. Compounds Used for Anxiety

Patients who fail to respond to a trial of office counseling or medication, who are unable to fulfill their responsibilities, who exhaust the patience and resources of significant others, who pose a diagnostic dilemma, who consume inordinate quantities of medical resources, or whose symptoms are becoming increasingly worse should be evaluated by a psychiatrist.

Somatizing Disorders

Definitions

Somatizing disorders are those in which psychological conflicts are expressed in the form of physical symptoms. There is a spectrum of somatizing disorders based on the degree to which the patient is consciously aware of or responsible for the onset of the symptoms. The spectrum ranges from the deliberate malingerer to the so-called *hysterical*, who is completely unaware of the link between her psyche and her physical symptom ([73](#)).

Malingering

Malingering is the deliberate mimicking of signs and symptoms of physical or mental illness in order to achieve a tangible personal gain, such as exemption from dangerous military duties or exoneration from criminal responsibility. Factitious disorder, or *Munchausen syndrome*, is a related but poorly understood condition in which the patient actively causes physical damage to herself or feigns somatic symptoms that result in repeated hospital admissions and painful, dangerous, invasive diagnostic and therapeutic procedures. These patients introduce feces or purulent material into wounds or intravenous lines, inject themselves with insulin, or produce hemorrhages.

Significant iatrogenic conditions, such as adhesions from surgery or Cushing's syndrome from the administration of steroids, may develop. These patients are initially engaging but eventually frustrate the staff. When the staff becomes suspicious and calls for a psychiatric consultation, the patient generally flees, only to reappear in another medical facility. As a result, there are little data about the etiology, incidence, and management of this condition. Often these patients are medically sophisticated because they or their family members have had some kind of medical training, as well as knowledge gained during previous hospitalizations. Mothers may enact this disorder through their children, by deliberately making them ill; this is called *Munchausen's by proxy*. Declaring that the patient "only wants attention" is not helpful. Most people want attention, but very few are willing to go to these lengths to get it.

Somatization Disorder

Somatization disorder consists of multiple physical symptoms for which adequate medical bases cannot be established, with these symptoms leading either to numerous medical visits or to impairment in the patient's performance of her responsibilities. The disorder must begin before age 30 and continue for many years after. The diagnosis requires symptoms of pain related to at least four different anatomic sites or physiologic functions, two gastrointestinal symptoms, one sexual or reproductive symptom and one pseudoneurologic symptom or deficit other than pain (seizures, paresis). The patient's perception is that she is "sickly." She responds accurately to questions about her past symptoms and treatments but may not volunteer information about them unless she is asked.

Conversion Disorder

Conversion disorder is the condition formerly called *hysteria*. The patient loses a voluntary motor or sensory function that cannot be explained by medical illness, that is not deliberately produced by the patient, and that appears to be related to psychological stress or conflict. The prognosis is directly related to the length of time from onset to diagnosis and treatment ([74,75,76](#) and [77](#)).

Pain disorder is a conversion condition with pain as the only symptom.

Body dysmorphic disorder is preoccupation with a trivial or imagined defect in bodily appearance, a preoccupation that is not alleviated by the many medical and surgical treatments on which the patient insists. The gynecologist should hesitate to refer such a patient to a plastic surgeon, although plastic surgeons are quite familiar with the condition.

Hypochondriasis is not a matter of particular numbers or types of symptoms. It is a patient's (nonpsychotic) conviction or fear that she suffers from a serious disease.

Epidemiology

Somatization is believed to be the most common and most difficult set of psychological conditions in office practice. It has been estimated that 60% to 80% of the general population experiences one or more somatic symptoms in a given week. Somatization disorder occurs almost exclusively in women; menstrual complaints may be an early sign. Lifetime prevalence in women is 0.2% to 2.0%. Conversion disorder is 2 to 10 times more frequent in women than in men (there is no gender difference in children), and it is more common in rural and disadvantaged populations with little medical sophistication. Conversion disorder may develop into somatization disorder. Reported rates of somatization disorder range from 11 to 300 per 100,000. Pain disorder is extremely common in both genders. Hypochondriasis is equally distributed between men and women; prevalence in general medical practice is estimated to be 4% to 9%. There are few statistics about body dysmorphic disorder, but it seems to be equally distributed between men and women, with an average age of onset of about 30 years.

Assessment

Most somatizing disorders are chronic. The goal of treatment in primary care is not to eliminate all the somatic symptoms but to help the patient cope with them with as little effect on her relationships and responsibilities as possible. Because patients often seek care simultaneously or sequentially from several physicians, it is crucial to ask about all past and current diagnostic procedures, diagnoses, treatments, and responses. Her level of function over the years is also important; prognosis is inversely related to chronicity. The gynecologist needs to know what the patient believes is wrong with her and what she believes she needs in the way of diagnostic and therapeutic interventions.

Management

The management of somatizing disorders is focused on the avoidance of unnecessary medical interventions, iatrogenic medical or psychological complications, and disability. Unfortunately, it is never possible to definitively rule out all possible medical causes. The literature is full of case presentations of patients with multiple sclerosis, brain tumors, and intermittently flaring infections, labeled for years as neurotic before the condition was diagnosed correctly. Patients who for years have had benign gastrointestinal symptoms can get appendicitis.

Patients who have a somatizing disorder often approach each new clinician as the one who, unlike the incompetent and insensitive physicians she has consulted in the past, will finally get to the bottom of her troubles and allow her to live the perfect life that her symptoms have denied her. The gynecologist must not get caught up in these expectations but rather remind the patient that symptoms that have resisted diagnosis and treatment for many years are likely to be challenging ones.

As with anxious patients, it is important not to structure the doctor-patient relationship so that the patient receives attention inconsistently and only in response to escalating symptoms and demands. It is best to schedule frequent, brief office visits during which the clinician allots a small amount of time to listen to and sympathize with the patient's somatic complaints and spends the bulk of the time reinforcing the patient's efforts to function despite her symptoms. Family members should be encouraged to facilitate function rather than invalidism.

It is often tempting to unmask patently psychologically based symptoms by tricking the patient: shouting "Fire!" in the vicinity of a "paralyzed" patient, searching the patient's hospital room or belongings for paraphernalia used to cause symptoms, documenting the patient's behavior when she does not realize she is being observed. Some of these attempts are useful diagnostically, but not therapeutically, and some (searches) are unethical and illegal. Humiliating a frustrating patient may be momentarily gratifying, and may force her to relinquish a symptom, at least temporarily. She may seek care elsewhere, relieving the original treatment team but exacerbating her dysfunction, distrust, and demands on the health care system as a whole.

Patients with conversion, somatization, and hypochondriacal disorders often benefit from prescriptive behavioral regimens aimed at saving face and improving function. It was once believed that a patient so relieved of one symptom would soon substitute another, but this assumption has not been confirmed by empirical evidence. The behavioral regimen should consist of health-promoting activities relevant to the target symptoms, planned in a step-wise progression, and recommended with reasonable medical conviction and authority. For example, the patient with psychogenic difficulty swallowing should be advised to drink only clear

liquids, at specified intervals, for a specified number of days, and then go on similarly to full liquids, purees, soft foods, and finally a regular diet. The patient with difficulties in the extremities can undertake an exercise regimen. The patient's preoccupation with her symptoms can be channeled into documentation of her progress in a log that she brings to her medical appointments. She should be advised not to dwell on her symptoms apart from this important notation.

It is critical to remember that patients with somatic complaints due to depression, posttraumatic stress disorder and other anxiety disorders, and domestic violence frequently seek care from gynecologists. In the case of domestic violence, the gynecologist is often the only human contact the abuser allows the patient outside the domestic situation (78,79 and 80). These possibilities must be ruled out before care is directed to symptom management.

There is considerable cross-cultural variation in the extent to which feelings and psychological conflicts are somatized. In many Asian cultures, for example, complaints about problems with feelings, behaviors, and interpersonal relationships are almost unheard of; these problems are expressed, diagnosed, and treated somatically. On the other hand, some very sophisticated and psychologically informed patients in the West may dismiss serious somatic signs and symptoms as indications of psychological conflict.

Referral

Patients with somatizing disorders may resist mental health referral more adamantly than any other single class of patients. Focused as they are on physical symptoms, these patients can regard referral as a message that their complaints are not being taken seriously and as a sign of contempt and rejection by the gynecologist. It is particularly useful with these patients to emphasize that distinctions between mind and body are artificial. The brain is part of the body. Our language expresses this synthesis; anxiety causes "butterflies in the stomach," aggravation "gives us a headache," and unwelcome news "gives us a heart attack."

The referral should be framed as support for the patient's suffering rather than as a statement that her problems are "all in her head." The mental health professional should be introduced as a member of the medical team. Some medical institutions have dedicated psychiatric consultation, medical psychiatry, or behavioral medicine services offering expertise in the psychological complications of disease and in somatization. Because so-called *somatic* and *psychological* symptoms often coexist and interact, the gynecologist should work in collaboration with the mental health professional.

Personality Disorders

Personality disorders are pervasive, lifelong, maladaptive patterns of perception and behavior. Patients with personality disorders do not consider themselves symptomatic, but as treated unfairly by circumstances and other people. They view their own behaviors, which can wreak havoc in the health care setting as well as in patients' lives, as normal, expectable, inevitable reactions to these perceived circumstances. To make matters worse, their behaviors tend to provoke in others the very responses that confirm their expectations. For example, a patient who is convinced that people always abandon her clings desperately to others, eventually driving them away.

Personality disorders are organized into clusters in DSM IV. Patients often manifest characteristics of several disorders within a cluster and between clusters.

Cluster A

Paranoid personality disorder
Schizoid personality disorder
Schizotypal personality disorder

Cluster B

Narcissistic personality disorder
Histrionic personality disorder
Borderline personality disorder
Antisocial personality disorder

Cluster C

Avoidant personality disorder
Dependent personality disorder
Obsessive-compulsive personality disorder

Individuals with Cluster A disorders are isolated, suspicious, detached, and odd. Narcissistic patients are grandiose, arrogant, envious, and entitled. Histrionic individuals are flamboyant and provocative. Antisocial patients disregard laws and rules of common decency toward others. Borderline personality disorder causes patients to have difficulty controlling their impulses and maintaining stable moods and relationships. They also engage in self-destructive behaviors. They fluctuate between overvaluation and castigation of the same person, or direct these feelings alternately between one person and another. When this happens on a gynecology service or in the office, it can precipitate significant tensions among the staff. Recent research reveals that many women who have been abused are diagnosed as borderline when posttraumatic stress disorder more accurately fits their symptoms. *Posttraumatic stress disorder* is a less stigmatizing and more treatable condition than abuse.

Epidemiology

Lifetime prevalence of personality disorders as a group is 2.5%. Cluster A disorders are more common in males. Within Cluster B, 75% of cases are female; the prevalence in the general population is 2%. Personality disorders such as narcissistic personality are more common in the clinical population than in the general population. Among cluster C disorders, dependent personality is one of the most frequently diagnosed. Obsessive-compulsive personality is twice as common in males as in females. It is important to distinguish the personality disorder from the symptomatic obsessive-compulsive disorder. There is a strong association between personality disorders and a history of childhood abuse. The possibility of an ongoing abusive situation should be considered as well.

Assessment

The impact of personality disorders ranges widely. At one end of the spectrum, the disorder is an exaggerated personality style. At the other end of the spectrum, the individual suffers terrible emotional pain and is unable to function in work roles or relationships, spending significant periods of time in psychiatric hospitals. As the definition implies, the patient will not seek treatment for the signs and symptoms listed in the diagnostic criteria but instead will have complaints about her treatment by others, their responses to her, and the unfairness and difficulties of life in general. Taking the history, the clinician should frame questions in those same terms: how long have these troubles gone on, and how much do they interfere with her ability to work and relate to others? Personality disorders do not bring patients to gynecologists' offices directly, but they greatly complicate things once patients arrive there.

Management

It generally requires intense and lengthy psychotherapy to effect significant improvement in patients who have personality disorders. The challenge in the gynecology setting is to minimize contention and drain on medical staff while maximizing the likelihood of effective diagnosis and treatment of the patient's medical problems. The most helpful single step is the identification of the personality disorder. Diagnosis enables the gynecologist to recognize the reasons for a patient's problem behaviors, to avoid becoming entangled in fruitless interactions with the patient, and to set limits on her demands that are neither withholding nor overindulgent.

There is increasing evidence that psychotropic medications are useful for personality disorders. Treatment should be provided in consultation with a psychiatrist. The patient's ability to use the medication properly is compromised by impulsivity, self-destructive tendencies, and unstable relationships. Low doses of major tranquilizers are sometimes helpful, especially when the patient has brief psychotic episodes. Minor tranquilizers pose significant risk of habituation, overdose, and physical and psychological habituation. They can be prescribed for temporary stresses, but only in a quantity sufficient for several days and with no refill allowed. At the same time, some patients' anxiety, demands, and power struggles are eased when they are given control over their own use of medication. Such an approach requires enough familiarity with the patient to ensure her safety.

Because the patient with a personality disorder attributes her problems to others, her symptoms cannot be adduced as reasons for psychiatric referral, but her suffering can be. If a diagnosis of a personality disorder is noted in the patient's chart or on insurance forms, it is essential that she be so informed. It is useful to review the DSM IV criteria with her so that she understands the basis for the diagnosis.

Adjustment Disorders

Definitions

Adjustment disorders are temporary, self-limited responses to life stressors that are part of the normative range of human experience (unlike those that precipitate posttraumatic stress disorder). The patient has mood or anxiety symptoms that are sufficient to lead her to seek medical care but that do not meet criteria of sufficient quantity or quality to qualify for psychiatric diagnosis. The diagnosis requires an identifiable stressor, onset within 3 months after the stress begins, and spontaneous resolution within 6 months after the stressor ends. Obviously the latter cannot be determined until the symptoms resolve—but they do rule out the disorder if the symptoms persist beyond that time ([81,82](#)).

Adjustment disorders can be distinguished from normal grieving. Grieving produces symptoms similar to those of depression. Interference with function does not persist, but some degree of sadness and preoccupation with the lost loved one often goes on for months and years.

Epidemiology

Adjustment disorders affect males and females equally. Approximately 5% to 20% of patients in outpatient mental health treatment suffer from adjustment disorders. There is little literature on the subject; one study reported a 2.3% prevalence among a sample of patients receiving care in a walk-in general health clinic.

Management

Patients with adjustment disorders can be treated effectively with brief counseling in the primary care setting. The counseling can be provided by the gynecologist or by a nurse clinician, social worker, or psychologist, preferably a member of the office or hospital staff who is familiar with the gynecologist and the practice. The medical setting is sometimes the only one where the patient can vent her feelings and think through her situation. Counseling is aimed at facilitating the patient's own coping skills and helping her to make autonomous decisions about her situation. The gynecologist should follow the patient's progress and facilitate referral to a psychiatrist if symptoms do not resolve.

Eating Disorders

Definitions

Preoccupation with thinness, sometimes to the point of pathology, is a major problem for women in North America. Only a small number of women profess to be satisfied with their weights and body shapes. Nearly all admit to current or recent attempts to limit food intake. Physicians often share social prejudices against overweight patients and can easily exacerbate patients' concerns by making chance comments.

Anorexia nervosa is characterized by severe restrictions on food intake, often accompanied by excessive physical exercise and the use of diuretics or laxatives. Clinical features include menstrual irregularities or amenorrhea, intense, irrational fear of becoming fat, preoccupation with body weight as an indicator of self-worth, and inability to acknowledge the realities and dangers of the condition. Some patients approach gynecologists for care of infertility ([83](#)).

Bulimia is characterized by eating binges followed by self-induced vomiting or purging. Patients' weights may be normal or somewhat more. Patients have drastically low self-esteem, and the condition is frequently comorbid with depression ([84](#)).

Obesity is an increasingly frequent health problem, with little evidence that any nonsurgical approach is effective over time. Sensible eating should be encouraged, and fad or crash diets are medically and psychologically counterproductive ([85](#)).

Epidemiology

More than 90% of cases of anorexia and bulimia occur in females. The prevalence is 0.5% to 1.0% in late adolescence and 1% to 3% in early adulthood. There is some evidence of familial transmission.

Assessment

The clinician treating the anorexic patient needs to know how much insight she has into her problem and to assess her mood, relationships, and general level of function. Anorexia poses significant risks of severe metabolic complications and death, often from cardiac consequences of electrolyte abnormalities. Thorough physical and laboratory examination is critical; immediate hospitalization may be necessary.

Management

Patients with anorexia or bulimia should be treated by mental health professionals, preferably subspecialists in this area. The conditions are highly refractory to treatment; patients can resort to elaborate subterfuges to conceal their failure to eat and gain weight. Antidepressant medication is sometimes helpful. Amenorrheic patients should not be treated with ovulation induction. Evaluation for osteopenia and osteoporosis is necessary.

Psychotic Disorders

Definitions

Psychotic disorders are characterized by major distortions of thinking and behavior. They include schizophrenia, schizophreniform disorders, schizoaffective disorders, delusional disorders, and brief psychotic disorders. General medical and toxic conditions must be ruled out. Distinctions between the disorders are based on symptoms, time course, severity, and associated affective symptoms. **The hallmark of psychosis is the presence of delusions or hallucinations.** Hallucinations are sensory perceptions in the absence of external sensory stimuli. Delusions are bizarre beliefs about the nature of motivation of external events. Because there is no reliable definition of "bizarre," the diagnostician working with a patient from an unfamiliar culture must determine whether a given belief is normal in that culture. Delusions and hallucinations are the "positive symptoms" of schizophrenia. The "negative symptoms" include apathy and loss of connection to others and to interests. The negative symptoms may be more disabling than the positive.

Epidemiology

Schizophrenia occurs in approximately 1% of the population worldwide ([86](#)). Onset is in the late teens to mid-30s. Women succumb later and have more prominent mood symptoms and a better prognosis than men. The risk is 10 times greater for first-degree biologic relatives and for individuals of low socioeconomic status. It is unclear whether indigent status is a precipitating stress or a result of psychotic illness.

Assessment

There is wide variability in the functional impact of psychotic disorders. Patients must not be assumed to be incompetent to make medical decision or lead independent lives, especially if they comply with treatment. Patients must be asked specifically about their living situations and coping skills. When psychotic women have responsibility for the care of children, their ability to do so should be assessed in consultation with a mental health expert. Motherhood and child custody are exceedingly sensitive matters for these vulnerable patients.

A relentlessly downhill course is not inevitable; remissions and recovery can occur. Therefore, the patient's mental status must be examined. Under the pressures of a busy medical setting, psychotic illnesses can be overlooked, only to erupt in the labor room, operating room, or recovery room. Patients who believe that conspiracies or Martians are responsible for their symptoms can answer yes-or-no questions without revealing their delusions. Open-ended questions are more useful (87).

Sensationalized media accounts of violent crimes committed by psychotic patients exacerbate public misconceptions about these diseases. Statistically, individuals with psychoses are more likely to be victims than perpetrators of crime. Untreated patients, especially when under the influence of alcohol or other substances, are at somewhat increased risk of violent behavior.

Management

Psychotic illnesses are nearly always managed by psychiatrists. However, a primary care practitioner can readily assume responsibility, in consultation with a psychiatrist, for a stable patient who complies with treatment. When a patient expresses delusions, the clinician may indicate that he or she does not share them, but should not debate with the patient (88,89 and 90). It is important to concentrate on the patient's strengths. She can easily be humiliated by thoughtless epithets or behaviors that betray the expectation of violence or incompetence. Patients with severe cases must be treated with an integrated system of social services, family support, rehabilitation, general medical care, psychotherapy, and psychopharmacology. In the process of referral to a mental health professional, the primary clinician should be clear, matter-of-fact, open, and confident of the possibility of successful treatment (91).

Benign conditions of the female genital tract include lesions of the uterine corpus and cervix, ovaries and fallopian tubes, and the vagina and vulva. A classification of the benign lesions of the vulva, vagina, and cervix appears in [Table 13.1](#). Leiomyoma, polyps, and hyperplasia are the most common benign conditions of the uterus in adult women. Benign tumors of the ovaries are listed in [Table 13.2](#).

Vulva
Blau condition
Epidermal lesions
Tumors and cysts
Ulcers
Extragenital epithelial disorders
Vagina
Endometriosis
Metrorrhagia, menorrhagia, and irregular uterine cycle
Subacute leukorrhea (leukocytorrhoea)
Vaginal atrophy or dyspareunia
Disorders of leukorrhea
Polypoid vaginal prolapse
Polypoid vaginal prolapse
Cystocele
Uterine prolapse
Uterine prolapse
Protruding vaginal polypoid
Stenosis
Stricture
Cervix
Cervicitis
Leukorrhea
Polypoid vaginal prolapse
Polypoid vaginal prolapse

Table 13.2. Benign Ovarian Tumors

Common gynecologic problems include abnormal bleeding, a pelvic mass, and vulvovaginal symptoms. The causes of vaginal bleeding and a pelvic mass vary by age group ([Table 13.3](#)). For each age group, the most common causes of these problems are described, along with techniques of diagnosis and principles of management. Malignant diseases are presented in Chapters 30 through 35.

Causes of bleeding by approximate frequency and age group					
Prepubertal	Adolescent	Reproductive	Perimenopausal	Postmenopausal	Other
Uterine prolapse	Atrophic vaginitis	Endometrial polypoid lesions	Fibroids	Endometrial cancer	Exogenous hormone use
Prepubertal	Endometrial	Pregnancy	Fibroids	Endometrial cancer	Exogenous hormone use
Prepubertal	Pregnancy	Atrophic	Cervical and endometrial polyps	Hyperplasia	
Tumor	Coagopathy	Fibroids	Thrombotic thrombocytopenic syndrome	Other tumor—colorectal, uterine, cervical	
		Cervical and endometrial polyps			
		Thrombotic thrombocytopenic syndrome			
Causes of pelvic mass by approximate frequency and age group					
Adolescent	Prepubertal	Adolescent	Reproductive	Perimenopausal	Postmenopausal
Functional cyst	Functional cyst	Functional cyst	Functional cyst	Fibroids	Clear cell tumor
Endometrial tumor	Granulosa cell tumor	Pregnancy	Pregnancy	Epithelial ovarian tumor	Functional cyst
		Obstructive gynecologic lesion	Luteal phase	Functional cyst	Borderline malignant tumor or sarcoma
		Obstructive gynecologic lesion	Epithelial ovarian tumor		Metastasis
		Epithelial ovarian tumor			

Table 13.3. Causes of Bleeding and Pelvic Mass By Approximate Frequency and Age Group

Abnormal Bleeding

Prepubertal Age Group

To appropriately evaluate a young girl with vaginal bleeding, the events of puberty must be understood (1,2). The hormonal changes that control the cyclic functioning of the hypothalamic–pituitary–ovarian axis are described in Chapter 7. An understanding of the normal sequence and timing of these events is critical to an appropriate assessment of a girl at the onset of bleeding (see Chapter 23).

Differential Diagnosis

Slight vaginal bleeding can occur within the first few days of life because of withdrawal from the high level of maternal estrogens. New mothers of female infants should be informed of this possibility in an effort to preclude unnecessary anxiety. After the neonatal period, a number of causes of bleeding should be considered in this age group (Table 13.4). Menses rarely occurs before breast budding (3,4). Vaginal bleeding in the absence of secondary sexual characteristics should be evaluated carefully.

Vulvar and external

Table 13.4. Causes of Vaginal Bleeding in Prepubertal Girls

The causes of bleeding in this age group range from the medically mundane to malignancies that may be life-threatening. The source of the bleeding is sometimes difficult to identify, and parents who observe blood in a child's diapers or panties may be unsure of the source. Pediatricians will usually look for urinary causes of bleeding, and gastrointestinal factors should also be considered.

Vulvar Lesions Vulvar irritation can lead to pruritus with excoriation, maceration of the vulvar skin, or fissures that can bleed. Other visible external causes of bleeding in this age group include urethral prolapse, condylomas, or molluscum contagiosum. Urethral prolapse can present acutely with a tender mass that may be friable or bleed slightly; it occurs more commonly in African American girls. It may be confused with a vaginal mass. The classic presentation is a mass symmetrically surrounding the urethra. This condition can be managed medically with the application of topical estrogens (5). The presence of a condyloma should prompt questioning about abuse, although it has been suggested that a condyloma that appears during the first 2 years of life may have been acquired perinatally from a mother with human papillomavirus infection (6,7). Excoriation and hemorrhage into the skin can cause external bleeding.

Foreign Body A foreign body in the vagina is a common cause of vaginal discharge, which may appear purulent or bloody. Young children explore all orifices and may place all varieties of small objects inside their vaginas (Fig. 13.1). An object, such as a small plastic toy, can sometimes be palpated on rectal examination. The most common foreign bodies are small pieces of toilet paper that find their way into the vagina (8). One recent study suggests that the presence of vaginal foreign bodies may be a marker for sexual abuse; although this is by no means always the case, the possibility of abuse should be kept in mind in examining any child with vulvovaginal symptoms (9).

Figure 13-1 Foreign body (plastic toy) in the vagina of an 8-year-old girl.

Precocious Puberty Precocious puberty (see Chapter 23) occasionally is marked by vaginal bleeding in the absence of other secondary sexual characteristics, although it is more common for the onset of breast budding or pubic hair growth to occur before vaginal bleeding. Although a large observational study suggests that the onset of pubertal changes—breast budding and pubic hair—may occur earlier than had originally been thought, the onset of menarche before age 8 is sufficiently early to warrant evaluation for precocious puberty (2).

Trauma Trauma can be a cause of genital bleeding. **A careful history should be obtained from one or both parents or caretakers and the child herself, because trauma caused by sexual abuse is often not recognized.** Physical findings that are inconsistent with the description of the alleged accident should prompt consideration of abuse and appropriate consultation or referral to an experienced social worker or sexual abuse team. **There is a mandatory legal obligation to report suspected child physical abuse in all states;** most states specifically require reporting child sexual abuse as well, but even in those that do not, the laws

are broad enough to encompass sexual abuse implicitly (10). Even the suspicion of sexual abuse requires notification. In general, straddle injuries affect the vulvar area, whereas penetrating injuries with lesions of the fourchette or lesions that extend through the hymenal ring are less likely to occur as a result of accidental trauma (Fig. 13.2) (11).

Figure 13-2 Straddle injury—vulvar hematoma in a 13-year-old girl.

The medical evaluation of suspected child sexual abuse is best managed by individuals who have experience in assessing the physical findings, laboratory results, and the children's statements and behaviors. Genital findings have been described as follows (12):

1. Normal or unrelated to abuse
2. Nonspecific for abuse
3. Concerning for abuse
4. Clear evidence of blunt force or penetrating trauma.

The overall classification of the likelihood for abuse can be categorized as follows (12):

1. No evidence of abuse
2. Possible abuse
3. Probable abuse
4. Definitive evidence of abuse or penetrating trauma.

Most cases of child sexual abuse do not come to light with an acute injury and instead are associated with normal or nonspecific genital findings (13,14). Forms of abuse such as fondling or digital penetration may not result in lasting visible genital lesions.

Other Causes Other serious but rare causes of true vaginal bleeding include vaginal tumors. The most common tumor in the prepubertal age group is a rhabdomyosarcoma (sarcoma botryoides), which is associated with bleeding and a grapelike clustered mass (Chapter 31). Other forms of vaginal tumor are also rare but should be ruled out if no other obvious source of bleeding is found externally.

Hormonally active ovarian tumors can lead to endometrial proliferation and bleeding. Exogenously administered estrogens can result in bleeding. This can be caused by the prolonged use of topical estrogens prescribed as therapy for vulvovaginitis or labial adhesions or can result from accidental ingestion of prescription estrogens.

HR color=#000000 noShade SIZE=1> **Diagnosis**

A careful examination is indicated when a child makes genital complaints. The technique of examining the prepubertal child is described in Chapter 1. **If no obvious cause of bleeding is visible externally or within the distal vagina, an examination can be performed using anesthesia and an endoscope to completely visualize the vagina and cervix. This exam is best performed by a clinician with experience in pediatric and adolescent gynecology.**

If an ovarian or vaginal mass is suspected, a pelvic ultrasonographic examination can provide useful information. The appearance of the ovaries (normal prepubertal size and volume, follicular development, cystic or solid) can be noted, as well as the size and configuration of the uterus. **The prepubertal uterus has a distinctive appearance, with equal proportions of cervix and fundus and a size of approximately 2 to 3.5 cm in length and 0.5 to 1 cm in width (Fig. 13.3).** The fundus enlarges with estrogen stimulation. An ultrasonographic examination should be the first imaging study performed; more sophisticated imaging techniques such as magnetic resonance imaging (MRI) or computed tomography (CT) scanning are rarely indicated.

Figure 13-3 Pelvic ultrasound (transabdominal) of a premenarchal 10-year-old girl. U, uterine corpus; C, cervix. Note that the body of the uterus is about the same size as the cervix.

Management

The management of bleeding in the prepubertal age group is directed toward the cause of bleeding. If bloody discharge believed to be due to nonspecific vulvovaginitis persists despite therapy, further evaluation to rule out the presence of a foreign body may be necessary. Skin lesions (chronic irritation) and lichen sclerosus may be difficult or frustrating to manage but can be treated with a course of topical steroids; lichen sclerosus often requires ongoing maintenance therapy. **Vaginal and ovarian tumors should be managed in consultation with a gynecologic oncologist.**

Adolescence

To assess vaginal bleeding during adolescence, it is necessary to have an understanding of the range of normal menstrual cycles (see Chapter 7). **During the first 2 years after menarche, most cycles are anovulatory.** Despite this, they are somewhat regular, within a range of approximately 21 to 40 days (15,16 and 17). In more than one-fourth of girls, a pattern of plus or minus 10 days and a cycle length of 21 to approximately 42 days are established within the first three cycles; in one-half of girls, the pattern is established by the seventh cycle; and in two-thirds of girls, such a pattern is established within 2 years of menarche (17).

Normal Menses

The mean duration of menses is 4.7 days; 89% of cycles last ≤ 7 days. The average blood loss per cycle is 35 ml (18), and the major component of menstrual discharge is endometrial tissue. Recurrent bleeding in excess of 80 ml/cycle results in anemia.

Quantitative information about the volume of menstrual blood loss is of little clinical use, however. The common clinical practice of asking how many pads or tampons are soaked on a heavy day or per cycle can give a rough approximation of blood loss (3 to 5 pads per day is typical). Individual variations in fastidiousness, lack of familiarity with the volume of blood loss other than one's own, and errors in estimation or recollection result in inaccuracies in estimations of menstrual volume. One study found that one-third of individuals who estimated their cycles to be moderate or light had bleeding in excess of 80 ml/cycle, whereas nearly one-half of those who described the bleeding as heavy had flow less than 80 ml/cycle (19). In addition, the amount of menstrual blood contained in each tampon or pad may vary both within brands as well as from one brand to another (20).

The transition from anovulatory to ovulatory cycles takes place during the first several years after menarche. It results from the so-called *maturation of the hypothalamic–pituitary–ovarian axis*, characterized by positive feedback mechanisms in which a rising estrogen level triggers a surge of luteinizing hormone and ovulation. Most adolescents have ovulatory cycles by the end of their second year of menstruation, although most cycles (even anovulatory ones) remain within a rather narrow range of approximately 21 to 42 days.

Cycles that are longer than 42 days, cycles that are shorter than 21 days, and bleeding that lasts more than 7 days should be considered out of the ordinary, particularly after the first 2 years from the onset of menarche. The variability in cycle length is greater during adolescence than adulthood; thus, greater irregularity is acceptable if significant anemia or hemorrhage is not present. However, consideration should be given to an evaluation of possible causes of abnormal menses (particularly underlying causes of anovulation such as androgen excess syndromes) for girls whose cycles are consistently outside normal ranges (21) or whose cycles were previously regular and become irregular.

Differential Diagnosis

Anovulation Anovulatory bleeding can be too frequent, prolonged, or heavy, particularly after a long interval of amenorrhea. The physiology of this phenomenon relates to a failure of the feedback mechanism in which rising estrogen levels result in a decline in follicle-stimulating hormone (FSH) with subsequent decline of estrogen levels. In anovulatory cycles, estrogen secretion continues, resulting in endometrial proliferation with subsequent unstable growth and incomplete shedding. The clinical result is irregular, prolonged, and heavy bleeding. Conditions that are associated with anovulation are listed in Table 13.5 and more fully discussed in Chapter 24, Chapter 25, and Chapter 27.

Eating disorders
Anorexia nervosa
Bulimia nervosa
Excessive physical exercise
Chronic illness
Alcohol and other drug abuse
Stress
Thyroid disease
Hypothyroidism
Hyperthyroidism
Diabetes mellitus
Androgen excess syndromes

Table 13.5. Conditions Associated with Anovulation and Abnormal Bleeding

Studies of adolescent menses show differences in rates of ovulation based on the number of months or years postmenarche. The younger the age at menarche, the sooner regular ovulation is established. In one study, the time from menarche until 50% of the cycles were ovulatory was 1 year for girls whose menarche occurred when they were younger than 12 years of age, 3 years for girls whose menarche occurred between 12 and 12.9 years of age, and 4.5 years for girls whose menarche occurred at 13 years of age or older (22).

Pregnancy-related Bleeding The possibility of pregnancy must be considered when an adolescent seeks treatment for abnormal bleeding. Bleeding in pregnancy can be associated with a spontaneous abortion, ectopic pregnancy, or other pregnancy-related complications such as a molar pregnancy. In the United States, 50% of 17-year-old females have had sexual intercourse (23). Issues of confidentiality for adolescent health care are addressed in Chapter 1.

Exogenous Hormones The cause of abnormal bleeding that is experienced while an individual is taking exogenous hormones usually is very different from bleeding that occurs without hormonal manipulation (24). Oral contraceptive use is associated with breakthrough bleeding, which occurs in as many as 30% to 40% of individuals during the first cycle of combination pill use. In addition, irregular bleeding can result from missed pills (25,26). Strict compliance with correct and consistent pill taking is difficult for many individuals who take oral contraceptives; one study reported that only 40% of women took a pill every day (27). Other studies suggest that adolescents have an even more difficult time taking oral contraceptives, missing an average of three pills per month (28). With this many missed pills, it is not surprising that some individuals experience irregular bleeding. The solution is to emphasize consistent pill taking; if the individual is unable to comply with daily pill use, perhaps an alternative contraceptive method may be preferable.

Other methods of contraception can also produce irregular bleeding.

Irregular bleeding occurs frequently in users of *depomedroxyprogesterone acetate (DMPA)*, although at the end of 1 year, more than 50% of users will be amenorrheic (29). The implantable subdermal *levonorgestrel* implant also is associated with relatively high rates of irregular and unpredictable bleeding (30). Other contraceptive methods, including the monthly injectable combination contraceptive and the progestin-containing intrauterine system are associated with irregular bleeding in the first few months of use (31,32). Although the mechanism of bleeding associated with these hormonal methods is not well established, many believe that bleeding occurs from an atrophic endometrium, suggesting options for therapy (24). However, it should not be assumed that any bleeding occurring while an individual is using a hormonal method of contraception is caused by that method. Other local causes of bleeding, such as cervicitis or endometritis, also can occur during hormone therapy (33).

Hematologic Abnormalities In the adolescent age group, the possibility of a hematologic cause of abnormal bleeding must be considered. One classic study reviewed all patient visits of adolescents to an emergency room with the complaint of excessive or abnormal bleeding (Fig. 13.4) (34). The most common coagulation abnormality diagnosed was idiopathic thrombocytopenic purpura, followed by von Willebrand's disease. Adolescents who have severe menorrhagia, especially at menarche, should be screened for coagulation abnormalities, including von Willebrand's disease.

Figure 13-4 Etiology of menorrhagia in adolescents. (From Classens AE, Cowell CA. Acute adolescent menorrhagia. *Am J Obstet Gynecol* 1981;139:277–280, with permission.)

Infections Irregular or postcoital bleeding can be associated with chlamydial cervicitis. **Adolescents have the highest rates of chlamydial infections of any age group, and screening for chlamydia should be performed routinely among sexually active teens (35).**

Menorrhagia can be the initial sign for patients infected with sexually transmissible organisms. Adolescents have the highest rates of pelvic inflammatory disease (PID) of any age group when only sexually experienced individuals are considered (36) (see Chapter 15).

Other Endocrine or Systemic Problems Abnormal bleeding can be associated with thyroid dysfunction. Signs and symptoms of thyroid disease can be somewhat subtle in teens (Chapter 25). Hepatic dysfunction should be considered, because it can lead to abnormalities in clotting factor production.

Polycystic ovarian syndrome (PCOS) can occur during adolescence, and manifestations of excess androgen effect (hirsutism, acne) should prompt evaluation (37). **Androgen disorders occur in about 5% to 10% of women, making them the most common endocrine disorders in women** (Chapter 25). Classic PCOS, functional ovarian hyperandrogenism, or partial late-onset congenital adrenal hyperplasia all can occur in adolescence (38). **These disorders are often overlooked, unrecognized, or untreated.** Women with even mild disorders are candidates for intervention. These disorders may be a harbinger of diabetes, endometrial cancer, and cerebrovascular disease.

Acne, hirsutism and menstrual irregularities are often dismissed as normal during adolescence but may be manifestations of hyperandrogenism (39). If an androgen abnormality is not treated, it is likely to persist beyond adolescence. Obesity, hirsutism, and acne should be evaluated to minimize the significant psychosocial costs (40). Androgenic changes are partially reversible if detected early and managed appropriately. Behavioral changes (diet and exercise) are desirable. Signs of insulin resistance (acanthosis nigricans) should also be evaluated and managed appropriately.

Anatomic Causes Obstructive or partially obstructive genital anomalies typically present during adolescence. müllerian abnormalities, such as obstructing longitudinal vaginal septa or uterus didelphis, can cause hematocolpos or hematometra. If these obstructing anomalies have or develop a small outlet, the sign may be of persistent dark brownish discharge (old blood) rather than or in addition to a pelvic mass. Many varieties of uterine and vaginal anomalies exist and should be managed by or in consultation with clinicians who have sufficient experience and expertise with these anomalies. Fig. 13.5 illustrates situations in which abnormal bleeding can occur as a result of obstructing septa.

Figure 13-5 The types of obstructive or partially obstructive genital anomalies that can occur during adolescence.

Diagnosis

Any adolescent with abnormal bleeding should undergo sensitive pregnancy testing, regardless of whether she states that she has had intercourse. The medical consequences of failing to diagnose a pregnancy are too severe to risk missing the diagnosis. Complications of pregnancy should then be managed accordingly.

Laboratory Testing In addition to a pregnancy test, laboratory testing should include a complete blood count with platelets, coagulation studies, and bleeding time. Thyroid studies also may be appropriate. A complete pelvic examination is appropriate if the patient has been sexually active, is having severe pain, or an anomaly is suspected. Cultures for gonorrhea and testing for chlamydia infection are appropriate if the patient has been sexually active. Some young teens who have a history that is classic for anovulation, who deny sexual activity, and who agree to return for follow-up evaluation may be managed with a limited gynecologic examination and pelvic ultrasonography.

Imaging Studies If the pregnancy test is positive, pelvic imaging using ultrasonography may be necessary to confirm a viable intrauterine pregnancy and rule out a spontaneous abortion or ectopic pregnancy. If a pelvic mass is suspected on examination, or if the examination is inadequate (more likely to be the case in an adolescent than an older woman) and additional information is required, pelvic ultrasonography may be helpful. **Although transvaginal ultrasonographic examination can be more helpful than transabdominal ultrasonography in ascertaining details of pelvic anatomy, the use of the vaginal probe may not be possible in a young girl or one who has not used tampons or had intercourse.** Direct communication between the clinician and the radiologist can be helpful in identifying candidates for transvaginal ultrasonographic examination.

Other imaging studies are not indicated as initial testing but may be helpful in selected instances. If a pelvic ultrasonographic examination does not lead to clarification of the anatomy when vaginal septa, uterine septa, uterine duplication, or vaginal agenesis are suspected, MRI can be helpful in delineating anatomic abnormalities. It has been suggested that this imaging technique may replace laparoscopy in the evaluation of uterine and vaginal developmental anomalies (41). CT scanning may be helpful in detecting nongenital intraabdominal abnormalities.

Management

Management of bleeding abnormalities related to pregnancy, thyroid dysfunction, hepatic abnormalities, hematologic abnormalities, or androgen excess syndromes should be directed to treating the underlying condition. Oral contraceptives can be extremely helpful in managing androgen excess syndromes. After specific diagnoses have been ruled out by appropriate laboratory testing, anovulation or dysfunctional bleeding becomes the diagnosis of exclusion.

Anovulation: Mild Bleeding

Adolescents who have mildly abnormal bleeding, as defined by adequate hemoglobin levels and minimal disruption of daily activities, are best treated with frequent reassurance, close follow-up, and supplemental iron. If the patient has been bleeding heavily or for a prolonged interval, however, an apparent decrease in the bleeding does not necessarily mean that therapy is not required. This type of on-again, off-again bleeding characterizes anovulatory bleeding and is likely to continue in the absence of therapy.

A patient who is mildly anemic will benefit from hormone therapy. If the patient is not bleeding at the time of evaluation, a combination low-dose oral contraceptive can be prescribed to be used in the manner in which it is used for contraception (21 days of hormonally active pills, followed by 7 days of placebo, during which time withdrawal bleeding is expected). If the patient is not sexually active, she should be reevaluated after three to six cycles to determine if she desires to continue this regimen. Parents may sometimes object to the use of oral contraceptives if their daughter is not sexually active (or if they believe her not

to be or even if they would like her not to be). These objections are frequently based on misconceptions about the potential risks of the pill and can be overcome by careful explanation of the pill's role as medical therapy. If the medication is discontinued when the young woman is not sexually active and she subsequently becomes sexually active and requires contraception, it may be difficult to explain the reinstitution of oral contraceptives to the parents. Consideration can certainly be given to continuing the pill, and parents should be reassured that there are no medical risks associated with prolonged use.

Sometimes, providing parents with accurate information about the safety of oral contraceptives, emphasizing that currently available oral contraceptive preparations contain lower doses of estrogens and progestins than those used in the 1960s and 1970s, and emphasizing the hormonal rather than contraceptive function, may not be persuasive. In such cases, cyclic progestins are an alternative. **Medroxyprogesterone acetate, 5 to 10 mg/day for 10 to 13 days every 1 to 2 months, prevents excessive endometrial buildup and irregular shedding caused by unopposed estrogen stimulation.** This therapy also should be reevaluated regularly and accompanied by oral administration of iron. Eventual maturation of the hypothalamic–pituitary–ovarian axis usually will result in the establishment of regular menses unless there are underlying conditions such as hyperandrogenism. Individuals may choose to continue oral contraceptives for contraception or their noncontraceptive benefits (improvement of acne, decreased dysmenorrhea, and lighter, more regular menstrual flow).

Acute Bleeding: Moderate

Patients who are bleeding acutely but who are stable and do not require hospital admission will require doses of hormones that are much higher than those in oral contraceptives. An effective regimen is the use of combination monophasic oral contraceptives (every 6 hours for 4 to 7 days). After that time, the dose should be tapered or stopped to allow withdrawal flow. With this therapy, the patient and her parents should be given specific written and verbal instructions warning them about the potential side effects of high-dose hormone therapy—nausea, breast tenderness, and breakthrough bleeding. The patient should be instructed to call with any concerns rather than discontinue the pills, and she must understand that stopping the prescribed regimen may result in a recurrence of heavy bleeding.

Both the patient and her mother should be warned to expect heavy withdrawal flow for the first period. It will be controlled by the institution of combination low-dose oral contraceptive therapy given once daily and continued for three to six cycles to allow regular withdrawal flow. If the patient is not sexually active, the pill may be discontinued and the menstrual cycles may be reassessed.

Acute Bleeding: Emergency Management

The decision to hospitalize a patient depends on the rate of current bleeding and the severity of any existing anemia. The actual acute blood loss may not adequately be reflected in the initial blood count but will be revealed with serial hemoglobin assessments. The cause of acute menorrhagia may be a primary coagulation disorder (34), so measurements of coagulation and hemostasis, including bleeding time, should be performed for any adolescent patients with acute menorrhagia. Von Willebrand's disease, platelet disorders, or hematologic malignancies can all cause menorrhagia. Depending on the patient's level of hemodynamic stability or compromise, a blood sample can be analyzed for type and screen. The decision to transfuse must be considered carefully, and the benefits and risks should be discussed with the adolescent and her parents. Generally, there is no need for transfusion unless the patient is hemodynamically unstable.

In patients who, by exclusion, have been diagnosed as having dysfunctional bleeding, hormone therapy usually makes it possible to avoid surgical intervention (dilation and curettage [D & C], operative hysteroscopy, or laparoscopy). A patient who has been hospitalized for severe bleeding requires aggressive management as follows:

1. **After stabilization, when appropriate laboratory assessment and an examination have established a working diagnosis of anovulation; hormonal management will usually control bleeding.**
2. **Conjugated estrogens, either 25 to 40 mg given intravenously every 6 hours or 2.5 mg given orally every 6 hours, will usually be effective.**
3. **If estrogens are not effective, the patient should be reevaluated, and the diagnosis should be reassessed.** The failure of hormonal management suggests that a local cause of bleeding is more likely. In this event, consideration should be given to a pelvic ultrasonographic examination to determine any unusual causes of bleeding (such as uterine leiomyomas or endometrial hyperplasia) and to assess the presence of intrauterine clots that may impair uterine contractility and prolong the bleeding episode.
4. **If intrauterine clots are detected, evacuation of the clots (suction curettage or D & C) is indicated.** Although a D & C will provide effective immediate control of the bleeding, it is unusual to reach this step in adolescents.

More drastic forms of treatment other than a D & C (such as ablation of the endometrium by laser or rollerball devices) are considered inappropriate for adolescents because of concerns about future fertility.

If intravenous or oral administration of estrogen controls the bleeding, oral progestin therapy should be instituted and continued for several days to stabilize the endometrium. This therapy can be accomplished by using a combination oral contraceptive, usually one with 30 to 35 µg of estrogen, or by using the tapering regimen previously described. The medication can be tapered and ultimately stopped to allow withdrawal bleeding. Low-dose combination oral contraception should be continued for three to six cycles, or longer if desired, to provide normal menstrual cycles.

In general, the prognosis for regular ovulatory cycles and subsequent normal fertility in young women who experience an episode of abnormal bleeding is good, particularly for patients who develop abnormal bleeding as a result of anovulation within the first years after menarche and in whom there are no signs of other specific conditions. Some girls, including those in whom there is an underlying medical cause, such as polycystic ovary syndrome, will continue to have abnormal bleeding into middle and late adolescence and adulthood and will benefit from the ongoing use of oral contraceptives to manage hirsutism, acne, and irregular periods. Ovulation induction may be necessary to achieve fertility in these individuals. Girls with coagulopathies may also benefit from ongoing oral contraceptive use.

Long-term Hormonal Suppression

For patients with underlying medical conditions, such as coagulopathies or a malignancy requiring chemotherapy, long-term therapeutic amenorrhea with menstrual suppression using the following regimens may be necessary:

1. Progestins, such as oral *norethindrone*, *norethindrone acetate*, or *medroxyprogesterone acetate*, on a continuous daily basis
2. Continuous (nonscyclic) combination regimens of oral estrogen and progestins (birth control pills) that do not include a withdrawal bleeding–placebo week
3. Depot formulations of progestins (*DMPA*), with or without concurrent estrogens
4. Gonadotropin-releasing hormone (GnRH) analogs with or without estrogen add-back therapy.

The choice of regimen depends on any contraindications (such as active liver disease precluding the use of estrogens) and the clinician's experience. Although the goal of these long-term suppressive therapies is amenorrhea, all of these regimens may be accompanied by breakthrough bleeding. They require regular follow-up visits and continued patient encouragement. Occasional episodes of spotting and mild breakthrough bleeding that do not result in a lowered hemoglobin level may be managed expectantly. When breakthrough bleeding affects the hemoglobin level, it should be evaluated with respect to the underlying disease. For example, in a patient with underlying platelet dysfunction, breakthrough bleeding may reflect a lowered platelet count. Bleeding in a patient with hepatic disease may reflect worsening hepatic function. Supplemental low-dose estrogen can be helpful in the management of excessive breakthrough bleeding that has no specific cause other than the hormone therapy.

Reproductive Age Group

Normal Menses

Beyond the first 1 to 2 years after menarche, menstrual cycles generally conform to a cycle length of 21 to 35 days, with a duration of less than 7 days of menstrual flow. As a woman approaches menopause, cycle length becomes more irregular as more cycles become anovulatory. Although the most frequent cause of irregular bleeding is hormonal, other causes occur more often during the adolescent years. Pregnancy-related bleeding (spontaneous abortion, ectopic pregnancy) should always be considered, and a pregnancy test should always be obtained as part of the evaluation of abnormal bleeding. Although a variety of terms have been used to describe abnormal menses ([Table 13.6](#)), accurate characterization of the bleeding based on recorded records (preferably charted prospectively)

may be more important than the use of the specific term.

Term	Interval	Duration	Amount
Menorrhagia	Regular	Prolonged	Excessive
Metrorrhagia	Irregular	±Prolonged	Normal
Metrometrorrhagia	Irregular	Prolonged	Excessive
Hypermenorrhea	Regular	Normal	Excessive
Hypomenorrhea	Regular	Normal or less	Less
Oligomenorrhea	Infrequent or irregular	Variable	Scanty

Table 13.6. Abnormal Menses—Terminology

Dysfunctional Uterine Bleeding The term *dysfunctional uterine bleeding* has been used to describe abnormal bleeding for which no specific cause has been found. It most often implies a mechanism of anovulation, although not all bleeding that is outside the normal range (either in cycle length or duration) is anovulatory. The term is a diagnosis of exclusion, which is probably more confusing than enlightening.

Most anovulatory bleeding is a result of what has been termed *estrogen breakthrough*. In the absence of ovulation and the production of progesterone, the endometrium responds to estrogen stimulation with proliferation. This endometrial growth without periodic shedding results in eventual breakdown of the fragile endometrial tissue. Healing within the endometrium is irregular and dyssynchronous. Relatively low levels of estrogen stimulation will result in irregular and prolonged bleeding, whereas higher sustained levels result in episodes of amenorrhea followed by acute, heavy bleeding.

Pregnancy-related Bleeding Spontaneous abortion can be associated with excessive or prolonged bleeding. In the United States, more than 50% of pregnancies are unintended (42), and 10% of women are at risk for unintended pregnancy but use no method of contraception. About one-half of unintended pregnancies are a result of nonuse of contraception; however, the other one-half are contraceptive failures (43). Unintended pregnancies are most likely to occur among adolescents and women over 40 years of age (Chapter 10). A woman may be unaware that she has conceived and may seek care because of abnormal bleeding. If an ectopic pregnancy is ruled out, the management of spontaneous abortion may include either observation, if the bleeding is not excessive, or curettage or D & C, depending on the clinician's judgment and the patient's preference (44,45 and 46).

Exogenous Hormones Irregular bleeding that occurs while a woman is using contraceptive hormones should be considered in a different context than bleeding that occurs in the absence of exogenous hormone use. Breakthrough bleeding during the first 1 to 3 months of oral contraceptive use occurs in up to 30% to 40% of users and should almost always be managed expectantly with reassurance, because the frequency of breakthrough bleeding decreases with each subsequent month of use (25). Irregular bleeding can also result from inconsistent pill taking (47,48 and 49).

Not all bleeding that occurs while an individual is taking oral contraceptives is a consequence of hormonal factors. In one study, women who experienced irregular bleeding while taking oral contraceptives were found to have a higher frequency of chlamydia infection (33).

Irregular bleeding is almost invariably present during the first year of use of both the subdermal implant *levonorgestrel* and *DMPA* (29,30). Because irregular bleeding is so often present with these two methods of contraception, counseling prior to their use is imperative. Women who do not believe that they can cope with irregular, unpredictable bleeding may not be good candidates for these methods. As with oral contraceptives, the possibility of nonhormonal causes of bleeding (e.g., chlamydial cervicitis) should be considered. When an individual is using one of these methods, reassurance and counseling should be provided. The exact mechanism of irregular bleeding associated with progestin-only methods is not well established but may be related to incomplete suppression of follicular activity with periodic elevations of estradiol (24). The additional oral use of estrogen has been reported to improve bleeding with both *DMPA* and the subdermal *levonorgestrel* (29,50,51). Combination oral contraceptives have also been used in patients with the subdermal *levonorgestrel* implants. For a patient who is considering removal of the implants because of irregular bleeding and who may choose an oral contraceptive as an alternative, the use of combination pills can allow both the clinician and the patient to assess the patient's tolerance of and compliance with oral contraceptive therapy. The use of nonsteroidal antiinflammatory drugs (NSAIDs) has been shown to result in decreased bleeding (50).

Endocrine Causes Both hypothyroidism and hyperthyroidism can be associated with abnormal bleeding. With hypothyroidism, menstrual abnormalities including menorrhagia are common (Chapter 25). The most common cause of thyroid hyperfunctioning in premenopausal women is Graves' disease, which occurs 4 to 5 times more often in women than men. Hyperthyroidism can result in oligomenorrhea or amenorrhea, and it can also lead to elevated levels of plasma estrogen (52).

Diabetes mellitus can be associated with anovulation, obesity, insulin resistance, and androgen excess. Androgen disorders are very common among women of reproductive age and should be evaluated and managed. Because androgen disorders are associated with significant cardiovascular disease, the condition should be diagnosed promptly. This condition becomes more immediately of concern in older women of reproductive age. Management of bleeding disorders associated with androgen excess consists of an appropriate diagnostic evaluation followed by the use of oral contraceptives (in the absence of significant contraindications), coupled with dietary and exercise modification.

Anatomic Causes Anatomic causes of abnormal bleeding in women of reproductive age occur more frequently than in women in other age groups. Uterine leiomyomas occur in as many as one-half of all women older than 35 years of age and are the most common tumors of the genital tract (53). Although they are asymptomatic in many or even most women, they have been estimated to be clinically significant in at least 25% of the American female population of reproductive age. They are more common in African American women and have been associated with obesity (54,55). The mechanism of abnormal bleeding related to leiomyomas is not well established. Several theories have been postulated, including dysregulation of a number of growth factors that regulate angiogenesis in a uterus in which leiomyomas are present.

Growth factors that are currently being investigated for their role in the process of abnormal bleeding associated with leiomyomas include basic fibroblast growth factor, vascular endothelial growth factor, heparin-binding epidermal growth factor, platelet-derived growth factor, transforming growth factor- β , parathyroid hormone-related protein, and prolactin (56).

Diagnosis is based on the characteristic finding of an irregularly enlarged uterus. The size and location of the usually multiple leiomyomas can be confirmed and documented with pelvic ultrasonography (Fig. 13.6). If the examination is adequate and symptoms are absent, ultrasonography is not always necessary unless an ovarian mass cannot be excluded.

Figure 13-6 Transvaginal pelvic ultrasound demonstrating multiple uterine leiomyomas.

Endometrial polyps are a cause of intermenstrual bleeding, irregular bleeding, and menorrhagia. The diagnosis is based on either visualization with hysteroscopy or sonohysteroscopy, or on the microscopic assessment of tissue obtained by a biopsy done in the office or a curettage specimen.

Abnormal bleeding, either intermenstrual or postcoital, can be caused by cervical lesions. Bleeding can also result from endocervical polyps and infectious cervical lesions, such as condylomas, herpes simplex virus ulcerations, chlamydial cervicitis, or cervicitis caused by other organisms.

Other benign cervical lesions, such as wide eversion of endocervical columnar epithelium or Nabothian cysts, may be noted on examination but rarely cause symptoms.

Coagulopathies and Other Hematologic Causes The presence of excessively heavy menses should prompt an evaluation of hematologic status. A complete blood count will be helpful in detecting anemia, significant problems such as leukemia, or disorders associated with thrombocytopenia. Abnormal liver function, which can be seen with alcoholism or other chronic liver diseases, results in inadequate production of clotting factors and can lead to excessive menstrual bleeding. Coagulation abnormalities such as von Willebrand's disease can have a variable clinical picture and may escape diagnosis until the reproductive years (57,58). Oral contraceptives, which increase the level of factor VIII, can be helpful and newer therapies, including desmopressin acetate, may be necessary, particularly before surgical procedures are performed.

Infectious Causes Women with cervicitis, particularly chlamydial cervicitis, can experience irregular bleeding and postcoital spotting (see Chapter 15). Therefore, cervical testing for chlamydia should be considered, especially for sexually active adolescents, women in their twenties, and women who are not in a monogamous relationship. Endometritis can cause excessive menstrual flow. Thus, a woman who seeks treatment for menorrhagia and increased menstrual pain and has a history of light-to-moderate previous menstrual flow may have an upper genital tract infection or PID (endometritis, salpingitis, oophoritis). Occasionally, chronic endometritis will be diagnosed when an endometrial biopsy is obtained for evaluation of abnormal bleeding in a patient without specific risk factors for PID.

Neoplasia Abnormal bleeding is the most frequent symptom of women with invasive cervical cancer. An obvious cervical lesion should be evaluated by biopsy, because the results of a Papanicolaou (Pap) test may be falsely negative with invasive lesions as a result of tumor necrosis. Unopposed estrogen has been associated with a variety of abnormalities of the endometrium, from cystic hyperplasia to adenomatous hyperplasia, hyperplasia with cytologic atypia, and invasive carcinoma. **Endometrial hyperplasia, hyperplasia with atypia, and invasive endometrial cancer can be diagnosed by endometrial sampling or D & C. Such sampling is mandatory in the evaluation of abnormal bleeding in women older than 35 to 40 years of age, obese women, and those with a history of anovulation.** Although vaginal neoplasia is uncommon, the vagina should be evaluated carefully when there is abnormal bleeding. This includes attention to all surfaces of the vagina, including anterior and posterior areas that may be obscured by the vaginal speculum on examination.

Diagnosis

For all women, the evaluation of excessive and abnormal menses includes a thorough medical and gynecologic history, the exclusion of pregnancy, and a careful gynecologic examination. For women of normal weight between the ages of approximately 20 and 35 years who do not have clear risk factors for sexually transmitted diseases (STDs), who have no signs of androgen excess, who are not using exogenous hormones, and who have no other findings on examination, management may be based on a clinical diagnosis.

Laboratory Studies In any patients with excessive bleeding, an objective measurement of hematologic status should be performed with a complete blood count to detect anemia or thrombocytopenia. A pregnancy test should be performed to rule out pregnancy-related problems. In addition, because of the possibility of a primary coagulation problem, screening coagulation studies such as a prothrombin time and partial thromboplastin time should be considered; an assessment of bleeding time may help diagnose von Willebrand's disease, although if this diagnosis is strongly suspected further testing may be necessary (59).

Imaging Studies Women with abnormal bleeding who have a history consistent with chronic anovulation, who are obese, or who are older than 35 to 40 years of age require further evaluation. A pelvic ultrasonographic examination may be helpful in delineating anatomic abnormalities if the examination results are suboptimal or if an ovarian mass is suspected. A pelvic ultrasonographic examination is the best technique for evaluating the uterine contour, endometrial thickness, and ovarian structure. Ultrasonography is particularly valuable in determining whether a pelvic mass is cystic or solid. The use of a vaginal probe transducer allows assessment of endometrial and ovarian disorders, particularly in women who are obese.

Sonohystero-graphy involves the infusion of saline into the uterine cavity during transvaginal ultrasonography. This technique has been reported to be especially helpful in visualizing intrauterine problems such as polyps (60).

Transvaginal ultrasonography alone has also been reported to have value in differentiating benign polyps from malignant lesions. Although these techniques are helpful in visualizing intrauterine pathology, histologic evaluation is required to rule out malignancy (61). Other techniques, such as CT scanning and MRI, are not as helpful in the initial evaluation and should be reserved for specific indications, such as exploring the possibility of other intraabdominal disorders or adenopathy. Contrast-enhanced MRI shows promise for staging endometrial cancer (62).

Endometrial Sampling Endometrial sampling should be performed to evaluate abnormal bleeding in women who are at risk for endometrial polyps, hyperplasia, or carcinoma. The technique of D & C, which in the past was used extensively for the evaluation of abnormal bleeding, has been replaced largely by endometrial biopsy in the office. The classic study in which a D & C was performed before hysterectomy with the conclusion that less than one-half of the endometrium was sampled in more than one-half of the patients has led to questioning the use of D & C for endometrial diagnosis (63,64).

It has been argued that there is no longer a place for a "blind" D & C, because hysteroscopy can direct a biopsy to a specific area of the uterus (65). **In most cases, however, endometrial biopsy done in the office can be performed instead of a D & C.** Indications for a hysteroscopy with endometrial sampling include the following:

1. Cervical stenosis precluding adequate endometrial biopsy
2. Patient intolerance of endometrial biopsy
3. Anatomic factors (e.g., massive obesity) precluding adequate endometrial biopsy
4. The presence of abnormal bleeding in a patient who is undergoing another surgical procedure performed with general anesthesia.

A number of devices are designed for endometrial sampling (Fig. 13.7), including an inexpensive disposable flexible plastic sheath with an internal plunger that allows tissue aspiration, disposable plastic cannulae of varying diameters that attach to a manually locking syringe that allows the establishment of a vacuum, and cannulae (both rigid metal and plastic) with tissue traps that attach to an electric vacuum pump. Several studies comparing the adequacy of sampling using these devices with D & C have shown a comparable ability to detect abnormalities. It should be noted that these devices are designed to obtain a tissue sample rather than a cytologic washing. Devices designed to obtain an endometrial sample for assessment of cytology are also available; they have been shown to detect invasive cancer as well as D & C but to have a lower sensitivity for detecting premalignant lesions.

Figure 13-7 Devices used for sampling endometrium. From top to bottom: serrated Novak, Novak, Kevorkian, Explora (Mylex), and Pipelle (Unimar). (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 2000:408, with permission.)

Management

Nonsurgical Management Most bleeding problems, including anovulatory bleeding can be managed nonsurgically (66). Treatment with NSAIDs such as *ibuprofen* and *mefenamic acid* has been shown to decrease menstrual flow by 30% to 50% (67). Antifibrinolytics, currently not available for use in the United States, have been shown to be effective in reducing menstrual blood loss (68,69). *Levonorgestrel*-containing intrauterine devices also have been shown to reduce menstrual blood loss (70).

Hormonal management of abnormal bleeding frequently can control excessive or irregular bleeding. Although there is a paucity of randomized controlled trials demonstrating the effectiveness of oral contraceptives in reducing menstrual flow, oral contraceptives have long been used clinically to decrease menstrual flow (71,72). Although this effect was first demonstrated with oral contraceptive formulations that contained higher doses of both estrogens and progestins than the agents used today, low-dose combined oral contraceptives have been shown to have a similar effect (73). Low-dose oral contraceptives may be used during the perimenopausal years in healthy nonsmoking women who have no major cardiovascular risk factors. The benefits of menstrual regulation in such women often override the potential risks.

For patients in whom estrogen use is contraindicated, progestins, both oral and parenteral, can be used to control excessive bleeding. Cyclic oral *medroxyprogesterone acetate*, administered from days 5 to 26 of the cycle, results in a reduction of menstrual flow, although it is less effective than the progestin-containing intrauterine device (70). The benefits to the patient with oligomenorrhea and anovulation include a regular flow and the prevention of long intervals of amenorrhea, which may end in unpredictable, profuse bleeding. This therapy reduces the risk of hyperplasia resulting from persistent, unopposed estrogen stimulation of the endometrium. Depot formulations of *medroxyprogesterone acetate* also have been used to establish amenorrhea in women at risk of excessive bleeding.

In Europe, the intrauterine device containing norgestrel has long been used therapeutically to deliver progestin locally to the endometrium in women with abnormal bleeding who have been diagnosed with dysfunctional uterine bleeding (74). This device was approved for use in the United States in 2000, and its use has been suggested as a cost-effective alternative to hysterectomy for excessive bleeding (75).

Surgical Therapy The surgical management of abnormal bleeding should be reserved for situations in which medical therapy has been unsuccessful or is contraindicated. The D & C, although sometimes appropriate as a diagnostic technique, is questionable as a therapeutic modality. One study reported a measured reduction in menstrual blood loss for the first menstrual period only (76). Other studies have suggested a longer-lasting benefit (77).

The surgical options range from hysteroscopy with resection of submucous leiomyomas to laparoscopic techniques of myomectomy to uterine artery embolization to endometrial ablation (Chapter 21) to hysterectomy (Chapter 22). The choice of procedure depends on the cause of the bleeding. The assessment of the relative advances, risks, benefits, complications, and indications of these procedures is a subject of ongoing clinical research (78,79). The proposed advantages of techniques other than hysterectomy include a shorter recovery time and less early morbidity. However, symptoms can recur or persist; repeat procedures or subsequent hysterectomy may be required if conservative options are chosen. Quality of life outcomes should be assessed, and current studies do not indicate there is a definitive management advantage to any particular technique (80,81).

Much has been written about the psychologic sequelae of hysterectomy, and some of the aforementioned surgical techniques have been developed in an effort to provide less drastic management options. Most well-controlled recent studies have suggested that, in the absence of preexisting psychopathology, indicated but elective surgical procedures for hysterectomy have few, if any, significant psychologic sequelae (including depression) (82) (Chapter 12).

Postmenopausal Women

Differential Diagnosis

The causes of postmenopausal bleeding and the percentage of patients who seek treatment for different conditions are presented in [Table 13.7](#).

Factor	Approximate Percentage
Exogenous estrogens	30
Atrophic endometritis/vaginitis	30
Endometrial cancer	15
Endometrial or cervical polyps	10
Endometrial hyperplasia	5
Miscellaneous (e.g., cervical cancer, uterine sarcoma, urethral caruncle, trauma)	10

From Hacker NF, Moore JG. *Essentials of obstetrics and gynecology*, 3rd ed. Philadelphia: WB Saunders, 1998:635, with permission.

Table 13.7. Etiology of Postmenopausal Bleeding

Benign Disorders Women who are taking hormone replacement therapy during menopause may be using a variety of hormonal regimens that can result in bleeding (see [Chapter 29](#)). In the classic sequential method of administration, estrogens are given for the first 25 days of each month. A progestin, often 5 to 10 mg/day of *medroxyprogesterone acetate*, is added to the last 10 to 13 days of this regimen in an effort to reduce the risk of endometrial hyperplasia and neoplasia. Most women who take these hormones in this way will experience withdrawal bleeding, which is perceived by the patient as a menstrual period. Although the incidence of withdrawal bleeding does decline somewhat with age and duration of therapy, more than 50% of women continue to experience bleeding after 65 years of age.

Because some women become symptomatic during the days when they are not taking estrogens, as in the previously described regimen, many clinicians have modified this regimen to include continuous (every day) estrogen therapy. In addition, studies have assessed endometrial response to varying durations of progestin regimens; longer duration of therapy is associated with a lower risk of hyperplasia. It has been suggested that endometrial sampling is indicated for any bleeding that occurs beyond the expected time of withdrawal following cyclic progestin therapy. **A significant change in withdrawal bleeding (e.g., absence of withdrawal**

bleeding for several months followed by resumption of bleeding or a marked increase in the amount of bleeding) should prompt endometrial sampling.

Patient compliance has been a significant issue with hormone replacement therapy. Missed doses of medication and failure to take the medication in the prescribed fashion can lead to irregular bleeding or spotting that is benign in origin but that can result in patient dissatisfaction (83).

The primary problems that women report with hormone replacement therapy include vaginal bleeding and weight gain. The use of a continuous low-dose combined regimen has the advantage that, for many women, bleeding will ultimately cease after a period of several months during which irregular and unpredictable bleeding may occur (84). Some women are unable to tolerate these initial months of irregular bleeding. The risk of endometrial hyperplasia or neoplasia with this regimen appears to be low.

Other benign causes of bleeding include atrophic vaginitis and cervical polyps, which may become apparent as postcoital bleeding or spotting. Women who experience bleeding after menopause may attempt to minimize the extent of the problem; they may describe only "spotting" or "pink or brownish discharge." However, any indication of bleeding or spotting should be evaluated. In the absence of hormone therapy, any bleeding after menopause (classically defined as absence of menses for 1 year) should prompt evaluation with endometrial sampling. At least one-fourth of postmenopausal women with bleeding have a neoplastic lesion.

Endometrial polyps and other abnormalities can be seen in women who are taking tamoxifen. These polyps can be benign, although they must be distinguished from endometrial malignancies, which may also occur with this medication.

Neoplasia Endometrial, cervical, and ovarian malignancies must be ruled out in cases of postmenopausal bleeding. **A Pap test is essential when postmenopausal bleeding is noted, although the Pap test is an insensitive diagnostic test for detecting endometrial cancer.** The Pap test results are negative in some cases of invasive cervical carcinoma because of tumor necrosis.

Cervical malignancy is diagnosed by cervical biopsy of grossly visible lesions and colposcopically directed biopsy for women with abnormal Pap test results (Chapter 16). Functional ovarian tumors may produce estrogen and lead to endometrial hyperplasia or carcinoma, which may cause bleeding.

Diagnosis

Pelvic examination to detect local lesions and a Pap test to assess cytology are essential first steps in finding the cause of postmenopausal bleeding. Endometrial sampling, through office biopsy, hysteroscopy, or D & C, is usually considered essential. Pelvic ultrasonographic examination and, in particular, vaginal ultrasonography or sonohysterography can suggest the cause of bleeding. Initial biopsy done in the office is more cost effective than D & C, surgery, or observation alone (85). The cost effectiveness of other screening strategies, including transvaginal ultrasonography or sonohysterography, has not been well studied. It has been suggested that an endometrial thickness of less than 6 mm (4 to 5 mm in some reports) measured by transvaginal ultrasonography is unlikely to indicate endometrial cancer.

Management

The management of atrophic vaginitis includes topical or systemic use of estrogens after other causes of abnormal bleeding have been excluded. Cervical polyps can easily be removed in the office.

Endometrial Hyperplasia The terminology that has been used to describe endometrial hyperplasia is confusing, and the clinician must consult with the pathologist to ensure an understanding of the diagnosis. **The following lesions are considered to be benign: anovulatory, proliferative, cystic glandular hyperplasia, simple cystic hyperplasia (Fig. 13.8), simple hyperplasia, and adenomatous hyperplasia without atypia.** These terms reflect and describe an exaggerated proliferative response of the endometrium. In most cases, benign endometrial hyperplasia is resolved with D & C or progestin therapy. Repeat surveillance with endometrial biopsy may be warranted.

Figure 13-8 Simple cystic hyperplasia of the endometrium. The normal tabular pattern is replaced by cystically dilated proliferative endometrial glands. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Lippincott Williams & Wilkins, 1994:126, with permission.)

The presence of atypia with abnormal proliferation, including features of back-to-back crowding of the glands, with epithelial activity demonstrated by papillary projections into the glands, is associated with an increased risk of progression to endometrial carcinoma (Fig. 13.9). These architectural abnormalities may be associated with individual cellular atypia (enlarged, irregular nuclei, chromatin clumping, and prominent nucleoli). The presence of mitotic activity also can be variable.

Figure 13-9 Atypical hyperplasia (complex hyperplasia with severe nuclear atypia). The proliferative endometrial glands reveal considerable crowding and papillary infoldings. The endometrial stroma, although markedly diminished, can still be recognized between the glands. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Lippincott Williams & Wilkins, 1994:127, with permission.)

The management of endometrial hyperplasia rests on an understanding of the natural history of the lesion involved. In one study, only 2% of 122 patients with hyperplasia without cytologic atypia progressed to carcinoma, whereas 23% of those with atypical hyperplasia subsequently developed carcinoma (86). Architectural complexity and crowding appears to place patients at greater risk for progression than does the presence of cytologic atypia alone.

These data suggest that most women with endometrial hyperplasia will respond to progestin therapy and are not at increased risk of developing cancer. Patients who do not respond are at a significantly increased risk of progressing to invasive cancer and should be advised to have a hysterectomy. Patients who are unlikely to respond can be identified on the basis of cytologic atypia. A suggested scheme of management is outlined in [Fig. 13.10](#). This treatment is discussed in more detail in Chapter 30.

Figure 13-10 Management of endometrial hyperplasia. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 2000:422, with permission.)

Pelvic Mass

The probable causes of a pelvic mass found on physical examination or through radiologic studies are vastly different in a prepubertal child than they are during adolescence or during the postmenopausal years ([Table 13.3](#)). A pelvic mass may be gynecologic in origin or it may arise from the urinary tract or bowel. The gynecologic causes of a pelvic mass may be uterine, adnexal, or more specifically ovarian.

Prepubertal Age Group

Differential Diagnosis

Fewer than 5% of ovarian malignancies occur in children and adolescents. Ovarian tumors account for approximately 1% of all tumors in these age groups. Germ cell tumors make up one-half to two-thirds of ovarian neoplasms in individuals younger than 20 years of age. A review of studies conducted from 1940 until 1975 concluded that 35% of all ovarian neoplasms occurring during childhood and adolescence were malignant ([87](#)). In girls younger than 9 years of age, approximately 80% of the ovarian neoplasms were found to be malignant ([88,89](#)). Germ cell tumors account for approximately 60% of ovarian neoplasms in children and adolescents compared with 20% of these tumors in adults ([87](#)). Epithelial neoplasms are rare in the prepubertal age group; thus, data usually are reported from referral centers. However, some reports include only neoplastic masses, whereas others include nonneoplastic masses; some series combine data from prepubertal and adolescent girls. One community survey of ovarian masses revealed that the frequency of malignancy was much lower than previously reported; of all ovarian masses confirmed surgically in childhood and adolescence, only 6% of masses were malignant neoplasms, and only 10% of neoplasms were malignant ([90](#)). Surgical decision making clearly influences the statistics on incidence; the surgical excision of functional masses that would resolve in time inflates the percentage of benign masses. In one series, nonneoplastic masses in young women and girls younger than 20 years of age constituted two-thirds of the total ([91](#)). Even in girls younger than 10 years of age, 60% of the masses were nonneoplastic, and two-thirds of the neoplastic masses were benign. Functional, follicular cysts can occur in fetuses, newborns, and prepubertal children. They may be associated with sexual precocity.

Abdominal or pelvic pain is one of the most frequent initial symptoms. In a prepubertal child, a pelvic mass very quickly becomes abdominal in location as it enlarges because of the small size of the pelvic cavity. The diagnosis of ovarian masses in the prepubertal age group is difficult because of the rarity of the condition (and therefore a low index of suspicion), because many symptoms are nonspecific, and acute symptoms are more likely to be attributed to more common entities such as appendicitis. Abdominal palpation and bimanual rectoabdominal examination are important in any child who has nonspecific abdominal or pelvic complaints. An ovarian mass that is abdominal in location can be confused with other abdominal masses occurring in children, such as Wilms' tumor or neuroblastoma. Acute pain is often associated with torsion. The ovarian ligament becomes elongated as a result of the abdominal location of these tumors, thus creating a predisposition to torsion.

Diagnosis and Management

In recent years, ultrasonography has become an excellent tool for predicting the presence of a simple ovarian cyst. [Figure 13.11](#) outlines a plan of management for pelvic masses in the prepubertal age group. Unilocular cysts are virtually always benign and will regress in 3 to 6 months; thus, they do not require surgical management with oophorectomy or oophorocystectomy. Close observation is recommended, although there is a risk of ovarian torsion that must be discussed with the child's parents. Recurrence rates after cyst aspiration (either ultrasonographically guided or with laparoscopy) may be as high as 50%. Attention must be paid to long-term effects on endocrine functioning as well as future fertility; preservation of ovarian tissue is a priority for patients with benign tumors. Premature surgical therapy for a functional ovarian mass can result in ovarian and tubal adhesions that can affect future fertility.

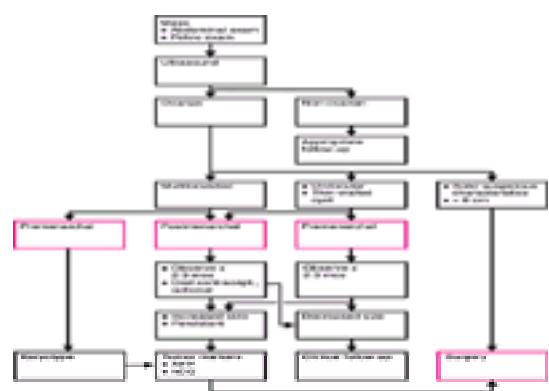

Figure 13-11 Management of pelvic masses in premenarchal and adolescent girls.

Additional imaging studies, such as CT scanning, MRI, or Doppler flow studies, may be helpful in establishing the diagnosis ([92](#)). Because the risk of a germ cell tumor is high, the finding of a solid component mandates surgical assessment ([93](#)).

Adolescent Age Group

Differential Diagnosis

Ovarian Masses

Many series report ovarian tumors occurring in both children and adolescents. Some reports divide their findings by age group, although this is less helpful than a division by pubertal development. The clinician's response to a pelvic or abdominal mass varies in relation to the patient's pubertal status, because the likelihood of

functional masses increases after menarche. **The risk of malignant neoplasms is lower among adolescents than among younger children. Epithelial neoplasms occur with increasing frequency with age. Germ cell tumors are the most common tumors of the first decade of life but occur less frequently during adolescence** (Chapter 32). **Mature cystic teratoma is the most frequent neoplastic tumor of children and adolescents, accounting for more than one-half of ovarian neoplasms in women younger than 20 years of age** (94).

It is well established that neoplasia can arise in dysgenetic gonads. Malignant tumors have been found in about 25% of dysgenetic gonads of patients with a Y chromosome (95). Gonadectomy is recommended for patients with XY gonadal dysgenesis or its mosaic variations (96).

Functional ovarian cysts occur frequently in adolescence. They may be an incidental finding on examination or may be associated with pain caused by torsion, leakage, or rupture. Endometriosis is less common during adolescence than in adulthood, although it can occur during adolescence. In series of adolescents referred with chronic pain, 50% to 65% have been found to have endometriosis (97). Although endometriosis can occur in young women with obstructive genital anomalies (presumably as a result of retrograde menstruation), most adolescents with endometriosis do not have associated obstructive anomalies (98). In young women, endometriosis may have an atypical appearance, with nonpigmented or vesicular lesions, peritoneal windows, and puckering.

Uterine Masses

Other causes of pelvic masses, such as uterine abnormalities, are rare in adolescence. Uterine leiomyomas are not commonly seen in this age group. Obstructive uterovaginal anomalies occur during adolescence, at the time of menarche, or shortly thereafter. The diagnosis is frequently neither suspected nor delayed, particularly when the patient is seen by a general surgeon (99). A wide range of anomalies can be seen, from imperforate hymen to transverse vaginal septa, to vaginal agenesis with a normal uterus and functional endometrium, vaginal duplications with obstructing longitudinal septa, and obstructed uterine horns. Patients may seek treatment for cyclic pain, amenorrhea, vaginal discharge, or an abdominal, pelvic, or vaginal mass (Fig. 13.5). A hematocolpos, hematometra, or both frequently will be present, and the resulting mass can be quite large.

Inflammatory Masses

Adolescents have the highest rates of PID of any age group, if one considers only individuals at risk for STD (i.e., those who have had sexual intercourse) (36). Thus, an adolescent who has pelvic pain may be found to have an inflammatory mass. The diagnosis of PID is primarily a clinical one based on the presence of lower abdominal, pelvic, and adnexal tenderness; cervical motion tenderness; a mucopurulent discharge; and the signs of elevated temperature, white blood cell count, or sedimentation rate (Chapter 15). PID is clearly associated with the risks of acquiring STD, and methods of contraception may either decrease the risk (oral contraceptives, male latex condoms) or increase it (the intrauterine device in the interval immediately after insertion) (100,101). Inflammatory masses may consist of a tuboovarian complex (a mass consisting of matted bowel, tube, and ovary), tuboovarian abscess (a mass consisting primarily of an abscess cavity within an anatomically defined structure such as the ovary), pyosalpinx or, chronically, hydrosalpinx.

Pregnancy

In adolescents, pregnancy should always be considered as a cause of a pelvic mass. In the United States, more than 50% of adolescent young women have experienced sexual intercourse by 17 years of age (23). Most pregnancies in adolescents are unintended; 82% of pregnancies in adolescents under age 15, 83% in women aged 15 to 17, and 75% of pregnancies in women aged 18 to 19 are unintended (42). Adolescents may be more likely than adults to deny the possibility of pregnancy because of wishful thinking, anxiety about discovery by parents or peers, or unfamiliarity with menstrual cycles and information about fertility. Ectopic pregnancies may cause pelvic pain and an adnexal mass. With the availability of quantitative measurements of b-human chorionic gonadotropin (hCG), more ectopic pregnancies are being discovered before rupture, allowing conservative management with laparoscopic surgery or medical therapy with *methotrexate* (Chapter 17). The risk of ectopic pregnancy varies by method of contraception; users of no contraception have the highest risk, whereas oral contraceptive users have the lowest risk (102). As in older patients, paraovarian cysts and nongynecologic masses can appear as a pelvic or abdominal mass in adolescents.

Diagnosis

A history and pelvic examination are critical in the diagnosis of a pelvic mass. Considerations in adolescents include the anxiety associated with a first pelvic examination, as well as issues of confidentiality related to questions of sexual activity. Techniques for history taking and the performance of the first examination are discussed in Chapter 1.

Laboratory studies should always include a pregnancy test (regardless of stated sexual activity), and a complete blood count may be helpful in diagnosing inflammatory masses. Tumor markers, including α -fetoprotein and hCG, may be elaborated by germ cell tumors and can be useful in preoperative diagnosis as well as follow-up (Chapter 32).

As in all age groups, the primary diagnostic technique for evaluating pelvic masses in adolescents is ultrasonography. Although transvaginal ultrasonographic examinations may provide more detail than transabdominal ultrasonography, particularly for inflammatory masses, a transvaginal examination may not be well tolerated by adolescents (103). For cases in which the ultrasonographic examination is inconclusive, CT or MRI may be helpful. An accurate preoperative assessment of anatomy is critical, particularly in cases of uterovaginal malformations. MRI can be useful for evaluating this group of rare anomalies (104,105). Some sort of imaging technique should be used in evaluating adolescents who come in with abdominal pain, because an unexpected finding of a complex uterine or vaginal anomaly requires careful surgical planning and decision making.

Management

The management of masses in adolescents depends on the suspected diagnosis as well as the initial complaint. **Figure 13.11** outlines a plan of management for pelvic masses in adolescents. **Asymptomatic unilocular cystic masses are best managed conservatively, because the likelihood of malignancy is low. If surgical management is required based on symptoms or uncertainty of diagnosis, attention should be paid to minimizing the risks of subsequent infertility resulting from pelvic adhesions. In addition, every effort should be made to conserve ovarian tissue. In the presence of a malignant unilateral ovarian mass, management may include unilateral oophorectomy rather than more radical surgery, even if the ovarian tumor has metastasized** (Chapter 32). **Analysis of frozen sections may not be reliable. In general, conservative surgery is appropriate; further surgery can be performed, if necessary, after an adequate histologic evaluation of the ovarian tumor.**

Some surgeons advocate the use of laparoscopy in the management of suspected acute PID to confirm the diagnosis, and to perform irrigation, lysis of adhesions, drainage and irrigation of unilateral or bilateral pyosalpinx or tuboovarian abscess, or extirpation of significant disease (106,107). While symptoms persist in a patient with the clinical diagnosis of PID or tuboovarian abscess, laparoscopy should be considered to confirm the diagnosis. A clinical diagnosis may be incorrect in up to one-third of patients (108). The surgical management of inflammatory masses is rarely necessary in adolescents, except to treat rupture of tuboovarian abscess or failure of medical management with broad-spectrum antibiotics (Chapter 15). Conservative, unilateral adnexectomy usually can be performed in these situations, rather than a pelvic clean-out, maintaining reproductive potential. Percutaneous drainage, transvaginal ultrasonographic drainage, and laparoscopic management of tuboovarian abscesses are becoming more popular, although, as with the laparoscopic management of ovarian masses, the surgeon's skill and experience are critical and prospective studies are lacking (109). Laparoscopic management has been associated with a risk of major complications, including bowel obstruction and bowel or vessel injury (110).

Reproductive Age Group

Conditions diagnosed as a pelvic mass in women of reproductive age are presented in [Table 13.8](#).

Full urinary bladder
Unruptured cyst
Sheddy anteflexed or retroflexed uterus
Pregnancy (with or without concomitant leiomyomas)
Intramural
Subserosal
Ovarian or adnexal masses
Functional cysts
Intraovarian masses
Subovarian masses
Ovarian abscess
Appendicitis abscess
Adnexal torsion and ovarian
Posterior wall
Bound to sigmoid
Neoplastic tumors
Sarcoma
Malignant
Parasitiasis or parasitic cysts
Metastatic carcinoma
Enterogenous conditions that must be excluded
Pelvic kidney
Carcinoma of the colon, rectum, appendix
Carcinoma of the fallopian tube
Heterotopical testis (anterior sacral meningocoele)
Uterine sarcoma or other malignant tumor

Table 13.8. Conditions Diagnosed as a Pelvic Mass in Women of Reproductive Age

Differential Diagnosis

It is difficult to determine the frequency of diagnoses of pelvic mass in women of reproductive age, because many pelvic masses are not ultimately treated with surgery. Nonovarian or nongynecologic conditions may be confused with an ovarian or uterine mass (Table 13.8). There are series in which the frequency of masses found at laparotomy is reviewed, although the varying indications for surgery, indications for referral, type of practice (gynecologic oncology versus general gynecology), and patient populations (a higher percentage of African Americans with uterine leiomyomas, for example) will affect the percentages. Benign masses, such as functional ovarian cysts, will often not require surgery.

Age is an important determinant of the likelihood of malignancy. In one series of women who underwent laparotomy for pelvic mass, malignancy was seen in only 10% of those younger than 30 years of age, and most of these tumors had low malignant potential (111). The most common tumors found during laparotomy for pelvic mass are mature cystic teratomas or dermoids (seen in one-third of women younger than 30 years of age) and endometriomas (approximately one-fourth of women 31 to 49 years of age) (111).

Uterine Masses

Uterine leiomyomas, also known as myomas or fibroids, are by far the most common benign uterine tumors. Other benign uterine growths, such as uterine vascular tumors, are rare. Uterine leiomyomas are usually diagnosed on physical examination. They may be subserosal, intramural, or submucosal in location within the uterus or located in the cervix, in the broad ligament, or on a pedicle (Fig. 13.12). They are estimated to be present in at least 20% of all women of reproductive age and may be discovered incidentally during routine annual examination. Leiomyomas are more common in African American than in white women. Asymptomatic fibroids may be present in 40% to 50% of women older than 35 years of age (55). They may occur singly but often are multiple. They may cause a range of symptoms, from abnormal bleeding to pelvic pressure, which may lead to the diagnosis. Fewer than one-half of uterine leiomyomas are estimated to produce symptoms, however (112).

Figure 13-12 Uterine leiomyomas in various anatomic locations. (From Hacker NF, Moore JG. *Essentials of obstetrics and gynecology*, 3rd ed. Philadelphia: WB Saunders, 1998:413, with permission.)

The cause of uterine leiomyomas is unknown. Several studies have suggested that each leiomyoma arises from a single neoplastic cell within the smooth muscle of the myometrium (113). There appears to be an increased familial incidence (55). Hormonal responsiveness and binding has been demonstrated *in vitro*. Fibroids have the potential to enlarge during pregnancy as well as to regress after menopause.

Grossly, fibroids are discrete nodular tumors that vary in size and number (Fig. 13.13). They may be microscopic or huge (a uterine weight of 74 lb has been reported). They may cause symmetric uterine enlargement or they may distort the uterine contour significantly. The consistency of an individual leiomyoma varies from hard and stony (as with a calcified leiomyoma) to soft (as with cystic degeneration), although the usual consistency is described as firm or rubbery. Although they do not have a true capsule, the margins of the tumor are blunt, noninfiltrating, and pushing, and are usually separated from the myometrium by a pseudocapsule of connective tissue, which allows easy enucleation at the time of surgery. There is usually one major blood vessel supplying each tumor. The cut surface is characteristically whorled.

Figure 13-13 Multiple uterine leiomyomas.

Degenerative changes are reported in approximately two-thirds of all specimens (114). Leiomyomas, with an increased number of mitotic figures, may occur in various forms: (a) during pregnancy or in women taking progestational agents, (b) with necrosis, and (c) as a **smooth muscle tumor of uncertain malignant potential (defined as having 5 to 9 mitoses per 10 high-power fields (hpf) that do not demonstrate nuclear atypia or giant cells, or with a lower mitotic count (2 to 4 mitoses/10 hpf) that does demonstrate atypical nuclear features or giant cells)**. Studies suggest that malignant degeneration of a preexisting leiomyoma is extremely uncommon, occurring in less than 0.5% (115).

Leiomyosarcoma is a rare malignant neoplasm composed of cells that have smooth muscle differentiation (Chapter 30). The typical patient with leiomyosarcoma is in her mid-50s and seeks treatment for abnormal bleeding. In most cases, diagnoses are determined (postoperatively) after microscopic examination of a uterus removed because of suspected leiomyomas. **Sarcomas that have a malignant behavior have ≥ 10 mitoses/hpf.**

Uterine fibroids are frequently diagnosed on the basis of clinical findings of an enlarged, irregular uterus on pelvic examination. They are also frequently noted on ultrasonography obtained for a variety of indications and may be an incidental finding. However, any pelvic tumor potentially can be confused with an enlarged uterus.

The most common initial symptom associated with fibroids, and the one that most frequently leads to surgical intervention, is menorrhagia. Chronic pelvic pain may also be present. Pain may be characterized as dysmenorrhea, dyspareunia, or pelvic pressure (Chapter 14). Acute pain may result from torsion of a pedunculated leiomyoma or infarction and degeneration. The following urinary symptoms may be present:

1. Frequency, which may result from extrinsic pressure on the bladder.
2. Partial ureteral obstruction may be caused by pressure from large tumors at the pelvic brim. Reports suggest some degree of ureteral obstruction in 30% to 70% of tumors above the pelvic brim. Ureteral compression is 3 to 4 times more common on the right, because the left ureter is protected by the sigmoid colon.
3. Rarely, complete urethral obstruction, resulting from elevation of the base of the bladder by the cervical or lower uterine leiomyoma with impingement on the region of the internal sphincter, may occur.

Leiomyomas are an infrequent primary cause of infertility and have been reported as a sole cause in only a small percentage of infertile patients (116). One review of myomectomies performed for all indications noted a history of infertility in 27% of women (112). Pregnancy loss or complications can occur in women with leiomyomas, although most patients have uncomplicated pregnancies and deliveries. One study calculated a 10% rate of pregnancy complications in women with fibroids (117). **Although growth of leiomyomas may occur with pregnancy, no demonstrable change in size (based on serial ultrasonographic examination) has been noted in 70% to 80% of patients (118,119).** The risk of pregnancy complications is influenced by both myoma location and size (120).

The following symptoms may infrequently be associated with leiomyomas:

1. Rectosigmoid compression, with constipation or intestinal obstruction
2. Prolapse of a pedunculated submucous tumor through the cervix, with associated symptoms of severe cramping and subsequent ulceration and infection (uterine inversion has also been reported)
3. Venous stasis of the lower extremities and possible thrombophlebitis secondary to pelvic compression
4. Polycythemia
5. Ascites.

Ovarian Masses

During the reproductive years, the most common ovarian masses are benign. About two-thirds of ovarian tumors are encountered during the reproductive years. Most ovarian tumors (80% to 85%) are benign, and two-thirds of these occur in women between 20 and 44 years of age. **The chance that a primary ovarian tumor is malignant in a patient younger than 45 years of age is less than 1 in 15.** Most tumors produce few or only mild, nonspecific symptoms. The most common symptoms include abdominal distension, abdominal pain or discomfort, lower abdominal pressure sensation, and urinary or gastrointestinal symptoms. If the tumor is hormonally active, symptoms of hormonal imbalance, such as vaginal bleeding related to estrogen production, may be present. Acute pain may occur with adnexal torsion, cyst rupture, or bleeding into a cyst. Pelvic findings in patients with benign and malignant tumors differ. Masses that are unilateral, cystic, mobile, and smooth are most likely to be benign, whereas those that are bilateral, solid, fixed, irregular, and associated with ascites, *cul-de-sac* nodules, and a rapid rate of growth are more likely to be malignant.

In terms of assessing ovarian masses, the distribution of primary ovarian neoplasms by decade of life can be helpful (121). Ovarian masses in women of reproductive age are most likely to be benign, but the possibility of malignancy must be considered (Fig. 13.14).

Figure 13-14 Preoperative evaluation of the patient with an adnexal mass. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 2000:465.)

Nonneoplastic Ovarian Masses Functional ovarian cysts include follicular cysts, corpus luteum cysts, and theca lutein cysts. All are benign and usually do not cause symptoms or require surgical management. The annual rate of hospitalization for functional ovarian cysts has been estimated to be as high as 500 per 100,000 woman-years in the United States, although little is known about the epidemiology of the condition (122). **The most common functional cyst is the follicular cyst, which is rarely larger than 8 cm.** A cystic follicle can be defined as a follicular cyst when its diameter is greater than 3 cm. These cysts are usually found incidental to pelvic examination, although they may rupture, causing pain and peritoneal signs (Fig. 13.15). They usually resolve in 4 to 8 weeks.

Figure 13-15 Follicular cysts of the ovary.

Corpus luteum cysts are less common than follicular cysts. Corpus luteum cysts may rupture, leading to a hemoperitoneum and requiring surgical management (Fig. 13.16). Patients taking anticoagulant therapy are at particular risk for rupture. Rupture of these cysts occurs more often on the right side and may occur during

intercourse. Most ruptures occur on cycle days 20 to 26 ([123](#)).

Figure 13-16 Corpus luteum cyst of the ovary. The left ovary is normal and the right ovary has a ruptured hemorrhagic corpus luteum cyst.

Theca lutein cysts are the least common of functional ovarian cysts. They are usually bilateral and occur with pregnancy, including molar pregnancies. They may be associated with multiple gestations, molar pregnancies, choriocarcinoma, diabetes, Rh sensitization, clomiphene citrate use, human menopausal gonadotropin–human chorionic gonadotropin ovulation induction, and the use of GnRH analogs. Theca lutein cysts may be quite large (up to 30 cm), are multicystic, and regress spontaneously ([124,125](#)).

Combination monophasic oral contraceptive therapy has been reported to markedly reduce the risk of functional ovarian cysts ([126](#)). It appears that, in comparison with previously available higher-dose pills, the effect of cyst suppression with current low-dose oral contraceptives is attenuated ([127,128](#)). Most studies have suggested that the use of triphasic oral contraceptives is not associated with an appreciable increased risk of functional ovarian cysts ([129](#)). It has been suggested that smokers have as much as a twofold increased risk of developing ovarian cysts, although other studies have not found smoking to be a risk factor ([130,131](#)).

Other Benign Masses Women with endometriosis may develop ovarian endometriomas (“chocolate” cysts), which can enlarge to 6 to 8 cm in size. A mass that does not resolve with observation may be an endometrioma (Chapter 26).

Although enlarged, polycystic ovaries were originally considered the *sine qua non* of PCOS, polycystic ovaries probably represent a final common phenotype of a wide variety of causes; they are not always present with other features of the syndrome. The prevalence of PCOS among the general population depends on the diagnostic criteria used. In one study, 257 volunteers were examined with ultrasonography; 22% were found to have polycystic ovaries ([132](#)). The finding of bilaterally enlarged ovaries on examination or polycystic ovaries on ultrasonographic examination should prompt evaluation for the full-blown syndrome which includes hyperandrogenism and chronic anovulation as well as polycystic ovaries. Therapy for PCOS is medical and generally not surgical.

Neoplastic Masses More than 80% of benign cystic teratomas (dermoid cysts) occur during the reproductive years, although dermoid cysts have a wider age distribution than other ovarian germ cell tumors ([133](#)). Histologically, benign cystic teratomas have an admixture of elements ([Fig. 13.17](#)). In one study of ovarian masses that were surgically excised, dermoid cysts represented 62% of all ovarian neoplasms in women younger than 40 years of age ([121](#)). Malignant transformation occurs in less than 2% of dermoid cysts in women of all ages; most cases occur in women older than 40 years of age. The risk of torsion with dermoid cysts is approximately 15%, and it occurs more frequently than with ovarian tumors in general, perhaps because the high-fat content of most dermoid cysts, allowing them to float within the abdominal and pelvic cavity ([Fig. 13.18](#)). As a result of this fat content, on pelvic examination, a dermoid cyst frequently is described as anterior in location. They are bilateral in approximately 10% of cases, although many have advanced the argument against bivalving a normal-appearing contralateral ovary because of the risk of adhesions, which may result in infertility. **An ovarian cystectomy is almost always possible, even if it appears that only a small amount of ovarian tissue remains.** Preserving a small amount of ovarian cortex in a young patient with a benign lesion is preferable to the loss of the entire ovary ([134](#)). Laparoscopic cystectomy is often possible, and intraoperative spill of tumor contents is rarely a cause of complications ([135,136](#)).

Figure 13-17 Histologic appearance of a mature cystic teratoma of the ovary.

Figure 13-18 Mature cystic teratoma (dermoid cyst) of the ovary associated with adnexal torsion.

The risk of epithelial tumors increases with age. Although serous cystadenomas are often considered the more common benign neoplasm, in one study, benign cystic teratomas represented 66% of benign tumors in women younger than 50 years of age; serous tumors accounted for only 20% ([121](#)). **Serous tumors are generally benign; 5% to 10% have borderline malignant potential and 20% to 25% are malignant.** Serous cystadenomas are often multilocular, sometimes with papillary components ([Fig. 13.19](#)). The surface epithelial cells secrete serous fluid, resulting in a watery cyst content. Psammoma bodies, which are areas of fine calcific granulation, may be scattered within the tumor and are visible on radiograph. A frozen section is necessary to distinguish between benign ([Fig. 13.20](#)), borderline, and malignant serous tumors, because gross examination alone cannot make this distinction. Mucinous ovarian tumors may grow to large dimensions ([Fig. 13.21](#)). Benign mucinous tumors typically have a lobulated, smooth surface, are multilocular, and may be bilateral in up to 10% of cases. Mucoid material is present within the cystic loculations ([Fig. 13.22](#)). **Five to ten percent of mucinous ovarian tumors are malignant.** They may be difficult to distinguish histologically from metastatic gastrointestinal malignancies. Other benign ovarian tumors include fibromas ([Fig. 13.23](#)) (a focus of stromal cells), Brenner tumors ([Fig. 13.24](#)) (which appear grossly

similar to fibromas and which are frequently found incidentally), and mixed forms of tumors such as the cystadenofibroma.

Figure 13-19 Gross appearance of a multilocular serous cystadenoma of the ovary. (From Scully RE. Atlas of tumor pathology. Tumors of the ovary, maldeveloped gonads, fallopian tube, and broad ligament. Washington, DC: Armed Forces Institute of Pathology; 1998:54; Fascicle 23, with permission.)

Other Adnexal Masses

Masses that include the fallopian tube are related primarily to inflammatory causes in this age group. A tuboovarian abscess can be present in association with PID ([Chapter 15](#)). In addition, a complex inflammatory mass consisting of bowel, tube, and ovary may be present without a large abscess cavity. Ectopic pregnancies can occur in the reproductive age group and must be excluded when a patient presents with pain, a positive pregnancy test, and an adnexal mass ([Chapter 17](#)). Paraovarian cysts may be noted either on examination or on imaging studies. In many instances, a normal ipsilateral ovary can be visualized using ultrasonography. The frequency of malignancy in paraovarian tumors is quite low, although one review reported malignancy in 2% of patients ([137](#)).

Diagnosis

A complete pelvic examination, including rectovaginal examination and Pap test, should be performed. Estimations of the size of a mass should be presented in centimeters rather than in comparison to common objects or fruit (e.g., orange, grapefruit, tennis ball, golf ball). After pregnancy has been excluded, one simple office technique that can help determine whether a mass is uterine or adnexal includes sounding and measuring the depth of the uterine cavity.

Other Studies Endometrial sampling with an endometrial biopsy or D & C is mandatory when both a pelvic mass and abnormal bleeding are present. An endometrial lesion—carcinoma or hyperplasia—may coexist with a benign mass such as a leiomyoma. In a woman with leiomyomas, abnormal bleeding cannot be assumed to be caused solely by the fibroids. Clinicians differ in recommendations about the need for endometrial biopsy when the diagnosis is leiomyomas with regular menses.

Studies of the urinary tract may be necessary if urinary symptoms are prominent, including cystometric measurements if incontinence or pressure is a prominent symptom. Cystoscopy may sometimes be necessary or appropriate to rule out intrinsic bladder lesions. Ultrasonography or an intravenous pyelogram may be appropriate to demonstrate ureteral deviation, compression, or dilation in the presence of moderately large and laterally located fibroids or other pelvic mass. Such findings rarely provide an indication for surgical intervention for otherwise asymptomatic leiomyomas.

Laboratory Studies Laboratory studies that are indicated for women of reproductive age with a pelvic mass include pregnancy test, cervical cytology, complete blood count, erythrocyte sedimentation rate, and testing of stool for occult blood. The value of tumor markers, such as CA125 in a premenopausal woman with a pelvic mass, has been widely debated. **A number of benign conditions, including uterine leiomyomas, PID, pregnancy, and endometriosis can cause elevated CA125 levels, and thus may lead to unnecessary surgical intervention.**

Imaging Studies Other studies may be necessary or appropriate. The most commonly indicated study is pelvic ultrasonography, which will help document the origin of the mass to determine whether it is uterine, adnexal, bowel, or gastrointestinal. The ultrasonographic examination also provides information about the size of the mass and its consistency—unilocular cyst, mixed echogenicity ([Fig. 13.25](#)), multiloculated cyst, solid cyst ([Fig. 13.26](#))—which can help determine management.

Figure 13-25 Transvaginal ultrasonogram of a unilocular ovarian cyst. This is characteristic of a benign process or corpus luteum cyst.

Figure 13-26 Transvaginal ultrasonogram of a complex, predominantly solid mass.

The value of transvaginal and transabdominal ultrasonography in the diagnosis of pelvic masses has been compared. Transvaginal scanning has the advantage of providing additional information about the internal architecture or anatomy of the mass. Heterogeneous pelvic masses, described as tuboovarian abscesses on transabdominal ultrasonography, can be separated on transvaginal scans into pyosalpinx, hydrosalpinx, tuboovarian complex, and tuboovarian abscess ([103](#)) ([Fig. 13.27](#)).

Figure 13-27 Transvaginal ultrasonogram of bilateral tuboovarian abscesses.

The diagnostic accuracy of transvaginal ultrasonography in diagnosing endometrioma can be quite high ([Fig. 13.28](#)). Endometriomas can have a variety of ultrasonographic appearances, from purely cystic to varying degrees of complexity with septation or debris, to a solid appearance. A scoring system that can help predict benign versus malignant adnexal masses is presented in [Table 13.9](#). Other ultrasonographic indices have been developed in an attempt to predict the risk of malignancy in ovarian masses ([138,139](#)). The indices have included not only characterizations of morphology such as septations, solid components, and ovarian size, but also demographic factors (i.e., age) as well as color flow imaging and Doppler waveform analysis ([140,141](#)). Although an analysis of such features may be helpful, histologic confirmation of surgically removed persistent masses remains the standard of care ([142](#)).

Table 13.9. Ultrasonographic Scoring System for Adnexal Masses^a

CT is seldom indicated as a primary diagnostic procedure, although it may be helpful in planning treatment when a malignancy is strongly suspected or when a nongynecologic disorder may be present. An abdominal flat plate radiograph is not a primary diagnostic procedure, although taken for other indications it may reveal calcifications that can assist in the discovery or diagnosis of a mass. Pelvic calcifications (teeth) consistent with a benign cystic teratoma ([Fig. 13.29](#)), a calcified uterine fibroid, or scattered calcifications consistent with psammoma bodies of a papillary serous cystadenoma can be seen on abdominal radiograph.

Figure 13-29 Benign cystic teratoma (dermoid cyst) of the ovary with teeth seen on abdominal radiograph.

Hysteroscopy provides direct evidence of intrauterine pathology or submucous leiomyomas that distort the uterine cavity (see [Chapter 21](#)). Hysterosalpingography will demonstrate indirectly the contour of the endometrial cavity and any distortion or obstruction of the uterotubal junction secondary to leiomyomas, an extrinsic mass, or peritubal adhesions. The techniques combining hysterosalpingography, in which fluid is instilled into the uterine cavity, with transvaginal ultrasonography have been helpful in the diagnosis of intrauterine pathology.

MRI may be most useful in the diagnosis of uterine anomalies, although its value rarely justifies the increased cost of the procedure over ultrasonography for the diagnosis of other pelvic masses ([143,144](#) and [145](#)).

Management

The management of a pelvic mass is based on an accurate diagnosis. An explanation of this diagnosis should be conveyed to the patient, along with a discussion of the likely course of the disease (e.g., growth of uterine leiomyomas, regression of fibroids at menopause, regression of a follicular cyst, the uncertain malignant potential of an ovarian mass). All options for management should be presented and discussed, although it is appropriate for the physician to state a recommended

approach with an explanation of the reasons for the recommendation. Management should be based on the primary symptoms and may include observation with close follow-up, temporizing surgical therapies, medical management, or definitive surgical procedures.

Management of Leiomyomas

Nonsurgical Management Judicious patient observation and follow-up are indicated primarily for uterine leiomyomas; intervention is reserved for specific indications and symptoms (146). Periodic examinations are indicated to ensure that the tumors are not growing rapidly. Uterine size should be recorded on the patient's chart, and the location of palpable and ultrasonographically localized leiomyomas should be described and diagrammed.

The use of GnRH agonists results in a 40% to 60% decrease in uterine volume and can be of value in some clinical situations. Treatment results in hypoestrogenism, which has been associated with reversible bone loss and symptoms such as hot flashes. Thus, treatment has been limited to short-term use, although low-dose hormonal replacement may be effective in minimizing the hypoestrogenic effects. Regrowth of leiomyomas is experienced within a few months after stopping therapy in about one-half of women treated. Some indications for the use of GnRH agonists in women with leiomyomas are as follows:

1. Preservation of fertility in women with large leiomyomas before attempting conception, or preoperative treatment before myomectomy
2. Treatment of anemia to allow recovery of normal hemoglobin levels before surgical management, minimizing the need for transfusion or allowing autologous blood donation
3. Treatment of women approaching menopause in an effort to avoid surgery
4. Preoperative treatment of large leiomyomas to make vaginal hysterectomy, hysteroscopic resection or ablation, or laparoscopic destruction more feasible
5. Treatment of women with medical contraindications to surgery
6. Treatment of women with personal or medical indications for delaying surgery.

Newer therapies combining GnRH agonists with estrogen add-back therapy have been promising in reducing side effects of agonist therapy alone, although this is a costly alternative (147). *Tibolone*, a synthetic steroid with estrogenic, progestational, and androgenic activity, has been widely used outside the United States for treatment of menopausal symptoms; its use with GnRH agonists as add-back therapy holds promise for longer-term therapy of leiomyoma (148). The use of GnRH antagonists holds promise, because it appears to be less likely than agonist therapy to result in bleeding early in therapy; it also causes rapid uterine shrinkage (149,150).

RU486, a progesterone antagonist, also has been shown to decrease the size of uterine leiomyoma (151). As the role of growth factors in leiomyoma-associated bleeding is better elucidated, treatment targeted at the growth factor or its receptor may prove useful. In addition, as the molecular biology and genetics of leiomyoma are better understood, newer nonsurgical therapies may be developed.

Surgical Therapy Determining potential indications for surgical treatment requires careful judgment and assessment of the degree of associated symptoms. **Asymptomatic leiomyomas do not usually require surgery.** Some indications for surgery include the following:

1. Abnormal uterine bleeding with resultant anemia, unresponsive to hormonal management
2. Chronic pain with severe dysmenorrhea, dyspareunia, or lower abdominal pressure or pain
3. Acute pain, as in torsion of a pedunculated leiomyoma, or prolapsing submucosal fibroid
4. Urinary symptoms or signs such as hydronephrosis after complete evaluation
5. Infertility, with leiomyomas as the only abnormal finding
6. Markedly enlarged uterine size with compression symptoms or discomfort.

Rapid enlargement of the uterus during the premenopausal years or any increase in uterine size in a postmenopausal woman have been suggested as indications for surgery because of the inability to exclude uterine sarcoma.

Although the absolute risk of uterine sarcomas developing in a fibroid uterus has been reported to be less than 2 to 3 per 1,000, one study found sarcomas to be no more common in women with rapid uterine growth than those without such growth (152). However, rapid enlargement has not been well defined, and serial measurements may be hampered by variations in the interpretation of size by the examiner or series of examiners.

Hysterectomy has long been viewed as the definitive management of symptomatic uterine leiomyomas (Chapter 22). Myomectomy is an alternative to hysterectomy for patients who desire childbearing, who are young, or who prefer that the uterus be retained. Recent studies suggest that the morbidity of abdominal myomectomy and hysterectomy are similar, although previous reports had suggested higher risks for myomectomy, including the risks of hemorrhage and transfusion requirements (153,154). Blood loss and risk of transfusion are greater for women with larger uteri (155). Laparoscopic myomectomy minimizes the size of the abdominal incision, although several small incisions are required. The biggest concerns with laparoscopic myomectomy include the removal of large myomas through small incisions and the repair of the uterus (146). Instruments that efficiently morcellate the myomas have been developed, although skilled surgical techniques are required. There is controversy as to whether laparoscopic suturing provides strength and healing equivalent to that achieved with laparotomy. Risks include the need to convert to a laparotomy and the risk of uterine rupture with subsequent pregnancy (146). Vaginal myomectomy is indicated in the case of a prolapsed pedunculated submucous fibroid. Hysteroscopic resection of small submucous leiomyomas is a technique that may offer benefits for a selected group of patients (Chapter 21). **The recurrence risk for leiomyomas has been reported to be as high as 50% after myomectomy, with up to one-third requiring repeat surgery (112,156).** Endometrial ablation can decrease bleeding for women with primary intramural fibroids and can be performed using a variety of techniques, including laser ablation, thermal ablation, resection, or chemical destruction (146).

The preoperative use of GnRH agonists for both hysterectomy and myomectomy result in a decrease in uterine size. The expense, side effects, and time required to achieve a significant decrease in size are limitations to their use. The use of GnRH agonists may make surgical plans less distinct and thus myomectomy technically more difficult.

Nonextirpative approaches to the management of leiomyomas include myolysis and uterine artery embolization, although long-term safety and efficacy have not yet been demonstrated. Uterine artery embolization has been reported to have serious consequences, including infection, massive bleeding, and necrosis requiring emergency surgery (157). Pain is frequently a consequence. The procedure has been characterized as investigational (146). Myolysis involves the use of lasers to coagulate or needle electrodes to deliver an electrical current to individual leiomyomas (158).

Ovarian Masses

The now-routine application of ultrasound technology to gynecologic examinations has led to the more frequent detection of ovarian cysts. Ultrasonography is a relatively easy diagnostic study to perform, but this ease has led to the labeling of physiologic ovarian morphology, cystic follicles, as pathologic and the referral of patients for therapies, including surgery, without indications. **Treatment of ovarian masses that are suspected to be functional tumors is expectant.** A classic study popularized the use of oral contraceptives as suppressive therapy, although the results of this study have been misinterpreted (159). In this study, 286 patients (aged 16 to 48 years) with adnexal masses were treated with combination oral contraceptives. Eighty-one women had a persistent mass after this therapy; surgery was performed on these women, none of whom was found to have a physiologic cyst. This study has been interpreted to indicate that suspected functional cysts should be treated with oral contraceptives, although there are no data to indicate a more rapid resolution with oral contraceptives than with time alone. If a woman needs contraception and wishes to use oral contraceptives for birth control or for noncontraceptive indications, it is perfectly acceptable to prescribe them in this setting. However, **a number of randomized prospective studies have shown no acceleration of the resolution of functional ovarian cysts (which were associated with the use of clomiphene citrate or human menopausal gonadotropins) with oral contraceptives compared with observation alone (160,161 and 162).** **However, oral contraceptives are effective in reducing the risk of subsequent ovarian cysts.**

Symptomatic cysts should be evaluated promptly, although mildly symptomatic masses suspected to be functional should be managed with analgesics rather than surgery to avoid the development of adhesions that may impair subsequent fertility. Surgical intervention is warranted in the presence of severe pain or the suspicion of malignancy or torsion. **On ultrasonography, large cysts and those that have multiloculations, septa, papillae, and increased blood flow should be suspected of neoplasia. If a malignant cyst is suspected at any age, exploratory laparotomy should be performed promptly.**

Ovarian or adnexal torsion is suspected on the basis of peritoneal signs and the acuity of onset. Doppler flow studies suggesting abnormal flow are highly predictive

of torsion (163). The absence of internal ovarian flow is not specific to torsion, and may be seen with cystic lesions, although in these situations peripheral flow is typically visualized (164). Visualization of a twisted vascular pedicle has also been shown to be highly predictive (165). Normal flow does not exclude torsion, and in one study 60% of surgically confirmed cases of torsion had normal Doppler flow (163). **The management of suspected ovarian torsion, which can occur at any age, from prepubertal to postmenopausal, is surgical.** Previous studies have suggested that ovarian torsion requires oophorectomy on the basis that the untwisting (detorsion) of the ovarian pedicle would lead to emboli. Recent studies have suggested that the primary management should be detorsion with ovarian cystectomy, if a cyst is present; normal ovarian function frequently results even in ovaries that do not initially appear to be viable (166,167 and 168). This management is particularly important in prepubertal and young women (169). Oophoropexy may be helpful in preventing recurrent torsion (169,170).

Ultrasonographic or CT-directed aspiration procedures should not be used in women in whom there is a suspicion of malignancy. In the past, laparoscopic surgery for ovarian masses has been reserved for diagnostic or therapeutic purposes in patients at very low risk for malignancy. One survey of gynecologic oncologists' experiences with patients who had originally undergone laparoscopic management of malignant or borderline tumors suggested that so-called *benign* characteristics do not preclude malignancy and that laparoscopic management can be associated with partial or incomplete excision, delays in definitive surgery, or seeding and spread of disease (171,172 and 173). Even with frozen section, there is a possibility of a missed diagnosis of malignancy, which would necessitate reexploration. Whether this practice results in long-term compromise of outcome is unclear; thus, the laparoscopic management of complex masses that may be malignant remains controversial (171,174). More recently, the laparoscopic management of masses without selection for benign characteristics has been advocated provided the surgeon has expertise in operative laparoscopy, the capability for immediate and accurate pathologic examination is available, and appropriate further treatment can be instituted if indicated (including laparotomy for malignancy) (175).

The management of presumptive benign ovarian masses with operative laparoscopy has become increasingly common. The choice of surgical approach (laparotomy or laparoscopy) should be based on the surgical indications, the patient's condition, the surgeon's expertise and training, informed patient preference, and the most recent data supporting the chosen approach (176). The clear advantage of this technique is the shorter hospital stay, shorter recovery time, and lessened postoperative pain. Few controlled trials have been performed to compare the laparoscopic approach with laparotomy (128) (Chapter 21). Surgical complications include bowel injury, ureteral or other urinary tract injury, cannula site vessel injury, or incisional hernia (177). In one series the overall complication rate was 13.3% (177). Randomized clinical trials evaluating laparoscopy versus laparotomy in the treatment of ovarian masses have been performed and typically demonstrate a shorter hospitalization time with less postoperative pain and a shorter recovery period (135,178,179).

The role of laparoscopy has been even more controversial in the removal of dermoid cysts than with other benign masses. Concern centers around prevention of spill of the cyst contents. Randomized clinical trials have been reported with variable findings regarding spill; some studies suggest that cyst contents are more likely to spill with laparoscopy, whereas others do not find a difference or note no increase in morbidity when spillage occurred (180,181 and 182). Culdotomy and the use of an endoscopic specimen bag have been associated with lower rates of tumor spillage (182,183).

Postmenopausal Age Group

Differential Diagnosis

Ovarian Masses

During the postmenopausal years, the ovaries become smaller (129):

1. **Before menopause, the dimensions are approximately 3.5 × 2 × 1.5 cm.**
2. **In early menopause, the ovaries are approximately 2 × 1.5 × 0.5 cm.**
3. **In late menopause, they are even smaller: 1.5 × 0.75 × 0.5 cm.**

Barber has described the postmenopausal palpable ovary (PMPO) syndrome, suggesting that any ovary that is palpable on examination beyond the menopause is abnormal and deserves evaluation (184); however, this has not been shown to be a reliable predictor of malignancy (Chapter 32). Clearly, body habitus makes a difference in the ease of examination, but a postmenopausal ovary that, on palpation, is comparable in size to a premenopausal ovary is abnormally large. Ovarian cancer is predominantly a disease of postmenopausal women; the incidence increases with age, and the average patient age is about 56 to 60 years (Chapter 32).

With increased use of pelvic ultrasonographic evaluation, a new problem has arisen in postmenopausal women: the discovery of a small ovarian cyst. This is particularly troublesome in a woman who is entirely asymptomatic and whose ultrasonographic examination was performed for indications unrelated to pelvic pathology. It has been suggested that **when the cyst is asymptomatic, small (<5 cm in diameter), unilocular, and thin-walled, with a normal CA125 level, the risk of malignancy is extremely low and these masses can be followed conservatively, without surgery** (185,186,187,188 and 189). Surgery may be indicated in some women with a strong family history of ovarian, breast, endometrial, or colon cancer, or a mass that appears to be enlarging (see Chapter 32). The addition of color flow Doppler examination may be helpful in distinguishing benign from malignant masses (190,191).

Uterine and Other Masses

In women who have been receiving regular gynecologic care, the discovery of a new pelvic mass after menopause is worrisome because the likelihood of malignant neoplasm is high if it is an ovarian tumor. Many postmenopausal women have not had regular gynecologic care, however, so the discovery of a mass may reflect the persistence of uterine fibroids that had not previously been discovered. Some women may not remember having been told they had a pelvic mass. Thus, a review of medical records may be helpful in determining the preexistence of a benign pelvic mass. Other benign masses can occur in this age group, including paraovarian cysts and unusual tumors, such as benign retroperitoneal cysts of müllerian type (192).

Diagnosis

A personal and family medical history is helpful in detecting individuals at increased risk for the development of ovarian cancer. Several hereditary family cancer syndromes involve ovarian neoplasms (see Chapter 32). However, patients with hereditary forms of epithelial ovarian cancer account for only a small percentage of all cases; 90% to 95% of cases of ovarian cancer are sporadic and without identifiable heritable risk (193).

In one multicenter prospective study, the individual accuracy of pelvic examination, ultrasonography, and serum CA125 assessments in discriminating between benign and malignant pelvic masses was approximately the same (approximately 75%) (194). When the results of all three examinations were negative, no malignancy was found.

Management

The use of improved imaging techniques may allow the nonoperative management of ovarian masses that are probably benign (Table 13.9). When surgery is believed to be indicated, based on characteristics of the mass, a family or personal medical history, or the patient's desire for definitive diagnosis, selection of the appropriate surgical procedure is critical for effective therapy. The standard of care continues to be laparotomy, with appropriate staging procedures performed as necessary (Chapter 32), although laparoscopy has shown promise as a technique that offers the potential for lower morbidity. Ovarian cystectomy or oophorectomy may be indicated.

Vulvar Conditions

Vulvar and vaginal symptoms are a common initial complaint to gynecologists. The presence of vulvar symptoms may prompt a patient to seek care; however, this anatomic site is not one that is easily inspected by the patient. Thus, vulvar lesions may be noted on examination and may not have been noticed by the patient. Vulvar self-examination should be encouraged and could potentially result in the earlier diagnosis of vulvar lesions such as melanoma (195).

Neonatal

In the neonatal age group, various developmental and congenital abnormalities may be noted. Whereas an extensive discussion of these abnormalities is beyond the scope of this text, obstetricians will recognize that they must be prepared to deal with the parents and family when an infant is born with ambiguous genitalia. The etiology of these problems, as well as intersex disorders that may be discovered in an older child, can be complex. Chromosomal abnormalities, enzyme deficiencies (including 17- or 21-hydroxylase deficiency as causes of congenital adrenal hyperplasia), or prenatal masculinization of a female fetus resulting from maternal androgen-secreting ovarian tumors or, rarely, drug exposures can all result in genital abnormalities that are noted at birth. These abnormalities are addressed in Chapter 23.

Ambiguous genitalia represents a social and potential medical emergency that is best handled by a team of specialists, which may include urologists, neonatologists, endocrinologists, and pediatric gynecologists. The first questions parents ask after a baby is born include "Is it a boy or a girl?" In the case of ambiguous genitalia, the parents should be informed that the baby's genitals are not fully developed and, therefore, a simple examination of the external genitalia cannot determine the actual sex. The parents should be told that data will be collected but that it may take several days or longer to determine the baby's intended sex. In some situations, it may be best to state simply that the baby has some serious medical complications. The issues of gender assignment and timing of surgical therapy are controversial and should be managed by clinicians with extensive experience in the field ([196,197](#)).

Other genital abnormalities may be noted at birth, although few obstetricians or pediatricians carefully examine the external genitalia of female neonates. It has been argued that careful inspection of the external genitalia of all female infants should be performed, with gentle probing of the introitus and anus to determine the patency of the hymen or a possible imperforate anus. If patency is in doubt, a rectal thermometer may be used to gently test the patency. It has been suggested that this examination should be performed on all female infants in the delivery room ([198](#)). Various types of hymenal configurations in the newborn have been described, ranging from imperforate to microperforate, to cribriform, to hymenal bands, and hymens with central anterior, posterior, or eccentric orifices ([199](#)). An examination during the neonatal period would prevent the discovery of an imperforate hymen or vaginal septum only after a young woman experiences periodic pelvic and abdominal pain with the development of a large hematometra or hematocolpos.

Congenital vulvar tumors may include strawberry hemangiomas, which are relatively superficial vascular lesions, and large cavernous hemangiomas. Treatment is controversial; many lesions will spontaneously regress. Some clinicians have advocated cryotherapy, argon laser therapy, or sclerosing solutions ([200](#)).

Childhood

It may be difficult for a young child to describe vulvar sensations. Parents may notice the child crying during urination, scratching herself repeatedly, or complaining of vague symptoms. Often, the child's pediatrician will have evaluated the child for urinary tract infection. Evaluation for pinworms is also warranted, because pinworms can cause severe itching in the vulvar as well as perianal area. Vulvovaginitis is the most common gynecologic problem of childhood. Prepubertally, the vulva, vestibule, and vagina are anatomically and histologically vulnerable to infection with the bacteria typically present in the perianal area. The physical proximity of the vagina and vestibule to the anus can result in overgrowth of bacteria that can cause primary vulvitis and secondary vaginitis (see [Chapter 15](#)). Yeast infections are uncommon in prepubertal children who are toilet trained.

The clinician should be familiar with normal prepubertal genital anatomy and hymenal configuration ([201,202](#)). The unestrogenized vulvar vestibule is mildly erythematous and can be confused with infection. In addition, smegma around and beneath the prepuce may resemble patches of candida vulvitis. In prepubertal girls, the vulvar area is quite susceptible to chemical irritants.

Chronic skin conditions such as lichen sclerosus, psoriasis, seborrheic dermatitis, and atopic vulvitis may occur in children ([203](#)). Lichen sclerosus, the cause of which is not well established, has a characteristic "cigarette paper" appearance in a keyhole distribution (around the vulva and anus) ([Fig. 13.30](#)). Lichen sclerosus should be treated in pediatric patients as it is in adults; there is some suggestion that the condition may regress as the child progresses through adrenarche and menarche. The use of ultrapotent steroids topically has been successful in children as well as adults ([204](#)).

Figure 13-30 A: Lichen sclerosus in a 7-year-old girl. (From Novak ER, Woodruff JB, eds. *Novak's gynecologic and obstetric pathology*, 7th ed. Philadelphia: WB Saunders, 1974:21, with permission.) B: Histologic appearance of lichen sclerosus.

Labial agglutination may occur as a result of chronic vulvar inflammation from any cause ([Fig. 13.31](#)). The treatment of labial agglutination consists of a brief course (2 to 4 weeks) of externally applied estrogen cream. The area of agglutination (adhesion) will become thin as a result, and separation can often be performed in the office with the use of a topical anesthetic (e.g., lidocaine jelly) ([Fig. 13.32](#)). Urethral prolapse may cause acute pain or bleeding, or the presence of a mass may be noted.

Figure 13-31 Posterior labial agglutination in a 9-year-old girl.

Figure 13-32 Cotton-tipped applicator placed inside the labial agglutination shown in [Figure 13.31](#).

Vulvovaginal complaints of any sort in a young child should prompt the consideration of possible sexual abuse. Sexually transmitted infections may occur in prepubertal children (205). Sensitive but direct questioning of the parent or caretaker and the child should be a part of the evaluation; if sexual abuse is suspected, reporting to the appropriate social services agency is required.

Adolescence

Adolescents with gonadal dysgenesis or androgen insensitivity may have abnormal pubertal development and primary amenorrhea (Chapter 23). Various developmental abnormalities—vaginal agenesis, imperforate hymen, transverse and longitudinal vaginal septa, vaginal and uterine duplications, hymenal bands, and septa—most commonly occur in early adolescence with amenorrhea (for the obstructing abnormalities) or with concerns such as inability to use tampons (for hymenal and vaginal bands and septa). These developmental abnormalities must be evaluated carefully to determine both external and internal anatomy.

A tight hymenal ring may be discovered because of concerns about the inability to use tampons or initiate intercourse. Manual dilation can be successful, as can small relaxing incisions at 6 o'clock and 8 o'clock in the hymenal ring. This can sometimes be done in the office using local anesthesia but may require conduction or general anesthesia in the operating room. Hymenal bands are not rare and also lead to difficulty in using tampons; they usually can be incised in the office using local anesthetic.

The condition of hypertrophy of the labia minora has been described, along with surgical procedures to correct this developmental abnormality (206). This condition is more appropriately considered a variant of normal, with reassurance rather than a cosmetic surgical reduction as the primary therapy. Genital ulcerations may be noted in girls with leukemia or other cancers requiring chemotherapy (207). The possibility of sexual abuse, incest, or involuntary intercourse should be considered for young adolescents with vulvovaginal complaints, STDs, or pregnancy.

Reproductive Age Women

In postmenarchal individuals, vulvar symptoms are most often related to a primary vaginitis and a secondary vulvitis. The presence of vaginal discharge can lead to vulvar irritative symptoms, or candidal vulvitis may be present. The causes of vaginitis and cervicitis are covered in [Chapter 15](#). As noted, young children may have a difficult time describing vulvar symptoms; adult women describe vulvar symptoms using a variety of terms (itching, pain, discharge, discomfort, burning, external dysuria, soreness, pain with intercourse or sexual activity). Burning with urination from noninfectious causes may be difficult to distinguish from a urinary tract infection, although some women can distinguish pain when the urine hits the vulvar area (an external dysuria) from burning pain (often suprapubic in location) during urination. A urine culture may be necessary to help make the distinction. Itching is a very common vulvar symptom. A variety of vulvar conditions and lesions can present with pruritus.

A number of skin conditions that occur on other areas of the body may occur on the vulvar area. [Table 13.10](#) contains a list of these conditions classified by either infectious or noninfectious causes. Whereas the diagnosis of some of these conditions is apparent from inspection alone (e.g., a skin tag) ([Fig. 13.33](#)), any lesions that appear atypical or in which the diagnosis is not clear should be analyzed by biopsy.

Noninfectious	Infectious
Acanthosis nigricans	Candida
Actinic dermatitis	Folliculitis
Beyers's disease	Human papillomavirus
Contact dermatitis	Sexual transmission, e.g., chlamydia, gonorrhea
Crohn's disease	Noninfectious vaginitis
Dyskeratosis	Pubic lice
Hyperkeratosis	Scabies
Lichen sclerosus	Tinea
Lichen planus	
Paget's disease	
Psoriasis	
Razor bumps	
Squamous	
Squamous dysplasia	
Vulvar intraepithelial neoplasia	

*Hidradenoma, sebaceous cyst, and other benign lesions are not listed.

Table 13.10. Subacute and Chronic Recurrent Conditions of the Vulva

Figure 13-33 Large benign skin tag from left labium majus.

Pigmented vulvar lesions include benign nevi, lentiginos, melanosis, seborrheic keratosis, and some vulvar intraepithelial neoplasias (VIN), especially multifocal VIN 3. Suspicious pigmented vulvar lesions, in particular, should warrant biopsy to rule out VIN or malignant melanoma (208). Approximately 10% of white women have a pigmented vulvar lesion; some of these lesions may be malignant (Chapter 33) or have the potential for progression (VIN) (Chapter 16). The behavior of some nevocellular lesions (representing about 2% of nevi) is not well established but has been linked to melanoma (209). Multiple hyperpigmented lesions of typical lentigo simplex and melanosis are common, and any areas with irregular borders should be evaluated by biopsy ([Fig. 13.34](#)).

Figure 13-34 Lentigo simplex and melanosis of vulva. Note multiple hyperpigmented lesions. (From Wilkinson EJ, Stone IK. *Atlas of vulvar disease*. Baltimore: Lippincott Williams & Wilkins, 1995:41, with permission.)

Vulvar Biopsy

A vulvar biopsy is essential in distinguishing benign from premalignant or malignant vulvar lesions, especially because many types of lesions may have a somewhat similar appearance. Vulvar biopsies should be performed liberally to ensure that these lesions are diagnosed and treated appropriately. A prospective study of vulvar lesions evaluated by biopsy in a gynecologic clinic found lesions occurring in the following order of frequency: epidermal inclusion cyst ([Fig. 13.35](#)), lentigo, Bartholin duct obstruction, carcinoma in situ, melanocytic nevi, acrochordon, mucous cyst, hemangiomas, postinflammatory hyperpigmentation, seborrheic keratoses, varicosities, hidradenomas, verruca, basal cell carcinoma, and unusual tumors such as neurofibromas, ectopic tissue, syringomas, and abscesses ([210](#)). Clearly, the frequency with which a lesion would be reported after a tissue biopsy is related to the frequency with which all lesions of a given pathology are evaluated in this manner. Thus, this listing probably underrepresents such common lesions as condylomas.

Figure 13-35 Inclusion cysts on right labium majus. (From Wilkinson EJ, Stone IK. *Atlas of vulvar disease*. Baltimore: Lippincott Williams & Wilkins, 1995:17, with permission.)

Biopsy is easily performed in the office using a local anesthetic. Typically, 1% lidocaine is infiltrated beneath the lesion using a small (25- to 27-gauge) needle. Disposable punch biopsy instruments come in a variety of sizes from 2- to 6-mm in diameter. They have the advantage of being sharp and thus facilitate obtaining a good specimen. Sterilizable instruments are also available and may be a more ecologically sound choice if they can be maintained and sharpened periodically. These skin biopsy instruments, along with fine forceps, scissors, and a scalpel, should be available in all outpatient gynecologic settings. For the smaller biopsies, it is usually unnecessary to place a suture. Topical silver nitrate can be used for hemostasis. Multiple tissue samples may be appropriate to obtain representative areas of a lesion if the lesion has a variable appearance or is multifocal. Although the vulvar biopsy procedure involves minimal discomfort, the biopsy sites will be painful for several days after the procedure. The prescription of a topical anesthetic such as 2% lidocaine jelly, to be applied periodically and before urinating, is appreciated by patients who require this procedure. Infection of the site can occur, and patients should be cautioned to report excessive erythema or purulent drainage.

Other Vulvar Conditions

Pseudofolliculitis, similar to what has been described as pseudofolliculitis barbae (razor bumps), may occur in women who follow the increasingly popular practice of shaving pubic hair to conform to a swimsuit ([210](#)). It consists of an inflammatory reaction surrounding an ingrown hair and occurs most commonly among individuals with curly hair, particularly African Americans.

Fox-Fordyce disease is characterized by a chronic, pruritic eruption of small papules or cysts formed by keratin-plugged apocrine glands. It is commonly present over the lower abdomen, mons pubis, labia majora, and inner portions of the thighs. Hidradenitis suppurativa is a chronic condition involving the apocrine glands with the formation of multiple deep nodules, scars, pits, and sinuses that occur in the axilla, vulva, and perineum ([Fig. 13.36](#)). Hyperpigmentation and secondary infection are often seen. Hidradenitis suppurativa can be extremely painful and debilitating. It is often treated with antibiotics (with coverage of both aerobic and anaerobic bacteria). Estrogens or antiandrogen therapy has been attempted; surgical therapy with wide local excision may be necessary. Therapy with isotretinoin and steroids has been reported to be successful ([211,212](#)).

Figure 13-36 Hidradenitis suppurativa involving both labia majora and crease folds. (From Wilkinson EJ, Stone IK. *Atlas of vulvar disease*. Baltimore: Williams & Wilkins, 1995:150, with permission.)

Acanthosis nigricans involves widespread velvety pigmentation in skin folds, particularly the axillae, neck, thighs, submammary area, and vulva and surrounding skin. It is of particular interest to gynecologists because of its association with hyperandrogenism and PCOS as such, it is associated with obesity, chronic anovulation, acne, glucose intolerance, and cardiovascular disease ([37,213](#)).

Intraepithelial Neoplasia

A classification of intraepithelial lesions of the vulva is presented in [Table 16.13](#).

Extramammary Paget's disease of the vulva is an intraepithelial neoplasia containing vacuolated Paget's cells (Chapter 16). Clinically, it may have an appearance varying from moist, oozing ulcerations to an eczematoid lesion with scaling and crusting, to a grayish lesion ([200](#)). A biopsy to confirm the diagnosis is mandatory.

Vulvar intraepithelial neoplasia is associated with human papillomavirus infection and is increasing in frequency, particularly among young women (Chapter 16) ([214](#)). Diagnosis requires biopsy of any suspicious vulvar lesions, particularly those that are pigmented or discolored. The increasing frequency of this entity makes a careful vulvar inspection mandatory during annual gynecologic examinations.

Vulvar Tumors, Cysts, and Masses

Condyloma acuminata are very common vulvar lesions and are usually easily recognized and treated with topical therapies such as tri- and bichloroacetic acid. Other sexually transmitted organisms, such as the virus responsible for *molluscum contagiosum* and the lesions of *syphilis* and *condyloma lata*, may occasionally be mistaken for vulvar condyloma acuminata caused by the human papillomavirus (see [Chapter 15](#)). A summary of benign vulvar tumors is listed in [Table 13.11](#). There is argument regarding whether sebaceous cysts exist on the vulva or whether these lesions are histopathologically epidermal or epidermal inclusion cysts ([215](#)). These cysts may result from the burial of fragments of skin after the trauma of childbirth or episiotomy.

1. Cystic Lesions	3. Anatomic
Bartholin duct cyst	Hemio
Cyst in the canal of Skene's duct	Uthelial diverticulum
Epithelial inclusion cyst	Varioloid
Skene duct cyst	
2. Solid Tumors	4. Infections
Arrector pilosus cyst	Abscess—Bartholin, Skene, peritonsillar, other
Angiolipoma	Condyloma lata
Bartholin gland adenoma	Molluscum contagiosum
Cherry angioma	Pilonidal sinus
Fibroma	5. Etiologic
Hemangioma	Endometriosis
Hydradenoma	Ectopic breast tissue
Lipoma	
Granular cell myoblastoma	
Neurofibroma	
Papillomatosis	

Table 13.11. Types of Vulvar Tumors

It has been argued that the commonly cited concept of milk lines extending into the vulva and accounting for lesions of mammary-like anogenital glands (e.g., fibroadenoma, lactating glands) is not supported by observations in human embryos; such studies show that primordia of the mammary glands do not extend beyond the axillary-pectoral area ([216](#)). Eccrine or apocrine glands have been suggested as the probable source of these unusual lesions.

Bartholin duct cysts are common vulvar lesions. They result from occlusion of the duct with accumulation of mucus and are frequently asymptomatic. Infection of the gland may result in the accumulation of purulent material, with the formation of a rapidly enlarging, painful, inflammatory mass (a Bartholin abscess). An inflatable bulb-tipped catheter has been described by Word and is quite easy to use ([217](#)). The small catheter is inserted through a small stab wound into the abscess after infiltration of the skin with local anesthesia; the balloon of the catheter is inflated with 2 to 3 ml of saline and the catheter remains in place for 4 to 6 weeks, allowing epithelialization of a tract and the creation of a permanent gland opening.

Skene duct cysts are cystic dilations of the Skene glands, typically located adjacent to the urethral meatus within the vulvar vestibule ([Fig. 13.37](#)). Although most are small and often asymptomatic, they may enlarge and cause urinary obstruction, requiring excision.

Figure 13-37 Skene duct cyst. (From Wilkinson EJ, Stone IK. *Atlas of vulvar disease*. Baltimore: Lippincott, Williams & Wilkins, 1995:21, with permission.)

The symptom of painful intercourse (dyspareunia) may be caused by many different vulvovaginal conditions, including common vaginal infections and vaginismus ([Chapter 15](#)). A careful sexual history is essential, as is a careful examination of the vulvar area and vagina. *Vulvodynia* is the term used to describe unexplained vulvar pain, sexual dysfunction, and the resultant psychological disability ([218](#)). The term *vulvar vestibulitis* has been used to describe a situation in which there is pain during intercourse, primarily during entry ([219,220](#)). The condition is characterized by tender areas surrounding the vulvar vestibule and hymenal ring (see [Chapter 14](#)). A number of recent studies have failed to demonstrate a consistent relationship with any genital infectious organism, including chlamydia, gonorrhea, *Trichomonas*, mycoplasma, *Ureaplasma*, *Gardnerella*, candida, or human papillomavirus ([221,222](#) and [223](#)). Although the symptoms of dyspareunia with insertion can be disabling, no curative therapies have been found. Surgical therapies have been suggested, and both medical and behavioral therapies are of some benefit ([224,225](#)). The visible lesion of vestibular papillomatosis may be a nonspecific response to discharge or inflammation.

Vulvar Ulcers

A number of STDs can cause vulvar ulcers, including herpes simplex virus, syphilis, lymphogranuloma venereum, and granuloma inguinale ([Chapter 15](#)). *Crohn's disease* can include vulvar involvement with abscesses, fistulae, sinus tracts, fenestrations, and other scarring. Although medical treatment with systemic steroids and other systemic agents is the mainstay of therapy, surgical therapy of both intestinal and vulvar disease may be required.

Behçet's disease is characterized by genital and oral ulcerations with ocular inflammation. The cause and the most effective therapy are not well established.

Lichen planus also causes oral and genital ulcerations. Typically, there is desquamative vaginitis with erosion of the vestibule. Treatment is based on the use of both topical and systemic steroids. Plasma cell mucositis appears as erosions in the vulvar area, particularly the vestibule. Biopsy is essential in making the diagnosis.

Postmenopausal Women

Vulvar Dystrophies

Several vulvar conditions occur most commonly in postmenopausal women. Symptoms are primarily itching and vulvar soreness, in addition to dyspareunia.

In the past, numerous terms have been used to describe disorders of vulvar epithelial growth that produce a number of nonspecific gross changes. These terms have included leukoplakia, lichen sclerosus et atrophicus, atrophic and hyperplastic vulvitis, and kraurosis vulvae. The malignant potential of the vulvar dystrophies is less than 5%; at particular risk is the patient with cellular atypia on initial biopsy. The International Society for the Study of Vulvar Diseases (ISSVD) has recommended a classification of vulvar dystrophies, which is presented in [Table 16.13](#).

Squamous Hyperplasia Squamous hyperplasia is seen most often in postmenopausal women but may occur during the reproductive years. Pruritus is the most common symptom. The lesion appears thickened and hyperkeratotic, and there may be excoriation. Squamous hyperplasia tends to be discrete but may be symmetric and multiple. Biopsies are necessary to make the diagnosis and to evaluate the presence of atypia and exclude malignancy.

The treatment is local application of a fluorinated corticosteroid ointment 2 times a day for 6 weeks. Typically, the lesion totally regresses. If a new lesion recurs, another biopsy should be performed and an additional 6 weeks of treatment with topical steroids should be given ([224](#)).

Lichen Sclerosus Lichen sclerosus is the most common white lesion of the vulva ([Fig. 13.38](#)). Lichen sclerosus can occur at any age, although it is most common among postmenopausal women and prepubertal girls ([224](#)). The symptoms are pruritus, dyspareunia, and burning. Lichen sclerosus characteristically is associated with decreased subcutaneous fat such that the vulva is atrophic, with small or absent labia minora, thin labia majora, and sometimes phimosis of the prepuce. The surface is pale with a shiny, crinkled pattern, often with fissures and excoriation. The lesion tends to be symmetric and often extends to the perineal and perianal areas. The diagnosis is confirmed by biopsy. Invasive cancer is only rarely associated with lichen sclerosus.

Figure 13-38 Lichen sclerosus of the vulva in a postmenopausal patient. (From Wilkinson EJ, Stone IK. *Atlas of vulvar disease*. Baltimore: Lippincott Williams & Wilkins, 1995:36, with permission.)

Treatment is with an ultrapotent topical steroid such as 0.05% clobetasol. Approximately 80% of patients have a satisfactory response ([226](#)). Maintenance therapy is important and may include the use of a lower potency steroid or the use of a topical emollient ([227](#)).

Urethral Lesions

Vulvar lesions that may be seen in other age groups, but that occur more commonly among older women, include urethral caruncles and prolapse of the urethral mucosa. Both conditions can be treated with topical or systemic estrogen preparations. Various vulvar skin lesions, including seborrheic keratoses and cherry hemangiomas (senile hemangiomas), occur more commonly on aging skin.

Vaginal Conditions

Vaginal discharge is one of the most common vaginal symptoms. Conditions ranging from vaginal candidiasis to chlamydia cervicitis to bacterial vaginosis to cervical carcinoma may cause vaginal discharge. Infectious vaginal conditions are addressed more completely in [Chapter 15](#). Vaginal lesions may occasionally be palpable to a woman. More commonly, vaginal lesions are discovered on examination by a clinician. They may contribute to symptoms (such as bleeding or discharge) or they may be entirely asymptomatic. Vaginitis, cervicitis, and vaginal or cervical lesions (including malignancies) can be causes of vaginal discharge. Other noninfectious causes of discharge are as follows:

1. Retained foreign body—tampon, pessary
2. Ulcerations—tampon-induced, lichen planus
3. Malignancy—cervical, vaginal
4. Postmenopausal atrophic vaginitis, postradiation vulvovaginitis

Pediatric

Sexual abuse should always be considered in prepubertal children with vaginal discharge. Although the use of routine STD cultures in girls with a history of sexual abuse has been questioned, vaginal culture for gonorrhea and chlamydia should be performed in girls with vaginal discharge ([228](#)). In prepubertal girls, vulvovaginitis is usually caused by multiple organisms that are present in the perineal area, although a single organism such as streptococcus or even, rarely, *Shigella* may be causative. Treatment should be initiated with a focus on hygienic and cleansing measures. A short-term (<4 weeks) course of topical estrogens and broad-spectrum antibiotics may be necessary. The problem can be recurrent.

A technique for obtaining vaginal cultures and for performing vaginal irrigation has been described by Pokorny ([229](#)). A catheter within a catheter can be fashioned using the tubing from an intravenous butterfly setup within a sterile urethral catheter. Nonbacteriostatic saline (1 ml) can be injected, aspirated, and sent for culture. Cultures taken in this manner are almost always better tolerated than cultures obtained using a cotton-tipped applicator. A larger quantity of saline can then be used to irrigate the vagina while the catheter is still within the vagina. Small foreign bodies can often be flushed from the vagina in this manner.

Adolescence and Older

Vaginal tampons have been associated with both microscopic and macroscopic ulcerations. Healing of the macroscopic ulcerations occurs within several weeks without specific therapy if tampon use is suspended. A follow-up examination to demonstrate healing is appropriate, with biopsy of any persistent ulcerations to rule out other lesions.

Toxic shock syndrome (TSS) has been associated with tampon use and vaginal *Staphylococcus aureus*-produced exotoxins. TSS consists of fever, hypotension, a diffuse erythroderma with desquamation of the palms and soles, plus involvement of at least three major organ systems ([230](#)). Vaginal involvement includes mucous membrane inflammation. TSS appears to be declining in frequency, and an increasing percentage of cases are not associated with menses ([231](#)).

Some vaginal lesions are asymptomatic and are noted incidentally on examination. *Fibroepithelial polyps* consist of polypoid folds of connective tissue, capillaries, and stroma covered by vaginal epithelium. Although they can be excised easily in the office, their vascularity can be troublesome, and excision is not necessary unless the diagnosis is in question. *Cysts of embryonic origin* can arise from mesonephric, paramesonephric, and urogenital sinus epithelium. *Gartner's duct cysts* are of mesonephric origin and are usually present on the lateral vaginal wall. They rarely cause symptoms and, therefore, do not require treatment. Other embryonic cysts

can arise anterior to the vagina and beneath the bladder. Cysts that arise from the urogenital sinus epithelium are located in the area of the vulvar vestibule. *Vaginal adenosis*, the presence of epithelial-lined glands within the vagina, has been associated with *in utero* exposure to diethylstilbestrol. No therapy is necessary, other than close observation and periodic palpation to detect nodules that may need to be evaluated by biopsy to rule out vaginal clear cell adenocarcinoma (Chapter 31).

Women will sometimes describe a bulging lesion of the vagina and vulvar area, variably associated with symptoms of pressure or discomfort. The most common cause of such a lesion is one of the disorders of vaginal support: cystocele, rectocele, or urethrocele. Management of these conditions is discussed in Chapter 20. Other genital lesions, such as urethral diverticula or occasionally embryonic cysts, may cause similar symptoms.

Pelvic pain is the most challenging symptom confronting the practitioner. The problems of acute, cyclic, and chronic pelvic pain encompass a large proportion of gynecologic complaints. The etiology of pelvic pain is diverse. Dysmenorrhea is one of the most common medical issues in gynecology.

Acute pain is intense and characterized by sudden onset, sharp rise, and short course. **Cyclic pain** refers to pain that occurs with a definite association to the menstrual cycle. **Dysmenorrhea**, or painful menstruation, is the most common cyclic pain phenomenon and is classified as **primary** or **secondary** on the basis of associated anatomic pathology (1). **Chronic pelvic pain** has been defined as pain of greater than 6 months' duration (2). Whereas acute pain is often associated with profound autonomic reflex responses, such as nausea, emesis, diaphoresis, and apprehension, obvious autonomic reflex responses are not present in chronic pelvic pain. In addition, acute pelvic pain often is associated with signs of inflammation or infection, such as fever and leukocytosis, which are absent in chronic pain states. The pathophysiology of acute pelvic pain involves mediators of inflammation present in high concentration as a result of infection, ischemia, or chemical irritation (3,4). By contrast, the etiology of chronic pelvic pain often is obscure. Additionally, chronic pain is characterized by physiologic, affective, and behavioral responses that are quite different from those associated with acute pain (5).

Acute Pain

The differential diagnosis of acute pelvic pain is outlined in Table 14.1. Assessing the character of the pain is helpful in creating a differential diagnosis. **Rapid onset of pain is most consistent with perforation of a hollow viscus or ischemia. Colic or severe cramping pain is commonly associated with muscular contraction or obstruction of a hollow viscus, such as intestine or uterus, whereas pain perceived over the entire abdomen suggests a generalized reaction to an irritating fluid within the peritoneal cavity.**

Differential Diagnosis of Dysmenorrhea		
Acute Pain		
1. Perforation of a hollow viscus		
2. Ischemia		
3. Obstruction of a hollow viscus		
4. Inflammation		
5. Infection		
6. Chemical irritation

Table 14.1. Differential Diagnosis of Acute Pelvic Pain

The viscera are relatively insensitive to pain. The first perception of visceral pain is a vague, deep, poorly localizable sensation associated with autonomic reflex responses; however, once the pain becomes localized, the pain is called *referred pain*. Referred pain is well localized and superficial. It is appreciated within the nerve distribution or dermatome of the spinal cord segment innervating the involved viscus. The location of the referred pain provides insight into the location of the primary disease process. The innervation of the pelvic organs is outlined in Table 14.2 (3).

Organ	Spinal Segments	Nerve
Perineum, vulva, lower vagina	S2-S4	Podendal, inguinal, genitofemoral, postgenitofemoral cutaneous
Upper vagina, cervix, lower uterine segment, posterior urethra, bladder trigone, uterovaginal and cervical ligaments, rectovaginal, lower ureters	S2-S4	Sacral afferents traveling through the pelvic plexus
Uterine fundus, proximal fallopian tubes, broad ligaments, upper bladder, cecum appendix, terminal large bowel	T11-T12, L1	Thoracolumbar splanchnic nerves through uterine and hypogastric plexus
Over two thirds of fallopian tubes, upper ureter	T9-T10	Thoracolumbar splanchnic nerves through mesenteric plexus
Ovaries	T9-T10	Thoracolumbar splanchnic nerves traveling with ovarian vessels through renal and aortic plexus and celiac and mesenteric ganglia

Table 14.2. Nerves Carrying Painful Impulses from the Pelvic Organs

In the evaluation of acute pelvic pain, early diagnosis is critical because significant delay increases morbidity and mortality. Central to correct diagnosis is an accurate history (Fig. 14.1). The date and character of the last and previous menstrual periods and the presence of abnormal bleeding or discharge should be ascertained. Menstrual, sexual, and contraceptive history and the past history of sexually transmitted conditions and previous gynecologic disorders are important. The patient should be questioned about her medical history and any previous surgery. Pain history should be obtained, including how and when the pain started; the presence of gastrointestinal symptoms (e.g., anorexia, nausea, vomiting, constipation, obstipation, flatus pattern); urinary symptoms (e.g., urgency, frequency, hematuria, or dysuria); and signs of infection (e.g., fevers, chills).

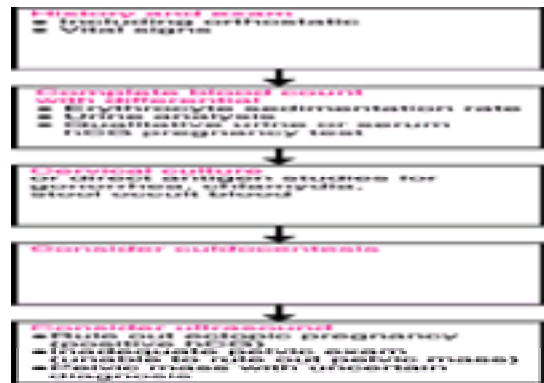

Figure 14.1 Diagnosis of acute pelvic pain.

Pathology

Abnormal Pregnancy

An ectopic pregnancy is defined as implantation of the fetus in the site other than the uterine cavity (see Chapter 17). Ninety-five percent of ectopic pregnancies develop in the fallopian tube. With the advent of sensitive pregnancy tests, misdiagnosis of ectopic pregnancy is less common. However, a substantial proportion of maternal mortality is still attributable to ectopic gestation.

Symptoms

Implantation of the fetus in the fallopian tube produces pain only with acute dilation of the tube. If tubal rupture occurs, localized abdominal pain tends to be temporarily relieved and is replaced by generalized pelvic and abdominal pain as the hemoperitoneum develops. Typically, there has been amenorrhea for 6 to 8 weeks and irregular bleeding or spotting related to fluctuating levels of human chorionic gonadotropin (hCG) and low progesterone concentrations. A mass in the cul-de-sac may produce an urge to defecate. Referred pain to the right shoulder often develops if the intraabdominal blood collection transverses the right colic gutter and irritates the diaphragm (C-3 to C-5 innervation). Dizziness or syncope can ensue if blood loss is significant.

Signs

Pulse and blood pressure taken in erect and supine positions (orthostatic vital signs) are especially helpful in documenting an early or small hemoperitoneum. In young women, there may be elevation of pulse or decrease in blood pressure only when altering position from supine to erect. Abdominal examination is usually notable for tenderness and guarding in one or both lower quadrants. With the development of hemoperitoneum, generalized abdominal distention and rebound tenderness are prominent, and bowel sounds are often decreased. Pelvic examination generally reveals mild tenderness on motion of the cervix. Adnexal tenderness is generally more pronounced on the side of the ectopic pregnancy. A mass consisting of a hematosalpinx or hematoma isolated by adhesions is sometimes present; however, a palpable mass is more often the corpus luteum of pregnancy. Low-grade fever and leukocytosis are uncommon but can be present if the tube has ruptured. The hematocrit often reveals progressive anemia indicating internal bleeding, although, because of vasoconstriction and subsequent hemoconcentration, low hematocrit is a late sign of blood loss in young women. The assessment of hematocrit must, therefore, be combined with evaluation of orthostatic vital signs.

Diagnosis

The diagnosis of ectopic pregnancy is discussed in Chapter 17. In women of reproductive age, serum or urine pregnancy test with sensitivity of greater than 20 IU/mL of hCG should be obtained; if positive, ectopic pregnancy must be excluded before the patient can be discharged or treated for another diagnosis. Acute pelvic pain during pregnancy can also result from other types of pathology. Once ultrasound has confirmed an intrauterine pregnancy, one must consider adnexal torsion, leakage or rupture of an ovarian cyst, degeneration of leiomyoma, or gastrointestinal or urinary pathology. Coexistent intrauterine and ectopic pregnancy is rare (1 in 30,000).

Leaking or Ruptured Ovarian Cyst

Functional cysts (e.g., follicle, corpus luteum) are the most common ovarian cysts and rupture more readily than do benign or malignant neoplasms. The pain associated with rupture of the ovarian follicle at the time of ovulation is called *mittelschmerz*. The small amount of blood leaking into the peritoneal cavity and high concentration of follicular fluid prostaglandins could cause this midcycle pelvic pain. However, the pain is mild or moderate and self-limited, and with an intact coagulation system, hemoperitoneum is unlikely. A hemorrhagic corpus luteum cyst can develop in luteal phase of the menstrual cycle. Rupture of this cyst can produce either a small amount of intraperitoneal bleeding or frank hemorrhage resulting in significant blood loss and hemoperitoneum.

Nonmalignant neoplasms, most commonly cystic teratomas (dermoid cysts) or cystadenomas, as well as inflammatory ovarian masses, such as endometriomas, can also leak or rupture. A history of a dermoid cyst or endometrioma that has not yet undergone surgical extirpation is not uncommon. Surgical exploration is indicated if rupture of the cyst leads to hemoperitoneum (corpus luteum) or chemical peritonitis (endometrioma, benign cyst teratoma), which could impair future fertility.

Symptoms

An ovarian cyst that is not torsing, rapidly expanding, infected, or leaking does not cause acute pain. A corpus luteum cyst is the most common cyst to rupture and lead to hemoperitoneum. Symptoms of a ruptured corpus luteum cyst are similar to those of a ruptured ectopic pregnancy. The onset of pain is usually sudden and is associated with increasing generalized abdominal pain and occasionally dizziness or syncope if a hemoperitoneum develops. A ruptured endometrioma or benign cystic teratoma (dermoid cyst) produces similar symptoms; however, dizziness and signs of hypovolemia are not present because blood loss is minimal.

Signs

Hypovolemia is present only when there is a hemoperitoneum. The most important sign is the presence of significant abdominal tenderness, often associated with rebound tenderness because of peritoneal irritation. The abdomen can be moderately distended with decreased bowel sounds. On pelvic examination, a mass is often present if the cyst is leaking and not completely ruptured. Fever and leukocytosis are rare. The hematocrit is decreased only if active bleeding is present.

Diagnosis

Pregnancy test, complete blood count, and ultrasound or culdocentesis confirm the diagnosis. Without orthostasis and with a relatively normal peripheral hematocrit, a hematocrit of 16% or less of the fluid obtained from the cul-de-sac is usually consistent with leakage of a small amount of blood into the peritoneal fluid and not a hemoperitoneum.

Management

Orthostasis, anemia, or hematocrit of the culdocentesis fluid of greater than 16% suggests hemoperitoneum and usually requires surgical treatment by laparoscopy or laparotomy. The culdocentesis is very helpful in determining the cause of peritonitis: fresh blood suggests a corpus luteum; chocolate "old" blood, an endometrioma; oily sebaceous fluid, a benign teratoma; purulent fluid, pelvic inflammatory disease (PID) or tuboovarian abscess. Patients who are not orthostatic or anemic and who have a small amount of blood in the cul-de-sac fluid (culdocentesis fluid hematocrit less than 16%) can often be observed in the hospital, without surgical intervention, or even discharged home from the emergency room after observation.

Torsion of Adnexa

Torsion (twisting) of the vascular pedicle of an ovary, fallopian tube, paratubal cyst, or rarely just a fallopian tube results in ischemia and rapid onset of acute pelvic pain. **A benign cystic teratoma is the most common neoplasm to undergo torsion.** Because of adhesions, ovarian carcinoma and inflammatory masses rarely are affected by torsion. It is also unusual for a normal tube and ovary to torse, although a polycystic ovary can undergo torsion.

Symptoms

The pain of torsion can be severe and constant or, if the torsion is partial and intermittently untwists, intermittent. The onset of the torsion and the symptoms of abdominal pain frequently coincide with lifting, exercise, or intercourse. Autonomic reflex responses are usually present (e.g., nausea, emesis, apprehension).

Signs

On examination, the abdomen is very tender, and localized rebound tenderness can be noted in the lower quadrants. The most important sign is the presence of a large pelvic mass on physical examination. Mild temperature elevation and leukocytosis may accompany the infarction. The diagnosis must be suspected in any woman with acute pain and unilateral adnexal mass.

Diagnosis

The process of torsion occludes the lymphatic and venous drainage of the involved adnexa; therefore, the mass rapidly increases in size and can be palpated on examination or visualized by ultrasound. Ultrasound confirms the presence of a mass but is not necessary if the examination reveals a large tender adnexal mass (at least 8 to 10 cm in diameter).

Management

Adnexal torsion must be treated surgically. If the tissue has not infarcted, the adnexa may be untwisted and a cystectomy performed if appropriate. If necrosis has occurred, an oophorectomy must be performed. Treatment may be accomplished by laparoscopy or laparotomy, depending on the size of the mass.

Acute Salpingo-oophoritis

The presentation and management of acute salpingo-oophoritis and PID are discussed in Chapter 15. PID is a polymicrobial infection consisting of the ascending spread of aerobic and anaerobic vaginal bacteria heralded by the acquisition of a sexually transmitted pathogen such as *Neisseria gonorrhoea* or *Chlamydia trachomatis*. Transcervical instrumentation (endometrial biopsy) of the endometrial cavity (hysterosalpingogram, termination of pregnancy, or parturition) also can cause endometritis or salpingo-oophoritis.

Symptoms

Gonococcal PID is manifested by the acute onset of pelvic pain that increases with movement, fever, purulent vaginal discharge, and sometimes nausea and vomiting. The pain is often associated with a menstrual period, a time when pathogens have ready access to the upper genital tract. Chlamydial salpingo-oophoritis is associated with more insidious symptoms, which can be confused with the symptoms of irritable bowel.

Signs

Direct and rebound abdominal tenderness with palpation are usually notable on examination. The most important signs of acute salpingo-oophoritis are cervical motion tenderness and bilateral adnexal tenderness. Evaluation of the pelvis may be difficult because of acute pain, but lack of a discrete mass or masses differentiates acute salpingo-oophoritis from tuboovarian abscess or torsion. There is often leukocytosis, or at least an elevated erythrocyte sedimentation rate (ESR), a nonspecific, although more sensitive, sign of inflammation.

Diagnosis

For the clinical diagnosis of PID to be most accurate, lower abdominal tenderness with or without rebound, cervical motion tenderness and adnexal tenderness all must be present (6,7 and 8). The accuracy of the diagnosis is further increased in the presence of one or more of the following objective signs: fever, leukocytosis, inflammatory mass, culdocentesis revealing white cells or bacteria on Gram stain, gram-negative intracellular diplococci on Gram stain of the cervix, or positive chlamydia antigen test of the cervix. Appendicitis often is mistaken for PID.

Management

Salpingo-oophoritis may be treated on an outpatient basis with broad-spectrum oral antibiotics (7,9,10). Criteria for hospitalization include suspected tuboovarian abscess, pregnancy, presence of an intrauterine device, uncertain diagnosis, nausea and vomiting precluding administration of oral medication, upper peritoneal signs, and failure to respond to oral antibiotics within 48 hours. Hospitalization also should be considered for episodes of PID in young women who desire future childbearing. Outpatient antibiotic regimens are often successful for uncomplicated PID; however, the patient must be reassessed within 48 hours and, if not significantly improved, admitted to the hospital for intravenous antibiotic therapy. The treatment of acute PID is outlined in detail in Chapter 15.

Tuboovarian Abscess

Tuboovarian abscesses, a sequela of acute salpingitis, are usually bilateral, but unilateral abscess formation is not rare. The symptoms and signs are similar to those of acute salpingitis, although pain and fever have often been present for longer than 1 week before presentation to the emergency room. A ruptured tuboovarian abscess is a life-threatening surgical emergency because gram-negative endotoxic shock can develop rapidly.

Signs

Tuboovarian abscesses can be palpated on bimanual examination as very firm, exquisitely tender, bilateral fixed masses. The abscesses can be palpated or "point" in

the pelvic cul-de-sac.

Diagnosis

The clinical diagnosis can be substantiated by ultrasonography. The differential diagnosis of a unilateral mass includes not only tuboovarian abscess but also adnexal torsion, endometrioma, leaking ovarian cyst, and periappendiceal abscess. If physical and ultrasound examination results are not definitive, laparoscopy or laparotomy must be performed.

Management

Unruptured tuboovarian abscesses may be treated medically with appropriate intravenous antibiotics and close monitoring to detect leakage or impending rupture. A ruptured tuboovarian abscess rapidly leads to diffuse peritonitis evidenced by tachycardia, rebound tenderness in all four quadrants of the abdomen, and, if progressive, hypotension and oliguria. Exploratory laparotomy with resection of infected tissue is mandatory.

Uterine Leiomyomas

Leiomyomas are uterine smooth muscle tumors. Discomfort may be present when myomas encroach on adjacent bladder, rectum, or supporting ligaments of the uterus, although acute pelvic pain attributable to uterine leiomyomas is rare. Acute pelvic pain can develop if the myoma undergoes degeneration or torsion. Degeneration of myomas occurs secondary to loss of blood supply, usually attributable to rapid growth associated with pregnancy. In a nonpregnant woman, degenerating uterine leiomyoma often is misdiagnosed, frequently being confused with subacute salpingo-oophoritis. A pedunculated subserosal leiomyoma can undergo torsion ischemic necrosis; when this situation occurs, it is associated with pain similar to that of adnexal torsion. When a submucous leiomyoma becomes pedunculated, the uterus contracts forcefully as if to expel a foreign body, and the resulting pain is similar to that of labor. The cramping pain is usually associated with hemorrhage.

Signs

Abdominal examination reveals an irregular solid mass or masses arising from the uterus. If degeneration occurs, the inflammation can cause abdominal tenderness in response to palpation and mild localized rebound tenderness. Elevation of temperature and leukocytosis also can occur.

Diagnosis and Management

Ultrasound is useful in distinguishing adnexal from uterine etiology of an eccentric mass. Degeneration of a leiomyoma is treated with observation and pain medication. A pedunculated, torsed, subserosal leiomyoma can easily be excised laparoscopically; however, surgery is not mandatory. A submucous leiomyoma with pain and hemorrhage should be excised transcervically, with hysteroscopic guidance if needed.

Endometriosis

A thorough discussion of endometriosis is presented in Chapter 26. Endometriosis is characterized by the presence and proliferation of endometrial tissue in sites outside the endometrial cavity. Women with endometriosis often experience dysmenorrhea (painful menses), dyspareunia (painful intercourse), and dyschezia (pain with bowel movements). There often is a history of luteal phase bleeding or infertility. Acute pain attributable to endometriosis is usually premenstrual and menstrual (dysmenorrhea); however, if nonmenstrual acute generalized pain occurs, a ruptured endometrioma (chocolate endometriotic cyst within the ovary) should be considered. In this situation, hemoperitoneum is absent, although the fluid from the chocolate cyst can cause chemical peritonitis.

Signs

The abdomen is often tender in the lower quadrants. Significant distention or rebound tenderness is usually not present. Pelvic examination often reveals a fixed, retroverted uterus with tender nodules in the uterosacral region or thickening of the cul-de-sac. An adnexal mass, if present, usually is fixed to the broad ligament and cul-de-sac.

Diagnosis

If a culdocentesis is performed, it will reveal the cyst contents of the ruptured endometrioma. If the diagnosis is unclear, ultrasound is helpful, and laparoscopy findings are definitive. In a patient who has an established diagnosis of endometriosis or who has recently been treated surgically for the disease, a trial of ovarian hormonal suppression (pseudomenopause) can be used to treat the condition and to confirm the correlation between the current pain and the underlying diagnosis of endometriosis.

Management

A ruptured endometrioma is an indication for laparoscopy or laparotomy with ovarian cystectomy or oophorectomy. If a small endometrioma (less than 3 cm) is suspected and there are no signs of rupture, medical management may proceed (see [Chapter 26](#)). Diagnostic laparoscopy can be performed if endometriosis or unruptured endometrioma is suspected but not confirmed.

Gastrointestinal Tract

Appendicitis is the most common intestinal source of acute pelvic pain in women. The symptoms and signs of appendicitis can be similar to those of PID.

The first symptom of appendicitis is typically diffuse abdominal pain, especially epigastric pain, associated with anorexia and nausea. Within a matter of hours, the pain generally shifts to the right lower quadrant. Fever, chills, emesis, and obstipation may ensue. However, this classic symptom pattern is often lacking. Atypical abdominal pain can occur when the appendix is retrocecal or entirely within the true pelvis. In this setting, tenesmus and diffuse suprapubic pain may result. The patient with appendicitis is more likely to have pronounced and persistent gastrointestinal symptoms than the patient with salpingo-oophoritis.

Signs

Local tenderness is usually elicited on palpation of the right lower quadrant (McBurney point). The appearance of severe generalized muscle guarding; abdominal rigidity; rebound tenderness, right-sided mass, or tenderness on rectal examination; positive psoas sign (pain with forced hip flexion or passive extension of hip); and obturator signs (pain with passive internal rotation of flexed thigh) indicates appendicitis. A low-grade temperature is generally present, but the temperature may be normal. The pelvic examination is usually without cervical motion or bilateral adnexal tenderness, but right-sided unilateral adnexal tenderness can be present.

Diagnosis

Many patients with acute appendicitis have a normal total leukocyte count; however, the differential usually reveals a left shift. Ultrasound examination of the pelvic organs generally has normal findings, whereas the appendix may be abnormal on ultrasound or computed tomography scan. Gastrografin or barium enema with normal filling of the appendix rules out appendicitis. Diagnostic laparoscopy can be useful to rule out other sources of pelvic pathology, but it is occasionally difficult to visualize the appendix sufficiently to rule out early appendiceal inflammation.

Management

Laparotomy, with a false-positive rate of 20%, is an acceptable approach and is preferable to continued observation with rupture and peritonitis. Not only is a ruptured appendix life-threatening but it also may have profound sequelae for the fertility of a young woman of reproductive age.

Acute Diverticulitis

Acute diverticulitis is a condition in which there is inflammation of a diverticulum or outpouching of the wall of the colon, usually involving the sigmoid. Diverticulitis typically affects postmenopausal women but can occur in women in their 30s and 40s.

Symptoms

The severe, left lower quadrant pain of diverticulitis can follow a long history of symptoms of irritable bowel (bloating, constipation, and diarrhea), although diverticulosis usually is asymptomatic. Diverticulitis is less likely to lead to perforation and peritonitis than is appendicitis. Fever, chills, and constipation typically are present, but anorexia and vomiting are uncommon.

Signs

Abdominal examination reveals distention with left lower quadrant tenderness on direct palpation and localized rebound tenderness. Abdominal and pelvic examination may reveal a poorly mobile, doughy inflammatory mass in the left lower quadrant. Bowel sounds are hypoactive and, if peritonitis is present, absent. Leukocytosis frequently is observed.

Diagnosis and Management

Computed axial tomography scan is a useful adjunct to history and physical examination. A barium enema is contraindicated. Diverticulitis is initially managed medically with broad-spectrum intravenous antibiotics. A diverticular abscess often requires surgical intervention.

Intestinal Obstruction

The most common causes of intestinal obstruction in women are postsurgical adhesions, hernia formation, inflammatory bowel disease, and carcinoma of the bowel or ovary.

Symptoms

Intestinal obstruction is heralded by the onset of colicky abdominal pain, followed by abdominal distention, vomiting, constipation, and obstipation. Higher and more acute obstruction results in early vomiting, whereas colonic obstruction presents with a greater degree of abdominal distention and obstipation. Vomiting first consists of gastric contents, followed by bile, then material with feculent odor, depending on the level of obstruction.

Signs

Marked abdominal distention is present. At the onset of mechanical obstruction, bowel sounds are high pitched and maximal during an episode of colicky pain. As the obstruction progresses, bowel sounds decrease and, when absent, suggest ischemic bowel. Elevated white blood cell count and fever often are present in the late stages.

Diagnosis and Management

Abdominal x-ray series showing a characteristic gas pattern help to rule out ileus and to determine whether obstruction is partial or complete. Complete obstruction requires surgical management, whereas partial obstruction often can be managed with intravenous fluids and nasogastric suction. The cause of the obstruction should be determined and treated if possible.

Urinary Tract

Ureteral colic due to ureteral lithiasis is caused by a sudden increase in intraluminal pressure and associated inflammation. Urinary tract infections producing acute pain include cystitis and pyelonephritis.

Symptoms and Signs

The pain of lithiasis is typically severe and crampy; it can radiate from the costovertebral angle to the groin. Hematuria is often present. Cystitis is associated with dull suprapubic pain, urinary frequency, urgency, dysuria, and occasionally hematuria. Because urethritis can occur secondary to chlamydia or gonorrhea and has similar symptoms, these infections must be ruled out, if appropriate. Pyelonephritis is associated with flank and costovertebral angle pain, although lateralizing lower abdominal pain occasionally is present. There is pain with firm pressure over the costovertebral angle in the case of lithiasis or pyelonephritis. Peritoneal signs are absent. Suprapubic tenderness may accompany cystitis.

Diagnosis

Diagnosis of stone is afforded by urinalysis revealing red blood cells and ultrasound or CT urogram or intravenous pyelogram outlining the stone. In the case of urinary tract infection, the diagnosis is based on urinalysis revealing bacteria and leukocytes and subsequently confirmed by culture.

Management

Expectant medical and surgical management are both options for renal lithiasis. Nonpregnant women with pyelonephritis and all women with cystitis can be treated on an outpatient basis.

Diagnostic Tools

All women of reproductive age with acute pelvic pain should have a complete blood count with differential, ESR, urinalysis, and a sensitive qualitative urine or serum pregnancy test (Fig. 14.1). The sedimentation rate is nonspecific but often is the only abnormal laboratory finding in women with subacute PID. Other studies that may be helpful include culdocentesis with hematocrit, if bloody fluid is obtained, and Gram stain and culture, if the fluid is purulent. The presence of cul-de-sac mass precludes culdocentesis. Pelvic ultrasound is useful to rule out ectopic gestation or to assess the adnexae if the results of the examination are confusing or difficult to interpret because of obesity or guarding. Abdominal x-ray series or upper or lower Gastrografin studies are helpful to rule out gastrointestinal pathology when gastrointestinal symptoms predominate. Computed tomography scan is useful for evaluation of retroperitoneal masses or abscesses related to the gastrointestinal tract. Diagnostic laparoscopy is reserved for establishing the diagnosis in patients who have acute abdomen of uncertain cause, for elucidating the nature of an ambiguous adnexal mass, or for delineating whether a pregnancy is intrauterine or extrauterine (if ultrasound results are negative or equivocal). If there is a clinical evidence of salpingo-oophoritis, diagnostic laparoscopy can be used to confirm the diagnosis. Visualization is hampered if diagnostic laparoscopy is performed for a large pelvic mass (>12 cm) and is relatively contraindicated in patients with peritonitis, severe ileus, or bowel obstruction. In these settings, laparotomy is preferable.

Cyclic Pain: Primary and Secondary Dysmenorrhea

Dysmenorrhea is a common gynecologic disorder affecting up to 50% of menstruating women (11). Primary dysmenorrhea refers to menstrual pain without pelvic pathology, whereas secondary dysmenorrhea is defined as painful menses associated with underlying pathology. Primary dysmenorrhea usually appears within 1 to 2 years of menarche, when ovulatory cycles are established. The disorder affects younger women but may persist into the 40s. Secondary dysmenorrhea usually develops years after menarche and can occur with anovulatory cycles. The differential diagnosis of secondary dysmenorrhea is outlined in

Table 14.3 (2).

Category	Item
Primary Dysmenorrhea	Endometriosis
	Adenomyosis
	Uterine fibroids
	Chronic pelvic inflammatory disease
	Contraceptive use
	Smoking
	Parity
	Menstrual history
	Family history
	Psychological factors
Secondary Dysmenorrhea	Endometriosis
	Adenomyosis
	Uterine fibroids
	Chronic pelvic inflammatory disease
	Contraceptive use
	Smoking
	Parity
	Menstrual history
	Family history
	Psychological factors

Table 14.3. Peripheral Causes of Chronic Pelvic Pain

Primary Dysmenorrhea

The cause of primary dysmenorrhea is increased endometrial prostaglandin production (12,13,14 and 15). These compounds are found in higher concentration in secretory endometrium than in proliferative endometrium. The decline of progesterone levels in the late luteal phase triggers lytic enzymatic action, resulting in a release of phospholipids with the generation of arachidonic acid and activation of the cyclooxygenase pathway. The biosynthesis and metabolism of prostaglandins and thromboxane derived from arachidonic acid are depicted in Fig. 14.2 (14). Women with primary dysmenorrhea have higher uterine tone with high-amplitude contractions resulting in decreased uterine blood flow (16). Vasopressin concentrations are also higher in women with dysmenorrhea (17).

Figure 14.2 The biosynthesis and metabolism of prostaglandins and thromboxane derived from arachidonic acid. (From Chaudhuri G. Physiologic aspects of prostaglandins and leukotrienes. *Semin Reprod Endocrinol* 1985;3:219, with permission.)

Symptoms

The pain of primary dysmenorrhea usually begins a few hours before or just after the onset of a menstrual period and may last up to 48 to 72 hours. The pain is similar to labor, with suprapubic cramping, and may be accompanied by lumbosacral backache, pain radiating down the anterior thigh, nausea, vomiting, diarrhea, and rarely syncopal episodes. The pain of dysmenorrhea is colicky in nature and is improved with abdominal massage, counterpressure, or movement of the body, unlike abdominal pain due to chemical or infectious peritonitis.

Signs

On examination, the vital signs are normal. The suprapubic region may be tender to palpation. Bowel sounds are normal, and there is no upper abdominal tenderness and no abdominal rebound tenderness. Bimanual examination at the time of the dysmenorrheic episode often reveals uterine tenderness; however, severe pain with movement of the cervix or palpation of the adnexal structures is absent. The pelvic organs are normal in primary dysmenorrhea.

Diagnosis

To diagnose primary dysmenorrhea, it is necessary to rule out underlying pelvic pathology and confirm the cyclic nature of the pain. The differential diagnosis of secondary dysmenorrhea includes primary dysmenorrhea and noncyclic pelvic pain. Whereas the diagnosis of primary dysmenorrhea is based on history and presence of a normal pelvic examination, the diagnosis of secondary dysmenorrhea may require review of a pain diary and an ultrasound examination or laparoscopy. During the pelvic examination, the size, shape, and mobility of the uterus, the size and tenderness of adnexal structures, and nodularity or fibrosis of uterosacral ligaments or rectovaginal septum should be assessed. Cervical studies for gonorrhea and chlamydia and, if relevant, a complete blood count with an ESR are helpful to rule out subacute salpingo-oophoritis. If no abnormalities are found, a tentative diagnosis of primary dysmenorrhea can be established.

Treatment

Prostaglandin synthase inhibitors are effective for the treatment of primary dysmenorrhea in about 80% of women (18,19). The inhibitors should be taken just before or at the onset of pain and then continuously every 6 to 8 hours to prevent reformation of prostaglandin by-products. The medication should be taken for the first few days of menstrual flow. A 4- to 6-month course of therapy is warranted before confirming treatment failure. Changes in dosages and types of inhibitors should be attempted if initial treatment is not successful. The medication may be contraindicated in patients with gastrointestinal ulcers or bronchospastic hypersensitivity to aspirin. Side effects are usually mild and include nausea, dyspepsia, diarrhea, and occasionally fatigue.

For the patient with primary dysmenorrhea who has no contraindications to oral contraceptive agents or who desires contraception, the oral contraceptives are the agent of choice. Oral contraceptives decrease endometrial proliferation and create an endocrine milieu similar to the early proliferative phase, when prostaglandin levels are lowest. More than 90% of women with primary dysmenorrhea experience relief with oral contraception (20). If the patient does not respond to this regimen, hydrocodone or codeine may be added for 2 to 3 days per month; however, before addition of the narcotic medication, psychological factors and other organic pathology should be ruled out with diagnostic laparoscopy. Pain management, in particular acupuncture or transcutaneous electrical nerve stimulation (TENS), may also be useful (21,22 and 23). In one study of women with primary dysmenorrhea undergoing TENS, 30% reported marked pain relief, 60% moderate pain relief, and 10% no relief (24). To evaluate more fully the evidence for treating primary dysmenorrhea with TENS and acupuncture, a forthcoming study by the Cochrane Library aims to analyze all prospective randomized controlled trials comparing these modalities with medical treatment or placebo (25). Methods used only rarely to treat primary dysmenorrhea include surgical laparoscopic uterine nerve ablation and presacral neurectomy.

Secondary Dysmenorrhea

Secondary dysmenorrhea usually occurs years after the onset of menarche. The definition does not reflect age of onset but rather is cyclic menstrual pain that occurs in association with underlying pelvic pathology. The pain of secondary dysmenorrhea often begins 1 to 2 weeks before menstrual flow and persists until a few days after the cessation of bleeding. The mechanisms underlying secondary dysmenorrhea are diverse and not fully elucidated, although most involve either excess prostaglandin production or hypertonic uterine contractions secondary to cervical obstruction, intrauterine mass, or the presence of a foreign body. However,

nonsteroidal antiinflammatory agents and oral contraceptive pills are less likely to provide pain relief in women with secondary dysmenorrhea than in those with primary dysmenorrhea. The most common cause of secondary dysmenorrhea is endometriosis, followed by adenomyosis and intrauterine device (for a discussion of endometriosis, see diagnosis of acute and chronic pain, this chapter and [Chapter 26](#)). The differential diagnosis of secondary dysmenorrhea is outlined in [Table 14.3](#). The management of secondary dysmenorrhea is treatment of the underlying disorder.

Adenomyosis

Dysmenorrhea associated with adenomyosis often begins up to a week before menses and may not resolve until after the cessation of menses. Associated dyspareunia, dyschezia, and metrorrhagia increase the probability of the diagnosis. Whereas endometriosis is characterized by ectopic endometrium appearing within the peritoneal cavity, adenomyosis is defined as presence of endometrial tissue within the myometrium, at least one high-power field from the basis of the endometrium. Adenomyosis, endometriosis, and uterine leiomyomas frequently coexist. Although occasionally noted in women in the younger reproductive years, the average age of symptomatic women is usually older than 40 years.

Symptoms

Adenomyosis often is asymptomatic. Symptoms typically associated with adenomyosis include excessively heavy or prolonged menstrual bleeding and dysmenorrhea, often beginning up to a week before the onset of a menstrual flow.

Signs

The uterus is diffusely enlarged, although usually less than 14 cm in size, and is often soft and tender, particularly at the time of menses. Mobility of the uterus is not restricted, and there is no associated adnexal pathology.

Diagnosis

Adenomyosis is a clinical diagnosis, and imaging studies, although helpful, are not definitive. Because of their cost and negligible improvement in diagnostic accuracy, these studies are not recommended routinely. In women with diffuse uterine enlargement and a negative pregnancy test, secondary dysmenorrhea may be attributed to adenomyosis; however, the pathologic confirmation of suspected adenomyosis can be made only at the time of hysterectomy. In one study to confirm preoperative diagnosis of adenomyosis before hysterectomy, the clinical diagnosis of adenomyosis was confirmed in only 48% of the cases ([26](#)).

Management

The management of adenomyosis clearly depends on the patient's age and desire for future fertility. Relief of secondary dysmenorrhea due to adenomyosis can be ensured after hysterectomy, but less invasive approaches can be tried initially. Nonsteroidal antiinflammatory agents, oral contraceptives, and menstrual suppression using progestins have all been found to be useful.

Chronic Pelvic Pain

Chronic pelvic pain remains an inclusive, general diagnosis that encompasses many more specific causes from endometriosis to nerve entrapment syndrome. Various forms of chronic pelvic pain affect 12% to 15% of women in the United States ([27](#)). The differential diagnosis of chronic pelvic pain is outlined in [Table 14.3](#). Patients with chronic pelvic pain are frequently anxious and depressed. Their marital, social, and occupational lives have usually been disrupted. These patients have often had poor treatment outcomes after traditionally effective gynecologic and medical therapy and may have undergone multiple unsuccessful surgical procedures for pain. About 12% of hysterectomies are performed for pelvic pain, and 30% of patients who present to pain clinics have already had a hysterectomy ([28,29](#)). **Anywhere from 20% to 80% of patients undergoing laparoscopy for chronic pelvic pain have no intraperitoneal pathology or have tissue distortion that does not correlate with the pain ([2](#)).** Additionally, the relationship can be inconsistent between the pain response and certain types of prevalent intraperitoneal pathology, such as endometriosis, adhesions, or venous congestion ([2](#)). Nongynecologic causes of pain, such as irritable bowel syndrome, interstitial cystitis, abdominal wall or pelvic floor myofascial syndrome, or nerve entrapment, are frequently overlooked but common causes of chronic pelvic pain.

Recent investigations have suggested that “plasticity” of the nervous system or alterations in signal processing may be involved in the maintenance of painful states ([2,4,30](#)). Various neurohumoral modulators, such as prostaglandins, vasoactive intestinal peptide, substance P, and endorphins, can modulate peripheral neurotransmission and also affect neurotransmission at the level of the spinal cord ([31](#)). The spinal cord is not a simple conduit between the periphery and the brain. It is an important site of “gating” mechanisms, such as excitation, inhibition, convergence, and summation of neural stimuli ([32](#)). The pain sensation is also modified by neurotransmitters within the brain, such as norepinephrine, serotonin, and g-aminobutyric acid (GABA), as well as by endogenous endorphin and nonendorphin algesic systems. Different regions of the brain are also important in altering the sensory and affective components of the pain response. **Evidence from animal studies indicates that supraspinal factors can interact at the level of the dorsal horn to modulate the sensory perception of pain from the pelvic viscera ([33](#)).** The sensory and affective component of pain is affected by early experience, conditioning, fear, arousal, depression, and anxiety ([30,34](#)).

Evaluation of Chronic Pelvic Pain

[Figure 14.3](#) outlines an approach to the patient with chronic pelvic pain. On the first visit, a thorough pain history should be performed, addressing the nature of each pain complaint: location, radiation, severity, aggravating and alleviating factors; effect of menstrual cycle, stress, work, exercise, intercourse, and orgasm; the context in which pain arose; and the social and occupational toll of the pain.

Figure 14.3 Evaluation of chronic pelvic pain.

The patient should be questioned about symptoms specific to the types of pathology (see [Table 14.3](#)):

1. Genital (abnormal vaginal bleeding, discharge, dysmenorrhea, dyspareunia, infertility)
2. Enterocoelic (constipation, diarrhea, flatulence, hematochezia, and relationship of pain to bowel movements)
3. Musculoskeletal (trauma, exacerbation with exercise, or postural changes)
4. Urologic (urgency, frequency, nocturia, dysuria, incontinence, hematuria)

The history should include gynecologic, medical, and surgical factors; medication intake; prior evaluations for pain; and operative and pathology reports ([2](#)). Symptoms

of an acute process (fever, anorexia, nausea, emesis, significant diarrhea, obstipation, abdominal distention, undiagnosed uterine bleeding, pregnancy, or recent abortion) should alert the physician to the possibility of an acute condition requiring immediate medical or surgical intervention. This occurrence is especially important if symptoms are accompanied by elevated temperature, orthostasis, peritoneal signs, pelvic or abdominal mass, abnormal complete blood count, positive genital or urinary tract cultures, or a positive pregnancy test.

A complete physical examination should be performed, with particular attention directed to the abdominal, lumbosacral, external genital, vaginal, bimanual, and rectovaginal examination. The examination should include evaluation of the abdomen with muscles tensed (head raised off the table or with straight leg raising) to differentiate abdominal wall and visceral sources of pain. Abdominal wall pain is augmented and visceral pain is diminished with these maneuvers (35,36). The patient should be examined while standing for hernias, both abdominal (inguinal and femoral) and pelvic (cystocele and enterocele). An attempt should be made to locate by palpation the tissues that reproduce the patient's pain. If abdominal wall sources of pain are noted, it is useful to block these areas with local anesthetics and then perform the pelvic examination (35,36).

The Psychological Component

A pain history includes the current and past psychological history addressing psychosocial factors; history of past (or current) physical, sexual, or emotional abuse; history of psychiatric hospitalization; suicide attempts; and chemical dependency (2). The attitude of the patient and her family toward the pain, resultant behavior of the patient and her family, and current upheavals in the patient's life should be discussed. The part of the history addressing sensitive issues may have to be reobtained after establishing rapport with the patient.

It is vital to appreciate the various influences that can distort pain perception and expression. A distinction can be drawn between factors leading to a painful condition and those now maintaining it. Whatever the original cause of the pain, when pain has persisted for any length of time, it is likely that other factors are now maintaining or at least contributing to it. The full physical evaluation, outlined previously, should be accompanied by a review of psychosocial factors. Pain is commonly accompanied by anxiety and depression, and these conditions need to be carefully assessed and treated (2). In a typical gynecologic setting, referral to a psychologist for parallel evaluation can evoke resistance. The inference is drawn that the referring physician is ascribing the pain to psychological causes. The patient needs to understand the reason for this referral and to be reassured that it is a routine and necessary part of the evaluation.

Gynecologic Causes

The most common gynecologic pathologies noted at the time of laparoscopy performed for chronic pelvic pain are endometriosis and adhesions. For a thorough discussion of endometriosis and treatment, see [Chapter 26](#).

Other Gynecologic Pathology: Leiomyomas, Ovarian Tumors, Pelvic Relaxation

Patients with obvious gynecologic pathology, such as benign or malignant ovarian cysts, uterine leiomyomas of sufficient size to encroach on supporting ligaments or other somatic structures, or significant pelvic relaxation should be evaluated and managed as is appropriate for the underlying condition (see [Chapter 13](#) and [Chapter 20](#)). Pain associated with these conditions is generally not severe, and appropriate surgical management is therapeutic.

Endometriosis

Endometriosis can be demonstrated in 15% to 40% of patients undergoing laparoscopy for chronic pelvic pain (37). Endometriosis produces a low-grade inflammatory reaction (38). However, the cause of the pain is not well established. There is no correlation between the location of disease and pain symptoms (39,40). There also appears to be no relationship between the incidence or severity of pain and the stage of the endometriotic lesions, and as many as 30% to 50% of patients have no pain regardless of stage. Similarly, 40% to 60% of patients have no tenderness on examination regardless of stage (40). However, deeply infiltrating rectovaginal septum lesions are strongly associated with pain (41,42), and **vaginal and uterosacral endometrioses are associated with complaints of deep dyspareunia (43).** Prostaglandin E and F_{2a} production from explants of petechial lesions present in mild, low-stage disease was found to be significantly greater than from the explants of powder-burn or black lesions, which are more common in patients with higher-stage endometriosis (44). Therefore, prostaglandin production may account for severe pain in some patients with mild disease.

Clinically, it is possible to determine whether there is a relationship between pain and endometriosis because of the hormonal sensitivity of the disease. **It has been debated whether a laparoscopic diagnosis of chronic pelvic pain secondary to endometriosis is necessary to initiate treatment. Recent reports have suggested otherwise, including one study that showed significant efficacy of gonadotropin-releasing hormone (GnRH) agonist treatment based on empirical diagnosis (45).** After induction of a hypoestrogenic state with GnRH analogues, those patients with pelvic pain and dysmenorrhea related to endometriosis should experience relief. The pain relief usually occurs within 2 months of treatment, but pain often returns to the pretreatment level by 18 months after treatment (46). **During long-term (12 or more months) treatment with GnRH analogues, hormonal add-back therapy (i.e., norethindrone acetate, 5 mg daily, with or without estrogen) prevents the long-term hypoestrogenic side effects, such as bone loss, with continued pain relief (47).** Intermenstrual pain that is not as consistently associated with endometriosis as is dysmenorrhea is somewhat less responsive to hormonal manipulation. **Endometriosis may benefit from surgical intervention, such as electrodissection, laser vaporization, or excision. In fact, in one recent prospective, randomized, double-blinded study with 63 women, laparoscopic laser treatment benefited 90% of women who initially responded at 1-year follow-up (48).**

Adhesions

Adhesions noted at the time of laparoscopy are often in the same general region of the abdomen as the pelvic pain complaint (49); however, **neither the specific location (i.e., adnexa structures, parietal, visceral peritoneum, or bowel) nor density of the adhesions correlates consistently with the presence of pain symptoms (50).** Uncontrolled prospective studies of adhesiolysis have not consistently demonstrated a significant reduction in pain scores (51). In one study of lysis of adhesions, a subgroup of women with anxiety, depression, multiple somatic symptoms, and social and occupational disruption responded poorly to adhesiolysis. The group without these symptoms did have significant improvement in pain (51). A prospective study, however, noted a significant improvement in pain on two of three methods of assessment only if the adhesions were dense and involved the bowel (52).

Symptoms

Noncyclic abdominal pain, sometimes increased with intercourse or activity, is a common pain complaint in women with adhesions, but there is no symptom pattern specific for adhesions. **Chronic pelvic pain developing from adhesions likely results from restriction of bowel mobility and distention (53).** Furthermore, dense adhesions involving bowel can result in a partial or complete bowel obstruction.

Signs

The abdominal wall must be carefully elevated for myofascial or neurologic sources of pain. Most women with adhesions will have had a prior surgical procedure with possible injury to abdominal wall structures that may be the cause of pain. Decreased mobility of pelvic organs or adnexal enlargement can often be noted in patients with adhesions.

Diagnosis

Diagnostic laparoscopy is recommended if other somatic causes are ruled out and the results of the psychological evaluation are negative. **Recent advances in microlaparoscopy have enabled the development of a new technique known as "conscious pain mapping," whereby physicians may better locate the specific adhesions associated with pelvic pain using local anesthesia and conscious sedation (54).** In an observational study of 50 women using local anesthesia, manipulation of appendiceal and pelvic adhesions contributed to observed pelvic pain (55). Further studies are needed to correlate the lysis of such painful adhesions with pain relief.

Management

At this time, the causal role of adhesions in the genesis of pelvic pain is uncertain, and lysis is recommended only after thorough multidisciplinary evaluation and in the context of an integrated treatment approach that addresses stress, mood, and associated behavioral responses. Repeated surgical procedures for lysis are not recommended.

Pelvic Congestion

In 1954, Taylor suggested that emotional stress could lead to autonomic nervous system dysfunction manifested as smooth muscle spasm and congestion of the veins draining the ovaries and uterus (56). Transuterine venography in women with chronic pelvic pain often reveals delayed disappearance of contrast medium from the uterine and ovarian veins (57). Considering that pregnant and postpartum women have asymptomatic pelvic congestion, the role of congested veins in the causation of pelvic pain is uncertain. The specific neurotransmitters involved in mediating sympathetic efferent maintained pain syndrome are unknown.

Signs and Symptoms

Typical symptoms include lower abdominal and back pain, secondary dysmenorrhea, dyspareunia, abnormal uterine bleeding, chronic fatigue, and irritable bowel symptoms. Pain usually begins with ovulation and lasts until the end of menses. The uterus is often bulky, and the ovaries are enlarged with multiple functional cysts. The uterus, parametria, and uterosacral ligaments are tender.

Diagnosis

Transuterine venography has been the primary method for diagnosis, although other modalities, such as pelvic ultrasound, magnetic resonance imaging, and laparoscopy, may demonstrate varicosities (58). Because of the cost and possible side effects of treatment, further management should be based on related symptoms and not simply on the presence of varicosities.

Management

Treatment of suspected pelvic congestion ranges from the less invasive hormonal suppression and cognitive behavioral pain management to the more invasive ovarian vein embolization or hysterectomy. Low-estrogen, progestin-dominant continuous oral contraceptives, high-dose progestins, and GnRH analogues often provide pain relief. Hormonal suppression should be the initial mode of treatment for women with suspected pelvic congestion. *Medroxyprogesterone acetate*, 30 mg daily, has been found to be useful (59). Concurrently, a multidisciplinary approach incorporating psychotherapy, behavioral pain management, or both is important. A positive interaction between medroxyprogesterone acetate and pain management has been noted (59). **Technically more invasive, transcatheter embolotherapy selectively catheterizes the ovarian and internal iliac veins, followed by contrast venography and embolization (60). Several small, uncontrolled studies with limited follow-up have reported pain reduction with transcatheter embolization of pelvic veins (61,62 and 63).** For women who have completed their childbearing, hysterectomy with possible oophorectomy is a reasonable option.

Salpingo-oophoritis

Patients with salpingo-oophoritis usually present with symptoms and signs of acute infection. Atypical or partially treated infection may not be associated with fever or peritoneal signs. Subacute or atypical salpingo-oophoritis is often a sequela of chlamydia or mycoplasma infection. Alternatively, a patient with multiple partners may develop frequent recurrent infections (64). Patients with initial gonococcal PID are more likely to develop recurrent infections (65). The mechanism for this increased susceptibility to future infections has not been delineated, although it has been suggested that the fallopian tube and cervix may lose some of their natural protective mechanisms against microorganisms.

Abdominal tenderness, cervical motion, and bilateral adnexal tenderness are typical of pelvic infection. A complete blood count and ESR as well as cervical study for gonorrhea and chlamydia should be performed. In all situations, laparoscopy, with peritoneal fluid cultures, is usually diagnostic. Patients with either abnormal ESR or abnormal clinical examination should be treated empirically for salpingo-oophoritis before laparoscopy.

Ovarian Remnant Syndrome

Chronic pelvic pain in a patient who has had a hysterectomy and bilateral salpingo-oophorectomy for severe endometriosis or PID may be caused by the ovarian remnant syndrome. Ovarian remnant syndrome results from residual ovarian cortical tissue that is left *in situ* after a difficult dissection in an attempt to perform an oophorectomy. Often, the patient has had multiple pelvic operations with the uterus and adnexa removed sequentially.

Symptoms

The patient usually complains of lateralizing pelvic pain, often cycling with ovulation or the luteal phase, described as sharp and stabbing or as constant, dull, and nonradiating, possibly with associated genitourinary or gastrointestinal complaints (66). Symptoms tend to arise 2 to 5 years after initial oophorectomy. A tender mass in the lateral region of the pelvis is pathognomonic.

Diagnosis

Ultrasonography usually confirms a mass with the ultrasonographic characteristics of ovarian tissue. In a patient who has had bilateral salpingo-oophorectomy and is not taking hormonal replacement, estradiol and follicle-stimulating hormone (FSH) assays reveal a characteristic premenopausal picture, although on occasion the remaining ovarian tissue may not be active enough to suppress FSH levels (67,68).

Management

Initial medical treatment with either *danazol*, high-dose progestins, or oral contraceptives usually provides mixed results. Patients usually experience relief of pain with a GnRH agonist, although these medications are impractical for long-term therapy. **Those who achieve relief with GnRH agonists also were relieved by subsequent surgery (69).** Laparoscopic examination is usually nonproductive because the ovarian mass may be missed or adhesions may prevent accurate diagnosis. Laparotomy is necessary for treatment, and the corrective surgery tends to be arduous, often involving inadvertent cystotomy, enterotomy, postoperative small bowel obstructions, and hematoma formation. Surgical pathology usually reveals the presence of ovarian tissue, sometimes with endometriosis, corpus lutea or follicle cysts, and fibrous adhesions (67,68).

Gastroenterologic Causes

The uterus, cervix, and adnexa share with the lower ileum, sigmoid colon, and rectum the same visceral innervation, with pain signals traveling through sympathetic nerves to spinal cord segments T10 to L1 (70). It is often difficult, therefore, to determine whether lower abdominal pain is of gynecologic or enterocoelic origin. Skillful medical history and examination are necessary to distinguish gynecologic from gastrointestinal etiology of pain.

P>

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is one of the more common causes of lower abdominal pain and may account for up to 60% of referrals to the gynecologist for chronic pelvic pain (70). The exact etiology of IBS is unknown; however, patients with IBS have pain with smaller volume of distention of the bowel than those without IBS (71). These patients also have an abnormal pain referral pattern with colonic distention. Visceral hypersensitivity or hyperalgesia has been postulated as the cause of

pain, although the cause of this hyperalgesia is not known (72).

Symptoms

The predominant symptom of IBS is abdominal pain. Other symptoms include abdominal distention, excessive flatulence, alternating diarrhea and constipation, increased pain before a bowel movement, decreased pain after a bowel movement, and pain exacerbated by events that increase gastrointestinal motility, such as high-fat diet, stress, anxiety, depression, and menses. The pain is usually intermittent, occasionally constant, cramplike, and more likely to occur in the left lower quadrant. The criteria for diagnosis include at least 12 weeks (not necessarily consecutive) in the preceding 12 months of abdominal discomfort or pain that has at least two of the following features: relief with defecation, onset associated with change in stool frequency, or onset associated with change in form (appearance) of stool.

Signs

On physical examination, the finding of a palpable tender sigmoid colon or discomfort during insertion of the finger into the rectum and finding hard feces in the rectum are suggestive of IBS (70).

Diagnosis

The diagnosis of IBS is usually based on history and physical examination, and although suggestive, especially in young women, the findings are not specific. In one study, 91% of patients with IBS had two or more IBS symptoms (abdominal distention, relief of pain with bowel movement, more frequent bowel movements with the onset of pain, looser bowel movements with the onset of pain), whereas 30% of patients with organic disease had two or more of these symptoms (73). Therefore, a complete blood count, stool sample to test for white cells and occult blood, and sigmoidoscopy or colonoscopy or barium enema are usually required, particularly in older individuals and in young individuals who have not responded to initial treatment. The results of these studies are all normal in patients with IBS.

Management

Current medical therapy for IBS is generally unsatisfactory, and placebo response rates are high (74). A multidisciplinary program consisting of medical and psychological approaches is recommended. The treatment consists of reassurance, education, stress reduction, bulk-forming agents, and low-dose tricyclic antidepressants. The multidisciplinary management approach addresses the cognitive, affective, and behavioral components of the pain. Therapy may decrease the intensity of nociceptor stimulation as well as change the interpretation of the meaning of pain.

Inflammatory bowel disease, such as Crohn's disease or ulcerative colitis, infectious enterocolitis, intestinal neoplasms, appendicitis, and hernia must be ruled out with appropriate history and physical examination, complete blood count, and stool cultures as well as visualization of colonic mucosa when appropriate.

Urologic Causes

Chronic pelvic pain of urologic origin may be related to recurrent cystourethritis, urethral syndrome, sensory urgency of uncertain cause, as well as interstitial cystitis. With an appropriate diagnostic workup, infiltrating bladder tumors, ureteral obstruction, renal lithiasis, and endometriosis can easily be ruled out as possible causes.

Urethral Syndrome

Urethral syndrome is defined as a symptom complex including dysuria, frequency and urgency of urination, suprapubic discomfort, and often dyspareunia in the absence of abnormality of urethra or bladder. The cause of urethral syndrome is uncertain and has been attributed to a subclinical infection, urethral obstruction, and psychogenic and allergic factors (75).

Symptoms

Urinary urgency, frequency, suprapubic pressure, and other less frequent symptoms such as bladder or vaginal pain, urinary incontinence, postvoid fullness, dyspareunia, and suprapubic pain are commonly observed.

Signs

Physical and neurologic examinations should be performed. The anal reflex should document that S2 to S4 spinal segments have not been interrupted (75). Anatomic abnormalities, including pelvic relaxation, urethral caruncle, and hypoestrogenism, should be evaluated. The patient should also be evaluated for vaginitis. The urethra should be carefully palpated to detect purulent discharge.

Diagnosis

A clean catch or catheterized urine specimen for routine urinalysis and culture should be obtained to rule out urinary tract infection. As indicated, urethral and cervical cultures for chlamydia should be obtained, and a wet prep for vaginitis should be performed. Urethral syndrome should be considered if the results of urine and urethral cultures are negative, the evaluation does not disclose vulvovaginitis, and no allergic phenomenon causing contact dermatitis of the urethra can be detected. Ureoplasma, chlamydia, candida, trichomonas, gonorrhea, and herpes should be ruled out. Cystoscopic evaluation should be performed to rule out urethral diverticulum, interstitial cystitis, and cancer.

Management

Various forms of therapy have been suggested for urethral syndrome. Those patients in whom no infectious agent is present but who have sterile pyuria respond to a 2- to 3-week course of *doxycycline* or *erythromycin* (75). Long-term, low-dose antimicrobial prophylaxis is often used in women with urgency and frequency symptoms who have had a history of recurrent urinary tract infections. Some of these women may continue to have symptoms when their urine is not infected and then redeveloped bacteria over time (75). It is recommended that all postmenopausal women be given a trial of local estrogen therapy for about 2 months. If there is no improvement after antibiotic or estrogen therapy, urethral dilation can be considered. Positive results also have been noted with biofeedback techniques (75).

Interstitial Cystitis

Interstitial cystitis occurs more often in women than men. Most patients are between 40 and 60 years of age. The cause of interstitial cystitis is unknown, although an autoimmune etiology is generally accepted (75).

Symptoms

Symptoms include severe and disabling urinary frequency and urgency, nocturia, dysuria, and occasional hematuria. Suprapubic, pelvic, urethral, vaginal, or perineal pain is common and can be relieved partially by emptying of the bladder.

Signs

Pelvic examination usually reveals anterior vaginal wall and suprapubic tenderness. Urinalysis may reveal microhematuria without pyuria, although results may be normal.

Diagnosis

The diagnosis is based on symptoms and characteristic cystoscopic findings ([75,76](#)). Cystoscopy performed in the awake patient may reveal only bladder hypersensitivity; under anesthesia, however, with sufficient distention of the bladder, submucosal hemorrhages and cracking of the mucosa may be noted ([70](#)). Although the histologic features of the biopsy specimen are nonspecific, there is usually submucosal edema, vasodilation, and infiltration by macrophages, plasma cells, and eosinophils.

Management

Because the etiology is uncertain, management has been empirical. Various pharmaceutical approaches, including anticholinergic, antispasmodic, and antiinflammatory agents, have been used. **Response to treatment also has been noted with the use of tricyclic antidepressants or *pentosan polysulfate sodium*, which is approved for therapy ([77](#)).** Hydrostatic bladder distention may produce temporary relief by creating detrussor ischemia and decreased innervation of the bladder wall. Biofeedback and behavioral therapy has also been used with some success ([75](#)).

Neurologic and Musculoskeletal Causes

Nerve Entrapment

Abdominal cutaneous nerve injury or entrapment may occur spontaneously or within weeks to years after transverse suprapubic skin or laparoscopy incisions ([35,78](#)). The ilioinguinal or ileohypogastric nerves may become trapped between the transverse and internal oblique muscles, especially when the muscles contract. Alternatively, the nerve may be ligated or traumatized during the surgery. Symptoms of nerve entrapment include burning, aching pain in the dermatomal distribution of the involved nerve ([79,80](#)). Hip flexion and exercise exacerbate pain. The pain is usually judged as coming from the abdomen, not the skin.

Signs

On examination, the pain usually can be localized with the fingertip. The maximal point of tenderness in an iliohypogastric or ilioinguinal injury is usually at the rectus margin, medial and inferior to the anterior iliac spine. Tentative diagnosis is confirmed with the diagnostic nerve block with 0.25% *bupivacaine*. Patients usually report immediate relief of symptoms after injection, and at least 50% experience relief lasting longer than a few hours ([35](#)).

Management

Many patients may require no further intervention, although some patients require up to five biweekly injections. If injection is successful in producing only limited pain relief and there are no contributory visceral or psychological factors, cryoneurolysis or surgical removal of the involved nerve is recommended.

Myofascial Pain

Myofascial syndrome has been documented in about 15% of patients with chronic pelvic pain ([81](#)). These patients are noted to have trigger points if examined carefully ([82](#)). Trigger points are initiated by pathogenic autonomic reflex of visceral or muscular origin ([82,83](#)). The referred pain of the trigger point occurs in a dermatomal distribution, and it is thought to be due to nerves from the muscle or deeper structures sharing a common second-order neuron in the spinal cord. Painful trigger points characteristically can be abolished with the injection of local anesthetic into the painful points ([82](#)). Trigger points are often present in women with chronic pelvic pain irrespective of presence or type of underlying pathology. In one study, 89% of women with chronic pelvic pain had abdominal, vaginal, or lumbosacral trigger points ([82](#)). In the absence of the initial or continued organic pathology, various factors are theorized to predispose to the chronicity of the myofascial syndrome, including psychological, hormonal, and biomechanical factors ([83,84](#)).

Symptoms

Abdominal wall pain is often exacerbated during the premenstrual period or by stimuli to the dermatome of trigger points (e.g., full bladder, bowel, or any stimulation to organs that share the dermatome of the involved nerve) ([36](#)).

Signs

On examination, fingertip pressure on the trigger points evokes local and referred pain. Tensing of the rectus muscles by either straight leg lifting or raising the head off the table increases the pain. A specific jump sign can be elicited by palpation with fingertip or a cotton swab. An electric (tingling) sensation confirms correct needle placement ([36,82](#)).

Management

Injection of the trigger point with 3 mL of 0.25% bupivacaine provides relief that usually outlasts the duration of the anesthetic action. After four to five biweekly injections, the procedure should be abandoned if long-lasting relief is not obtained ([82](#)). Concomitant with injection of trigger points, multidisciplinary pain management should be undertaken, especially if anxiety, depression, history of physical or sexual abuse, sexual dysfunction, or social or occupational disruption are present.

Low Back Pain Syndrome

Women complaining of lower back pain without pelvic pain rarely have gynecologic pathology as the cause of their pain. However, low back pain may accompany gynecologic pathology. Back pain may be caused by gynecologic, vascular, neurologic, psychogenic, or respondologenic (related to the axial skeleton and its structure) pathology ([2](#)).

Symptoms

Women with low back pain syndrome often have pain occurring after trauma or physical exertion, in the morning on arising, or with fatigue. Nongynecologic low back pain can intensify with the menstrual cycle.

Signs

Examination consists of inspection, evaluation with movement, and palpation. Various anatomic structures in the spine should be considered as sources of pain. Muscles, vertebral joints, and disks (including lumbosacral junction, paravertebral sacrospinal muscles, and sacroiliac joints) are common sources of spondylogenic pain that must be examined carefully ([2,85](#)).

Diagnosis

Diagnostic imaging studies performed while the patient is standing, lying, and sitting with maximal flexion can be helpful. An elevated ESR suggests pain of inflammatory or neoplastic origin.

Management

Orthopedic or rheumatologic consultation should be sought before initiating management for back pain unless the source could be referred gynecologic pain.

Psychological Factors

From a psychological perspective, various factors may promote the chronicity of pain, including the meaning attached to the pain, anxiety, the ability to redirect attention, personality, mood state, past experience, and reinforcement contingencies that may amplify or attenuate pain (2). The Minnesota Multiphasic Personality Inventory (MMPI) studies of women with chronic pelvic pain reveal a high prevalence of a convergence “V” profile (elevated scores on the hypochondriasis, hysteria, and depression scales). Studies of MMPI profiles of women with chronic pain without obvious pathology compared with women with endometriosis-related pain or controls suggest that MMPI profiles are unable to distinguish patients with obvious organic findings. Both pain groups differ from controls (2). **Furthermore, treatment resulting in subjective improvement in pain severity and increased activity level produces a significant improvement in personality profile (86).**

There is also a close relationship between depression and pain (87). Both give rise to similar behavior, such as behavioral and social withdrawal and decreased activity, and may be mediated by the same neurotransmitters, including as norepinephrine, serotonin, and endorphins (2). Antidepressants appear to relieve both depression and pain. Childhood physical and sexual abuse has also been noted to be more prevalent in women with chronic pelvic pain than those with other types of pain and controls (52% versus 12%) (88). **In a comparison of women with chronic pelvic pain, women with nonpelvic chronic pain (headache), and pain-free women, a higher lifetime prevalence of major sexual abuse (56%) and physical abuse (50%) was found in the chronic pelvic pain group (89).** Individual differences in personality and habitual coping strategies may also influence response to pain and pain recurrence.

Management Approach

In patients with no obvious pathology and in those with pathology that has an equivocal role in pain production, multidisciplinary therapy is usually preferable. This approach incorporates the skills of the gynecologist, psychologist, and ideally anesthesiologist. A low dose of a tricyclic antidepressant is combined with behavioral therapy directed toward reducing reliance on pain medication, increasing activity, and relieving the impact the pain has on the women's overall lifestyle (2). Women with depression should be treated with an appropriate therapeutic dose of antidepressant medication (90). **Only one small, randomized, controlled trial has looked at the effect of selective serotonin reuptake inhibitors on pelvic pain. It failed to show a significant difference in pain or functional ability in a short follow-up period (91).** The approach to women with chronic pain must be therapeutic, supportive, and sympathetic. Offering regular follow-up appointments instead of asking the patient to return only if pain persists reinforces pain behavior. Specific skills can be taught to the patient using cognitive behavioral approaches. Women are offered ways to enhance opportunities for control of pain. Psychotherapy is indicated for women who have pronounced depression, sexual difficulties, or indications of past trauma. Various strategies, including relaxation techniques, stress management, sexual and marital counseling, hypnosis, and other psychotherapeutic approaches, have been found to be useful. Acupuncture may also be helpful (92). Diagnostic uterosacral, hypogastric, or epidural nerve blocks can be used (93).

Multidisciplinary Approach

Various studies of multidisciplinary pain management have been performed. Retrospective, uncontrolled studies revealed relief of pain in 85% of the subjects (92,94). One prospective randomized study revealed a similar response rate, which was significantly better than that of traditional therapy (95).

Surgical Therapy

Laparoscopy

Those women with disabling cyclic pain that does not respond to nonsteroidal antiinflammatory medication or oral contraceptives should undergo laparoscopic evaluation. Diagnostic laparoscopy has become a standard procedure in the evaluation of patients with chronic noncyclic pelvic pain; however, laparoscopy should be withheld until other nongynecologic somatic or visceral causes of pain have been eliminated. During diagnostic laparoscopy, endometriotic lesions should be excised for biopsy, and if infection is suspected, cultures should be performed. All visible endometriosis should be surgically excised or electrocoagulated. Patients with dysmenorrhea may benefit from transection of the uterosacral ligaments. The uterosacral ligaments carry the principal afferent nerve supply from the uterus to the hypogastric nerve. The original procedure was performed by a colpotomy and was noted to have a success rate of 70% (96). Laparoscopic nerve ablation was found to relieve dysmenorrhea in 85% of patients (97). **Nonrandomized retrospective and prospective studies have suggested that diagnostic laparoscopy provides a positive psychological effect on the treatment of chronic pelvic pain (98).**

Lysis of Adhesions

The role of pelvic adhesions in pain is unclear (2). Adhesiolysis, even by laparoscopy, is frequently complicated by adhesion reformation (99). However, other etiologies must be treated first. Psychological consultation and management should precede or accompany the lysis of adhesions.

Presacral Neurectomy

Presacral neurectomy or sympathectomy was first described for dysmenorrhea (100). The discovery of highly successful medical therapies has largely supplanted presacral neurectomy; however, presacral neurectomy may be indicated for primary or secondary dysmenorrhea unrelieved by traditional therapy and unresponsive to multidisciplinary pain management. The response rate to presacral neurectomy for secondary dysmenorrhea varies between 50% and 75% (2,99). The neurectomy only relieves pain deriving from the cervix, uterus, and proximal fallopian tubes (T11 to L2). The nerve supply to the adnexal structures (T9 to T10) bypasses the hypogastric nerve. Therefore, lateralizing visceral pain is unlikely to be relieved by presacral neurectomy. Intraoperative complications, such as hemorrhage or ureteral injury, can occur in a small percentage of cases. The sacral nerve supply is unaffected by division of the presacral nerve; thus, normal micturition, defecation, and parturition are preserved. A local anesthetic hypogastric block performed under fluoroscopic guidance can help to predict the response to this operation.

Hysterectomy

Hysterectomy has often been performed to cure pelvic pain; however, 30% of patients presenting to pain clinics have already undergone hysterectomy without experiencing pain relief (28). Hysterectomy is particularly useful for women who have completed childbearing and have secondary dysmenorrhea or chronic pain related to endometriosis, to uterine pathology, such as adenomyosis, or to pelvic congestion. Before recommending hysterectomy for pain or unilateral adnexectomy for unilateral pain, it is useful to apply the PREPARE mnemonic in discussions with the patient (101): the Procedure that is being done, Reason or indication, Expectation or desired outcome of the procedure, Probability that the outcome will be achieved, Alternatives and nonsurgical options, and Risks as well as Expense (see Chapter 3). Hysterectomy for central pelvic pain in women with dysmenorrhea, dyspareunia, and uterine tenderness provided relief of pain in 77% of women in one retrospective study (102) and in 74% of women in one prospective cohort study (103). Nevertheless, 25% of women in the retrospective study noted a persistence or worsening of pain at 1-year follow-up (104).

Genitourinary tract infections are among the most frequent disorders for which patients seek care from gynecologists. By understanding the pathophysiology of these diseases and having an effective approach to their diagnosis, physicians can institute appropriate antimicrobial therapy to treat these conditions and reduce long-term sequelae.

The Normal Vagina

Normal vaginal secretions are composed of vulvar secretions from sebaceous, sweat, Bartholin, and Skene glands; transudate from the vaginal wall; exfoliated vaginal and cervical cells; cervical mucous; endometrial and oviductal fluids; and microorganisms and their metabolic products. The type and amount of exfoliated cells, cervical mucus, and upper genital tract fluids are determined by biochemical processes that are influenced by hormone levels ([1](#)). Vaginal secretions may increase in the middle of the menstrual cycle because of an increase in the amount of cervical mucus. These cyclic variations do not occur when oral contraceptives are used and ovulation does not occur.

The vaginal desquamative tissue is made up of vaginal epithelial cells that are responsive to varying amounts of estrogen and progesterone. Superficial cells, the predominant cell type in women of reproductive age, predominate when estrogen stimulation is present. Intermediate cells predominate during the luteal phase because of progestogenic stimulation. Parabasal cells predominate in the absence of either hormone, a condition that may be found in postmenopausal women who are not receiving hormonal replacement therapy.

The normal vaginal flora is predominantly aerobic, with an average of six different species of bacteria, the most common of which is hydrogen peroxide-producing lactobacilli. The microbiology of the vagina is determined by factors that affect the ability of bacteria to survive ([2](#)). These factors include vaginal pH and the availability of glucose for bacterial metabolism. **The pH of the normal vagina is lower than 4.5, which is maintained by the production of lactic acid.** Estrogen-stimulated vaginal epithelial cells are rich in glycogen. Vaginal epithelial cells break down glycogen to monosaccharides, which can then be converted by the cells themselves and lactobacilli to lactic acid.

Normal vaginal secretions are floccular in consistency, white in color, and usually located in the dependent portion of the vagina (posterior fornix). Vaginal secretions can be analyzed by a wet-mount preparation. A sample of vaginal secretions is suspended in 0.5-mL of normal saline in a glass tube, transferred to a slide, covered with a slip, and assessed by microscopy. Some clinicians prefer to prepare slides by suspending secretions in saline placed directly on the slide. Secretions should not be placed on the slide without saline because this method causes drying of the vaginal secretions and does not result in a well-suspended preparation. Microscopy of normal vaginal secretions reveals many superficial epithelial cells, few white blood cells (less than 1 per epithelial cell), and few, if any, clue cells. **Clue cells are superficial vaginal epithelial cells with adherent bacteria, usually *Gardnerella vaginalis*, which obliterates the crisp cell border when visualized microscopically.** Potassium hydroxide 10% (KOH) may be added to the slide, or a separate preparation can be made, to examine the secretions for evidence of fungal elements. The results are negative in women with normal vaginal microbiology. Gram stain reveals normal superficial epithelial cells and a predominance of gram-positive rods (lactobacilli).

Vaginal Infections

Bacterial Vaginosis

Bacterial vaginosis (BV) has previously been referred to as nonspecific vaginitis or *Gardnerella* vaginitis. It is an alteration of normal vaginal bacterial flora that results in the loss of hydrogen peroxide-producing lactobacilli and an overgrowth of predominantly anaerobic bacteria ([3,4](#)). **The most common form of vaginitis in the United States is BV (5).** Anaerobic bacteria can be found in less than 1% of the flora of normal women. In women with BV, however, the concentration of anaerobes, as well as *G. vaginalis* and *Mycoplasma hominis*, is 100 to 1,000 times higher than in normal women. Lactobacilli are usually absent.

It is not known what triggers the disturbance of normal vaginal flora. It has been postulated that repeated alkalization of the vagina, which occurs with frequent sexual intercourse or use of douches, plays a role. After normal hydrogen peroxide-producing lactobacilli disappear, it is difficult to reestablish normal vaginal flora, and recurrence of BV is common.

Numerous studies have shown an association of BV with significant adverse sequelae. Women with BV are at increased risk for pelvic inflammatory disease (PID) ([6](#)), postabortal PID ([7](#)), postoperative cuff infections after hysterectomy ([8](#)), and abnormal cervical cytology ([9](#)). Pregnant women with BV are at risk for premature rupture of the membranes ([10](#)), preterm labor and delivery ([10](#)), chorioamnionitis, and postcesarean endometritis ([11](#)). It is not known whether screening for, and treatment of, BV will decrease the risk for these adverse sequelae.

Diagnosis

Bacterial vaginosis is diagnosed on the basis of the following findings ([12](#)):

1. A fishy vaginal odor, which is particularly noticeable following coitus, and vaginal discharge are present.
2. Vaginal secretions are gray and thinly coat the vaginal walls.
3. The pH of these secretions is higher than 4.5 (usually 4.7 to 5.7).
4. Microscopy of the vaginal secretions reveals an increased number of clue cells, and leukocytes are conspicuously absent. In advanced cases of BV, more than 20% of the epithelial cells are clue cells.
5. The addition of KOH to the vaginal secretions (the “whiff” test) releases a fishy, amine-like odor.

Culture of *G. vaginalis* is not recommended as a diagnostic tool because of its lack of specificity.

Treatment

Ideally, treatment of BV should inhibit anaerobes but not vaginal lactobacilli. The following treatments are effective ([13](#)):

1. *Metronidazole*, an antibiotic with excellent activity against anaerobes but poor activity against lactobacilli, is the drug of choice for the treatment of BV. A dose of 500 mg administered orally twice a day for 7 days should be used. Patients should be advised to avoid using alcohol during treatment with oral *metronidazole* and for 24 hours thereafter.
2. *Metronidazole* gel, 0.75%, one applicator (5 g) intravaginally once or twice daily for 5 days, may also be prescribed.
3. An alternative regimen uses a single, 2-g oral dose of *metronidazole*.

The overall cure rates range from 75% to 84% for the above regimens ([13](#)).

Clindamycin in the following regimens also is effective:

1. *Clindamycin* cream, 2%, one applicator full (5 g) intravaginally at bedtime for 7 days
2. *Clindamycin*, 300 mg, orally twice daily for 7 days
3. *Clindamycin* ovules, 100 mg, intravaginally once at bedtime for 3 days

Many clinicians prefer intravaginal treatment because of a lack of systemic side effects such as mild-to-moderate gastrointestinal upset and unpleasant taste. Treatment of the male sexual partner has not been shown to improve therapeutic response and therefore is not recommended.

Trichomonal Vaginitis

Trichomonal vaginitis is caused by the sexually transmitted, flagellated parasite, *Trichomonas vaginalis*. The transmission rate is high; 70% of males contract the disease after a single exposure to an infected female, which suggests that the rate of male-to-female transmission is even higher. The parasite is an anaerobe that has the ability to generate hydrogen to combine with oxygen to create an anaerobic environment. It exists only in trophozoite form. Trichomonal vaginitis often accompanies BV, which can be diagnosed in up to 60% of patients with trichomonal vaginitis.

Diagnosis

Local immune factors and inoculum size influence the appearance of symptoms. Symptoms and signs may be much milder in patients with a smaller inoculum of trichomonads, and trichomonal vaginitis often is asymptomatic ([14,15](#)).

1. Trichomonal vaginitis is associated with a profuse, purulent, malodorous vaginal discharge that may be accompanied by vulvar pruritus.
2. Vaginal secretions may exude from the vagina.
3. In patients with high concentrations of organisms, a patchy vaginal erythema and colpitis macularis (“strawberry” cervix) may be observed.
4. The pH of the vaginal secretions is usually higher than 5.0.
5. Microscopy of the secretions reveals motile trichomonads and increased numbers of leukocytes.
6. Clue cells may be present because of the common association with BV.
7. The whiff test may also be positive.

Morbidity associated with trichomonal vaginitis may be related to BV. Patients with trichomonal vaginitis are at increased risk for postoperative cuff cellulitis following hysterectomy ([8](#)). Pregnant women with trichomonal vaginitis are at increased risk for premature rupture of the membranes and preterm delivery. Because of the sexually transmitted nature of trichomonal vaginitis, women with this infection should be tested for other sexually transmitted diseases (STDs), particularly *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Serologic testing for syphilis and human immunodeficiency virus (HIV) infection should also be considered.

Treatment

The treatment of trichomonal vaginitis can be summarized as follows:

1. *Metronidazole* is the drug of choice for treatment of vaginal trichomoniasis. Both a single-dose (2 g orally) and a multidose (500 mg twice daily for 7 days) regimen are highly effective and have cure rates of about 95%.
 2. The sexual partner should also be treated.
 3. *Metronidazole* gel, although highly effective for the treatment of BV, should not be used for the treatment of vaginal trichomoniasis.
 4. Women who do not respond to initial therapy should be treated again with *metronidazole*, 500 mg, twice daily for 7 days. If repeated treatment is not effective, the patient should be treated with a single 2-g dose of *metronidazole* once daily for 3 to 5 days.
 5. Patients who do not respond to repeated treatment with *metronidazole* and for whom the possibility of reinfection has been excluded should be referred for expert consultation. In these uncommon refractory cases, an important part of management is to obtain cultures of the parasite to determine its susceptibility to *metronidazole*.
-

Vulvovaginal Candidiasis

It is estimated that as many as 75% of women experience at least one episode of vulvovaginal candidiasis (VVC) during their lifetimes ([16](#)). Almost 45% of women will experience two or more episodes ([17](#)). Fortunately, few are plagued with a chronic, recurrent infection. *Candida albicans* is responsible for 85% to 90% of vaginal yeast infections. Other species of *Candida*, such as *C. glabrata* and *C. tropicalis*, can cause vulvovaginal symptoms and tend to be resistant to therapy. *Candida* are dimorphic fungi existing as blastospores, which are responsible for transmission and asymptomatic colonization, and as mycelia, which result from blastospore germination and enhance colonization and facilitate tissue invasion. The extensive areas of pruritus and inflammation often associated with minimal invasion of the lower genital tract epithelial cells suggest that an extracellular toxin or enzyme may play a role in the pathogenesis of this disease. A hypersensitivity phenomenon also may be responsible for the irritative symptoms associated with VVC, especially for patients with chronic, recurrent disease. Patients with symptomatic disease usually have an increased concentration of these microorganisms (<10⁴/mL) compared with asymptomatic patients (<10³/mL) ([18](#)).

Factors that predispose women to the development of symptomatic VVC include antibiotic use ([19,20](#)), pregnancy ([21](#)), and diabetes ([22](#)). Through a mechanism referred to as *colonization resistance*, lactobacilli prevent the overgrowth of the opportunistic fungi. Antibiotic use disturbs the normal vaginal flora, decreasing the concentration of lactobacilli and other normal flora, and thus allowing an overgrowth of fungi. Pregnancy and diabetes are both associated with a qualitative decrease

in cell-mediated immunity, leading to a higher incidence of candidiasis.

Diagnosis

The symptoms of VVC consist of vulvar pruritus associated with a vaginal discharge that typically resembles cottage cheese.

1. The discharge can vary from watery to homogeneously thick. Vaginal soreness, dyspareunia, vulvar burning, and irritation may be present. External dysuria (“splash” dysuria) may occur when micturition leads to exposure of the inflamed vulvar and vestibular epithelium to urine. Examination reveals erythema and edema of the labia and vulvar skin. There may be discrete pustulopapular peripheral lesions. The vagina may be erythematous with an adherent, whitish discharge. The cervix appears normal.
2. The pH of the vagina in patients with VVC is usually normal (4,5).
3. Fungal elements, either budding yeast forms or mycelia, appear within as many as 80% of cases. The results of saline preparation of the vaginal secretions usually are normal, although there may be a slight increase in the number of inflammatory cells in severe cases.
4. The whiff test is negative.
5. A presumptive diagnosis can be made in the absence of microscopy-proven fungal elements if the pH and the results of the saline preparation are normal. A fungal culture is recommended to confirm the diagnosis.

Treatment

1. Topically applied azole drugs are the most commonly available treatment for VVC and are more effective than *nystatin* (13) (Table 15.1). Treatment with azoles results in relief of symptoms and negative cultures among 80% to 90% of patients who have completed therapy. Symptoms usually take 2 to 3 days to resolve. There is a trend to shorten the duration of therapy to 1 to 3 days. Although the shorter period of therapy implies a shortened duration of treatment, because the short-course formulations have higher concentrations of the antifungal agent, they cause an inhibitory concentration in the vagina that persists for several days.

Antifungal
Bucconazole
2% cream, 5 g intravaginally for 3 days ^a
2% cream, 5 g BUDOR, single intravaginal application ^b
Chlormerolol
1% cream, 5 g intravaginally for 2–34 days ^a
100-mg vaginal tablet for 7 days ^a
100-mg vaginal tablet, oral tablets for 3 days ^a
100-mg vaginal tablet, single dose ^a
Miconazole
2% cream, 5 g intravaginally for 7 days ^a
200-mg vaginal suppository for 3 days ^a
100-mg vaginal suppository for 7 days ^a
Propiconazole
100,000 Units vaginal tablet, one tablet for 14 days
Tioconazole
6.5% ointment, 5 g intravaginally, single dose ^a
Terconazole
0.4% cream, 5 g intravaginally for 7 days ^a
0.4% cream, 5 g intravaginally for 3 days ^a
80-mg suppository for 3 days ^a

Table 15.1 Vulvovaginal Candidiasis—Topical Treatment Regimens

2. An oral antifungal agent, *fluconazole*, used in a single 150-mg dose, has been approved for the treatment of VVC. It appears to have equal efficacy when compared with topical azoles in the treatment of mild-to-moderate VVC (23). Patients should be advised that their symptoms will not disappear for 2 to 3 days so that they will not expect additional treatment. Patients with severe symptoms may benefit from an additional 150-mg dose given 72 hours after the first dose.
3. Adjunctive treatment with a weak topical steroid, such as 1% *hydrocortisone* cream, may be helpful in relieving some of the external irritative symptoms.

Chronic Vulvovaginal Candidiasis

A small number of women develop chronic recurrent VVC. These women experience persistent irritative symptoms of the vestibule and vulva. Burning replaces itching as the prominent symptom in patients with chronic VVC. The diagnosis should be confirmed by direct microscopy of the vaginal secretions and by fungal culture.

Many women with chronic vaginitis presume that they have a chronic yeast infection when this is not the case. Many of these patients have chronic atopic dermatitis or atrophic vulvovaginitis.

The treatment of patients with chronic VVC consists of inducing a remission of chronic symptoms with *ketoconazole* (400 mg/day) or *fluconazole* (150 mg/3 days) until symptoms resolve. Patients should then be maintained on prophylactic doses of these agents (*ketoconazole*, 100 mg/d; *fluconazole*, 150 mg weekly) for 6 months (24).

Inflammatory Vaginitis

Desquamative inflammatory vaginitis is a clinical syndrome characterized by diffuse exudative vaginitis, epithelial cell exfoliation, and a profuse purulent vaginal discharge (25). The cause of inflammatory vaginitis is unknown, but Gram stain findings reveal a relative absence of normal long gram-positive bacilli (lactobacilli) and their replacement with gram-positive cocci, usually streptococci. Women with this disorder have a purulent vaginal discharge, vulvovaginal burning or irritation, and dyspareunia. A less frequent complaint is vulvar pruritus. Vaginal erythema is present, and there may be an associated vulvar erythema, vulvovaginal ecchymotic spots, and colpitis macularis. The pH of the vaginal secretions is uniformly higher than 4.5 in these patients.

Initial therapy is the use of 2% *clindamycin* cream, one applicator full (5 g) intravaginally once daily for 7 days. Relapse occurs in about 30% of patients, who should be retreated with intravaginal 2% *clindamycin* cream for 2 weeks. When relapse occurs in postmenopausal patients, supplementary hormonal replacement therapy should be considered.

Atrophic Vaginitis

Estrogen plays an important role in the maintenance of normal vaginal ecology. Women undergoing menopause, either occurring naturally or secondary to surgical removal of the ovaries, may develop inflammatory vaginitis, which may be accompanied by an increased, purulent vaginal discharge. In addition, they may note dyspareunia and postcoital bleeding resulting from atrophy of the vaginal and vulvar epithelium. Examination reveals atrophy of the external genitalia, along with a loss of the vaginal rugae. The vaginal mucosa may be somewhat friable in areas. Microscopy of the vaginal secretions shows a predominance of parabasal epithelial cells and an increased number of leukocytes.

Atrophic vaginitis is treated with topical estrogen vaginal cream. Use of 1 g of *conjugated estrogen cream* intravaginally each day for 1 to 2 weeks generally provides relief. Systemic estrogen replacement therapy should be considered to prevent recurrence of this disorder.

Cervicitis

The cervix is made up of two different types of epithelial cells: squamous epithelium and glandular epithelium. The cause of cervical inflammation depends on the epithelium affected. The ectocervical epithelium can become inflamed by the same microorganisms that are responsible for vaginitis. In fact, the ectocervical squamous epithelium is an extension of and is continuous with the vaginal epithelium. *Trichomonas*, *Candida*, and herpes simplex virus (HSV) can cause inflammation of the ectocervix. Conversely, *N. gonorrhoeae* and *C. trachomatis* infect only the glandular epithelium and are responsible for mucopurulent endocervicitis (MPC) (26).

Diagnosis

The diagnosis of MPC is based on the finding of a purulent endocervical discharge, generally yellow or green in color and referred to as “mucopus” (27).

1. After removal of ectocervical secretions with a large swab, a small cotton swab is placed into the endocervical canal and the cervical mucus is extracted. The cotton swab is inspected against a white or black background to detect the green or yellow color of the mucopus. In addition, edema, erythema, and friability of the zone of ectopy (glandular epithelium) are present. Although edema and erythema of the endocervix can be difficult to distinguish, friability or easily induced bleeding can be assessed by touching the ectropion with a cotton swab or spatulum.
2. Placement of the mucopus on a slide that can be Gram stained will reveal the presence of an increased number of neutrophils (>30 per high-power field). The presence of intracellular gram-negative diplococci, leading to the presumptive diagnosis of gonococcal endocervicitis, also may be detected. If the Gram stain results are negative for gonococci, the presumptive diagnosis is chlamydial MPC.
3. Tests for both gonorrhea (culture on Thayer-Martin media or polymerase chain reaction [PCR]) and chlamydia (cell culture, enzyme-linked immunosorbent assay [ELISA], chlamydiazyme, direct fluorescent antibody [MicroTrak], or PCR) should be performed. The microbial etiology of endocervicitis is unknown in about 50% of cases in which gonococci or chlamydia are not detected.

Treatment of MPC consists of an antibiotic regimen recommended for the treatment of uncomplicated lower genital tract infection with both chlamydia and gonorrhea (13) (Table 15.2). It is imperative that all sexual partners be treated with a similar antibiotic regimen. MPC is commonly associated with BV, which, if not treated concurrently, leads to a significant persistence of the symptoms and signs of MPC.

<i>Neisseria gonorrhoeae</i> endocervicitis
Ceftriaxone, 400 mg orally (single dose), or Ceftriaxone, 125 mg intramuscularly (single dose), or Ciprofloxacin, 500 mg orally (single dose)*, or Ofloxacin, 400 mg orally (single dose)*, or levofloxacin 250 mg orally in a single dose *quinolones should not be used for infections acquired in Asia or the Pacific, including Hawaii
<i>Chlamydia trachomatis</i> endocervicitis
Azithromycin, 1 g orally (single dose), or Doxycycline, 100 mg orally twice daily for 7 days, or Ofloxacin, 300 mg orally twice daily for 7 days, or levofloxacin, 500 mg orally for 7 days Erythromycin base, 500 mg orally 4 times a day for 7 days, or Erythromycin ethylsuccinate, 800 mg orally 4 times a day for 7 days

Table 15.2 Treatment Regimens for Gonococcal and Chlamydial Infections

Pelvic Inflammatory Disease

PID is caused by microorganisms colonizing the endocervix ascending to the endometrium and fallopian tubes. PID is a clinical diagnosis implying that the patient has upper genital tract infection and inflammation. The inflammation may be present at any point along a continuum that includes endometritis, salpingitis, and peritonitis (Fig. 15.1).

Figure 15.1 Microorganisms originating in the endocervix ascend into the endometrium, fallopian tubes, and peritoneum, causing pelvic inflammatory disease (endometritis, salpingitis, peritonitis). (From Soper DE. Upper genital tract infections. In: Copeland LJ, ed. *Textbook of gynecology*. Philadelphia: WB Saunders, 1993:521.)

PID commonly is caused by the sexually transmitted microorganisms *N. gonorrhoeae* and *C. trachomatis* (28,29 and 30). Endogenous microorganisms found in the vagina, particularly the BV microorganisms, also often are isolated from the upper genital tract of women with PID. The BV microorganisms include anaerobic bacteria such as *Prevotella* and peptostreptococci as well as *G. vaginalis*. BV often occurs in women with PID, and the resultant complex alteration of vaginal flora may facilitate the ascending spread of pathogenic bacteria by enzymatically altering the cervical mucus barrier (31). Less frequently, respiratory pathogens such as *Haemophilus influenzae*, group A streptococci, and pneumococci can colonize the lower genital tract and cause PID.

Diagnosis

Traditionally, the diagnosis of PID has been based on a triad of symptoms and signs, including pelvic pain, cervical motion and adnexal tenderness, and the presence of fever. It is now recognized that there is wide variation in many symptoms and signs among women with this condition, which makes the diagnosis of acute PID difficult. Many women with PID exhibit subtle or mild symptoms that are not readily recognized as PID. Consequently, delay in diagnosis and therapy probably contributes to the inflammatory sequelae in the upper reproductive tract (32).

In the diagnosis of PID, the goal is to establish guidelines that are sufficiently sensitive to avoid missing mild cases but sufficiently specific to avoid giving antibiotic therapy to women who are not infected. Genitourinary tract symptoms may indicate PID; therefore, the diagnosis of PID should be considered in women with any genitourinary symptoms, including, but not limited to, lower abdominal pain, excessive vaginal discharge, menorrhagia, metrorrhagia, fever, chills, and urinary symptoms (33). **Some women may develop PID without having any symptoms.**

Pelvic organ tenderness, either uterine tenderness alone or uterine tenderness with adnexal tenderness, is present in patients with PID. Cervical motion tenderness suggests the presence of peritoneal inflammation, which causes pain when the peritoneum is stretched by moving the cervix and causing traction of the adnexa on the pelvic peritoneum. Direct or rebound abdominal tenderness may be present.

Evaluation of lower genital tract secretions, both vaginal and endocervical, is a crucial part of the workup of a patient with PID (34). In women with PID, an increased number of polymorphonuclear leukocytes may be detected in a wet mount of the vaginal secretions or in the mucopurulent discharge.

More elaborate tests may be used in women with severe symptoms because an incorrect diagnosis may cause unnecessary morbidity (35) (Table 15.3). These tests include endometrial biopsy to confirm the presence of endometritis, ultrasound or radiologic tests to characterize a tuboovarian abscess (TOA), and laparoscopy to confirm salpingitis visually.

Symptoms
None necessary
Signs
Pelvic organ tenderness
Leukorrhea and/or mucopurulent endocervicitis
Additional criteria to increase the specificity of the diagnosis
Endometrial biopsy showing endometritis
Elevated C-reactive protein or erythrocyte sedimentation rate
Temperature higher than 38°C
Leukocytosis
Positive test for gonorrhea or chlamydia
Definitive criteria
Ultrasound documenting tuboovarian abscess
Laparoscopy visually confirming salpingitis

Table 15.3 Clinical Criteria for the Diagnosis of Pelvic Inflammatory Disease

Treatment

Therapy regimens for PID must provide empirical, broad-spectrum coverage of likely pathogens (13,36), including *N. gonorrhoeae*, *C. trachomatis*, gram-negative facultative bacteria, anaerobes, and streptococci. Recommended regimens for the treatment of PID are listed in Table 15.4. Hospitalization is recommended, especially when the diagnosis is uncertain, pelvic abscess is suspected, clinical disease is severe, or compliance with an outpatient regimen is in question. Hospitalized patients can be considered for discharge when their fever has lysed (<99.5°F for more than 24 hours), the white blood cell count has become normal, rebound tenderness is absent, and repeat examination shows marked amelioration of pelvic organ tenderness (37).

Outpatient Treatment
Regimen A
Ceftriaxone, 500 mg orally 2 times daily for 14 days, or
Cefoxitin, 300 mg orally twice daily for 14 days
Plus
Doxycycline, 100 mg orally 2 times daily for 14 days
or
Metronidazole, 500 mg orally 2 times daily for 14 days
Regimen B
Ceftriaxone, 2 g intramuscularly, plus probenecid, 5 g orally concurrently, or
Cefoxitin, 300 mg intramuscularly, or
Equivalent cephalosporin
Plus
Doxycycline, 100 mg orally 2 times daily for 14 days
or
Metronidazole, 500 mg orally twice a day for 14 days
Hospital Treatment
Regimen A
Ceftriaxone, 2 g intravenously every 8 hours, or
Cefoxitin, 2 g intravenously every 12 hours,
Plus
Doxycycline, 100 mg orally or intravenously every 8 hours
Regimen B
Ceftriaxone, 900 mg intravenously every 8 hours
Plus
Clindamycin, loading dose intravenously or intramuscularly (2 mg/kg of body weight)
followed by a maintenance dose (1.8 mg/kg) every 8 hours

Table 15.4 CDC Guidelines for Treatment of Pelvic Inflammatory Disease

Sexual partners of women with PID should be evaluated and treated for urethral infection with chlamydia or gonorrhea (Table 15.2). Urethral tests from male sexual partners of women with nongonococcal, nonchlamydial PID commonly reveals the presence of one of these STDs (38,39).

Tuboovarian Abscess

TOA is an end-stage process of acute PID. TOA is diagnosed when a patient with PID has a pelvic mass that is palpable during bimanual examination. The condition usually reflects an agglutination of pelvic organs (tube, ovary, bowel) forming a palpable complex. Occasionally, an ovarian abscess can result from the entrance of microorganisms through an ovulatory site. **Treatment of TOA involves the use of an antibiotic regimen administered in a hospital (Table 15.4). About 75% of women with TOA respond to antimicrobial therapy alone. Failure of medical therapy suggests the need for drainage of the abscess (40).** Although this may require surgical exploration, percutaneous drainage guided by imaging studies (ultrasound or computed tomography scan) has been used successfully.

Other Major Infections

Genital Ulcer Disease

In the United States, most patients with genital ulcers have genital HSV or syphilis (41,42 and 43). Chancroid is the next most common cause of sexually transmitted genital ulcers, followed by the rare occurrence of lymphogranuloma venereum (LGV) and granuloma inguinale (donovanosis). These diseases are associated with an increased risk for HIV infection. Other infrequent and noninfectious causes of genital ulcers include abrasions, fixed drug eruptions, carcinoma, and Behçet's disease.

Diagnosis

A diagnosis based on history and physical examination often is inaccurate. Therefore, evaluation of all women with genital ulcers should include a serologic test for syphilis (43). Because of the consequences of inappropriate therapy, such as tertiary disease and congenital syphilis in pregnant women, diagnostic efforts are directed at excluding syphilis. An optimal workup of the patient with a genital ulcer includes the performance of a dark-field examination or direct immunofluorescence test for *Treponema pallidum*, culture or antigen test for HSV, and culture for *Haemophilus ducreyi*. Dark-field or fluorescent microscopes and selective media to culture for *H. ducreyi* are often not available in most offices and clinics. Even after complete testing, the diagnosis remains unconfirmed in one fourth of patients with genital ulcers. For this reason, most clinicians base their initial diagnosis and treatment recommendations on their clinical impression of the appearance of the genital ulcer (Fig. 15.2) and knowledge of the most likely cause in their patient population (42).

Figure 15.2 Showing the appearance of the ulcers of chancroid (A), herpes (B), and syphilis (C). The ulcer of chancroid has irregular margins and is deep with undermined edges. The syphilis ulcer has a smooth, indurated border and a smooth base. The genital herpes ulcer is superficial and inflamed. (Modified from Schmid GP, Shcalla WO, DeWitt WE. Chancroid. In: Morse SA, Moreland AA, Thompson SE, eds. *Atlas of sexually transmitted diseases*. Philadelphia: JB Lippincott, 1990.)

Several clinical presentations are highly suggestive of specific diagnoses:

1. **A nonpainful and minimally tender ulcer, not accompanied by inguinal lymphadenopathy, is likely to be syphilis, especially if the ulcer is indurated.** A nontreponemal rapid plasma reagin (RPR) test, or venereal disease research laboratory (VDRL) test, and a confirmatory treponemal test—fluorescent treponemal antibody absorption (FTA ABS) or microhemagglutinin–*T. pallidum* (MHA TP), should be used to diagnose syphilis presumptively. The results of nontreponemal tests usually correlate with disease activity and should be reported quantitatively.
2. **Grouped vesicles mixed with small ulcers, particularly with a history of such lesions, are almost pathognomonic of genital herpes.** Nevertheless, laboratory confirmation of the diagnosis is recommended because the diagnosis of genital herpes is traumatic for many women, alters their self-image, and affects their perceived ability to enter new sexual relationships and bear children. Culture is the most sensitive and specific test; sensitivity approaches 100% in the vesicle stage and 89% in the pustular stage and drops to as low as 33% in patients with ulcers. Nonculture tests are about 80% as sensitive as culture. Because false-negative results are common with HSV cultures, especially in patients with recurrent infections, type-specific serologic tests (type-specific glycoprotein G-based antibody assay) are useful in confirming a clinical diagnosis of genital herpes.
3. **One to three extremely painful ulcers, accompanied by tender inguinal lymphadenopathy, are unlikely to be anything except chancroid.** This is especially true if the adenopathy is fluctuant.
4. **An inguinal bubo accompanied by one or several ulcers is most likely chancroid. If there is no ulcer, the most likely diagnosis is LGV.**

Treatment

Chancroid Recommended regimens for the treatment of chancroid include *azithromycin*, 1 g orally in a single dose; *ceftriaxone*, 250 mg intramuscularly in a single dose; *ciprofloxacin*, 500 mg orally twice a day for 3 days; or *erythromycin* base, 500 mg orally 4 times daily for 7 days. Patients should be reexamined 3 to 7 days after initiation of therapy to ensure the gradual resolution of the genital ulcer, which can be expected to heal within 2 weeks unless it is unusually large.

Herpes A first episode of genital herpes should be treated with acyclovir, 400 mg orally three times a day; or *famciclovir*, 250 mg orally three times a day; or *valacyclovir*, 1.0 g orally twice a day for 7 to 10 days or until clinical resolution is attained. Although these agents provide partial control of the symptoms and signs of clinical herpes, it neither eradicates latent virus nor affects subsequent risk, frequency, or severity of recurrences after the drug is discontinued. Daily suppressive therapy (*acyclovir*, 400 mg orally twice daily; or *famciclovir*, 250 mg twice daily; or *valacyclovir*, 1.0 g orally once a day) reduces the frequency of HSV recurrences by at least 75% among patients with six or more recurrences of HSV per year. Suppressive treatment does not totally eliminate symptomatic or asymptomatic viral shedding or the potential for transmission.

Syphilis Parenteral **penicillin G** administration is the preferred treatment of all stages of syphilis. *Benzathine penicillin G*, 2.4 million units intramuscularly in a single dose, is the recommended treatment for adults with primary, secondary, or early latent syphilis. The Jarisch-Herxheimer reaction is an acute febrile reaction—accompanied by headache, myalgia, and other symptoms—that may occur within the first 24 hours after any therapy for syphilis; patients should be advised of this possible adverse reaction.

Latent syphilis is defined as those periods after infection with *T. pallidum* when patients are seroreactive but show no other evidence of disease. Patients with latent syphilis of longer than 1 year's duration or of unknown duration should be treated with *benzathine penicillin G*, 7.2 million units total, administered as three doses of 2.4 million units intramuscularly each, at 1-week intervals. All patients with latent syphilis should be evaluated clinically for evidence of tertiary disease (e.g., aortitis, neurosyphilis, gumma, and iritis). Quantitative nontreponemal serologic tests should be repeated at 6 months and again at 12 months. An initially high titer (1:32) should decline at least fourfold (two dilutions) within 12 to 24 months.

Genital Warts

External genital warts (EGWs) are a manifestation of human papillomavirus (HPV) infection (44). The nononcogenic HPV types 6 and 11 are usually responsible for EGWs. The warts tend to occur in areas most directly affected by coitus, namely the posterior fourchette and lateral areas on the vulva. Less frequently, warts can be found throughout the vulva, in the vagina, and on the cervix. Minor trauma associated with coitus can cause breaks in the vulvar skin, allowing direct contact between the viral particles from an infected male and the basal layer of the epidermis of his susceptible sexual partner. Infection may be latent or may cause viral particles to replicate and produce a wart. EGWs are highly contagious; more than 75% of sexual partners develop this manifestation of HPV infection when exposed.

The goal of treatment is removal of the warts; it is not possible to eradicate the viral infection. Treatment is most successful in patients with small warts that have been present for less than 1 year. It has not been determined whether treatment of EGWs reduces transmission of HPV. Selection of a specific treatment regimen depends on the anatomic site, size, and number of warts, as well as expense, efficacy, convenience, and potential adverse effects (Table 15.5). Recurrences more often result from reactivation of subclinical infection than reinfection by a sex partner; therefore, examination of sex partners is not absolutely necessary. However, many of these sex partners may have EGWs and may benefit from therapy and counseling concerning transmission of warts.

Modality (%)	Efficacy (%)	Recurrence Risk
Cryotherapy	63-88	21-39
Imiquimod 5% cream [†]	33-72	13-19
Podophyllin 10%-25%	33-79	27-45
Podofilox 0.5% [*]	45-88	33-40
Trichloroacetic acid 80%-90%	81	35
Electrodeiccation or cautery	94	22
Laser [*]	43-93	29-95
Interferon	44-61	0-57

^{*}May be self-applied by patients at home.

[†]Expensive; reserve for patients who have not responded to other regimens.

Table 15.5 Treatment Options for External Genital and Perianal Warts

Human Immunodeficiency Virus

It is estimated that almost 20% of individuals with HIV are women. Intravenous drug use and heterosexual transmission each are responsible for about 40% of acquired immunodeficiency syndrome (AIDS) cases in women in the United States (45). Infection with HIV produces a spectrum of disease that progresses from an asymptomatic state to full-blown AIDS. The pace of disease progression in untreated adults is variable. The median time between infection with HIV and the development of AIDS is 10 years, with a range from a few months to more than 12 years. In a study of adults infected with HIV, symptoms developed in 70% to 85% of infected adults, and AIDS developed in 55% to 60% within 12 years after infection. The natural history of the disease can be significantly altered by antiretroviral therapy. Women with HIV-induced altered immune function are at increased risk for infections such as tuberculosis (TB), bacterial pneumonia, and *Pneumocystis carinii* pneumonia (PCP). Because of its impact on the immune system, HIV affects the diagnosis, evaluation, treatment, and follow-up of many other diseases and may decrease the efficacy of antimicrobial therapy for some STDs.

Diagnosis

Infection is most often diagnosed by HIV type 1 antibody tests. Antibody testing begins with a sensitive screening test such as ELISA or a rapid assay. If confirmed by Western blot or other supplemental testing, a positive antibody test result means a person is infected with HIV and is capable of transmitting the virus to others. HIV antibody is detectable in more than 95% of patients within 6 months of infection. Women diagnosed with any STD, particularly genital ulcer disease, should be offered HIV testing (42). Women at risk for STD, such as those with multiple sexual partners or whose partners have multiple sexual partners, should be offered HIV testing.

The initial evaluation of an HIV-positive woman includes screening for diseases associated with HIV such as TB and STDs, administration of recommended vaccinations (hepatitis B, pneumococcal, and influenza), and behavioral and psychosocial counseling. Intraepithelial neoplasia is strongly associated with HPV infection and has been found to occur in high frequency in women co-infected with HPV and HIV.

Treatment

Decisions regarding the initiation of antiretroviral therapy should be guided by monitoring the laboratory parameters of HIV RNA (viral load) and CD4⁺ T-cell count, as well as the clinical condition of the patient. The primary goals of antiretroviral therapy are maximal and durable suppression of viral load, restoration or preservation of immunologic function, improvement of quality of life, and reduction of HIV-related morbidity and mortality. For the most part, women with acute retroviral syndrome, those within 6 months of HIV seroconversion, and all symptomatic patients should be offered treatment. In addition, treatment should be offered to those women with fewer than 350 CD4⁺ T cells or plasma HIV RNA levels exceeding 30,000 copies/mL (bDNA assay). Patients must be willing to accept therapy to avoid the emergence of resistance due to poor compliance. It has been shown that dual nucleoside regimens plus a protease inhibitor provide a better durable clinical benefit than monotherapy.

In addition, patients with less than 200 CD4⁺ T cells/ μ L should receive prophylaxis against opportunistic infections such as trimethoprim-sulfamethoxazole or aerosol pentamidine for the prevention of PCP pneumonia.

Urinary Tract Infection

Acute Cystitis

Women with acute cystitis generally have an abrupt onset of multiple, severe urinary tract symptoms including dysuria, frequency, and urgency associated with suprapubic or low back pain. Suprapubic tenderness may be noted on physical examination. Urinalysis reveals pyuria and sometimes hematuria. Several factors increase the risk for cystitis, including sexual intercourse, the use of a diaphragm and a spermicide, delayed postcoital micturition, and a history of a recent urinary tract infection ([47,48](#) and [49](#)).

Escherichia coli is the most common pathogen isolated from the urine of young women with acute cystitis, and it is present in 80% of cases ([50](#)). *Staphylococcus saprophyticus* is present in an additional 5% to 15% of patients with cystitis. The pathophysiology of cystitis in women involves the colonization of the vagina and urethra with coliform bacteria from the rectum. For this reason, the effects of an antimicrobial agent on the vaginal flora play a role in the eradication of bacteriuria.

Treatment

High concentrations of *trimethoprim* and the fluoroquinolones in vaginal secretions result in eradicating *E. coli* but minimally altering normal anaerobic and microaerophilic vaginal flora. An increasing linear trend in the prevalence of resistance among *E. coli* (9% to 18%) to *trimethoprim* and *trimethoprim-sulfamethoxazole* has been noted. In contrast, no such increase in resistance was noted with *nitrofurantoin* and *ciprofloxacin*. *Nitrofurantoin* (macrocrystals, 100 mg orally twice daily for 7 days) or a *fluoroquinolone* (*ciprofloxacin*, 250 mg orally twice daily for 3 days) are the optimal choices for empirical 3-day therapy for uncomplicated cystitis ([51](#)).

In patients with typical symptoms, an abbreviated laboratory workup followed by empirical therapy is suggested. The diagnosis can be presumed if pyuria is detected by microscopy or leukocyte esterase testing. Urine culture is not necessary, and a short course of antimicrobial therapy should be given. No follow-up visit or culture is necessary unless symptoms persist or recur.

Recurrent Cystitis

About 20% of premenopausal women with an initial episode of cystitis have recurrent infections. More than 90% of these recurrences are caused by exogenous reinfection. Recurrent cystitis should be documented by culture to rule out resistant microorganisms. Patients may be treated by one of three strategies: (a) continuous prophylaxis, (b) postcoital prophylaxis, or (c) therapy initiated by the patient when symptoms are first noted.

Postmenopausal women may also have frequent reinfections. Hormonal replacement therapy or topically applied estrogen cream, along with antimicrobial prophylaxis, is helpful in treating these patients.

Urethritis

Women with dysuria caused by urethritis have a more gradual onset of mild symptoms, which may be associated with abnormal vaginal discharge or bleeding related to concurrent cervicitis. Patients may also have a new sex partner or experience lower abdominal pain. Physical examination may reveal the presence of mucopurulent cervicitis or vulvovaginal herpetic lesions. *C. trachomatis*, *N. gonorrhoeae*, or genital herpes may cause acute urethritis. Pyuria is present on urinalysis, but hematuria is rarely seen. Treatment regimens for chlamydia and gonococcal infections are presented in [Table 15.2](#).

Occasionally, vaginitis caused by *C. albicans* or trichomonas is associated with dysuria. On careful questioning, patients generally describe external dysuria, sometimes associated with vaginal discharge, and pruritus and dyspareunia. They usually do not experience urgency or frequency. Pyuria and hematuria are absent.

Acute Pyelonephritis

The clinical spectrum of acute, uncomplicated pyelonephritis in young women ranges from gram-negative septicemia to a cystitis-like illness with mild flank pain. *E. coli* accounts for more than 80% of these cases. Microscopy of unspun urine reveals pyuria and gram-negative bacteria. A urine culture should be obtained in all women with suspected pyelonephritis; blood cultures should be performed in those who are hospitalized because results are positive in 15% to 20% of cases. In the absence of nausea and vomiting and severe illness, outpatient oral therapy can be given safely. Patients who have nausea and vomiting, are moderately to severely ill, and are pregnant should be hospitalized. Outpatient treatment regimens include *trimethoprim-sulfamethoxazole* (160 to 800 mg every 12 hours) or a quinolone (e.g., *ofloxacin*, 200 to 300 mg every 12 hours) for 10 to 14 days. Inpatient treatment regimens include the use of parenteral *ceftriaxone* (1 to 2 g daily), *ampicillin* (1 g every 6 hours), and *gentamicin* (especially if *Enterococcus* species are suspected) or *aztreonam* (1 g every 8 to 12 hours). Symptoms should resolve after 48 to 72 hours. If fever and flank pain persist after 72 hours of therapy, ultrasound or computed tomography should be considered to rule out a perinephric or intrarenal abscess or ureteral obstruction. A follow-up culture should be obtained 2 weeks after the completion of therapy.

Intraepithelial disease frequently occurs and often coexists in the cervix, vagina, and vulva. The cause and epidemiologic basis are common in all three locations, and treatment typically is ablative and conservative. Early diagnosis and management are essential to prevent disease from progressing to invasive cancer.

Cervical Intraepithelial Neoplasia

The concept of *preinvasive disease* of the cervix was introduced in 1947, when it was recognized that epithelial changes could be identified that had the appearance of invasive cancer but were confined to the epithelium (1). Subsequent studies showed that if these lesions are not treated, they can progress to cervical cancer (2). Improvements in cytologic assessment led to the identification of early precursor lesions called *dysplasia*, which signaled possible development of future cancer. For a number of years, carcinoma *in situ* (CIS) was treated very aggressively (most often with hysterectomy), whereas dysplasias were believed to be less significant and were not treated or were treated by colposcopic biopsy and cryosurgery. The concept of *cervical intraepithelial neoplasia* (CIN) was introduced in 1968, when Richart indicated that all dysplasias have the potential for progression (3). It is now recognized that most CIN 1 lesions regress spontaneously if untreated (4); nevertheless, CIN refers to a lesion that may progress to invasive carcinoma. This term is equivalent to the term *dysplasia*, which means abnormal maturation; consequently, proliferating metaplasia without mitotic activity should not be called dysplasia. Squamous metaplasia should not be diagnosed as dysplasia (or CIN) because it does not progress to invasive cancer.

The criteria for the diagnosis of intraepithelial neoplasia may vary according to the pathologist, but the significant features are cellular immaturity, cellular disorganization, nuclear abnormalities, and increased mitotic activity. The extent of the mitotic activity, immature cellular proliferation, and nuclear atypicity identify the degree of neoplasia. If the mitoses and immature cells are present only in the lower one third of the epithelium, the lesion usually is designated as CIN 1. Involvement of the middle and upper thirds is diagnosed as CIN 2 and CIN 3, respectively (Fig. 16.1).

Figure 16.1 Diagram of the different grades of cervical intraepithelial neoplasia.

Cervical Anatomy

The cervix is composed of *columnar epithelium*, which lines the endocervical canal, and *squamous epithelium*, which covers the exocervix (5). The point at which they meet is called the *squamocolumnar junction* (SCJ) (Fig. 16.2 and Fig. 16.3).

Figure 16.2 The cervix and the transformation zone.

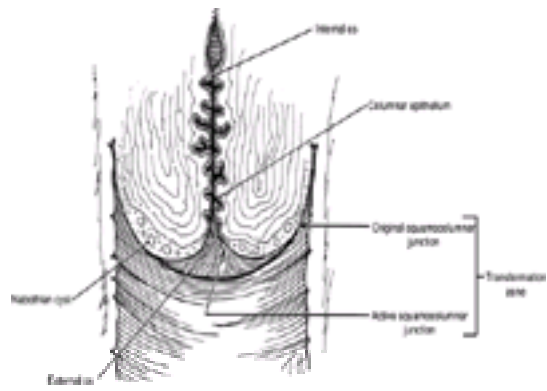

Figure 16.3 Cross-section of the cervix and the endocervix.

The SCJ rarely remains restricted to the external os. Instead, it is a dynamic point that changes in response to puberty, pregnancy, menopause, and hormonal stimulation (Fig. 16.4). In neonates, the SCJ is located on the exocervix. At menarche, the production of estrogen causes the vaginal epithelium to fill with glycogen. Lactobacilli act on the glycogen to the pH, stimulating the subcolumnar reserve cells to undergo *metaplasia* (5).

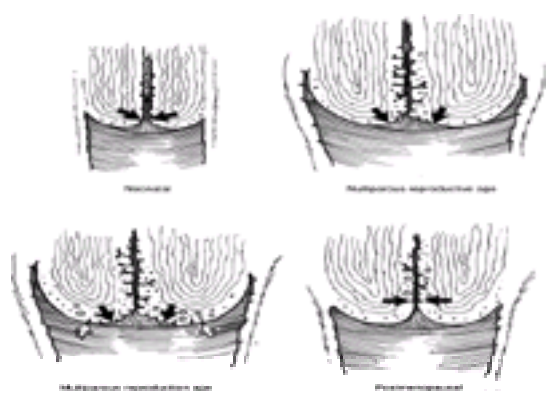

Figure 16.4 Different locations of the transformation zone and the squamocolumnar junction during a woman's lifetime. The arrows mark the active transformation zone.

Metaplasia advances from the original SCJ inward, toward the external os, and over the columnar villi. This process establishes an area called the *transformation zone*. The transformation zone extends from the original SCJ to the physiologically active SCJ. As the metaplastic epithelium in the transformation zone matures, it begins to produce glycogen and eventually resembles the original squamous epithelium, colposcopically and histologically.

In most cases, CIN is believed to originate as a single focus in the transformation zone at the advancing SCJ. The anterior lip of the cervix is twice as likely to develop CIN as the posterior lip, and CIN rarely originates in the lateral angles. Once CIN occurs, it can progress horizontally to involve the entire transformation zone but usually does not replace the original squamous epithelium. This progression usually results in CIN with a sharp external border. Proximally, CIN involves the cervical clefts, and this area tends to have the most severe CIN lesions. The extent of involvement of these cervical glands has significant therapeutic implications because the entire gland must be destroyed to ensure elimination of the CIN (5).

The only way to determine where the original SCJ was located is to look for nabothian cysts or cervical cleft openings, which indicate the presence of columnar epithelium. Once the metaplastic epithelium matures and forms glycogen, it is called the *healed transformation zone* and is relatively resistant to oncogenic stimuli. However, the entire SCJ with early metaplastic cells is more susceptible to oncogenic factors, which may cause these cells to transform into CIN. Therefore, **CIN is most likely to begin either during menarche or after pregnancy, when metaplasia is most active. Conversely, a woman who has reached menopause without developing CIN has little metaplasia and is at a lower risk.** It has been established that oncogenic factors are introduced through sexual intercourse. Several agents, including sperm, seminal fluid histones, trichomonas, chlamydia, herpes simplex virus, and human papillomavirus (HPV), have been studied. It is now known that HPV plays an important role in the development of CIN.

Normal Transformation Zone

The original squamous epithelium of the vagina and exocervix is described as having four layers (5):

1. The *basal layer* is a single row of immature cells with large nuclei and a small amount of cytoplasm.
2. The *parabasal layer* includes two to four rows of immature cells that have normal mitotic figures and provide the replacement cells for the overlying epithelium.
3. The *intermediate layer* includes four to six rows of cells with larger amounts of cytoplasm in a polyhedral shape separated by an intercellular space. Intercellular bridges, where differentiation of glycogen production occurs, can be identified with light microscopy.
4. The *superficial layer* includes five to eight rows of flattened cells with small uniform nuclei and a cytoplasm filled with glycogen. The nucleus becomes pyknotic, and the cells detach from the surface (exfoliation). These cells form the basis for Papanicolaou (Pap) testing.

Columnar Epithelium Columnar epithelium has a single layer of columnar cells with mucus at the top and a round nucleus at the base. The glandular epithelium is composed of numerous ridges, clefts, and infoldings and, when covered by squamous metaplasia, leads to the appearance of gland openings. Technically, the endocervix is not a gland, but the term *gland openings* is often used.

Metaplastic Epithelium Metaplastic epithelium, found at the SCJ, begins in the subcolumnar reserve cell (Fig. 16.4). Under stimulation of lower vaginal acidity, the reserve cells proliferate, lifting the columnar epithelium. The immature metaplastic cells have large nuclei and a small amount of cytoplasm without glycogen. As the cells mature normally, they produce glycogen, eventually forming the four layers of epithelium. The metaplastic process begins at the tips of the columnar villi, which are exposed first to the acid vaginal environment. As the metaplasia replaces the columnar epithelium, the central capillary of the villus regresses, and the epithelium flattens out, leaving the epithelium with its typical vascular network. As metaplasia proceeds into the cervical clefts, it replaces columnar epithelium and similarly flattens the epithelium. The deeper clefts, however, may not be completely replaced by the metaplastic epithelium, leaving mucus-secreting columnar epithelium trapped under the squamous epithelium. Some of these glands open onto the surface; others are completely encased, with mucus collecting in nabothian cysts. Gland openings and nabothian cysts mark the original SCJ and the outer edge of the original transformation zone (5).

Human Papillomavirus

The cytologic changes of HPV were first recognized by Koss and Durfee (6) in 1956 and given the term *koilocytosis*. Their significance was not recognized until 20 years later, when Meisels and colleagues (7) reported these changes in mild dysplasia (Fig. 16.5). Molecular biologic studies have demonstrated high levels of HPV

DNA and capsid antigen, indicating productive viral infection in these koilocytic cells (8). The HPV genome has been demonstrated in all grades of cervical neoplasia (9). As the CIN lesions become more severe (Fig. 16.6), the koilocytes disappear, the HPV copy numbers decrease, and the capsid antigen disappears, indicating that the virus is not capable of reproducing in less differentiated cells (10). Instead, it appears that portions of the HPV DNA become integrated into the host cell. Integration of the transcriptionally active DNA into the host cell appears to be necessary for malignant growth (11). Malignant transformation appears to require the expression of E6 and E7 oncoproteins produced by HPV (12). Because HPV will not grow in cell culture, there is no direct evidence of the carcinogenesis of HPV. However, a cell culture system has been described for growing keratinocytes that allows for stratification and will produce differentiated specific keratinase (13). When normal cells are transfected with the plasmid-containing HPV-16, the transfected cells produced cytologic abnormalities identical to those seen in intraepithelial neoplasia. The E6 and E7 oncoproteins are identifiable in the transfected cell lines, providing the strongest laboratory evidence of a cause-and-effect relationship (14). Cervical cancer cell lines that contain active copies of HPV 16 or 18 (SiHa, HeLa, C 4-11, Ca Ski) demonstrate the presence of HPV-16 E6 and E7 oncoproteins (15).

Figure 16.5 Cervical intraepithelial neoplasia grade 1 with koilocytosis. The normal maturation process and differentiation from the basal and parabasal layers to the intermediate and superficial layers are maintained. In the upper layers, koilocytes are characterized by perinuclear halos, well-defined cell borders, and nuclear hyperchromasia, irregularity, and enlargement. (From Fu YS, Woodruff JD. Pathology. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:118, with permission.)

Figure 16.6 Cervical intraepithelial neoplasia grade 3 with the entire thickness of the epithelium replaced by abnormal cells that have large hyperchromatic, irregular nuclei. The normal maturation is lost. Mitotic figures are seen in the superficial layers (left upper corner). (From Fu YS, Woodruff JD. Pathology. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:119, with permission.)

HPV DNA can be detected in most women with cervical neoplasia (16,17). There is a 10-fold or greater risk for cervical neoplasia associated with the detection of HPV DNA. The relative risk for neoplasia associated with HPV is as high as 40, with a lower 95% confidence limit of 15 (16). **The percentage of intraepithelial neoplasia apparently attributed to HPV infection approaches 90% (17).**

Although the number of known genital HPV types now exceeds 20, only certain types count for about 90% of high-grade intraepithelial lesions and cancer (HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, and -58) (17). Type 16 is the most common HPV type in invasive cancer and in CIN 2 and CIN 3 and is found in 47% of women in both categories (18). It is also the most common HPV type in women with normal cytology.

Unfortunately, HPV-16 is not very specific; it can be found in 16% of women with low-grade lesions and in up to 14% of women with normal cytology. **HPV-18 is found in 23% of women with invasive cancers, 5% of women with CIN 2 and CIN 3, 5% of women with HPV and CIN 1, and fewer than 2% of patients with negative findings (17). Therefore, HPV-18 is more specific than HPV-16 for invasive tumors.**

Usually, HPV infections do not persist. Most women have no apparent clinical evidence of disease, and the infection is eventually suppressed or eliminated (16). Other women exhibit low-grade cervical lesions that may regress spontaneously. A minority of women exposed to HPV develop persistent infection that may progress to CIN (16,19). Factors that may have a role in this progression include smoking, contraceptive use, infection with other sexually transmitted diseases, or nutrition (16,18). Any factor that influences the integration of HPV DNA into the human genome may cause progression to invasive disease (20).

Papanicolaou Test Classifier

In 1988, the first National Cancer Institute (NCI) workshop was held in Bethesda, Maryland, resulted in the development of the Bethesda System for cytologic reporting (21). A standardized method of reporting cytology findings was needed to facilitate peer review and quality assurance. **Recently, the terminology was refined in the Bethesda III System (2001) potentially premalignant squamous lesions fall into three categories: atypical squamous cells (ASC), low-grade squamous intraepithelial lesions (LSIL), and high-grade squamous intraepithelial lesions (HSIL) (22).** The ASC category is subdivided into two categories: those of unknown significance (ASC-US), and those in which high-grade lesions must be excluded (ASC-H). Low-grade squamous intraepithelial lesions include CIN 1 (mild dysplasia) and the changes of HPV, termed *koilocytotic atypia*. The HSIL category includes CIN 2 and CIN 3 (moderate dysplasia, severe dysplasia, and carcinoma *in situ*). A comparison of the various terms as they relate is shown in Table 16.1.

Bethesda System	Dysplasia/CIN System	Papanicolaou System
Within normal limits	Normal	I
Infection (organisms should be specified)	Inflammatory atypia (vaginitis)	II
Reactive and reparative changes		
Squamous cell abnormalities		
Atypical squamous cells (ASC)		
(1) of unknown significance (ASC-US)	Squamous atypia HPV atypia, exclude LSIL	III
(2) exclude high-grade lesions (ASC-H)	Exclude HSIL	
Low-grade squamous intraepithelial lesion (LSIL)	HPV atypia	
High-grade squamous intraepithelial lesion (HSIL)	Mild dysplasia Moderate dysplasia	CIN 1 CIN 2
	Severe dysplasia Carcinoma <i>in situ</i> Squamous cell carcinoma	CIN 3 IV V

CIN, cervical intraepithelial neoplasia.

Table 16.1. Comparison of Cytology Classification Systems

Cellular changes associated with HPV (i.e., koilocytosis and CIN 1) are incorporated within the category of LSIL because the natural history, distribution of various HPV types, and cytologic features of both of these lesions are the same (20). **Long-term follow-up studies have shown that lesions properly classified as koilocytosis progress to high-grade intraepithelial neoplasia in 14% of cases (22) and that lesions classified as mild dysplasia progress to severe dysplasia or CIS in 16% of cases (4).** It was initially thought that lesions classified as koilocytosis would contain only low-risk HPV types, such as 6 and 11, whereas high-risk HPV types, such as 16 and 18, would be limited to true neoplasms, including CIN 1, thus justifying the distinction. Histopathologic and molecular virologic correlation, however, has demonstrated a similar heterogeneous distribution of low- and high-risk HPV types in both koilocytosis and CIN 1 (23). Studies evaluating the dysplasia, CIS, and CIN terminology have demonstrated a lack of interobserver and intraobserver reproducibility (24). The greatest lack of reproducibility is between koilocytosis and CIN 1 (25). Thus, on the basis of clinical behavior, molecular biologic findings, and morphologic features, HPV changes and CIN 1 appear to be the same disease. The rationale for combining CIN 2 and CIN 3 into the category of HSIL is similar. The biologic studies reveal the similar mix of high-risk HPV types in the two lesions, and the separation of the lesions has been shown to be irreproducible (24,25). In addition, the management of CIN 2 and CIN 3 is similar, so that separation serves no useful clinical purpose.

Diagnosis

The Papanicolaou Test

The Pap test has been successful in reducing the incidence of cervical cancer by 79% and the mortality by 70% since 1950 (26). Despite this, there will be 4,100 deaths in the United States in 2002 (27), and cases of cancer continue to occur in patients who have had regular Pap tests. The Agency for Health Care and Policy Research (AHCPR) undertook a literature review of conventional cervical cytology testing techniques and compared them to newer technologies designed to reduce the false-negative rate (28). The AHCPR project analyzed five reports and concluded that the sensitivity of conventional cytologic testing in detecting cervical cancer precursor lesions was 51%. This is a false-negative rate of 49%. Previously, it had been widely believed that sensitivity of the Pap test was in the 80% range (29). Recommendations for Pap test screening were based on this perceived 80% sensitivity. The recommendation that three annual Pap tests be performed is predicated on a false-negative rate that would reduce the risk for missed lesions to less than 1% after the first three tests. If the test sensitivity were 80%, then the sensitivity of three negative tests would be 99.2%, which achieves the screening goal. However, the 51% test sensitivity would have a sensitivity of only 86.8% after three tests.

It is obvious that improvement in the conventional Pap test technique is necessary. False-negative errors occur in sampling, preparation, and interpretation. Sampling errors occur because a lesion is too small to exfoliate cells or the device used did not pick up the cells and transfer them to the glass slide. Preparation errors may occur because of poor fixation on the glass slide, leading to air-drying and an inability to interpret the results. The slide may also be too thick and obscured by vaginal discharge, blood, or mucus. The thick slide also leads to poor fixation because the fixative does not penetrate the cell sample. Interpretive errors occur when the slide contains diagnostic cells that the screening technician did not identify.

Sampling and preparation errors can be alleviated by using a liquid-based media to collect the cytologic sample. The AHCPR reported that liquid-based cytology assessment improved the sensitivity of the Pap test to the stated goal of 80%. The cell sample is collected with an endocervical brush used in combination with a plastic spatula or with a plastic broom. The sample is then rinsed in a vial containing liquid preservative. This technique transfers 80% to 90% of the cells to the liquid media, as compared with the only 10% to 20% transferred to the glass slide with conventional cytologic testing. In addition, using liquid-based media eliminates air-drying. The cells are retrieved from the vial by passing the liquid through a filter, which traps the larger epithelial cells, separating them from the small blood and inflammatory cells. This leads to a thin layer of diagnostic cells properly preserved and more easily interpreted by the cytologist. This technique reduces the rate of unsatisfactory smears encountered with conventional cytologic testing by 70% to 90% (32). Liquid-based cytology is now performed by more than 50% of the laboratories in the United States.

A second new technology of cervical cytologic assessment, the AutoPap Screening System, has been approved by the U.S. Food and Drug Administration for primary screening and rescreening of samples initially read as normal. This technique uses an automated microscope coupled to a special digital camera. The system scans the slide and uses computer imaging techniques to analyze each field of view on the slide. Computer algorithms are then used to rank each slide on the basis of the probability that the sample may contain an abnormality. The selected slides are then reviewed by a cytotechnologist or a cytopathologist. This technique has reduced the false-negative rate by 32% (33). The AutoPap Screening System is not in widespread use at the moment.

Atypical Squamous Cells

The ASC category is restricted to those test results disclosing abnormal cells that are truly of unknown significance. The ASC category does not include benign, reactive, and reparative changes that should be coded as normal in the Bethesda system. Because of the lack of diagnostic criteria and the fear of medical-legal action, the diagnosis has become quite common, ranging from 3% to 25% in some centers (34). When standardized diagnostic criteria are used, the rate of ASC results should be 3% to 5% (35). **The older term, ASCUS (Bethesda II classification) is now subdivided into ASC-US and ASC-H (Bethesda III classification).**

The cytologic diagnosis of ASCUS is associated with a 10% to 20% incidence of CIN 1 and a 3% to 5% risk for CIN 2 or 3 (36,37,38 and 39). It has become apparent that CIN 1 is most often a benign HPV infection and will regress spontaneously in more than 60% of the cases (40); therefore, the goals of triage of an ASCUS Pap test result is to identify more advanced CIN 2 and 3 lesions.

Triage options include the following: 1) Repeat Pap test every 4 to 6 months with referral for colposcopy if any subsequent abnormality is detected; 2) Immediate colposcopy; 3) HPV testing.

The option of repeat Pap testing is weakened by the 20% to 50% false-negative rate in identifying CIN lesions as well as the noncompliance of the patient. About 50% of patients will still undergo colposcopy because of subsequent abnormal Pap test results, making this option nearly as costly as immediate colposcopy (36). Immediate colposcopy is assumed to be the most sensitive method of detecting CIN 2 or 3 (36,39). Because 80% of patients will not have significant lesions, it is important to not overinterpret the colposcopic findings and to be conservative in performing biopsies. There is also the risk that pathologists will overinterpret the biopsy results and the patient will be diagnosed with CIN when metaplasia is the only finding. Several studies have documented the usefulness of HPV testing in the assessment of ASCUS Pap test results (41,42 and 43). These studies have shown that HPV testing can identify patients 90% of the patients with CIN 2 or 3 lesions.

To compare the aforementioned triage method in a prospective randomized fashion, the NCI funded an ASCUS/LSIL Triage Study (ALTS) whose results for ASCUS were recently published (44). Patients with ASCUS or LSIL were randomized to three triage arms: (a) immediate colposcopy, (b) HPV test, and (c) conservative management by repeat Pap test. There were 1,163 women in the immediate colposcopy group, and 14 refused the examination. The results of colposcopy are assumed to reflect the prevalent disease rates, which were as follows: CIN 1, 14.3%; CIN 2, 16.1%; and CIN 3, 5%. Thus, 75% of the women with ASCUS had negative colposcopy results and did not have a biopsy (25%) or had a biopsy that had negative results. The HPV test results were positive in 56.1% of the patients, and 6.1% of the patients did not return for colposcopy. Of the 494 who underwent colposcopy, the results were as follows: CIN 1, 22.5%; CIN 2, 11.9%; and CIN 3, 15.6%. The sensitivity of HPV test was 95.9% for the detection of CIN 2 and 96.3% for the detection of CIN 3.

In the conservatively managed group, only one follow-up Pap test was reported. To be effective, it is recognized that Pap test must be done every 6 months. Despite this, the results of the single follow-up Pap test were included. Using a cutoff that includes any positive finding of ASCUS or greater, the sensitivity is 85% for CIN 2 and 85.3% for CIN 3, with 58.6% of patients being referred for colposcopy. If LSIL is used as a cutoff, 26.2% of the patients are referred, with sensitivity of 64.0% for both CIN 2 and 3. Using HSIL as the cutoff, 6.9% are referred, and the sensitivity falls to 44%.

The conclusion of the ALTS trial is that HPV triage is highly sensitive in identifying CIN 2 and 3 lesions, with an acceptable rate of referral for colposcopy. Cost-effective analysis of the findings will await the completion of the conservative arm of the study.

In 2001, the American Society for Colposcopy and Cervical Pathology (ASCCP) sponsored an NCI Consensus Conference to provide guidelines for the management of abnormal cervical cytology. They utilized information from the ALTS Trial and used Bethesda III terminology. Women with ASL-US should be managed with 1) a program of 2 repeat pap smears with referral of any abnormality to colposcopy 2) immediate colposcopy 3) testing for high risk type HPV. Testing for HPV DNA is the preferred method when liquid-based cytology is used. Women who are positive will be referred for colposcopy, and those who are negative will return to yearly cytology (41).

Low-grade Squamous Intraepithelial Lesions

The cytologic diagnosis of LSIL is reproducible and accounts for 1.6% of cytologic diagnoses (35). About 75% of the patients have CIN, with 20% being CIN 2 or 3 (36,37 and 38). These patients require additional evaluation. The ALTS trial closed the HPV test arm early because the HPV positivity rate was 82% and, therefore, was not a valid discriminator in determining the presence of disease. The immediate colposcopy arm and cytology follow-up have not been published. Until these data are available, **the standard practice is to perform colposcopy to evaluate a single LSIL result.**

High-grade Squamous Intraepithelial Lesions

Any woman with a cytologic specimen suggesting the presence of HSIL should undergo colposcopy and directed biopsy. After colposcopically directed biopsy and determination of the distribution of the lesion, ablative therapy and destruction of the entire T-zone should be performed.

Colposcopy Findings

Acetowhite Epithelium Epithelium that turns white after application of acetic acid (3% to 5%) is called **acetowhite epithelium** (28). The application of acetic acid coagulates the proteins of the nucleus and cytoplasm and makes the proteins opaque and white (5).

The acetic acid does not affect mature, glycogen-producing epithelium because the acid does not penetrate below the outer one third of the epithelium. The cells in this region have very small nuclei and a large amount of glycogen (not protein). These areas appear pink during colposcopy. Dysplastic cells are those most affected. They contain large nuclei with abnormally large amounts of chromatin (protein). The columnar villi become “plumper” after acetic acid is applied; these cells are then easier to see. They appear slightly white, particularly in the presence of the beginning signs of metaplasia. The immature metaplastic cells have larger nuclei and also show some effects of the acetic acid. Because the metaplastic epithelium is very thin, it is not as white or opaque as CIN but instead appears gray and filmy (5).

Leukoplakia Translated literally, *leukoplakia* is white plaque (5). In colposcopic terminology, this plaque is white epithelium visible before application of acetic acid. Leukoplakia is caused by a layer of keratin on the surface of the epithelium. Immature squamous epithelial cells have the potential to develop into keratin-producing cells or glycogen-producing cells. In the vagina and on the cervix, the normal differentiation is toward glycogen. Keratin production is abnormal in the cervicovaginal mucosa. Several things can cause leukoplakia, including HPV; keratinizing CIN; keratinizing carcinoma; chronic trauma from diaphragm, pessary, or tampon use; and radiotherapy.

Leukoplakia should not be confused with the white plaque of a monilial infection, which can be completely wiped off with a cotton-tipped applicator. Currently, the most common reason for leukoplakia is HPV infection (Fig. 16.7). Because it is not possible to see through the thick keratin layer to the underlying vasculature during colposcopy, such areas should undergo biopsy to rule out keratinizing carcinoma.

Figure 16.7 Cervical intraepithelial neoplasia type 1, mild dysplasia associated with human papillomavirus infection of the cervix. There is a shiny, snow-white color and a micropapillary surface contour. (From **Berek JS, Hacker NF**, eds. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:207, with permission.)

Punctuation *Punctuation* refers to dilated capillaries terminating on the surface, which appear from the ends as a collection of dots (Fig. 16.8). When these vessels occur in a well-demarcated area of acetowhite epithelium, they indicate an abnormal epithelium—most often CIN (5) (Fig. 16.9). The punctate vessels are formed as the metaplastic epithelium migrates over the columnar villi. Normally, the capillary regresses; however, when CIN occurs, the capillary persists and appears more prominent.

Figure 16.8 Diagram of punctuation. The central capillaries of the columnar villi are preserved and produce the punctate vessels on the surface.

Figure 16.9 Human papillomavirus/cervical intraepithelial neoplasia type 1 presents as a white lesion with surface spicules.

Mosaic Terminal capillaries surrounding roughly circular or polygonal-shaped blocks of acetowhite epithelium crowded together are called mosaic because their appearance is similar to mosaic tile (Fig. 16.10). These vessels form a “basket” around the blocks of abnormal epithelium. They may arise from a coalescence of many terminal punctate vessels or from the vessels that surround the cervical gland openings (5). Mosaicism tends to be associated with higher-grade lesions and CIN 2 (Fig. 16.11) and CIN 3 (Fig. 16.12).

Figure 16.10 Mosaic pattern. This pattern develops as islands of dysplastic epithelium proliferate and push the ends of the superficial blood vessels away, creating a pattern that looks like mosaic tiles.

Figure 16.11 Human papillomavirus/cervical intraepithelial neoplasia grade 2. Cribriform pattern of HPV at periphery with mosaicism and punctation near the squamocolumnar junction.

Figure 16.12 Cervical intraepithelial neoplasia grade 3, showing a white lesion with associated punctation and coarse mosaicism.

Atypical Vascular Pattern Atypical vascular patterns are characteristic of invasive cervical cancer and include looped vessels, branching vessels, and reticular vessels. These patterns are discussed in Chapter 31.

Endocervical Curettage The entire coagulant from the endocervical curettage (ECC), placed on a piece of filter paper or brown paper towel, is immersed in 10% buffered formalin or Bouin’s solution. Absorbent paper towels should be avoided because they disintegrate when they become wet. The cheapest paper towels provide the best surface.

Cervical Biopsy The cervical biopsy sample is placed on a dry paper towel. The biopsy should be oriented on its side with the surface at right angles to the surface of the paper. It should be allowed to dry for a minute to ensure attachment to the piece of paper and then placed in the fixative with the specimen down. The specimen and paper will float, and the specimen will stay attached to the undersurface of the paper with its proper orientation. This allows the pathologist to orient the biopsy in the paraffin block and avoid tangential sectioning.

Correlation of Findings

Ideally, both the pathologist and colposcopist should review the colposcopic findings and the results of cytologic assessment, cervical biopsy, and ECC before deciding therapy (45,46 and 47). This is particularly true when operators are first learning the technique of colposcopy. The cytology results should not be sent to one laboratory and the histology results to another. The colposcopist should not treat the report but rather treat the disease. When the cytology and biopsy results correlate, the colposcopist can be reasonably certain that the worst lesion has been identified. If the cytology indicates a more significant lesion than the histology, the patient should undergo further evaluation and additional biopsies as necessary. An algorithm for the evaluation, treatment, and follow-up of an abnormal Pap test is presented in Fig. 16.13.

Figure 16.13 An algorithm for the evaluation, treatment, and follow-up of an abnormal Papanicolaou test.

Colposcopic Terminology

CIN 1

The spontaneous regression rate of biopsy-proven CIN 1 is 60% to 85% in prospective studies ([48,49,50](#) and [51](#)). The regressions typically occur within a 2-year follow-up with cytology and colposcopy. This information has led to the recommendation that patients who have biopsy diagnoses of CIN 1 with satisfactory colposcopy and who agree to the evaluation every 6 months may be treated by observation. If the lesions progress during follow-up or persist at 2 years, ablative treatment should be performed.

For patients who prefer treatment and for those who progress or persist, the choice of treatment is optional. A randomized prospective trial comparing cryosurgery to laser and laser electrosurgical excision procedure (LEEP) showed no difference in persistent disease rate (4%) or recurrent disease rate (17%) ([52](#)). Cryosurgery has the advantage of low cost and ease of use. The disadvantages are lack of tissue specimen, inability to adapt to lesion size, and posttreatment vaginal discharge.

CIN 2 and 3

There is agreement that all CIN 2 and 3 lesions require treatment. This recommendation is based on a metaanalysis showing that CIN 2 progresses to CIS in 20% of cases and to invasion in 5%. Progression of CIS to invasion is 5% ([49](#)).

Although CIN can be treated with a variety of techniques, the preferred treatment for CIN 2 and 3 has become LEEP. These techniques allow a specimen to be sent for evaluation and enable the pathologist to identify occult microinvasive cancer or adenomatous lesions. This ensures that adequate treatment of these lesions is accomplished. The persistent and recurrent disease rates are 4% to 10% ([52,53](#)).

Treatment of CIN

Most of the ablative techniques used to treat CIN can be performed in an outpatient setting, which is one of the main objectives in the management of this disease. Because all therapeutic modalities carry an inherent recurrence rate of up to 10%, cytologic follow-up at about 3-month intervals for 1 year is necessary. Ablative therapy is appropriate when the following conditions exist:

1. There is no evidence of microinvasive or invasive cancer on cytology, colposcopy, ECC, or biopsy.
2. The lesion is located on the ectocervix and can be seen entirely.
3. There is no involvement of the endocervix as determined by colposcopy and ECC.

Cryotherapy

Cryotherapy destroys the surface epithelium of the cervix by crystallizing the intracellular water, resulting in the eventual destruction of the cell. The temperature needed for effective destruction must be in the range of (–20° to –30°C). Nitrous oxide (–89°C) and carbon dioxide (–65°C) produce temperatures below this range and, therefore, are the most commonly used gases for this procedure.

The technique believed to be most effective is a freeze-thaw-freeze method in which an ice ball is achieved 5 mm beyond the edge of the probe. The time required for this process is related to the pressure of the gas; the higher the pressure, the faster the ice ball is achieved.

Cryotherapy has been shown to be an effective method of treatment for CIN with very acceptable failure rates under certain conditions ([54,55,56](#) and [57](#)). It is a relatively safe procedure with few complications. Cervical stenosis is rare but can occur. Posttreatment bleeding is uncommon and is usually related to infection.

Cure rates are related to the grade of the lesion; CIN 3 has a greater chance of failure ([Table 16.2](#)). Townsend has shown that cures are also related to the size of the lesion; those “covering most of the ectocervix” have failure rates as high as 42%, compared with a 7% failure rate for lesions less than 1 cm in diameter ([58](#)). Positive findings on ECC also can reduce the cure rate significantly. Endocervical gland involvement is important because the failure rate in women with gland involvement was 27%, compared with 9% in those who did not have such involvement ([59](#)).

Table 16.2. Results of Cryotherapy for Cervical Intraepithelial Neoplasia (CIN) Compared to Grade of CIN

Cryotherapy should be considered acceptable therapy when the following criteria are met:

1. Cervical intraepithelial neoplasia, grade 1 to 2
2. Small lesion
3. Ectocervical location only
4. Negative ECC findings
5. No endocervical gland involvement on biopsy

Laser

Laser vaporization therapy may be chosen for patients in whom the presence of invasive cancer has been ruled out, the entire lesion can be seen, and ECC results are negative ([60,61,62,63,64](#) and [65](#)). Laser vaporization is particularly applicable in the following situations:

1. Large lesions that the cryoprobe cannot adequately cover
2. Irregular cervix with a “fish mouth” appearance and deep clefts
3. Extension of disease to the vagina or satellite lesions on the vagina

4. Lesions with extensive glandular involvement in which the treatment must reach beyond the deepest gland cleft

The major advantage of laser vaporization therapy is the ability to control exactly the depth and width of destruction by direct vision through the colposcope. Several studies have demonstrated that CIN can be found at an average of 1.2 mm and up to a depth of 5.2 mm inside the cervical crypts, regardless of whether the lesion is located in the exocervix or endocervix (59). Wright has shown that destruction or resection of the tissue to a depth of 3.8 mm ablates all the involved glands in 99.7% of cases (62). Nevertheless, the tissue should be ablated to a depth of 7 mm, which is the location of the deepest endocervical gland. Both CIN 2 and CIN 3 with glandular involvement have deeper crypt involvement than CIN 1 lesions without endocervical gland involvement (61).

The other major advantage of laser therapy is the rapid posttreatment healing phase. This process takes about 3 to 4 weeks, after which time a new epithelium has formed completely and, in most cases, has a mature glycogen-containing epithelium. The healed cervix has a normal appearance with a small visible transformation zone at the cervical os.

Tissue Interaction When the laser beam contacts tissue, its energy is absorbed by the water in the cells, causing it to boil instantly. The cells explode into a puff of vapor (thus the term *laser vaporization*). The protein and mineral content is incinerated by the heat and leaves a charred appearance at the base of the exposed area. The depth of laser destruction is a function of the power of the beam (in watts), the area of the beam (in millimeters squared), and the length of time the laser remains in the tissue. The beam must be moved uniformly across the tissue surface to prevent deep destruction. The laser beam vaporizes a central area and leaves a narrow zone of heat necrosis surrounding the laser crater. The goal of laser vaporization is to minimize this area of tissue necrosis. This goal is accomplished by using high wattage (20 watts) with medium beam size (1.5 mm) and moving the beam uniformly but quickly over the surface. The zone of thermal necrosis will be 0.1 mm when the laser is used in this manner. Some lasers have a function called *super pulse*, in which the laser beam is electronically switched off and on thousands of times per second, thereby allowing the tissue to cool between pulses to create less thermal necrosis.

Results of Laser Therapy Laser therapy has extremely varied results (60,61,62,63,64,65,66 and 67). In general, the earlier reports showed a lower success rate; the improvement in success rate is attributed to the realization that the entire transformation zone needed to be treated, not just the individual identified lesions (Table 16.3). The therapeutic efficacy of laser conization versus knife conization is shown in Table 16.4, and a comparison of intraoperative and postoperative bleeding with the two procedures is listed in Table 16.5.

Table 16.5. Perioperative and Postoperative Bleeding From Cervical Conization: Comparison between Laser and Knife Techniques

The carbon dioxide laser is an excellent tool for the treatment of CIN. In properly selected patients, the success rate with laser vaporization is higher than 95% (Table 16.4). For patients who need diagnostic conization, the cone can be obtained by laser excision performed on an outpatient basis with less blood loss and fewer complications than with a cold knife conization (67,68,69,70,71 and 72).

Loop Electrosurgical Excision

Loop electrosurgical excision is a valuable tool for the diagnosis and treatment of CIN (73,74,75,76,77,78,79,80,81,82 and 83). It has the advantage of being able to perform simultaneously a diagnostic and therapeutic operation during one outpatient visit (61,62,63,64,65,66,67,68,69,70 and 71).

The tissue effect of electricity depends on the concentration of electrons (size of the wire), the power (watts), and the water content of the tissue. If low power or a large-diameter wire is used, the effect will be electrocautery, and the thermal damage to tissue will be extensive. If the power is high (35 to 55 watts) and the wire loop is small (0.5 mm), the effect will be electrosurgical, and the tissue will have little thermal damage. The actual cutting is a result of a steam envelope developing at the interface between the wire loop and the water-laden tissue. This envelope is then pushed through the tissue, and the combination of electron flow and acoustical events separates the tissue. After the excision, a 5-mm diameter ball electrode is used, and the power is set at 50 watts. The ball is placed near the surface so that a spark occurs between the ball and the tissue. This process is called *electrofulguration*, and it results in some thermal damage that leads to hemostasis. If too much

fulguration occurs, the patient will develop an eschar with more discharge, and the risk for infection and late bleeding will be higher.

Loop excision should not be used before identification of an intraepithelial lesion that requires treatment. The risk of the “see and treat” philosophy is that in women with only metaplasia, the entire transformation zone will be removed along with varying amounts of the cervical canal, thus potentially compromising fertility (81,82 and 83). This is particularly true of young women, who may have large, immature transformation zones with extensive acetowhite areas.

Complications following loop electrosurgical excision are fairly minimal and compare favorably with those following laser ablation and conization. Intraoperative hemorrhage, postoperative hemorrhage, and cervical stenosis can occur but at acceptably low rates, as noted in [Table 16.6](#). The SCJ is visible in more than 90% of patients after this procedure.

Complications	No. of Patients	Operative Hemorrhage	Postoperative Hemorrhage	Cervical Stenosis
Prendiville (73)	111	2	2	—
Whiteley (74)	80	0	3	—

Total	2,617	3 (0.01%)	48 (1.8%)	11 (0.4%)

Table 16.6. Complications of Electrosurgical Excision

One advantage of loop excision over other ablative procedures is the ability to diagnose unsuspected invasive disease ([Table 16.7](#)). The loop has several advantages over the laser:

Author (Ref. No.)	Patients	Microinvasive	Invasive
Prendiville (73)	102	1	—
Bigg (76)	1,000	5	—
Conzelmann (77)	98	—	1
Howe (78)	100	1	—
Chappatte (79)	100	3	—

Total	2,157	15 (0.7%)	1 (0.04%)

Table 16.7. Undiscovered Invasion in Electrosurgical Excision Specimens

1. Treatment time is shorter.
2. It is easier to learn.
3. There is no hazard to eyesight.
4. Equipment breakdowns occur less often.
5. The cone sample is better.
6. There is less handling of the tissues.
7. Discomfort is reduced.

One study of these two modes of therapy compared pain and operative time in a randomized fashion ([77](#)). Electrosurgical excision showed an advantage over laser therapy ([Table 16.8](#)).

Side Effect	Loop Excision (n = 98)	Laser (n = 101)
Not unpleasant	80 (82%)	32 (32%)
Moderately unpleasant	16 (16%)	50 (50%)
Very unpleasant	2 (2%)	19 (19%)
Operative time	20–50 sec (mean, 16 sec)	4–15 min (mean, 6.5 min)

From Conzelmann PC, Phipps JE, Lewis BV. Large loop excision of the transformation zone (LLETZ) compared to carbon dioxide laser in the treatment of CIN: a superior mode of treatment. *Int J Gynecol Obstet* 1990;37:995–999, with permission.

Table 16.8. Grade of Discomfort of Large-loop Excision Versus Laser Conization

The most important issue in selecting therapy is whether the loop is an effective means of eradicating CIN. A combined literature series indicated a recurrent rate of about 4% ([Table 16.9](#)). This rate compares favorably with the recurrence rate for other types of procedures used in the treatment of CIN.

Author (Ref. No.)	No. of Patients Treated	No. of Patients Recurred

Total	2,496	97 (3.9%)

Table 16.9. Results of Loop Electrosurgical Excision**Conization**

Conization of the cervix plays an important role in the management of CIN. Before the availability of colposcopy, conization was the standard method of evaluating an abnormal Pap test result. Conization is both a diagnostic and therapeutic procedure and has the advantage over ablative therapies of providing tissue for further evaluation to rule out invasive cancer ([67,68,69,70,71](#) and [72](#)).

Conization is indicated for diagnosis in women with HSIL based on a Pap test under the following conditions:

1. Limits of the lesion cannot be visualized with colposcopy.
2. The SCJ is not seen at colposcopy.
3. ECC histologic findings are positive for CIN 2 or CIN 3.
4. There is a lack of correlation between cytology, biopsy, and colposcopy results.
5. Microinvasion is suspected based on biopsy, colposcopy, or cytology results.
6. The colposcopist is unable to rule out invasive cancer.

Lesions with positive margins are more likely to recur after conization ([67,68](#) and [69](#)) ([Table 16.10](#)). Dempoulos and associates ([84](#)) has shown that endocervical gland involvement also is predictive of recurrence (23.6% with gland involvement compared with 11.3% without gland involvement).

Author (Ref. No.)	No. of Patients	Negative Margins	Positive Margins
Larson (67)	603	55	246

Total	3,000	147 (4.9%)	966 (31.9%)

Table 16.10. Recurrence of Cervical Intraepithelial Neoplasia After Cone Biopsy**Hysterectomy**

Hysterectomy is currently considered too radical for treatment of CIN. Coppleson ([85](#)) reported 38 cases of invasive cancer occurring after hysterectomy among 8,998 women (0.4%). The incidence of significant bleeding, infection, and other complications, including death, is higher with hysterectomy than with other means of treating CIN. There are some situations in which hysterectomy remains a valid and appropriate method of treatment for CIN:

1. Microinvasion
2. CIN 3 at limits of conization specimen
3. Poor compliance with follow-up
4. Other gynecologic problems requiring hysterectomy, such as fibroids, prolapse, endometriosis, and pelvic inflammatory disease

Glandular Cell Abnormalities**Atypical Glandular Cells of Undetermined Significance**

The Bethesda system includes a category for glandular cell abnormalities ([21](#)). These cells may be classified as (a) adenocarcinoma or (b) atypical glandular cells of undetermined significance (AGUS). **Atypical endocervical cells are important because of their risk for significant disease.** In a series of 63 patients from whom subsequent cervical biopsy or hysterectomy specimens were evaluated, 17 women had CIN 2 or CIN 3, 5 women had adenocarcinoma *in situ*, and 2 women had invasive adenocarcinoma ([86](#)). An additional 8 patients had CIN 1, and 2 women had endometrial hyperplasia. Overall, 32 patients (50.8%) had significant cervical lesions. This is a much higher positive rate than that for ASCUS Pap test results.

In adenocarcinoma *in situ* (AIS), the endocervical glandular cells are replaced by tall columnar cells with nuclear stratification, hyperchromasia, irregularity, and increased mitotic activity ([87](#)). Cellular proliferation results in crowded, cribriform glands. However, the normal branching pattern of the endocervical glands is maintained. Most neoplastic cells resemble those of the endocervical mucinous epithelium. Endometrioid and intestinal cell types occur less often. About 50% of women with cervical AIS also have squamous CIN. Thus, some of the AIS lesions represent incidental findings in specimens removed for treatment of squamous neoplasia. Because AIS is located near or above the transformation zone, conventional cervical specimens may not be effective to sample AIS. Obtaining specimens by cytobrush may improve detection of AIS. If the focus of AIS is small, cervical biopsy and ECC may have negative findings. In such cases, a more comprehensive survey of the cervix in the form of conization is necessary. This type of specimen also allows exclusion of coexisting invasive adenocarcinoma. **The term microinvasion should not be used to describe adenocarcinomas.** Once the gland has been invaded, there is no definable technique for identifying the true “depth of invasion” because the invasion may have originated from the mucosal surface or the periphery of the underlying glands. The “breakthrough” of the basement membrane cannot truly be described; therefore, the tumor is either AIS or invasive adenocarcinoma.

With the recent apparent increase in invasive adenocarcinoma of the endocervix, more attention has been directed toward AIS. There is evidence that AIS may progress to invasive cancer ([75](#)). Boone and colleagues reported a series of 52 cases of adenocarcinoma of the uterine cervix in which the results of 18 endocervical biopsies were interpreted as negative 3 to 7 years before the presentation with cancer ([87](#)). In 5 of these cases, AIS was found.

Bertrand and associates studied the anatomic distribution of AIS in 23 women ([88](#)). All 23 patients had AIS involving both the surface and the glandular endocervical epithelium, often with the deepest glandular cleft also involved. The entire endocervical canal was at risk; nearly half of the patients had lesions between 1.5 and 3 cm from the external os. Fifteen patients had unifocal disease, 3 had multifocal disease, and 5 patients had AIS of undermined type. Eleven of the 23 patients had squamous intraepithelial lesions as well as AIS. Muntz reported 40 patients with AIS who had cervical conization ([89](#)). Twenty-three of 40 (58%) had coexisting squamous intraepithelial lesions, and 2 patients had invasive squamous cell carcinoma. Of the 22 patients who underwent hysterectomy, the margins on the cone specimen were positive in 10 patients, and 70% had residual AIS, including 2 patients with foci of invasive adenocarcinoma. One of the 12 patients with negative margins had focal residual adenocarcinoma in the hysterectomy specimen. Eighteen women had conization only with negative margins and had no relapse of disease after a medium interval of 3 years. Thus, positive margins on the conization specimen are significant findings in these patients.

Poyner and coauthors published the results of a more alarming study of 28 patients with AIS ([90](#)). Of the 8 patients with positive margins who underwent repeat conization or hysterectomy, 3 had residual AIS, and 1 patient had invasive adenocarcinoma. Four of 10 patients with negative margins who underwent hysterectomy or repeat conization had residual AIS. One patient in whom the cone margin could not be evaluated was found to have invasive adenocarcinoma. Of the 15 patients treated conservatively with repeat conization of the cervix and close follow-up, 7 (47%) had a recurrent glandular lesion detected after the conization, including invasive adenocarcinoma in two women. More disturbing is the finding that a glandular lesion was not suspected in 48% of the patients, based on Pap test and ECC

results obtained before conization of the cervix.

AIS must be considered a serious cancer precursor of adenocarcinoma. The entire endocervical canal is at risk, and detection of the lesion with cytologic assessment or ECC may not be reliable. Any patient with a positive cone margin should undergo repeat conization. If fertility is not desired, a hysterectomy should be performed because of the risk for recurrence, even in the presence of negative margins.

Vaginal Intraepithelial Neoplasia

Vaginal intraepithelial neoplasia (VAIN) often accompanies CIN and is believed to have a similar cause (91). VAIN lesions may be extensions onto the vagina from the CIN, or they may be satellite lesions occurring mainly in the upper vagina. Because the vagina does not have a transformation zone with immature epithelial cells to be infected by HPV, the mechanism of entry of HPV is by way of skin abrasions from coitus or tampon use. As these abrasions heal with metaplastic squamous cells, the HPV may begin its growth in a manner similar to that in the cervical transformation zone (Fig. 16.14).

Figure 16.14 Vaginal condylomas in the posterior fornix.

Signs

VAIN lesions are asymptomatic. Because they often accompany active HPV infection, the patient may complain of vulvar warts or an odoriferous vaginal discharge from vaginal warts.

Screening

Women with an intact cervix should undergo routine cytologic screening. Because VAIN is nearly always accompanied by CIN, the Pap test result is likely to be positive when VAIN is present. The vagina should be carefully inspected by colposcopic examination at the time of colposcopy for any CIN lesion. Particular attention should be paid to the upper vagina. Women who have persistent positive Pap test results after treatment of CIN should be examined carefully for VAIN. For women in whom the cervix has been removed for cervical neoplasia, Pap testing should be performed at regular intervals initially, depending on the diagnosis and severity of lesion, and yearly thereafter.

Diagnosis

Colposcopic examination and directed biopsy are the mainstays of diagnosis of VAIN. Typically, the lesions are located along the vaginal ridges, are ovoid in shape and slightly raised, and often have surface spicules. VAIN 1 lesions usually are accompanied by a significant amount of koilocytosis, indicating their HPV origin (Fig. 16.15). As the lesions progress to VAIN 2, they have a thicker acetowhite epithelium, a more raised external border, and less iodine uptake (Fig. 16.16). When VAIN 3 occurs, the surface may become papillary, and the vascular patterns of punctation and mosaic may occur (Fig. 16.17). Early invasion is typified by vascular patterns similar to those of the cervix.

Figure 16.15 Human papillomavirus/vaginal intraepithelial neoplasia grade 1. Note the surface spicules with partial uptake of Lugol's stain.

Figure 16.16 Vaginal intraepithelial neoplasia grade 2. There are multifocal raised, ovoid lesions on the vaginal rugae that are outlined by Lugol's stain.

Figure 16.17 Vaginal intraepithelial neoplasia grade 3. The lesion is located in the center of human papillomavirus spicules with partial uptake of Lugol's stain.

Treatment

Patients with VAIN 1 and HPV infection do not require treatment. These lesions often regress, are often multifocal, and recur quickly when treated with ablative therapy. VAIN 2 lesions are generally treated by laser ablation. VAIN 3 lesions are more likely to harbor an early invasive lesion. Hoffman and colleagues reported 32 patients who underwent upper vaginectomy for VAIN 3 (92). Occult invasive carcinoma was found in 9 patients (28%). It is recommended in older patients that VAIN 3 lesions located in the dimples of the vaginal cuff be excised to rule out occult invasive cancer. **VAIN 3 lesions that are adequately sampled to rule out invasive disease can be treated with laser therapy.**

Cryosurgery should not be used in the vagina because the depth of injury cannot be controlled and inadvertent injury to the bladder or rectum may occur. Superficial fulguration with electrosurgical ball cautery may be used under colposcopic control to observe the depth of destruction by wiping away the epithelial tissue as it is ablated. Excision is an excellent method for treatment of upper vaginal lesions in a small area. Occasionally, total vaginectomy will be required for a VAIN 3 lesion occupying the entire vagina. It should be accompanied by a split-thickness skin graft. This aggressive treatment for widespread vaginal lesions should not be used for VAIN 2.

The malignant potential of VAIN appears to be less than that of CIN. In a review of 136 cases of CIS of the vagina over a 30-year period (91), 4 cases (3%) progressed to invasive vaginal cancer despite the use of various treatment methods.

Vulvar Intraepithelial Disease

Vulvar Dystrophies

In the past, terms such as *leukoplakia*, *lichen sclerosus et atrophicus*, *primary atrophy*, *sclerotic dermatosis*, *atrophic and hyperplastic vulvitis*, and *kraurosis vulvae* have been used to denote disorders of epithelial growth and differentiation (93). In 1966, Jeffcoate (94) suggested that these terms did not refer to separate disease entities because their macroscopic and microscopic appearances were variable and interchangeable. He assigned the generic term *chronic vulvar dystrophy* to the entire group of lesions.

The International Society for the Study of Vulvar Disease (ISSVD) recommended that the old "dystrophy" terminology be replaced by a new classification under the pathologic heading "nonneoplastic epithelial disorders of skin and mucosa." This classification is shown in Table 16.11. In all cases, diagnosis requires biopsy of suspicious-looking lesions, which are best detected by careful inspection of the vulva in a bright light aided, if necessary, by a magnifying glass (95).

Nonneoplastic epithelial disorders of skin and mucosa
Lichen sclerosus (lichen sclerosus et atrophicus)
Squamous hyperplasia (formerly hyperplastic dystrophy)
Other dermatoses
Mixed nonneoplastic and neoplastic epithelial disorders
intraepithelial neoplasia
Squamous intraepithelial neoplasia
VIN 1
VIN 2
VIN 3 (severe dysplasia or carcinoma in situ)
Non-squamous intraepithelial neoplasia
Paget's disease
Tumors of melanocytes, noninvasive
invasive tumors

VIN, vulvar intraepithelial neoplasia.
From Committee on Terminology, International Society for the Study of Vulvar Disease. New nomenclature for vulvar disease. *Int J Gynecol Pathol* 1989;8:83, with permission.

Table 16.11. Classification of Epithelial Vulvar Diseases

The malignant potential of these nonneoplastic epithelial disorders is low, particularly now that the lesions with atypia are classified as vulvar intraepithelial neoplasia (VIN). However, patients with lichen sclerosus and concomitant hyperplasia may be at particular risk (96).

Vulvar Intraepithelial Neoplasms

As with the vulvar dystrophies, there has been confusion regarding the nomenclature for VIN. Four major terms have been used: *erythroplasia of Queyrat*, *Bowen's disease*, *carcinoma in situ simplex*, and *Paget's disease*. In 1976, the ISSVD decreed that the first three lesions were merely gross variants of the same disease process and that all of these entities should be included under the umbrella term *squamous cell carcinoma in situ* (stage 0) (81). In 1986, the ISSVD recommended the term *vulvar intraepithelial neoplasia* (Table 16.11).

VIN is graded as 1 (mild dysplasia), 2 (moderate dysplasia), or 3 (severe dysplasia or CIS) on the basis of cellular immaturity, nuclear abnormalities, maturation disturbance, and mitotic activity. In VIN 1, immature cells, cellular disorganization, and mitotic activity occur predominantly in the lower one third of the epithelium, whereas in VIN 3, immature cells with scanty cytoplasm and severe chromatinic alterations occupy most of the epithelium (Fig. 16.18). Dyskeratotic cells and mitotic figures occur in the superficial layer. The appearance of VIN 2 is intermediate between VIN 1 and VIN 3. Additional cytopathic changes of HPV infection, such as perinuclear halos with displacement of the nuclei by the intracytoplasmic viral protein, thickened cell borders, binucleation, and multinucleation, are common in the superficial layers of VIN, especially in VIN 1 and VIN 2. These viral changes are not definitive evidence of neoplasia but are indicative of viral exposure (97). Most vulvar condylomas are associated with HPV-6 and -11, whereas HPV-16 is detected in more than 80% of VIN cases by molecular techniques.

Figure 16.18 Carcinoma *in situ* of the vulva (vulvar intraepithelial neoplasia grade 3). Immature atypical cells are seen throughout epithelium. (From **Fu YS, Woodruff JD.** Pathology. In: **Berek JS, Hacker NF,** eds. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:161, with permission.)

VIN 3 can be unifocal or multifocal. Typically, multifocal VIN 3 presents with small hyperpigmented lesions on the labia major ([Fig. 16.19](#)). Some cases of VIN 3 are more confluent, extending to the posterior fourchette and involving the perineal tissues. The term *bowenoid papulosis* (*bowenoid dysplasia*) has been used to describe multifocal VIN lesions ranging from grade 1 to 3. Clinically, patients with bowenoid papulosis present with multiple small pigmented papules (40% of cases) that are usually less than 5 mm in diameter. Most women with these lesions are in their 20s, and some are pregnant. After childbirth, the lesions may regress spontaneously. However, the term bowenoid papulosis is no longer recommended by the ISSVD.

Figure 16.19 Vulvar intraepithelial neoplasia grade 3 (VIN 3). **A:** A multifocal VIN 3 lesion with multiple small hyperpigmented lesions on the labia major. **B:** VIN 3 with more confluent hyperpigmented areas on the posterior fourchette with extensive perianal involvement. (From **Berek JS, Hacker NF,** eds. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:213, with permission.)

Paget's Disease of the Vulva

Extramammary Paget's disease of the vulva (AIS) was described 27 years after the description by Sir James Paget of the mammary lesion that now bears his name ([98](#)). Some patients with vulvar Paget's disease have an underlying adenocarcinoma, although the precise frequency is difficult to ascertain.

Most cases of vulvar Paget's disease are intraepithelial. Because these lesions demonstrate apocrine differentiation, the malignant cells are believed to arise from undifferentiated basal cells, which convert into an appendage type of cell during carcinogenesis ([Fig. 16.20](#)). The "transformed cells" spread intraepithelially throughout the squamous epithelium and may extend into the appendages. In most patients with an underlying invasive carcinoma of the apocrine sweat gland, Bartholin gland, or anorectum, the malignant cells are believed to migrate through the dermal ductal structures and reach the epidermis. In such cases, metastasis to the regional lymph nodes and other sites can occur.

Figure 16.20 Paget's disease of vulva. The epidermis is permeated by abnormal cells with vacuolated cytoplasm and atypical nuclei. This heavy concentration of abnormal cells in the parabasal layers is typical of Paget's disease. (From **Fu YS, Woodruff JD.** Pathology. In: **Berek JS, Hacker NF,** eds. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:162, with permission.)

Paget's disease must be distinguished from superficial spreading melanoma. All sections should be studied thoroughly using differential staining, particularly periodic acid–Schiff (PAS) and mucicarmine stains. Mucicarmine has routinely positive results in the cells of Paget's disease and negative results in melanotic lesion.

Clinical Features

Paget's disease of the vulva predominantly affects postmenopausal white women, and the presenting symptoms are usually pruritus and vulvar soreness. The lesion has an eczematoid appearance macroscopically and usually begins on the hair-bearing portions of the vulva ([Fig. 16.21](#)). It may extend to involve the mons pubis, thighs, and buttocks. Extension to involve the mucosa of the rectum, vagina, or urinary tract also has been described ([99](#)). The more extensive lesions are usually raised and velvety in appearance.

Figure 16.21 Paget's disease of the left labium majus treated by wide local excision. (From Wilkinson EJ, Stone IK. *Atlas of vulvar disease*. Baltimore: Williams & Wilkins, 1995:87, with permission.)

A second synchronous or metachronous primary neoplasm is associated with extramammary Paget's disease in about 30% of patients (100). Associated carcinomas have been reported in the cervix, colon, bladder, gallbladder, and breast. When the anal mucosa is involved, there usually is an underlying rectal adenocarcinoma (96).

Treatment

VIN The treatment of VIN has varied from wide excision to the performance of a superficial or "skinning" vulvectomy (101,102,103 and 104). Although the treatment originally recommended for CIS of the vulva was wide excision, fears that the disease frequently was preinvasive led to the widespread use of superficial vulvectomy (103). Because progression is relatively uncommon, typically occurring in 5% to 10% of cases (101), extensive surgery is not warranted. This is particularly true because many VIN lesions are found in premenopausal women.

The therapeutic alternatives for VIN are (a) simple excision, (b) laser ablation, and (c) superficial vulvectomy with or without split-thickness skin grafting.

Excision of small foci of disease produces excellent results and has the advantage of providing a histopathologic specimen. Although multifocal or extensive lesions may be difficult to treat by this approach, it offers the potential for the most cosmetic result. Repeat excision is often necessary but can typically be accomplished without vulvectomy (102,104).

The carbon dioxide laser can be used for multifocal lesions but is unnecessary for unifocal disease. The disadvantages are that it can be painful and costly and does not provide a histopathologic specimen (105).

Superficial vulvectomy is appropriate for extensive and recurrent VIN (104). The goal of the surgery is to extirpate all of the disease while preserving as much of the normal vulvar anatomy as possible. The anterior vulva and the clitoris should be preserved if possible. In some patients, the disease extends up the anus, which also must be resected. An effort should be made to close the vulvar defect primarily, reserving the use of skin grafts for instances in which the vulvar defect cannot be closed because the resection is so extensive. Split-thickness skin grafts can be harvested from the thighs or buttocks, but the latter is more easily concealed (106).

Paget's Disease Unlike squamous cell CIS, in which the histologic extent of disease usually correlates closely with the macroscopic lesion, Paget's disease usually extends well beyond the gross lesion (107). This extension results in positive surgical margins and frequent local recurrence unless a wide local excision is performed (108). **Underlying adenocarcinomas are usually apparent clinically, but this finding does not occur invariably; therefore, the underlying dermis should be removed for adequate histologic evaluation.** For this reason, laser therapy is unsatisfactory in treating primary Paget's disease. If underlying invasive carcinoma is present, it should be treated in the same manner as a squamous vulvar cancer. This treatment usually requires radical vulvectomy and at least an ipsilateral inguinal-femoral lymphadenectomy.

Recurrent lesions are almost always *in situ*, although there has been at least one report of an underlying adenocarcinoma in recurrent Paget's disease (100). In general, it is reasonable to treat recurrent lesions with surgical excision.

An abnormal gestation is either intrauterine or extrauterine. Extrauterine or ectopic pregnancy occurs when the fertilized ovum becomes implanted in tissue other than the endometrium. Although most ectopic gestations are located in the ampullary segment of the fallopian tube, such pregnancies may also occur in other sites ([Table 17.1](#)). Abnormal intrauterine pregnancy often results in pregnancy loss early in gestation. Such abnormalities can be related to a number of factors. With both abnormal intrauterine and extrauterine gestation, early recognition is key to diagnosis and management.

Abnormal Intrauterine Pregnancy	Extrauterine Pregnancy
Subclinical pregnancy	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Absence of clinical symptoms
Embryonic pregnancy	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Absence of clinical symptoms
Abnormal pregnancy	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms
Chromosomal pregnancy	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms • Chromosomal abnormality
Hydatidiform mole	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms • Hydatidiform mole
Abnormal extrauterine pregnancy	A pregnancy recognized by the following combination of criteria and located in the extrauterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms
Completed abortion	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms • Completed abortion
Inevitable abortion	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms • Inevitable abortion
Anembryonic gestation	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms • Anembryonic gestation
First trimester fetal death	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms • First trimester fetal death
Second trimester fetal death	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms • Second trimester fetal death
Recurrent spontaneous abortion	A pregnancy recognized by the following combination of criteria and located in the uterine cavity: • Positive serum hCG • Positive transvaginal ultrasound • Presence of a fetal pole • Presence of clinical symptoms • Recurrent spontaneous abortion

Table 17.1. Definitions of Types of Abnormal Intrauterine and Extrauterine Pregnancies

Abnormal Intrauterine Pregnancy

Spontaneous Abortion

Anembryonic gestation, inevitable abortion, incomplete abortion, and completed abortion are types of first-trimester abortions. **About 15% to 20% of known pregnancies terminate in spontaneous abortion. With the use of serial human chorionic gonadotropin (hCG) measurements to detect early subclinical pregnancy losses, the percentage increases to 30%. About 80% of spontaneous pregnancy losses occur in the first trimester; the incidence decreases with each gestational week.** In a study of 347 patients with a first-trimester pregnancy documented by ultrasound, the overall pregnancy loss was 6.1% to 4.2% in patients without bleeding and 12.4% in patients with bleeding ([1](#)). In women who have had one prior spontaneous abortion, the rate of spontaneous abortion in a subsequent pregnancy is about 20%; in women who have had three consecutive losses, the rate is 50%. The causes of this condition are varied and most often unknown ([Table 17.2](#)). Patients should be reassured that, in most cases, spontaneous abortion does not recur.

Pathologic (blighted) ovum—aneembryonic gestation
Embryonic anomalies
Chromosomal anomalies
Increased maternal age
Uterine anomalies
Intrauterine device
Teratogen
Mutagen
Maternal disease
Placental anomalies
Extensive maternal trauma

Table 17.2. Potential Causes of Spontaneous Pregnancy Loss

Threatened Abortion

Threatened abortion is defined as vaginal bleeding before 20 weeks of gestation. It occurs in about 30% to 40% of all pregnancies. The bleeding is usually light and may be associated with mild lower abdominal or cramping pain. It is often not possible to differentiate clinically between threatened abortion, completed abortion, and ectopic pregnancy in an unruptured tube. The differential diagnosis in these patients includes consideration of possible cervical polyps, vaginitis, cervical carcinoma, gestational trophoblastic disease, ectopic pregnancy, trauma, and foreign body. On physical examination, the abdomen usually is not tender and the cervix is closed. Bleeding can be seen coming from the os, and there is no cervical motion or adnexal tenderness. Although most patients experience bleeding at

8 to 10 weeks of gestation, the actual loss usually occurs before 8 weeks of gestation. Only 3.2% of patients experience a pregnancy loss after 8 weeks of gestation (2).

Evaluation of a threatened abortion should include serial hCG measurements unless the patient has an intrauterine pregnancy documented by ultrasound, eliminating the possibility of an ectopic pregnancy. Endovaginal ultrasonography can detect a gestational sac at an hCG level of 1,000 to 2,000 mIU/mL. By 7 weeks of gestation, a fetal pole with fetal cardiac activity can be seen. When a gestational sac is visualized, subsequent loss of the pregnancy occurs in 11.5% of patients. If a yolk sac is present, the loss rate is 8.5%; with an embryo of 5 mm, the loss rate is 7.2%; with an embryo of 6 to 10 mm, the loss rate is 3.2%; and when the embryo is 10 mm, the loss rate is only 0.5%. The fetal loss rate after 14 weeks of gestation is about 2% (3). Transvaginal measurement of gestational sac size is useful in differentiating viable from nonviable intrauterine pregnancies. A mean sac diameter greater than 13 mm without a visible yolk sac or a mean sac diameter greater than 17 mm lacking an embryo predicts nonviability in all cases (4).

There is no effective therapy for a threatened intrauterine pregnancy. Bedrest, although advocated, is not effective. Progesterone or sedatives should not be used. All patients should be counseled and reassured so that they understand the situation. Treatment should be given for any vaginal infection.

Inevitable Abortion

With an *inevitable abortion*, the volume of bleeding is often greater, and the cervical os is open and effaced, but no tissue has been passed. Most patients have crampy lower abdominal pain, and some have cervical motion or adnexal tenderness. When it is certain that the pregnancy is not viable because the cervical os is dilated or excessive bleeding is present, suction curettage should be performed. Blood type and Rh determination and a complete blood count should be obtained if there is any concern about the amount of bleeding. **Rh₀(D) immune globulin (RhoGAM) should be given either before or after the uterus is evacuated if the patient's blood is Rh negative.**

Incomplete Abortion

An incomplete abortion is a partial expulsion of the pregnancy tissue. Before 6 weeks of gestation, the placenta and fetus are generally passed together, but after this time, they are often passed separately. Although most patients have vaginal bleeding, only some have passed tissue. Lower abdominal cramping is invariably present, and the pain may be described as resembling labor. On physical examination, the cervix is dilated and effaced, and bleeding is present. Often, clots are admixed with products of conception. If the bleeding is profuse, the patient should be examined promptly for tissue protruding from the cervical os; removal of this tissue with a ring forceps reduces the bleeding. A vasovagal bradycardia may occur and responds to removal of the tissue. All patients with an incomplete abortion should undergo suction curettage as quickly as possible. A complete blood count, maternal blood type, and Rh determination should be obtained; **Rh-negative patients should receive Rh₀(D) immune globulin.**

If the patient is febrile, broad-spectrum antibiotic therapy should be administered before suction curettage is performed to reduce the incidence of postabortal endometritis and pelvic inflammatory disease, thereby reducing potential deleterious effects on fertility. The antibiotic regimen chosen should be similar to the regimens used for treatment of pelvic inflammatory disease (PID). In patients who do not have clinical signs of infection, prophylactic antibiotic therapy should be instituted. Suggested regimens include *doxycycline* (100 mg orally twice daily), *tetracycline* (250 mg orally four times daily for 5 to 7 weeks) or another antibiotic of similar spectrum.

Ectopic Gestation

Incidence

The most comprehensive data available on ectopic pregnancy rates have been collected by the Centers for Disease Control and Prevention (5). They show a significant increase in the number of ectopic pregnancies in the United States during the past 20 years (Fig. 17.1). In 1989, the latest year for which statistics were published, there were an estimated 88,400 ectopic pregnancies, at a rate of 16 ectopic pregnancies per 1,000 reported pregnancies. These numbers represent a fivefold increase compared with the 1970 rates. The highest rates occurred in women aged 35 to 44 years (27.2 per 1,000 reported pregnancies). When the data are analyzed by race, the risk for ectopic pregnancy among African Americans and other minorities (20.8 per 1,000) is 1.6 times greater than the risk among whites (13.4 per 1,000). In 1988, 44 deaths were attributed to complications of ectopic pregnancy, which represents 15% of all maternal deaths. The risk for death is higher for African Americans and other minorities than for whites (6). For both races, teenagers have the highest mortality rates, but the rate for African American and other minority teenagers is almost five times that for white teenagers. **After an ectopic pregnancy, there is a 7- to 13-fold increase in the risk for a subsequent ectopic pregnancy. The chance that a subsequent pregnancy will be intrauterine is 50% to 80%, and the chance that the pregnancy will be tubal is 10% to 25%; the remaining patients will be infertile (7,8 and 9).** Many variables make accurate assessment of risk very difficult (e.g., size and location of the ectopic pregnancy, status of the contralateral adnexa, treatment method, and history of infertility).

Figure 17.1 Estimation of the number of ectopic pregnancies (United States, 1970–1989). Dashed lines represent the upper and lower limits of 95% confidence intervals.

Etiology and Risk Factors

Tubal damage results from inflammation, infection, and surgery. Inflammation and infection may cause damage without complete tubal obstruction. Complete blockage may result from salpingitis, incomplete tubal ligation, tubal fertility surgery, partial salpingectomy, or congenital midsegment tubal atresia (10,11,12,13 and 14). Damage to the mucosal portion of the tube or fimbria accounts for about half of all tubal pregnancies (15). Tubal diverticula may result in abnormalities that entrap the blastocyst or impede transport (16,17). Tubal pregnancy may occur in a blocked tube with contralateral tubal patency, with the sperm migrating across the abdomen to fertilize an egg released from the blocked side.

Myoelectrical activity is responsible for propulsive activity in the fallopian tube (16). This activity facilitates movement of the sperm and ova toward each other and propels the zygote toward the uterine cavity. Estrogen increases smooth muscle activity, and progesterone decreases muscle tone. Aging results in progressive loss of myoelectrical activity along the fallopian tube, which may explain the increased incidence of tubal pregnancy in perimenopausal women (16). Hormonal control of the muscular activity in the fallopian tube may explain the increased incidence of tubal pregnancy associated with failures of the morning-after pill, minipill, progesterone-containing intrauterine devices (IUDs), and ovulation induction. Blighted ova occur more commonly in tubal conceptions than in intrauterine conceptions, although there is no increase in the incidence of chromosomal abnormalities in ectopic pregnancies (18).

Independent factors consistently shown to increase the risk for tubal pregnancy include the following:

1. Previous laparoscopically proven PID

2. Previous tubal pregnancy
3. Current IUD use
4. Previous tubal surgery for infertility

Many other factors, including contraceptive choice, prior surgery, previous pregnancies, and fertility status, also have been identified.

Pelvic Infection

The relationship of PID, tubal obstruction, and ectopic pregnancy is well documented (13,19). In a study of 415 women with laparoscopically proven PID, the incidence of tubal obstruction increased with successive episodes of PID: 13% after one episode, 35% after two, and 75% after three (19). Furthermore, after one episode of PID, the ratio of ectopic pregnancy to intrauterine pregnancy was 1 in 24, a sixfold increase over the incidence for women with laparoscopically negative results (1 in 147). In a prospective study of 1,204 patients followed until first pregnancy after infection, 47 of 746 (6%) women with laparoscopically documented PID had a tubal gestation, which is significantly higher than the 0.9% incidence in the control group (20).

Chlamydia is an important pathogen causing tubal damage and subsequent tubal pregnancy. Because many cases of chlamydia salpingitis are indolent, cases may not be recognized or, if recognized, may be treated on an outpatient basis. Chlamydia has been cultured from 7% to 30% of patients with tubal pregnancy (7,21). A strong association between chlamydia infection and tubal pregnancy has been shown with serologic tests for chlamydia (22,23,24 and 25). Conception is three times as likely to be tubal in women with anti-*Chlamydia trachomatis* titers higher than 1:64 than in those women whose titers were negative (7,26).

Contraceptive Use

Inert and copper-containing IUDs prevent both intrauterine and extrauterine pregnancies (27,28). **Women who conceive with an IUD in place, however, are 0.4 to 0.8 times more likely to have a tubal pregnancy than those not using contraceptives. However, because IUDs prevent implantation more effectively in the uterus than in the tube, a woman conceiving with an IUD is 6 to 10 times more likely to have a tubal pregnancy than if she conceives without using contraception (27,28).**

With copper IUDs, 4% of contraceptive failures are tubal pregnancies. Progesterone IUDs are less effective than copper IUDs in preventing tubal pregnancy; 17% of failures result in tubal pregnancy. Furthermore, the rate of ectopic pregnancy in women using progesterone IUDs is higher than in women not using contraceptives: 1.9 per 100 woman-years (versus 0.5 for copper IUDs) (29). This finding suggests that failures occur for different reasons. Although all IUDs prevent intrauterine implantation, copper IUDs prevent fertilization by cytotoxic and phagocytic effects on the sperm and oocytes. Progesterone-containing IUDs are probably less effective in preventing conception.

Duration of IUD use does not increase the absolute risk for tubal pregnancy (1.2 per 1,000 years of exposure), but with increasing use, there is an increase in the percentage of pregnancies that are tubal (30). It is unclear whether past use of IUDs increases the risk for tubal pregnancy. Only past use of the Dalkon shield is associated with a twofold increased risk (31). One study showed that previous use of an IUD for longer than 2 years was associated with a fourfold risk, but this risk was present for only the first year after discontinuation of IUD use (27). However, subsequent studies have found no increased risk for tubal pregnancy following IUD use (30,32).

The risk of the pregnancy being ectopic with combination oral contraceptive use has been calculated to be 0.5% to 4% (27,28,33). Past use of oral contraceptives does not increase the subsequent risk for ectopic pregnancy (8). Progesterone-only contraceptives, including oral contraceptives (minipill) and subdermal implants (*Norplani*), protect against both intrauterine and ectopic pregnancy when compared with no contraceptive use. If a pregnancy does occur, however, the chance of the pregnancy being ectopic is 4% to 10% for the minipill (34,35) and up to 30% if pregnancy occurs while implants are in place (36,37). Condom and diaphragm use protects against both intrauterine and ectopic pregnancy, and there is no increased incidence of ectopic pregnancy (30,33,38).

Sterilization

The greatest risk for pregnancy, including ectopic pregnancy, occurs in the first 2 years after sterilization (39). Despite a greater proportion of poststerilization failures resulting in ectopic pregnancy, the absolute rate of ectopic pregnancy is decreased. Calculating cumulative lifetime risk for ectopic pregnancy according to method of contraception, sterilized women have a lower cumulative risk for ectopic pregnancy than IUD users or nonusers of contraception, and women using barrier methods or oral contraceptives have the lowest risk (40).

The risk for tubal pregnancy after any sterilization procedure is 5% to 16% (10,39,40). The risk depends on the sterilization technique: about half of postelectrocautery failures are ectopic, compared with 12% after nonlaparoscopic, nonelectrocautery procedures (41). Laparoscopic coagulation has a reduced risk for pregnancy compared with mechanical devices, but the risk for ectopic pregnancy is increased ninefold when a failure does occur (10,42,43).

Tubal repair or reconstruction may be performed to correct an obstruction, lyse adhesions, or evacuate an unruptured ectopic pregnancy. Although it is clear that tubal surgery is associated with an increased risk for ectopic pregnancy, it is unclear whether the increased risk results from the surgical procedure or from the underlying problem. A fourfold to fivefold increased risk is associated with salpingostomy, neosalpingostomy, fimbrioplasty, anastomosis, and lysis of complex peritubal and periovarian adhesions (7,11,43). After tubal surgery, the overall rate of ectopic pregnancy is 2% to 7%, and the viable intrauterine pregnancy rate is 50%.

There has been a concern that conservation of the tube at the time of removal of an ectopic pregnancy would increase the risk for recurrent ectopic pregnancy. However, after either tubal removal or conservation, the rates for intrauterine pregnancy (40%) and ectopic pregnancy (12%) have been found to be identical (44). In another study, the incidence of ectopic pregnancy could be predicted by the status of the contralateral tube: normal (7%), abnormal (18%), or absent (25%) (42). In a study of pregnancy outcomes of 1,152 patients treated for ectopic pregnancy, preservation of the tube did not increase the incidence of repeat ectopic pregnancy, but it did improve overall fertility rates (45).

Sterilization reversal also increases risk for ectopic pregnancy. The exact risk depends on the method of sterilization, site of tubal occlusion, residual tube length, coexisting disease, and surgical technique. In general, the risk for reanastomosing a cauterized tube is about 15%, and it is less than 3% for reversal of Pomeroy or Fallope ring procedures (46,47).

Prior Abdominal Surgery

Many patients with ectopic pregnancies have a history of previous abdominal surgery (7,8,48). The role of abdominal surgery in ectopic pregnancy is unclear. In one study, there appeared to be no increased risk for cesarean delivery, ovarian surgery, or removal of an unruptured appendix (49). Other studies have shown that ovarian cystectomy or wedge resection increases the risk for ectopic pregnancy, presumably as a result of peritubal scarring (50,51). Although there is general agreement that an increased risk for ectopic pregnancy is associated with a ruptured appendix (7,43), one study did not confirm this finding (49).

Other Causes

Abortion There is no established association between ectopic pregnancy and spontaneous abortion (7,9,52). With recurrent abortion (fewer than two consecutive abortions) the risk is increased 2 to 4 times. This may reflect a shared risk factor, such as with luteal phase defect. Uncomplicated elective abortion, regardless of the number of procedures or gestational age at which they were performed, is not associated with increased risk (7,8,53,54). In areas with a high incidence of illegal abortion, the risk is increased 10-fold. Presumably, this increased incidence is secondary to postoperative infection and improperly performed procedures (54).

Infertility Although the incidence of ectopic pregnancy increases with age and parity, there is also a significant increase in nulliparous women undergoing infertility treatment (7,8,44). For nulliparous women, conceptions after at least 1 year of unprotected intercourse are 2.6 times more likely to be tubal (55). Additional risks for infertile women are associated with specific treatments, including reversal of sterilization, tuboplasty, ovulation induction, and *in vitro* fertilization (IVF).

Hormonal alterations characteristic of *clomiphene citrate* and gonadotropin ovulation-induction cycles may predispose tubal implantation. About 1.1% to 4.6% of conceptions associated with ovulation induction are ectopic pregnancies (8,55). In many of these patients, the results of hysterosalpingography are normal, and there is no evidence of intraoperative tubal pathology. Hyperstimulation, with high estrogen levels, may play a role in tubal pregnancy (56,57); however, not all studies have shown this relationship (58).

The first pregnancy obtained with IVF was a tubal pregnancy (59). About 2% to 8% of IVF conceptions are tubal. Tubal factor infertility is associated with a further increased risk of 17% (60,61 and 62). Predisposing factors are unclear but may include placement of the embryo high in the uterine cavity, fluid reflux into the tube, and a predisposing tubal factor that prevents the refluxed embryo from returning to the uterine cavity.

Salpingitis Isthmica Nodosa Salpingitis isthmica nodosa (SIN) is a noninflammatory pathologic condition of the tube in which tubal epithelium extends into the myosalpinx and forms a true diverticulum. The reported prevalence ranges from 1 in 146 to 11 in 100. This condition is found more often in the tubes of women with an ectopic pregnancy than in nonpregnant women (17,63,64). Myometrial electrical activity over the diverticula has been found to be abnormal (16). Whether tubal pregnancy is caused by SIN or whether the association is coincidental is unknown.

Endometriosis or Leiomyomas Endometriosis or leiomyomas can cause tubal obstruction. However, neither is commonly associated with ectopic pregnancy.

Diethylstilbestrol Women exposed to diethylstilbestrol (DES) *in utero* who subsequently conceive are at increased risk for ectopic pregnancy. In several case-control studies, these women were more than twice as likely to have a tubal pregnancy (65,66). The Collaborative Diethylstilbestrol-Adenosis Project, which monitored 327 DES-exposed women, found that about 50% had uterine cavity abnormalities (65). In DES-exposed women, the risk for ectopic pregnancy was 13% in those who had uterine abnormalities compared with 4% in those who had a normal uterus. No specific type of defect was related to the risk for ectopic pregnancy.

Smoking Current cigarette smoking is associated with a more than twofold increased risk for tubal pregnancy (28,51,67,68 and 69). A case-control study showed a dose relationship: current smokers of more than 20 cigarettes a day had a relative risk of 2.5 compared with nonsmokers, whereas smokers of 1 to 10 cigarettes had a risk of 1.3 (68). Alterations of tubal motility, ciliary activity, and blastocyst implantation are associated with nicotine intake.

Histologic Characteristics

Chorionic villi, usually found in the lumen, are pathognomic findings of tubal pregnancy. Gross or microscopic evidence of an embryo is seen in two thirds of cases (70). An unruptured tubal pregnancy is characterized by irregular dilation of the tube, with a blue discoloration caused by hematosalpinx. The ectopic pregnancy may not be readily apparent. Bleeding associated with tubal pregnancies is mainly extraluminal but may be luminal (hematosalpinx) and may extrude from the fimbriated end. A hematoma is frequently seen surrounding the distal segment of the tube. Patients who have tubal pregnancies that spontaneously resolve and those treated with *methotrexate* frequently have an enlargement of the ectopic mass associated with blood clots and extrusion of tissue from the fimbriated end. Hemoperitoneum is nearly always present but is confined to the cul-de-sac unless tubal rupture has occurred. The natural progression of tubal pregnancy is either expulsion from the fimbriated end (tubal abortion), involution of the conceptus, or rupture, usually around the eighth gestational week. Some tubal pregnancies form a chronic inflammatory mass that is associated with involution and reestablishment of menses and thus is difficult to diagnose. Extensive histologic sampling may be required to disclose a few ghost villi.

Histologic findings associated with tubal gestation include evidence of chronic salpingitis and SIN. Inflammation associated with salpingitis causes adhesions as a result of fibrin deposition. Healing and cellular organization lead to permanent scarring between folds of tissue. This scarring may allow transport of sperm but not the passage of the larger blastocyst. About 45% of patients with tubal pregnancies have pathologic evidence of prior salpingitis (71).

The etiology of SIN is unknown but is speculated to be an adenomyosis-like process or, less likely, inflammation (72,73). This condition is rare before puberty, indicating a noncongenital origin. Tubal diverticula are identified in about half of patients who have ectopic pregnancies, as opposed to 5% of women who do not have ectopic pregnancies (17).

Histologic findings include the Arias-Sella reaction, which is characterized by localized hyperplasia of endometrial glands that are hypersecretory (74). The cells have enlarged nuclei that are hyperchromatic and irregular. The Arias-Sella reaction is a nonspecific finding that can be seen in patients with intrauterine pregnancies (Fig. 17.2).

Figure 17.2 The Arias-Sella reaction of the endometrium. The glands are closely packed and hypersecretory with large, hyperchromatic nuclei suggesting malignancy. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:125, with permission.)

Diagnosis

The diagnosis of ectopic pregnancy is complicated by the wide spectrum of clinical presentations, from asymptomatic cases to acute abdomen and hemodynamic shock. The diagnosis and management of a ruptured ectopic pregnancy is straightforward; the primary goal is achieving hemostasis. If an ectopic pregnancy can be identified before rupture or irreparable tubal damage, consideration may be given to optimizing future fertility. With patients presenting earlier in the disease process, the number of those without symptoms or with minimal symptoms has increased. Therefore, there must be a high degree of suspicion of ectopic pregnancy, especially in areas of high prevalence. History and physical examination identify patients at risk, improving the probability of detection of ectopic pregnancy before rupture.

History

Patients who have an ectopic pregnancy generally have an abnormal menstrual pattern or the perception of a spontaneous pregnancy loss. Pertinent history includes the menstrual history, previous pregnancy, history of infertility, current contraceptive status, risk factor assessment, and current symptoms.

The classic symptom triad of ectopic pregnancy is pain, amenorrhea, and vaginal bleeding. This symptom group is present in only about 50% of patients, however, and is most typical in patients in whom an ectopic pregnancy has ruptured. Abdominal pain is the most common presenting complaint, but the severity and nature of the pain vary widely. There is no pathognomonic pain that is diagnostic of ectopic pregnancy. Pain may be unilateral or bilateral and may occur in the upper or lower abdomen. The pain may be dull, sharp, or crampy and either continuous or intermittent. With rupture, the patient may experience transient relief of the pain, as stretching of the tubal serosa ceases. Shoulder and back pain, thought to result from hemoperitoneal irritation of the diaphragm, may indicate intraabdominal hemorrhage.

Physical Examination

The physical examination should include measurements of vital signs and examination of the abdomen and pelvis. Frequently, the findings before rupture and hemorrhage are nonspecific, and vital signs are normal. The abdomen may be nontender or mildly tender, with or without rebound. The uterus may be slightly enlarged, with findings similar to a normal pregnancy (75). Cervical motion tenderness may or may not be present. An adnexal mass may be palpable in up to 50% of cases, but the mass varies markedly in size, consistency, and tenderness. A palpable mass may be the corpus luteum and not the ectopic pregnancy. With rupture and intraabdominal hemorrhage, the patient develops tachycardia followed by hypotension. Bowel sounds are decreased or absent. The abdomen is distended, with marked tenderness and rebound tenderness. Cervical motion tenderness is present. Frequently, the pelvic examination is inadequate because of pain and guarding.

History and physical examination may or may not provide useful diagnostic information. The accuracy of the initial clinical evaluation is less than 50% (76). Additional tests are frequently required to differentiate early viable intrauterine pregnancy or suspected ectopic or abnormal intrauterine pregnancy.

Laboratory Assessment

Quantitative b-hCG measurements are the diagnostic cornerstone for ectopic pregnancy. The hCG enzyme immunoassay, with a sensitivity of 25 mIU/mL, is an accurate screening test for detection of ectopic pregnancy. The assay is positive in virtually all documented ectopic pregnancies.

Reference Standards There are three reference standards for b-hCG measurement. The World Health Organization introduced the First International Standard (1st IS) in the 1930s. Testing for hCG and its subunits have improved over the years. The Second International Standard (2nd IS), introduced in 1964, has varying amounts of hCG a and b subunits. A purified preparation of b-hCG is now available. Originally referred to as the First International Reference Preparation (1st IRP), the test standard is now referred to as the Third International Standard (3rd IS). Although each standard has its own scale, as a general rule, the 2nd IS is about half of the 3rd IS. For example, if a level is reported as 500 mIU/mL (2nd IS), it is equivalent to a level of 1,000 mIU/mL (3rd IS). The assay standard used must be known in order to interpret hCG results correctly (77). In several recent articles, attention has been drawn to a problem known as phantom hCG, in which the presence of heterophile antibodies or proteolytic enzymes causes a false-positive hCG result. Because the antibodies are large glycoproteins, significant quantities of the antibody are not excreted in the urine. Thus, in the patient with hCG levels less than 1,000 mIU/mL, a confirmatory positive urine pregnancy test should be obtained before instituting treatment (78,79).

Doubling Time The hCG level correlates with the gestational age (80). During the first 6 weeks of amenorrhea, the serum hCG level increases exponentially. Thus, during this time period, the doubling time of hCG is relatively constant, regardless of the initial level. After the sixth week of gestation, when the hCG levels are higher than 6,000 to 10,000 mIU/mL, the hCG rise is slower and not constant (81).

The hCG doubling time can differentiate an ectopic pregnancy from an intrauterine pregnancy—a 66% rise in the hCG level over 48 hours (85% confidence level) represents the lower limit of normal values for viable intrauterine pregnancies (82). About 15% of patients with viable intrauterine pregnancies have less than a 66% rise in hCG level over 48 hours, and a similar percentage with an ectopic pregnancy have more than a 66% rise. If the sampling interval is reduced to 24 hours, the overlap between normal and abnormal pregnancies is even greater. Patients with a normal intrauterine pregnancy usually have more than a 50% rise in the hCG level over 48 hours when the starting level is less than 2,000 mIU/mL. **The hCG pattern that is most predictive of an ectopic pregnancy is one that has reached a plateau (a doubling time of more than 7 days). For falling levels, a half-life of less than 1.4 days is rarely associated with an ectopic pregnancy, whereas a half-life of more than 7 days is most predictive of ectopic pregnancy.**

Serial hCG levels are usually required when the initial ultrasound examination is indeterminate (i.e., when there is no evidence of an intrauterine gestation or extrauterine cardiac activity consistent with an ectopic pregnancy). When the hCG level is less than 2,000, doubling time predicts viable intrauterine gestation (normal rise) versus nonviability (subnormal rise). With normally rising levels, a second ultrasound is performed when the level is expected (by extrapolation) to reach 2,000 mIU/mL. Abnormally rising levels (less than 2,000 mIU/mL) indicate a nonviable pregnancy. The location (i.e., intrauterine versus extrauterine) must be determined surgically, either by laparoscopy or dilation and curettage. Indeterminate ultrasonography results, and an hCG level of less than 2,000 mIU/mL is diagnostic of nonviable gestation, either ectopic pregnancy or a complete abortion. As a general rule, a completed abortion has a rapidly falling hCG level (50% over 48 hours), whereas levels of an ectopic pregnancy rise or plateau.

Single hCG Level A single hCG measurement has limited usefulness because there is considerable overlap of values between normal and abnormal pregnancies at a given gestational age. The ectopic pregnancy site and hCG level do not correlate (83). Also, many patients in whom the diagnosis of ectopic pregnancy is being considered are uncertain about their menstrual dates. A single hCG level may be useful when measured by sensitive enzyme immunoassays that, if negative, exclude a diagnosis of ectopic pregnancy. Measurement of a single level may also be helpful in predicting pregnancy outcome after timed conceptions using advanced reproductive technology. If the hCG level is more than 300 mIU/mL on day 16 to 18 after artificial insemination, there is an 88% chance of a live birth (84). If the hCG level is less than 300 mIU/mL, the chance of a live birth is only 22%. Also, a single hCG level may facilitate the interpretation of ultrasonography when an intrauterine gestation is not visualized. An hCG level greater than the ultrasound discriminatory zone indicates a possible extrauterine pregnancy. However, determination of serial hCG levels may be needed to differentiate an ectopic pregnancy from a completed abortion. Further tests are required for patients in whom ultrasonography examinations are inconclusive and hCG levels are below the discriminatory zone.

Serum Progesterone

In general, the mean serum progesterone level in patients with ectopic pregnancies is lower than that in patients with normal intrauterine pregnancies (85,86). However, in studies of more than 5,000 patients with first-trimester pregnancies, a spectrum of progesterone levels in patients with both normal and abnormal pregnancies has been found (87,88 and 89). About 70% of patients with a viable intrauterine pregnancy have serum progesterone levels higher than 25 ng/mL, whereas only 1.5% of patients with ectopic pregnancies have serum progesterone levels higher than 25 ng/mL, and most of these pregnancies exhibit cardiac activity (87,88 and 89).

A serum progesterone level can be used as an ectopic pregnancy screening test for both normal and abnormal pregnancy, particularly in settings in which hCG levels and ultrasonography are not readily available. A serum progesterone level of less than 5 ng/mL is highly suggestive of an abnormal pregnancy, but it is not 100% predictive. The risk for a normal pregnancy with a serum progesterone level of less than 5 ng/mL is about 1 in 1,500 (90). Because of this, serum progesterone measurements alone cannot be used to predict pregnancy nonviability.

Other Endocrinologic Markers

In an effort to improve early ectopic pregnancy detection, various endocrinologic and protein markers have been studied. Estradiol levels increase slowly from conception until 6 weeks of gestation and then rise rapidly as placental production of estradiol increases (91). Estradiol levels are significantly lower in ectopic pregnancies when compared with viable pregnancies. However, there is considerable overlap between normal and abnormal pregnancies as well as between intrauterine and extrauterine pregnancies (92,93).

Maternal serum creatine kinase has been studied as a marker for ectopic pregnancy diagnosis (94). Maternal serum creatine kinase levels were significantly higher in all patients with tubal pregnancy when compared with those in patients who had missed abortions or normal intrauterine pregnancies, but no correlation was found between the creatine kinase level and the clinical presentation of the patient, and there was no correlation with the hCG levels.

Schwangerschafts protein 1 (SP₁), also known as pregnancy-associated plasma protein C (PAPP-C) or pregnancy-specific b glycoprotein (PSBS), is produced by the syncytiotrophoblast (92). The main advantage of SP₁ level assessment may be in the diagnosis of conception after recent hCG administration. A level of 2 ng/L might be used for the diagnosis of pregnancy; however, it is doubtful that a diagnosis can be established before delay of menses. Although the SP level increases late in all patients with a nonviable pregnancy, a single SP level does not have prognostic value (95).

Relaxin is a protein hormone produced solely by the corpus luteum of pregnancy. It appears in the maternal serum at 4 to 5 weeks of gestation, peaks at about 10 weeks of gestation, and decreases until term (96). Relaxin levels are significantly lower in ectopic pregnancies and spontaneous abortions than in normal intrauterine pregnancies. Prorenin and active renin levels are significantly higher in viable intrauterine pregnancies than in either ectopic pregnancies or spontaneous abortions, with a single level of more than 33 pg/mL excluding the diagnosis of ectopic pregnancy (97). However, the clinical utility of relaxin, prorenin, and renin levels in

diagnosing ectopic pregnancy has not yet been determined.

CA125 is a glycoprotein, the origin of which is uncertain during pregnancy. Levels of CA125 rise during the first trimester and return to a nonpregnancy range during the second and third trimesters. After delivery, maternal serum concentrations increase again (98,99). CA125 levels have been studied in an effort to predict spontaneous abortion. Although a positive correlation has been found between elevated CA125 levels 18 to 22 days after conception and spontaneous abortion, repeat measurements at 6 weeks of gestation did not correlate with outcome (100). Conflicting results have been reported—one study showed a higher serum CA125 level in normal than in ectopic pregnancies 2 to 4 weeks after a missed menses, whereas another study found higher CA125 levels for ectopic pregnancies compared with normal pregnancies (101,102).

Maternal serum *α*-fetoprotein (AFP) levels are elevated in ectopic pregnancies (103,104); however, the use of AFP measurements as a screening technique for ectopic pregnancy has not been studied. A combination of AFP with three other markers—b-hCG, progesterone, and estradiol—has a 98.5% specificity and 94.5% accuracy for the prediction of ectopic pregnancy.

C-reactive protein is an acute-phase reactant that increases with trauma or infection. Levels of this protein are lower in patients with ectopic pregnancy than in patients with an acute infectious process. Thus, when an infectious process is part of the differential diagnosis, measurement of C-reactive protein may be beneficial (105).

Ultrasound

Improvements in ultrasonography have resulted in the earlier diagnosis of intrauterine and ectopic gestations (106). However, the sensitivity of the b-hCG assay usually allows the diagnosis of pregnancy before direct visualization by ultrasonography.

The complete examination should include both transvaginal and transabdominal ultrasonography. Transvaginal ultrasonography is superior to transabdominal ultrasonography in evaluating intrapelvic structures. The closeness of the vaginal probe to the pelvic organs allows use of higher frequencies (5 to 7 mHz), which improves resolution. The diagnosis of an intrauterine pregnancy can be made 1 week earlier with transvaginal than with transabdominal ultrasound. The demonstration of an empty uterus, detection of adnexal masses and free peritoneal fluid, and direct signs of ectopic pregnancy are more reliably established with a transvaginal procedure (107,108,109,110 and 111). Transabdominal ultrasonography permits visualization of both the pelvis and abdominal cavity and should be included as part of the complete ectopic pregnancy evaluation to detect adnexal masses and hemoperitoneum.

The earliest ultrasonographic finding of an intrauterine pregnancy is a small fluid space and the gestational sac, surrounded by a thick echogenic ring, located eccentrically within the endometrial cavity. The earliest normal gestational sac is seen at 5 weeks of gestation with transabdominal ultrasonography and at 4 weeks of gestation with transvaginal ultrasonography (112). As the gestational sac grows, a yolk sac is seen within it, followed by an embryo with cardiac activity.

The appearance of a normal gestational sac may be simulated by intrauterine fluid collection, the pseudogestational sac, which occurs in 8% to 29% of patients with ectopic pregnancy (113,114 and 115). This ultrasonographic lucency, centrally located, probably represents bleeding into the endometrial cavity by the decidual cast. Clots within this lucency may mimic a fetal pole.

Morphologically, identification of the double decidual sac sign (DDSS) is the best known method of ultrasonographically differentiating true sacs from pseudosacs (116). The double sac, believed to be the decidua capsularis and parietalis, is seen as two concentric echogenic rings separated by a hypoechogenic space. Although useful, there are some limitations of sensitivity and specificity—the DDSS sensitivity ranges from 64% to 95% (115). Pseudosacs may occasionally appear as the DDSS; intrauterine sacs of failed pregnancies may appear as pseudosacs.

The appearance of a yolk sac within the gestational sac is superior to the DDSS in proving an intrauterine pregnancy (117). The yolk sac is consistently visible on transabdominal ultrasonography with a gestational sac size of 2 cm, and on transvaginal ultrasonography at a gestational sac size of 0.6 to 0.8 cm (118,119). Intrauterine sacs smaller than 1 cm on transabdominal ultrasonography and smaller than 0.6 cm on transvaginal ultrasonography are considered indeterminate. Larger sacs without DDSS or yolk sac represent either a failed intrauterine or ectopic pregnancy.

The presence of cardiac activity within the uterine cavity is definitive evidence of an intrauterine pregnancy. This finding essentially eliminates the diagnosis of ectopic pregnancy because the incidence of combined intrauterine and extrauterine pregnancy is 1 in 30,000.

The demonstration of an adnexal gestational sac with a fetal pole and cardiac activity is the most specific but least sensitive sign of ectopic pregnancy, occurring in only 10% to 17% of cases (105,120,121). The recognition of other characteristics of ectopic pregnancy has improved ultrasonographic sensitivity. Adnexal rings (fluid sacs with thick echogenic rings) that have a yolk sac or nonliving embryo are accepted as specific ultrasonographic signs of ectopic pregnancy (122). Adnexal rings are visualized in 22% of ectopic pregnancies using transabdominal ultrasonography and in 38% using transvaginal ultrasonography (107). Other studies have identified adnexal rings in 33% to 50% of ectopic pregnancies (105,121). The adnexal ring may not always be apparent because bleeding around the sac results in the appearance of a nonspecific adnexal mass.

Complex or solid adnexal masses are frequently associated with ectopic pregnancy (1,3,19); however, the mass may represent a corpus luteum, endometrioma, hydrosalpinx, ovarian neoplasm (e.g., dermoid cyst), or pedunculated fibroid. Free cul-de-sac fluid is frequently associated with ectopic pregnancy and is no longer considered evidence of rupture. The presence of intraabdominal free fluid should raise concern about tubal rupture (123).

Accurate interpretation of ultrasonography findings requires correlation with the hCG level (discriminatory zone) (114,119,122,124). All viable intrauterine pregnancies can be visualized by transabdominal ultrasonography for serum hCG levels higher than 6,500 mIU/mL; none are seen at 6,000 mIU/mL. Nonvisualization of an intrauterine gestation with serum hCG levels higher than 6,500 mIU/mL indicates an abnormal (failed intrauterine or ectopic) pregnancy. Intrauterine sacs seen at hCG levels below the discriminatory zone are abnormal and represent either failed intrauterine pregnancies or the pseudogestational sacs of ectopic pregnancy. If there is no definite sign of an intrauterine gestation (the empty uterus sign) and the hCG level is below the discriminatory zone, the differential diagnosis includes the following considerations:

1. Normal intrauterine pregnancy too early for visualization
2. Abnormal intrauterine gestation
3. Recent abortion
4. Ectopic pregnancy
5. Nonpregnant

The discriminatory zone has been lowered progressively with improvements in ultrasonography resolution. Discriminatory zones for transvaginal ultrasonography have been reported at levels from 1,000 to 2,000 mIU/mL (114,119,122,124). Discriminatory zones vary according to the expertise of the examiner and capability of the equipment.

Although the discriminatory zone for intrauterine pregnancy is well established, there is no such zone for ectopic pregnancy. Levels of hCG have not been shown to correlate with the size of ectopic pregnancy. Regardless of how high the hCG level may be, nonvisualization does not exclude ectopic pregnancy. An ectopic pregnancy may be present anywhere in the abdominal cavity, making ultrasonographic visualization difficult.

Doppler Ultrasound

A Doppler shift occurs whenever the source of an ultrasound beam is moving. The usual sources of Doppler-shifted frequencies are red blood cells. The presence of intravascular blood flow, flow direction, and flow velocity can be determined (125). Pulsed Doppler provides ultrasonographic control over which vessels are sampled. The vascular information is provided both by the shape of the time-velocity waveform (high- or low-resistance flow) and by its systolic, diastolic, and mean velocities (or Doppler frequency shifts) (126). Color-flow Doppler ultrasonography analyzes very-low-amplitude signals from an entire ultrasound tomogram; the Doppler shift is

then modulated into color. This information is used to gauge generalized tissue vascularity and to guide pulsed Doppler vascular sampling of specific vessels.

The waveform in the uterine arteries in the nongravid state and in the first trimester of pregnancy shows a high-resistance (little or no diastolic flow), low-velocity pattern. Conversely, a high-velocity, low-resistance signal is localized to the area of developing placentation ([127,128](#) and [129](#)). This pattern, seen near the endometrium, is associated with normal and abnormal intrauterine pregnancies and is termed *peritrophoblastic flow*. Whereas transvaginal ultrasonography requires a well-developed double decidual sac (or possibly cardiac activity) to localize an intrauterine gestation, the use of Doppler techniques allows detection of an intrauterine pregnancy at an earlier date. The combined use of Doppler and two-dimensional imaging allows the differentiation of pseudogestational sacs and true intrauterine gestational sacs ([130](#)) and the differentiation of the empty uterus sign as either the presence of an intrauterine pregnancy (normal and abnormal) or absence of an intrauterine pregnancy (with an increased risk for ectopic pregnancy) ([123](#)).

A similar high-velocity, low-impedance flow characterizes ectopic pregnancies. The addition of Doppler to the ultrasonographic evaluation of suspected ectopic pregnancy improves diagnostic sensitivity for individual diagnoses: from 71% to 87% for ectopic pregnancy, from 24% to 59% for failed intrauterine pregnancy, and from 90% to 99% for normal intrauterine pregnancy ([122,123,130](#)).

Dilation and Curettage

Uterine curettage is performed when the pregnancy has been confirmed to be nonviable and the location of the pregnancy cannot be determined by ultrasonography. The decision to evacuate the uterus in the presence of a positive pregnancy test must be made with caution to avoid the unintentional disruption of a viable intrauterine pregnancy. Although suction curettage traditionally has been performed in the operating room, it can now be accomplished under local anesthesia on an outpatient basis. Endometrial sampling methods (e.g., a Novak curettage or Pipelle endometrial sampling device) are accurate in diagnosing abnormal uterine bleeding, but their reliability for intrauterine pregnancy evacuation has not been studied. These devices might miss intrauterine villi and falsely suggest the diagnosis of ectopic pregnancy.

It is essential to confirm the presence of trophoblastic tissue as rapidly as possible so that therapy may be instituted. Once tissue is obtained by curettage, it can be added to saline, in which it will float ([Fig. 17.3](#)). Decidual tissue does not float. Chorionic villi are usually identified by their characteristic lacy frond appearance. The sensitivity and specificity of this technique are 95% when the tissue is examined with the aid of a dissecting microscope. Because flotation of curettings is not 100% accurate in differentiating an intrauterine from extrauterine gestation, histologic confirmation or serial b-hCG level measurement is required. A rapid assessment of the presence of chorionic villi may be obtained with frozen section, which avoids the at least 48-hour waiting period for permanent histologic evaluation. Immunocytochemical staining techniques have been used to identify intermediate trophoblasts that are not normally identified by light microscopy ([74](#)).

Figure 17.3 When floated in saline, chorionic villi are often readily distinguishable as lacy fronds of tissue. (From [Stovall TG, Ling FW. Extrauterine pregnancy: clinical diagnosis and management.](#) New York: McGraw-Hill, 1993:186, with permission.)

When frozen section is not available, serial hCG levels permit rapid diagnosis. After evacuation of an abnormal intrauterine pregnancy, the hCG level decreases by >15% within 12 to 24 hours. A borderline fall may represent interassay variability. A repeat level should be obtained in 24 to 48 hours to confirm the decline. If the uterus is evacuated and the pregnancy is extrauterine, the hCG level plateaus or continues to increase, indicating the presence of extrauterine trophoblastic tissue.

Culdocentesis

Culdocentesis has been used widely as a diagnostic technique for ectopic pregnancy. With the use of hCG testing and transvaginal ultrasound, however, culdocentesis is rarely indicated. The purpose of the procedure is to determine the presence of nonclotting blood, which increases the likelihood of ruptured ectopic pregnancy. After exposing the posterior vaginal fornix with a bivalve vaginal speculum, the posterior lip of the cervix is grasped with a tenaculum. The cul-de-sac is then entered through the posterior vaginal wall with an 18- to 20-gauge spinal needle with a syringe attached. As the cul-de-sac is entered, suction is applied, and the intraperitoneal contents are aspirated. If nonclotting blood is obtained, the results are positive. In the presence of serous fluid, results are negative. A lack of fluid return or clotted blood is nondiagnostic.

Historically, if the culdocentesis results were positive, laparotomy was performed for a presumed diagnosis of ruptured tubal pregnancy. However, **the results of culdocentesis do not always correlate with the status of the pregnancy.** Although about 70% to 90% of patients with ectopic pregnancy have a hemoperitoneum demonstrated by culdocentesis, only 50% of patients have a ruptured tube ([131](#)). Furthermore, about 6% of women with positive culdocentesis results do not have an ectopic gestation at the time of laparotomy. Nondiagnostic taps occur in 10% to 20% of patients with ectopic pregnancy and, therefore, are not definitive.

Laparoscopy

Laparoscopy is the gold standard for the diagnosis of ectopic pregnancy. Generally, the fallopian tubes are easily visualized and evaluated, although the diagnosis of ectopic pregnancy is missed in 3% to 4% of patients who have very small ectopic gestations. The ectopic gestation is usually seen distorting the normal tubal architecture. With earlier diagnosis, there is an increasing possibility that a small ectopic pregnancy may not be visualized. Pelvic adhesions or previous tubal damage may compromise assessment of the tube. False-positive results occur when tubal dilation or discoloration is misinterpreted as an ectopic pregnancy, in which case the tube can be incised unnecessarily and damaged.

Diagnostic Algorithm

The presenting symptoms and physical findings of patients with an unruptured ectopic pregnancy are similar to those of patients with a normal intrauterine pregnancy ([89](#)). History, risk factor assessment, and physical examination are the initial steps in the management of suspected ectopic pregnancy. Patients in a hemodynamically unstable condition should undergo immediate surgical intervention. Patients with a stable, relatively asymptomatic condition may be assessed as outpatients.

If the diagnosis of ectopic pregnancy can be confirmed without laparoscopy, several potential benefits result. First, both the anesthetic and surgical risks of laparoscopy are avoided; second, medical therapy becomes a treatment option. Because many ectopic pregnancies occur in histologically normal tubes, resolution without surgery may spare the tube from additional trauma and improve subsequent fertility. An algorithm for the diagnosis of ectopic pregnancy without laparoscopy proved to be 100% accurate in a randomized clinical trial ([132,133](#)) ([Fig. 17.4](#)). This screening algorithm combines the use of history and physical examination, serial hCG levels, serum progesterone levels, vaginal ultrasonography, and dilation and curettage. When hCG levels and transvaginal ultrasonography are available in a timely fashion, serum progesterone screening is not required. Serial hCG levels are used to assess pregnancy viability, correlated with transvaginal ultrasonography findings, and measured serially after a suction curettage.

Figure 17.4 Nonlaparoscopic algorithm for diagnosis of ectopic pregnancy.

In this algorithm, **transvaginal ultrasonography is used as follows:**

- 1. The identification of an intrauterine gestational sac or pregnancy effectively excludes the presence of an extrauterine pregnancy.** If the patient has a rising hCG level of more than 2,000 mIU/mL, and no intrauterine gestational sac is identified, the patient is considered to have an extrauterine pregnancy and can be treated without further testing.
- 2. Adnexal cardiac activity, when seen, definitively confirms the diagnosis of ectopic pregnancy.**
- 3. A tubal mass as small as 1 cm can be identified and characterized.** Masses greater than 3.5 cm with cardiac activity or larger than 4 cm without cardiac activity should not be treated with medical therapy.

Suction curettage is used to differentiate nonviable intrauterine pregnancies from ectopic gestations (less than 50% rise in hCG level over 48 hours, an hCG level of less than 2,000 mIU/mL, and an indeterminate sonogram). Performance of this procedure avoids unnecessary use of methotrexate in patients with abnormal intrauterine pregnancy that can only be diagnosed by evacuating the uterus. An unlikely potential problem with suction curettage is missing either an early nonviable intrauterine pregnancy or combined intrauterine and extrauterine pregnancies.

Treatment

Ectopic pregnancy can be treated either medically or surgically. Both methods are effective, and the choice depends on the clinical circumstances, the site of the ectopic pregnancy, and the available resources.

Surgical Treatment

Operative management is the most widely used treatment for ectopic pregnancy. There has been debate about which surgical procedure is best. Salpingo-oophorectomy was once considered appropriate because it was theorized that this technique would eliminate transperitoneal migration of the ovum or zygote, which was thought to predispose to recurrent ectopic pregnancy (134). Ovarian removal results in all ovulations occurring on the side with the remaining normal fallopian tube. Subsequent studies have not confirmed that ipsilateral oophorectomy increases the likelihood of conceiving an intrauterine pregnancy; therefore, this practice is not recommended (135).

Salpingectomy Versus Salpingostomy

Linear salpingostomy is currently the procedure of choice when the patient has an unruptured ectopic pregnancy and wishes to retain her potential for future fertility. The products of conception are removed through an incision made into the tube on its antimesenteric border. The procedure can be accomplished with either a needle tip cautery, laser, scalpel, or scissors. It can be done by operative laparoscopic techniques or laparotomy. In a study in which patients treated with either salpingectomy or salpingostomy were followed for a period of 3 years to about 12.5 years, there was no difference in pregnancy rates (136). A history of infertility is the most significant determinant of future fertility, and such patients are probably served better by salpingectomy to decrease their subsequent chance of a recurrent ectopic pregnancy. Linear salpingostomy is as effective as segmental resection with primary reanastomosis, even for ectopic pregnancies occurring in the isthmic tubal segment, and it is technically less difficult and has a shorter operative time (137).

Milking the tube to effect a tubal abortion has been advocated; if the pregnancy is fimbrial, this technique may be effective. However, when milking was compared with linear salpingostomy for ampullary ectopic pregnancies, milking was associated with a twofold increase in the recurrent ectopic pregnancy rate (138).

Laparotomy Versus Laparoscopy

Salpingostomy, salpingectomy, or segmental resection can be accomplished by laparoscopy or laparotomy. The approach used depends on the hemodynamic stability of the patient, the size and location of the ectopic mass, and the surgeon's expertise. **Laparotomy is indicated when the patient becomes hemodynamically unstable, whereas laparoscopy is reserved for patients who are hemodynamically stable. A ruptured ectopic pregnancy does not necessarily require laparotomy.** However, if large blood clots are present or the intraabdominal blood cannot be evacuated in a timely manner, laparotomy should be considered. Cornual or interstitial pregnancies often require laparotomy, although laparoscopic management has been described (139). Laparotomy is chosen for the management of most ovarian and abdominal pregnancies. In some cases, the patient may have extensive abdominal or pelvic adhesive disease, making laparoscopy difficult and laparotomy more feasible.

Laparoscopy has advantages over laparotomy for management of ectopic pregnancy. In a case-control study of 50 patients comparing the use of laparoscopy and laparotomy for ectopic pregnancy management, hospital stay was significantly shorter (1.3 ± 0.8 versus 3.0 ± 1.1 days), operative time was shorter (78 ± 26 versus 104 ± 27 minutes), and convalescence was shorter (9 ± 8 versus 26 ± 16 days) in the laparoscopy group (140). In a randomized study in which 30 patients in each group were compared, patients undergoing laparoscopic management had less estimated blood loss, shorter hospital stay, equivalent tubal pregnancy rates, and similar pregnancy and persistent trophoblast rates (141). In another study, patients were assigned during alternate months to undergo laparoscopic management ($n = 26$) or laparotomy ($n = 37$) (142). There were no differences in operative time, although patients undergoing laparoscopy had a significant decrease in blood loss, postoperative hospital stay, narcotic requirement, and time to return to normal activity. Laparoscopic management was associated with significant cost savings when compared with laparotomy (more than $\$5,528 \pm \$1,586$ versus more than $\$6,793 \pm \155). Using a prospective analysis, 105 patients with tubal pregnancy were stratified with regard to age and risk factors and then randomized to undergo either laparoscopic management or laparotomy (143). Subsequently, 73 patients underwent second-look laparoscopy to assess the degree of adhesion formation. Patients treated by laparotomy had significantly more adhesions at the surgical site than those treated by laparoscopy, but tubal patency rates were similar. Pregnancy rates were not analyzed.

Reproductive Outcome

Reproductive outcome after ectopic pregnancy is usually evaluated by determining tubal patency by hysterosalpingography, the subsequent intrauterine pregnancy rate, and the recurrent ectopic pregnancy rate. Pregnancy rates are similar in patients treated by either laparoscopy or laparotomy. Tubal patency on the ipsilateral side after conservative laparoscopic management is about 84%.

In a study of 143 patients followed after undergoing laparoscopic procedures for ectopic pregnancy, the overall intrauterine pregnancy rates for laparoscopic salpingostomy (60%) and laparoscopic salpingectomy (54%) were not significantly different (144). If the patient had evidence of tubal damage, pregnancy rates (42%) were significantly lower than in those women who did not have tubal damage (79%). In another study, the reproductive outcome of 188 patients followed for a mean of 7.2 years (range, 3 to 15 years) was reported after conservation by laparotomy for ectopic pregnancy (145). An intrauterine pregnancy occurred in 83 (70%) patients, with a recurrent ectopic pregnancy rate of 13%, suggesting that reproductive outcome after an ectopic pregnancy treated by laparotomy is similar to that of patients undergoing laparoscopic or medical management. Thus, when compared with medical therapy, surgical management appears to have equal reproductive outcome,

although a prospective randomized trial has not been reported.

Medical Treatment

The drug most frequently used for medical management of ectopic pregnancy is *methotrexate*, although other agents have been studied, including potassium chloride (KCl), hyperosmolar glucose, prostaglandins, and *RU-486*. These agents may be given systemically (intravenously, intramuscularly, or orally) or locally (laparoscopic direct injection, transvaginal ultrasound-directed injection, or retrograde salpingography).

Methotrexate

Methotrexate is a folic acid analogue that inhibits dehydrofolate reductase and thereby prevents synthesis of DNA. It has been used extensively in the treatment of gestational trophoblastic disease (see [Chapter 34](#)). Commonly reported side effects include leukopenia, thrombocytopenia, bone marrow aplasia, ulcerative stomatitis, diarrhea, and hemorrhagic enteritis. Other reported side effects include alopecia, dermatitis, elevated liver enzyme levels, and pneumonitis ([146](#)). However, no significant side effects have been reported at the low doses used for ectopic pregnancy treatment. Minor side effects have been reported with multiple doses; *citrovorum factor* reduces the incidence of these side effects and is generally used when prolonged treatment is required. Importantly, long-term follow-up of women treated with *methotrexate* for gestational trophoblastic disease shows no increase in congenital malformations, spontaneous abortions, or tumors recurring after chemotherapy ([147](#)). A smaller total dose of *methotrexate* is required, and shorter treatment duration is used for treatment of ectopic pregnancy than for gestational trophoblastic disease.

Initially, *methotrexate* was used for the treatment of trophoblastic tissue left *in situ* after exploration for an abdominal pregnancy ([148](#)). In 1982, Tanaka and colleagues treated an unruptured interstitial gestation with a 15-day course of intramuscular *methotrexate* ([149](#)). The use of *methotrexate* for primary treatment of ectopic pregnancy has been reported in more than 300 patients ([150,151,152,153,154,155,156,157,158](#) and [159](#)).

A trial of intramuscular *methotrexate* (1 mg/kg/day) followed by *citrovorum factor* (0.1 mg/kg/day) on alternate days was given to 100 patients with a success rate of 96% ([153,155](#)). This outpatient treatment protocol used *methotrexate* plus *citrovorum factor* given only until the hCG level began to decline. Treatment was given until there was at least a 15% decline between two consecutive daily hCG levels. *Citrovorum factor* is given on the day after the *methotrexate* is administered, even if no further *methotrexate* is indicated. Once *methotrexate* is discontinued, hCG levels are measured weekly until the results are negative. A second course of *methotrexate* plus *citrovorum factor* is given only if there is a plateau or rise in the hCG level. Of the 96 patients successfully treated, 17 required only one *methotrexate* and *citrovorum factor* dose, and 19 required four doses. Four patients treated with *methotrexate* failed therapy and required surgical treatment for tubal rupture, and each of these cases differed with respect to ectopic pregnancy size, hCG level, and time of rupture. Of five ectopic pregnancies with cardiac activity, four were successfully treated. No conclusions can be drawn regarding risk factors or predictors of ectopic pregnancy rupture.

Single-dose intramuscular *methotrexate* for ectopic pregnancy treatment was administered to 31 patients with an injection of 50 mg/m² without *citrovorum factor*. Of 30 patients, 29 (96.7%) were successfully treated, and no patients experienced *methotrexate*-related side effects. Some 200 patients have now been treated using the single-dose protocol outlined in [Table 17.3](#). Compared with the multidose protocol, single-dose *methotrexate* is less expensive, patient acceptance is greater because less monitoring is required during treatment, the incidence of side effects is decreased, and the treatment results and prospects for future fertility are comparable.

Day	Therapy*
0	D & C, hCG
1	CBC, SGOT, BUN, creatinine, blood type and Rh
4	Methotrexate 50 mg/m ² IM
7	hCG

CBC, complete blood count; SGOT, serum glutamic-oxaloacetic transaminase; BUN, blood urea nitrogen; IM, intramuscularly.

* If less than a 15% decline in human chorionic gonadotropin (hCG) level between days 4 and 7, give second dose of methotrexate, 50 mg/m², on day 7.

If more than a 15% decline in hCG level between days 4 and 7, follow weekly until hCG is below 10 mIU/mL.

In patients not requiring dilation and curettage (D & C) (hCG > 2,000 mIU/mL and no gestational sac on transvaginal ultrasonography), days 0 and 1 are combined.

Table 17.3. Single-dose Methotrexate Protocol for Ectopic Pregnancy

Initiating Methotrexate [Table 17.4](#) outlines a checklist that should be followed by the physician before initiating *methotrexate*. It also lists instructions that are helpful to the patient.

Physician Checklist
Obtain hCG level.
Perform transvaginal ultrasound within 48 hours.
Perform endometrial curettage if hCG level is less than 2,000 mIU/mL.
Obtain normal liver function (SGOT), normal renal function (BUN, creatinine), and a normal CBC (WBC < 2,000/mL and platelet count > 100,000).
Administer Rhogam if patient is Rh-negative.
Identify unruptured ectopic pregnancy smaller than 3.5 cm.
Obtain informed consent.
Prescribe FeSO ₄ 325 mg PO bid if hematocrit is less than 32%.
Schedule follow-up appointment on days 4, 6, and 7.
Patient Instructions
Refrain from alcohol use, multivitamins containing folic acid, and sexual intercourse until hCG level is negative.
Call your physician:
If you experience prolonged or heavy vaginal bleeding.
The pain is prolonged or severe (lower abdomen and pelvic pain is normal during the first 10–14 days of treatment).
Use oral contraception or barrier contraceptive methods.
<small>Note: 45%–75% of women experience successful methotrexate treatment and require surgery. hCG, human chorionic gonadotropin; SGOT, serum glutamic-oxaloacetic transaminase; BUN, blood urea nitrogen; CBC, complete blood count; WBC, white blood cell.</small>

Table 17.4. Initiation of Methotrexate: Physician Checklist and Patient Instructions

Patient Follow-up After intramuscular administration of *methotrexate*, patients are monitored on an outpatient basis. Patients who report severe pain or pain that is prolonged are evaluated by measuring hematocrit levels and performing transvaginal ultrasonography. The ultrasonography findings during follow-up, although not usually helpful, can be used to provide reassurance that the tube has not ruptured ([160](#)). Cul-de-sac fluid is very common, and the amount of fluid may increase if a tubal abortion occurs. However, it is usually not necessary to intervene surgically unless the patient has a precipitous drop in hematocrit levels or she becomes hemodynamically unstable.

Patients are asked not to become pregnant for at least 2 months after treatment. Hysterosalpingography can be performed, although the procedure is not mandatory.

Candidates for Methotrexate In order to maximize the safety of treatment and to eliminate the possibility of treating in the presence of a nonviable or early viable intrauterine pregnancy, patients considered candidates for *methotrexate* treatment should include those to whom the following factors apply:

1. An hCG level is present after salpingostomy or salpingotomy.
2. A rising or plateaued hCG level is present at least 12 to 24 hours after suction curettage.
3. No intrauterine gestational sac or fluid collection is detected by transvaginal ultrasound, the hCG level is greater than 2,000 mIU/mL, and an ectopic pregnancy mass of at least 3.5 to 4 cm is demonstrated.

Ultrasound findings should be interpreted with caution because most unruptured ectopic pregnancies will be accompanied by fluid in the cul-de-sac.

Side Effects Opponents of *methotrexate* therapy cite potential side effects as the reason not to use it. Most reported side effects have occurred in patients treated with intravenous *methotrexate* with higher doses and for more prolonged treatment courses than are now required. When using the single-dose intramuscular regimen, the incidence of side effects is less than 1%, and the failure rate is comparable to that of conservative laparoscopic surgery. One problem that remains puzzling is the inability to predict treatment failures with the use of *methotrexate*. However, the same is true with conservative surgical procedures; thus, the need to monitor hCG levels after either salpingostomy or *methotrexate* remains. In a review of more than 350 women treated with intramuscular *methotrexate*, Lipscomb and associates found that a high hCG concentration was the most important factor associated with failure of treatment with a single-dose *methotrexate* protocol (161). In patients with an hCG level of less than 10,000 mIU/mL, the overall success rate was 93.4%, as compared with 60.7% when the hCG level was greater than 10,000 mIU/mL. Although surgical management of ectopic pregnancy remains the mainstay of treatment worldwide, *methotrexate* treatment is appropriate in select patient populations.

Reproductive Function Although there are few data, reproductive function after *methotrexate* treatment can be assessed on the basis of tubal patency and pregnancy outcome. Tubal patency is reported to be 50% to 100%, with a mean of 71%, after systemic *methotrexate* treatment. In two separate reports of 23 and 62 patients, the tubal patency rates on the ipsilateral side were 81.4% and 82.3%, respectively (156,162).

Pregnancy outcome after *methotrexate* administration was reported in a group of 14 patients who attempted pregnancy after multiple intramuscular doses. Of these 14 women, 11 (78.6%) became pregnant; 10 of 11 (90.9%) were intrauterine pregnancies, and one (9%) was an extrauterine pregnancy (156). The mean time from first attempting to achieving pregnancy was 2.3 months (range, 1 to 4 months). In another study of 49 patients who were attempting pregnancy after completion of single-dose intramuscular *methotrexate* administration, 39 (80%) became pregnant; 34 (87%) were intrauterine pregnancies, and 5 (13%) were ectopic pregnancies (163). The mean time from attempting to achieving pregnancy was 3.2 ± 1.1 months. In 87 pregnancies after *methotrexate* therapy, the combined intrauterine pregnancy rate was 86%, and the ectopic pregnancy rate was 14%.

In a combined series of 527 patients treated by laparoscopic linear salpingostomy or salpingotomy, the intrauterine pregnancy rate was 54%, and the recurrent ectopic pregnancy rate was 13% (164). Comparison of laparoscopically treated patients with *methotrexate*-treated patients suggests that the two methods have similar reproductive outcomes.

Other Drugs and Techniques

Salpingocentesis is a technique in which agents such as KCl, *methotrexate*, prostaglandins, and hyperosmolar glucose are injected into the ectopic pregnancy transvaginally using ultrasound guidance, by transcervical tubal cannulization, or by laparoscopy. Agents injected under ultrasound guidance have included *methotrexate* (165,166,167,168 and 169), KCl (170), combined *methotrexate* and KCl (171), and *prostaglandin E₂* (172). The potential advantages of salpingocentesis include a one-time injection with the potential avoidance of systemic side effects. Reproductive function after this form of treatment has not been reported. Because of the limited experience, this treatment cannot be recommended until there is further study.

Agents injected into the amniotic sac at laparoscopy have included *prostaglandin F_{2a}* (173), hyperosmolar glucose (174), and *methotrexate* (175). This method has the obvious disadvantage of requiring laparoscopy, but it can be used if laparoscopy has been performed. Other agents reported for the treatment of ectopic pregnancy include *RU-486* (176) and anti-hCG antibody (177).

Types of Ectopic Pregnancy

Spontaneous Resolution

Some ectopic pregnancies resolve by resorption or by tubal abortion, obviating the need for medical or surgical therapy (178,179,180,181 and 182). The proportion of ectopic pregnancies that resolve spontaneously and the reason they do so while others do not are unknown. There are no specific criteria for patient selection that predict successful outcome after spontaneous resolution. A falling hCG level is the most common indicator used, but ectopic pregnancy rupture can occur even with falling hCG levels.

Persistent Trophoblastic Tissue

Persistent ectopic pregnancy occurs when a patient has undergone conservative surgery (e.g., salpingostomy, fimbrial expression) and viable trophoblastic tissue remains. Histologically, there is no identifiable embryo, the implantation is usually medial to the previous tubal incision, and residual chorionic villi are usually confined to the tubal muscularis. Peritoneal trophoblastic tissue implants may also be responsible for persistence (183,184,185,186,187 and 188).

The incidence of persistent ectopic pregnancy has increased with the increased use of surgery that conserves the tubes. Persistence is diagnosed when the hCG levels plateau after conservative surgery. Persistent ectopic gestation is best diagnosed by an initial measurement of serum hCG or progesterone 6 days postoperatively and at 3-day intervals thereafter (186).

Risk factors for persistent ectopic pregnancy are based on the type of surgical procedure, the initial hCG level, the duration of amenorrhea, and the size of the ectopic pregnancy. A slower decline of serum hCG levels has been seen in patients treated by salpingostomy compared with patients treated by salpingectomy. The incidence of persistence after laparoscopic linear salpingostomy ranges from 3% to 20% (189,190). It is uncertain whether the incidence of persistent ectopic pregnancy is the same or greater when the procedure is performed by laparoscopy versus laparotomy. In a review of medical records from 157 patients who underwent salpingostomy for intact ampullary ectopic pregnancy, 16 of 103 patients (16%) undergoing laparoscopic salpingostomy were treated for persistent ectopic pregnancy, whereas 1 of 54 women (2%) who had salpingostomy by laparotomy was treated for persistent ectopic pregnancy (185). Lundorff and colleagues reported that 23% of women with a preoperative hCG level of less than 3,000 mIU/mL developed persistent ectopic pregnancy, whereas only 1 of 67 with a level of more than 3,000 mIU/mL persisted (187). They also noted that 36% of women with an hCG level of more than 1,000 mIU/mL on the second postoperative day and 64% of patients with an hCG level of more than 1,000 mIU/mL on the seventh postoperative day developed persistence. Amenorrhea of less than 7 weeks' duration and ectopic mass smaller than 2 cm have also been reported to increase the risk for persistent ectopic pregnancy (185,187).

Treatment of persistent ectopic pregnancy can be either surgical or medical; surgical therapy consists of either repeat salpingostomy or, more commonly, salpingectomy. *Methotrexate* offers an alternative to patients who are hemodynamically stable at the time of diagnosis. *Methotrexate* may be the treatment of choice because the persistent trophoblastic tissue may not be confined to the tube and, therefore, not readily identifiable during repeat surgical exploration (190,191 and 192).

Chronic Ectopic Pregnancy

Chronic ectopic pregnancy is a condition in which the pregnancy does not completely resorb during expectant management. The condition arises when there is persistence of the chorionic villi with bleeding into the tubal wall, which is distended slowly and does not rupture. It may also arise from chronic bleeding from the fimbriated end of the fallopian tube with subsequent tamponade. In a series of 50 patients with a chronic ectopic pregnancy, pain was present in 86%, vaginal bleeding was present in 68%, and both symptoms were present in 58% (193). Ninety percent of the patients had amenorrhea ranging from 5 to 16 weeks (mean, 9.6 weeks). Most patients develop a pelvic mass that is usually symptomatic. The hCG level is usually low but may be absent; ultrasound may be helpful in the diagnosis; and rarely, bowel involvement or ureteral compression or obstruction exists (193,194).

This condition is treated surgically with removal of the affected tube. Often, the ovary must be removed because there is inflammation with subsequent adhesion development. A hematoma may be present secondary to chronic bleeding.

Nontubal Ectopic Pregnancy

Cervical Pregnancy

The incidence of cervical pregnancy in the United States ranges from 1 in 2,400 to 1 in 50,000 pregnancies ([195](#)). A variety of conditions are thought to predispose to the development of a cervical pregnancy, including previous therapeutic abortion, Asherman's syndrome, previous cesarean delivery, *diethylstilbestrol* exposure, leiomyomas, and IVF ([195,196](#) and [197](#)).

The diagnostic criteria for cervical pregnancy were established based on histologic analysis of a hysterectomy specimen ([195](#)). Clinical criteria include the following findings ([197](#)):

1. The uterus is smaller than the surrounding distended cervix.
2. The internal os is not dilated.
3. Curettage of the endometrial cavity is nonproductive of placental tissue.
4. The external os opens earlier than in spontaneous abortion.

Ultrasonographic diagnostic criteria have also been described that are helpful in differentiating a true cervical pregnancy from an ongoing spontaneous abortion ([Table 17.5](#)). Magnetic resonance imaging of the pelvis has also been used in this situation ([198](#)). Other potential diagnoses that must be differentiated from cervical pregnancy include cervical carcinoma, cervical or prolapsed submucous leiomyomas, trophoblastic tumor, placenta previa, and low-lying placenta.

-
1. Echo-free uterine cavity or the presence of a false gestational sac only
 2. Decidual transformation of the endometrium with dense echo structure
 3. Diffuse uterine wall structure
 4. Hourglass uterine shape

Table 17.5. Ultrasound Criteria for Cervical Pregnancy

When a cervical pregnancy is diagnosed before surgery, the preoperative preparation should include blood typing and cross-matching, establishment of intravenous access, and detailed informed consent. This consent should include the possibility of hemorrhage that may require transfusion or hysterectomy. Nonsurgical treatment, including intraamniotic and systemic methotrexate administration, has been used successfully ([199,200](#)).

The diagnosis may not be suspected until the patient is undergoing suction curettage for a presumed incomplete abortion and hemorrhage occurs. In some cases, bleeding is light, whereas in others, there is hemorrhage. Various techniques that can be used to control bleeding include uterine packing, lateral cervical suture placement to ligate the lateral cervical vessels, placement of a cerclage, and insertion of an intracervical 30-mL Foley catheter in an attempt to tamponade the bleeding. Alternatively, angiographic artery embolization can be used; or, if laparotomy is required, an attempt can be made to ligate the uterine or internal iliac arteries ([201,202](#) and [203](#)). When none of these methods is successful, hysterectomy is required.

Ovarian Pregnancy A pregnancy confined to the ovary represents 0.5% to 1% of all ectopic pregnancies and is the most common type of nontubal ectopic pregnancy. The incidence ranges from 1 in 40,000 to 1 in 7,000 deliveries ([204,205](#)). The diagnostic criteria were described in 1878 by Spiegelberg ([Table 17.6](#)). Unlike tubal gestation, ovarian pregnancy is associated with neither PID nor infertility. The only risk factor associated with the development of an ovarian pregnancy is the current use of an intrauterine device.

-
1. The fallopian tube on the affected side must be intact.
 2. The fetal sac must occupy the position of the ovary.
 3. The ovary must be connected to the uterus by the ovarian ligament.
 4. Ovarian tissue must be located in the sac wall.

From Spiegelberg O. *Caseistik der ovarialschwangerschaft*. *Arch Gynecol* 1878;13:71, with permission.

Table 17.6. Criteria for Ovarian Pregnancy Diagnosis

Patients have symptoms similar to those of ectopic pregnancies in other sites. Misdiagnosis is common because it is confused with a ruptured corpus luteum in up to 75% of cases ([204](#)). As with other types of ectopic pregnancy, an ovarian pregnancy has also been reported after hysterectomy ([206](#)). Ultrasonography has made preoperative diagnosis possible in some cases ([207](#)).

The treatment of ovarian pregnancy has changed. Whereas oophorectomy has been advocated in the past, ovarian cystectomy has become the preferred treatment ([208](#)). It is possible to perform cystectomy using laparoscopic techniques ([209,210](#)). Treatment with methotrexate or prostaglandin injection has also been reported ([210](#)).

Abdominal Pregnancy Abdominal pregnancies are classified as primary and secondary. [Table 17.7](#) lists criteria for classifying a primary abdominal pregnancy. Secondary abdominal pregnancies are by far the most common and result from tubal abortion or rupture or, less often, from subsequent implantation within the abdomen after uterine rupture. The incidence of abdominal pregnancy varies from 1 in 372 to 1 in 9,714 live births ([211](#)). Abdominal pregnancy is associated with high morbidity and mortality, with the risk for death 7 to 8 times greater than from tubal ectopic pregnancy and 90 times greater than from intrauterine pregnancy. There are scattered reports of term abdominal pregnancies. When this occurs, perinatal morbidity and mortality are high, usually as a result of growth restriction and congenital anomalies such as fetal pulmonary hypoplasia, pressure deformities, and facial and limb asymmetry. The incidence of congenital anomalies ranges from 20% to 40% ([212](#)).

1. Presence of normal tubes and ovaries with no evidence of recent or past pregnancy
2. No evidence of mesoplacental fistula
3. The presence of a pregnancy related exclusively to the peritoneal surface and early enough to eliminate the possibility of secondary implantation after primary tubal ligation

Table 17.7. Studdiford's Criteria for Diagnosis of Primary Abdominal Pregnancy

The presentation of patients with an abdominal pregnancy varies and depends on the gestational age. In the first and early second trimester, the symptoms may be the same as with tubal ectopic gestation; in advanced abdominal pregnancy, the clinical presentation is more variable. The patient may complain of painful fetal movement, fetal movements high in the abdomen, or sudden cessation of movements. Physical examination may disclose persistent abnormal fetal lies, abdominal tenderness, a displaced uterine cervix, easy palpation of fetal parts, and palpation of the uterus separate from the gestation. The diagnosis may be suspected when there are no uterine contractions after *oxytocin* infusion. Other diagnostic aids include abdominal x-ray, abdominal ultrasound, computed tomography scanning, and magnetic resonance imaging (213,214).

Because the pregnancy can continue to term, the potential maternal morbidity and mortality are very high. As a result, surgical intervention is recommended when an abdominal pregnancy is diagnosed. At surgery, the placenta can be removed if its vascular supply can be identified and ligated, but hemorrhage can occur, requiring abdominal packing that is left in place and removed after 24 to 48 hours. Angiographic arterial embolization has been described (215). If the vascular supply cannot be identified, the cord is ligated near the placental base, and the placenta is left in place. Placental involution can be monitored using serial ultrasonography and hCG levels. Potential complications of leaving the placenta in place include bowel obstruction, fistula formation, and sepsis as the tissue degenerates. Methotrexate treatment appears to be contraindicated because a high rate of complications has been reported, including sepsis and death, believed to be a result of rapid tissue necrosis (216).

Interstitial Pregnancy Interstitial pregnancies represent about 1% of ectopic pregnancies. These patients tend to present later in gestation than those with tubal pregnancies. Interstitial pregnancies often are associated with uterine rupture; therefore, they represent a disproportionately large percentage of fatalities from ectopic pregnancy. Treatment is cornual resection by laparotomy, although laparoscopic management has also been described (217).

Interligamentous Pregnancy Interligamentous pregnancy is a rare form of ectopic pregnancy that occurs in about 1 in every 300 ectopic pregnancies (218). An interligamentous pregnancy usually results from trophoblastic penetration of a tubal pregnancy through the tubal serosa and into the mesosalpinx, with secondary implantation between the leaves of the broad ligament. It can also occur if a uterine fistula develops between the endometrial cavity and the retroperitoneal space. As with an abdominal pregnancy, the placenta may be adherent to the uterus, bladder, and pelvic sidewalls. If possible, the placenta should be removed; when this is not possible, it can be left *in situ* and allowed to resorb. As in abdominal pregnancy, there are reported cases of live birth with this type ectopic gestation (218).

Heterotopic Pregnancy Heterotopic pregnancy occurs when there are coexisting intrauterine and ectopic pregnancies. The reported incidence varies widely from 1 in 100 to 1 in 30,000 pregnancies (219). Patients who have undergone ovulation induction have a much higher incidence of heterotopic pregnancy than those who have a spontaneous conception. An intrauterine pregnancy is seen during ultrasound examination, and an extrauterine pregnancy may be overlooked easily. Serial hCG levels are often not helpful because the intrauterine pregnancy causes the hCG level to rise appropriately.

The treatment of the ectopic pregnancy is operative; once the ectopic pregnancy has been removed, intrauterine pregnancy continues in most patients. It may be possible to use nonchemotherapeutic medical treatment such as KCl by transvaginal or laparoscopically directed injection for treatment of the ectopic pregnancy.

Multiple Ectopic Pregnancies Twin or multiple ectopic gestations occur less frequently than heterotopic gestations and may appear in a variety of locations and combinations. About 250 twin ectopic gestations have been reported (220). Although most reports are confined to twin tubal gestations, ovarian, interstitial, and abdominal twin pregnancies have been reported. Twin and triplet gestations have been reported following partial salpingectomy (221) and IVF (222). Management is similar to that for other types of ectopic pregnancy and is somewhat dependent on the location of the pregnancy.

Pregnancy After Hysterectomy The most unusual form of ectopic pregnancy is one that occurs after either vaginal or abdominal hysterectomy (223,224). Such a pregnancy may occur after supracervical hysterectomy because the patient has a cervical canal that may provide intraperitoneal access. Pregnancy may occur in the perioperative period with implantation of the fertilized ovum in the fallopian tube. Pregnancy after total hysterectomy probably occurs secondary to a vaginal mucosal defect that allows sperm into the abdominal cavity.

Diagnosis and management of common benign breast conditions, particularly those that mimic malignancy, and an appreciation of treatment options are essential for the practicing gynecologist (1). Benign breast disease is a complex entity of its own with a range of physiologic changes and clinical manifestations that have an impact on a woman's health independent of breast cancer risk (2).

Detection

History

Evaluation of a new breast complaint begins with symptom assessment by a thorough clinical history (3). The history should include questions regarding current symptoms, duration of the condition, fluctuation of the signs and symptoms, and factors that aggravate or relieve the complaint. Specific questions should address the following points:

- Nipple discharge
- Characteristics of discharge (appearance, spontaneous or nonspontaneous, unilateral or bilateral, single or multiple duct involvement)
- Breast mass (size and change in size, density, or texture)
- Breast pain (cyclic versus continuous)
- Association of symptoms with menstrual cycle
- Change in breast shape, size, or texture
- Previous breast biopsies.

The patient should be questioned about risk factors:

- Age of menarche
- Age of first pregnancy
- Age of menopause
- Family history of breast cancer
- Number of first-degree relatives with breast cancer and their ages when diagnosed
- Other malignancies (ovary, colon, and prostate)
- Pathology of previous breast biopsy.

It is important to obtain a thorough list of medications taken, including hormone therapy and herbal medications such as phytoestrogens. The gestational history should take into consideration the possibility of a current pregnancy. A personal history of exposure to radiation, especially in the treatment of childhood malignancies, is associated with a higher incidence of developing breast cancer (4). The goal of breast evaluation is to determine clearly if the complaint represents a benign breast condition or is suggestive of a neoplastic process.

Physical Examination

Breast tumors, particularly cancerous ones, usually are asymptomatic and are discovered only by physical examination or screening mammography. Typically, the breast changes slightly during the menstrual cycle. During the premenstrual phase, most women have increased innocuous nodularity and mild engorgement of the breast. Rarely, this can obscure an underlying lesion and make examination difficult. Findings should be carefully documented in the medical record to serve as a baseline for future reference.

Inspection

Inspection is done initially while the patient is seated comfortably with her arms relaxed at her sides. The breasts are compared for symmetry, contour, and skin appearance. Edema or erythema is identified easily, and skin dimpling or nipple retraction is shown by having the patient raise her arms above her head and then press her hands on her hips, thereby contracting the pectoralis muscles (Fig. 18.1). Palpable and even nonpalpable tumors that distort Cooper's ligaments may lead to skin dimpling with these maneuvers.

Figure 18.1 Raising the arm reveals retraction of the skin of the lower outer quadrant caused by a small palpable carcinoma. (From Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 2000:640, with permission.)

Palpation

While the patient is seated, each breast should be palpated methodically. Some physicians recommend palpating the breast in long strips, but the exact palpation technique used is probably not as important as the thoroughness of its application over the entire breast. One very effective method is to palpate the breast in enlarging concentric circles until the entire breast has been covered. A pendulous breast can be palpated by placing one hand between the breast and the chest wall and gently palpating the breast between both examining hands. The axillary and supraclavicular areas should be palpated for enlarged lymph nodes. The entire axilla, the upper outer quadrant of the breast, and the axillary tail of Spence are palpated for possible masses.

While the patient is supine with one arm over her head, the ipsilateral breast is again methodically palpated from the clavicle to the costal margin. If the breast is large, a pillow or towel should be placed beneath the scapula to elevate the side being examined; otherwise the breast tends to fall to the side, making palpation of the lateral hemisphere more difficult.

The major features to be identified on palpation of the breast are temperature, texture and thickness of skin, generalized or focal tenderness, nodularity, density, asymmetry, dominant masses, and nipple discharge. Most premenopausal patients have normally nodular breast parenchyma. The nodularity is diffuse but predominantly in the upper outer quadrants where there is more breast tissue. These benign parenchymal nodules are small, similar in size, and indistinct. By comparison, breast cancer is usually a nontender, firm mass with irregular margins. This mass feels distinctly different from the surrounding nodularity. A malignant mass may be fixed to the skin or to the underlying fascia. A suspicious mass is usually unilateral. Similar findings in both breasts are unlikely to represent malignant disease (5).

Breast Self-examination

Breast self-examination (BSE) increases early detection of cancer and may improve the survival of patients with breast carcinoma (6,7 and 8). In fact, most breast cancers are detected first by the patient rather than by the physician. Although young women have a low incidence of breast cancer, it is important to teach self-examination early so that it becomes habitual. Organizations such as the American Cancer Society sponsor courses in BSE. Reassurance, support, and patient education may encourage women to overcome psychological barriers to routine BSE (9). One study evaluated three different methods of instruction to determine compliance with BSE (10). The first arm evaluated the impact of physician message alone, the second arm assessed physician message in conjunction with a BSE class, and the third arm added follow-up reinforcement by phone or postcard to physician message and BSE class. The third produced the highest percentage of women doing BSE and is the ideal method of engaging patients to perform BSE.

The woman should inspect her breasts while standing or sitting before a mirror, looking for any asymmetry, skin dimpling, or nipple retraction. Elevating her arms over her head or pressing her hands against her hips to contract the pectoralis muscles will highlight any skin dimpling. While standing or sitting, she should carefully palpate her breasts with the fingers of the opposite hand. This may be performed while showering, because soap and water may increase the sensitivity of palpation. Finally, she should lie down and again palpate each quadrant of the breast, as well as the axilla.

Premenopausal women should examine their breasts monthly during the week after menses. It is helpful for all women to examine their breasts at the same time each month to develop a routine. All women should be instructed to report any abnormalities or changes to their physicians. If the physician cannot confirm the patient's findings, the examination should be repeated in 1 month or after her next menstrual period.

Breast Imaging

Mammography and ultrasonography are the most reliable and common imaging techniques for early detection of breast lesions (11,12). Full-field digital mammography is a modification of screen-film mammography, which records mammographic images on a computer (13). The U.S. Food and Drug Administration (FDA) approved a digital mammography system in March 2000 (14). This technology is still considered investigational and is not widely available (15). Some proposed advantages include lower radiation exposure, ability to manipulate a computerized image for optimal viewing, and distance consultations through tele-mammography (16). Magnetic resonance imaging (MRI) may be valuable for assessing breast lesions of an indeterminate nature detected by clinical and mammographic examination or occurring in patients who have implants (17). MRI and positron emission tomography (PET) have been used to identify occult lesions (18,19). Novel developments in breast imaging can be anticipated that will use functional imaging and molecular biology to create better methods to quantify the extent of disease as well as response to therapeutic interventions (20,21). A promising new approach uses technetium-99m (^{99m}Tc) sestamibi to detect breast cancer, especially in women with dense breast tissue (22).

Mammography

Slowly growing breast cancers can be identified by mammography at least 2 years before the mass reaches a size detectable by palpation (23). In fact, mammography is the only reproducible method of detecting nonpalpable breast cancer. However, its accurate use requires state-of-the-art equipment and a skilled radiologist. Vigorous compression of the breast is necessary to obtain good images, and patients should be forewarned that breast compression is uncomfortable. With a good technique and well-maintained modern equipment, the average mean glandular dose per mammographic image for all facilities in the United States inspected under the Mammography Quality Standards Act in the first one-half of 1997 was 1.6 mGy (160 mrad) (24).

Indications for Mammography

There are several indications for mammography:

1. To screen, at regular intervals, women who are at high risk for developing breast cancer. About one-third of the abnormalities detected on screening mammography prove malignant when biopsy is performed (25).
2. To evaluate a questionable or ill-defined breast mass or other suspicious change in the breast.
3. To establish a baseline breast mammogram and reevaluate patients at yearly intervals to diagnose a potentially curable breast cancer before it has been diagnosed clinically.
4. To search for occult breast cancer in a patient with metastatic disease in axillary nodes or elsewhere from an unknown primary origin.
5. To screen for unsuspected cancer prior to cosmetic operations or biopsy of a mass.
6. To monitor breast cancer patients who have been treated with a breast-conserving operation and radiation.

Screening

Approximately 35% to 50% of early breast cancers can be discovered only by mammography, and about 20% can be detected only by palpation. Mass screening programs to evaluate asymptomatic, healthy women combine physical examination with mammographic screening to identify breast abnormalities. During the past 25 years, there has been an increase in mammography, mammographic screening, and public awareness. The cancer detection rate for screening mammograms is 5 per 1,000 screening examinations (26). It is 11-fold higher for diagnostic mammograms at 55 per 1,000 diagnostic mammographic examinations (26). The mean diameter of breast cancers at diagnosis has decreased from 3 cm from 1979 to 1983 to 2 cm from 1989 to 1993, and this downward trend appears to be continuing (27,28). As the mean maximal diameter of breast cancers has decreased, there has been a simultaneous decrease in the number of positive axillary lymph nodes (28). Detecting breast cancer before it has spread to the axillary nodes greatly increases the chance of survival; about 85% of such women will survive at least 5 years (28).

Mammography's lack of sensitivity in dense breast tissue has led to questions concerning its screening value in women 40 to 50 years of age. In February 1993, the National Cancer Institute (NCI) held an international workshop on screening for breast cancer (23). The purpose of this workshop was to undertake a critical review of recent clinical screening trials. The participants examined only randomized studies and focused on clinical evidence related to the efficacy of breast cancer screening in various age groups. Of the eight randomized trials identified, only the Health Insurance Plan (HIP) project demonstrated a beneficial effect of screening for women between 40 and 49 years of age. This benefit was seen 10 to 18 years after entry into the study and resulted in a 25% decrease in deaths from breast cancer. Several Swedish trials showed a 13% decrease in breast cancer mortality for women in this age group after 12 years of follow-up; however, this decrease was not statistically significant (29,30). In a metaanalysis of five randomized trials, the breast cancer rates were independent of screening in women aged 40 to 49 years (31). The beneficial effect of screening in women aged 50 to 69 years was confirmed by all clinical trials. The efficacy of screening in women older than 70 years of age was inconclusive because of the small sample size.

This topic was once again revisited in 1997. The American Cancer Society (ACS) convened a workshop on breast cancer screening in 1997 to establish guidelines for early detection of breast cancer (32). The ACS recommends monthly BSE and clinical breast examination every 3 years between ages 18 and 39. They recommend a baseline mammogram at age 40 and annual mammography for women beginning at age 40 with no upper age limit (32). This recommendation has been adopted by the American Medical Association, American College of Radiology, American Society of Clinical Oncology, and the American College of Obstetricians and Gynecologists (33,34). In contrast, the NCI also met in 1997 to discuss, debate, and reach a consensus statement for breast cancer screening (35). They concluded that a beneficial effect was seen in women over 50 years of age, but a 17% reduction in breast cancer deaths in the 40- to 49-year age group with screening was not felt to be significant enough to mandate annual mammography examinations. The NCI recommendations for women with an average risk of breast cancer is screening mammography every 1 to 2 years for women between ages 40 and 49. Women with higher risk should seek the advice of a physician and have their individual risk assessed. In an overview of breast cancer screening, Kopans condemns the arbitrary categorization of women into two age groups (<50 and ≥50 years) (36). There is not an abrupt change in screening parameters at this age cutoff, and breast cancer in the younger woman is no less serious a problem, with potential years of life lost. He concludes that screening should begin at age 40 and continue on an annual basis to reduce breast cancer mortality by 24%.

There is a consensus that annual physical and mammographic examinations should be performed for women 50 years of age and older. Screening of women older than 70 years of age should be performed after consideration of the patient's comorbid conditions and her overall state of health. Recent reports evaluating the use of mammography in the older population revealed significantly smaller lesions and earlier stage of disease (37), with a 40% reduction in breast cancer mortality at 10 years (38) and a lower incidence of metastatic disease at time of breast cancer diagnosis (39).

Mammographic Abnormalities

A mammographic abnormality includes a mass (solid versus cystic), microcalcifications (benign, indeterminate, suspicious), asymmetric density, architectural distortion, and appearance of a new density. Mammographic abnormalities should be identified on two views and triangulate to the same location on those two views. Examples of mammographic abnormalities can be reviewed in several internet radiology libraries (40). Calcifications can be macrocalcifications, which are coarse and usually represent benign degenerative breast conditions. In breast cancer, the most common diagnostic mammographic abnormalities are clustered pleomorphic microcalcifications (41). Typically, five to eight or more calcifications are aggregated in one part of the breast. These calcifications may be associated with a mammographic mass density. A mass density may appear without evidence of calcifications. It can represent a cyst, benign tumor, or a malignancy. A malignant density usually has irregular or ill-defined borders and may lead to architectural distortion, which may be subtle and difficult to detect in a dense breast. Other mammographic findings suggesting breast cancer are architectural distortion, asymmetric density, skin thickening or retraction, or nipple retraction.

Mammographic Reports

The American College of Radiology has recommended the Breast Imaging Reporting and Data System (BI-RADS) as a standardized scheme for describing mammographic lesions (42). There are eight morphologic categories (42):

1. Calcification distribution
2. Number of calcification
3. Description of calcification
4. Mass margin
5. Shape of mass
6. Density of mass
7. Associated findings
8. Special cases.

In the BI-RADS system, there are six categories for mammographic findings (43):

1. 0 is incomplete, needs further imaging
2. 1 is negative
3. 2 is a benign finding
4. 3 is probably benign, short-interval follow-up recommended
5. 4 is a suspicious finding and biopsy should be considered
6. 5 is highly suggestive of malignancy and appropriate action should be undertaken.

The patient should be referred to a surgeon if the report identifies a lesion as a category 4 or 5 (44). A category 0 indicates incomplete evaluation and further diagnostic studies are required. A category 3 is a finding which is most likely benign and a short-interval follow-up is recommended.

Biopsy must be performed on patients with a dominant or suspicious mass despite absence of mammographic findings (45). Mammography should be performed before biopsy so other suspicious areas can be noted and the contralateral breast can be checked (Fig. 18.2).

Figure 18.2 Bilateral mammography shows the extent of breast carcinoma, illustrating the importance of bilateral mammography in the workup of a clinically apparent mass. (From Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*, 3rd ed. Baltimore: Lippincott Williams

Correlation of Findings

Mammography is never a substitute for biopsy because it may not reveal clinical cancer, especially when it occurs in the dense breast tissue of young women with fibrocystic changes. In fact, the sensitivity of mammography varies from approximately 60% to 90%, depending on the patient's age (breast density) and the size, location, and mammographic appearance of the tumor.

Mammography is less sensitive in young women with dense breast tissue than in older women, who tend to have fatty breasts in which mammography can detect at least 90% of malignancies. Small tumors, particularly those without calcifications, are more difficult to detect, especially in women with dense breasts. The specificity of mammography is about 30% to 40% for nonpalpable mammographic abnormalities and 85% to 90% for clinically evident malignancies ([46](#)).

Ultrasonography

Reliable, portable computer-enhanced ultrasonography with high-frequency transducers and improved imaging is now available to evaluate and treat problems of the breast ([47](#)). It is a sensitive, minimally invasive technique that is being used more frequently in evaluating some breast symptoms, especially in younger women with dense breast tissue ([48](#)). There are some lesions that can be detected only with ultrasonography ([49](#)). It is the preferred modality to distinguish a solid from a cystic mass ([47](#)). Screening breast ultrasonography identifies many irregularities and hypoechoic areas; the significance of these findings must be validated in prospective randomized studies ([50](#)). Most experts advise against screening ultrasonography. However, the role of ultrasonography to identify breast cancer is continuing to undergo evaluation ([51,52](#)).

Ultrasonography may be especially useful if the patient feels a mass, but the physician cannot detect an abnormality and the mammogram does not disclose one. Ultrasonography cannot reliably detect microcalcifications, and it is not as useful as mammography for fatty breasts. Ultrasonography may be useful in identifying noncalcified cancers in the dense breast tissue of premenopausal women, but it is usually used to distinguish a benign cyst from a solid tumor.

Handheld or real-time ultrasonography is 95% to 100% accurate in differentiating solid masses from cysts ([53](#)). However, this is of limited clinical value because a dominant mass should be evaluated by biopsy, and a cystic mass can be studied by needle aspiration, which is far less expensive than ultrasonography. The primary role of handheld ultrasonography is in the evaluation of a benign-appearing, nonpalpable density identified by mammography. If such a lesion proves to be a simple cyst, no further workup is necessary. Rarely, ultrasonography may identify a small cancer within a cyst—an intracystic carcinoma. These complex cysts warrant surgical biopsy.

Magnetic Resonance Imaging

MRI is increasing in popularity as a means of imaging the breast ([17,54](#)). It tends to be highly sensitive but not very specific, leading to biopsies of many benign lesions. Image enhancement with gadolinium can discriminate between benign and malignant lesions with varying degrees of accuracy.

Several roles have been proposed for breast MRI. Its lack of radiation exposure makes MRI ideal for mass screening of healthy women, although such widespread use is probably too costly. There may be a role for MRI in evaluation of specific conditions such as (a) focal, asymmetric areas detected mammographically, (b) postoperative scar, and (c) exclusion of silicone leak with implants. Focal asymmetry is usually benign but can represent a malignancy, and MRI may help identify patients in whom focal asymmetric areas should undergo biopsy. Usually, a scar can easily be distinguished from recurrent tumor based on the evaluation and diminution of the scar over time. Some scars, however, do not diminish rapidly and are confused with cancer or, more commonly, with recurrent cancer after breast-conserving operation and radiation. Ideally, such cases are evaluated with MRI, sometimes obviating the need for biopsy. MRI is extremely useful in identifying silicone released by a ruptured breast implant in patients with augmented breasts ([Fig. 18.3](#)). In patients with implants, MRI with gadolinium may be performed to detect breast cancer, even if free silicone is not suspected.

Figure 18.3 Mammography shows implant and extracapsular free silicone (*arrow*).

The International Cooperative Magnetic Resonance Mammography Study that is currently under way will help identify the advantages and limitations of MRI. At present, MRI should be considered only after conventional imaging is performed; it should be used neither as a screening tool nor a substitute for mammography or biopsy.

Technetium-99m Sestamibi Scan

Technetium-99m sestamibi is an agent approved for coronary imaging. It is metabolized in the mitochondria. Evaluation of patients using physical examination, mammography, ultrasonography, and sestamibi scan indicate an 88% positive predictive value and a 93% negative predictive value with a sensitivity of 84% and a specificity of 95% ([55](#)). In a multicenter prospective cohort clinical trial comparing mammography to sestamibi, a positive scintimammogram increases the ability to predict the presence of malignant disease ([56](#)). This modality is still undergoing evaluation.

Positive Emission Tomography Scan

PET is a diagnostic modality that assesses the metabolic activity of tumors. Radioactive fluorodeoxyglucose (FDG) is an analog of glucose that is metabolized by tissues of high metabolic rates. In two prospective trials comparing PET to mammography, primary breast lesions were correctly identified and lymph nodes status was determined with a high degree of sensitivity using PET ([57,58](#)). PET has been used to identify occult breast lesions with positive axillary lymph nodes ([59](#)).

Breast Biopsy

The diagnosis of breast cancer depends ultimately on examination of tissue removed by biopsy. Because cancer is found in the minority of patients who require biopsy for diagnosis of a breast mass, treatment should never be undertaken without an unequivocal histologic diagnosis of cancer.

The safest course is biopsy examination of all dominant masses found on physical examination and, in the absence of a mass, of suspicious lesions

shown by mammography. About 30% of lesions suspected to be cancer prove on biopsy to be benign, and about 15% of lesions believed to be benign prove to be malignant (25). Dominant masses or suspicious nonpalpable mammographic findings must be evaluated by biopsy (44,45). Histologic diagnosis should be obtained before conservation management to monitor breast mass. An exception may be a premenopausal woman with a nonsuspicious mass presumed to be fibrocystic disease. However, an apparently fibrocystic lesion that does not completely resolve within several menstrual cycles should be sampled for biopsy. Any mass in a postmenopausal woman who is not taking estrogen replacement should be presumed to be malignant. Figure 18.4 and Figure 18.5 present algorithms for management of breast masses in premenopausal and postmenopausal patients. Simultaneous evaluation of a breast mass using clinical breast examination, radiography, and fine-needle aspiration biopsy can lower the risk of missing cancer to only 1%, effectively reducing the rate of diagnostic failure and increasing the quality of patient care (60). Ultrasonography is frequently used in addition to these techniques; although not studied, it most likely further reduces the risk of failure to diagnose cancer.

Figure 18.4 Algorithm for management of breast masses in premenopausal women. (From Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 2000:652, with permission.)

Figure 18.5 Algorithm for management of breast masses in postmenopausal women. (From Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 2000:653, with permission.)

If the presence of breast cancer is strongly suggested by physical examination, the diagnosis can be confirmed by fine-needle cytologic assessment or core biopsy, and the patient may be counseled regarding treatment. Treatment should not be determined based on results of physical examination and mammography alone, in the absence of biopsy results. **The most reasonable approach to the diagnosis and treatment of breast cancer is outpatient biopsy (either needle or excision), followed by definitive surgery at a later date if needed.** This two-step approach allows patients to adjust to the diagnosis of cancer, carefully consider alternative forms of therapy, and seek a second opinion if they wish. Studies have shown no adverse effect from the 1- to 2-week delay associated with the two-step procedure (61). However, the two-step procedure should be reexamined in view of the increasing popularity of lumpectomy. Suspicious lesions may best be excised as the definitive lumpectomy specimen even if biopsy has not shown malignancy. The lumpectomy is, in essence, a biopsy that ensures a rim of normal tissue around the mass. It is better performed with the mass removed in its entirety than after a prior excisional biopsy.

Fine-needle Aspiration

Fine-needle aspiration cytology is a useful technique whereby cells from a breast tumor are aspirated with a small (usually 22-gauge) needle and examined by a pathologist. Precise guidelines for this technique are available (62). It can be performed easily, with no morbidity, and is much less expensive than excisional or open biopsy. However, it requires the availability of a pathologist skilled in the cytologic diagnosis of breast cancer to interpret the results, and it is subject to sampling problems, particularly when lesions are deep. Cytologic diagnoses must be correlated with clinical and imaging findings to achieve triple-test concordance and to decrease the false-negative rate (63). The triple test, comprising fine-needle aspiration, physical examination, and mammography, is the foundation of breast evaluation. The triple-test results are more powerful than each modality alone (64). The incidence of false-positive diagnoses was 0% to 0.3%, and the rate of false-negative diagnoses was 1.4% to 2.3% in several recent studies (64,65).

Most experienced clinicians will not leave a dominant mass in the breast even when fine-needle aspiration cytology results are negative. Some clinicians will monitor a mass when results of the clinical diagnosis, breast imaging studies, and cytologic studies are all in agreement. However, occasionally a malignancy will be diagnosed later, and such cases require periodic follow-up.

Core Biopsy

A core of tissue can be obtained from palpable lesions using a large cutting needle (66). Image-guided large-core needle biopsy is a reliable diagnostic alternative to surgical excision of suspicious nonpalpable breast lesions (67). As in the case of any needle biopsy, the main drawback is false-negative findings caused by improper positioning of the needle. False-negative findings may be reduced if core biopsy is performed with ultrasonographic direction.

Open Biopsy

Open biopsy with local anesthesia as a separate procedure prior to deciding on definitive treatment is the most reliable means of diagnosis. It is required when the results of needle biopsy are nondiagnostic or equivocal.

Histologic Analysis

Histologic evaluation with hematoxylin and eosin (H & E) staining confirms benign or malignant disease. Images of benign and malignant breast lesions can be viewed through the Internet Pathology Laboratory for Medical Education (68). The estrogen, progesterone, her-2/ neu receptor status, and proliferative indices of the tumor should be determined during initial biopsy. This assessment is performed on paraffin-fixed tissue by immunohistochemistry (69). Her-2/ neu assessment in breast cancer by immunohistochemistry (IHC) is appropriate for patients with tumors that score 3+. Fluorescence *in situ* hybridization (FISH) is recommended for 2+ IHC to more accurately assess her-2/ neu amplification and provide better prognostic information (70).

Nipple Discharge and Nipple Lavage

Cytologic examination of nipple discharge or cyst fluid is rarely performed. Mammography (or ductography) and breast biopsy may be performed when nipple discharge or cyst fluid is bloody or cytologically questionable. However, excision and examination of the involved ductal system is the preferred method of diagnosis, and cytologic assessment should not be relied on for diagnosis.

Ductal lavage using a microcatheter is a new modality that has recently been investigated in high-risk women (71). Patients undergo gentle nipple suction to elicit nipple fluid. A duct that yields fluid is then cannulated with a microcatheter and 10 to 20 ml of saline are introduced in 2- to 4-ml increments. The cytologic assessment of a sample obtained by ductal lavage is more sensitive than that of nipple aspiration. Ductal lavage is a better modality to obtain a large number of cells for cytological evaluation. It is safe and well tolerated (71).

Benign Breast Conditions

Benign breast disorders account for a significant number of breast complaints. These conditions are frequently considered in relation to the possibility of excluding breast cancer and are often not recognized for their own associated morbidity (72). In order to provide appropriate management, it is important to consider benign breast disorders from four aspects, (a) clinical picture, (b) medical significance, (c) treatment intervention, (d) and pathologic etiology (73).

Hughes has described a conceptual framework to understanding benign breast problems that is called Aberrations of Normal Development and Involution (ANDI) (2,72,73). It includes symptomatology, histology, endocrine state, and pathogenesis in a progression from a normal to a disease state. Most benign breast conditions arise from normal changes in breast development, hormone cycling, and reproductive evolution (72).

There are three life cycles that reflect different reproductive phases in a woman's life and are associated with unique breast manifestations.

1. During the early reproductive period (15 to 25 years) there is lobule and stromal formation. The ANDI conditions associated with this period are fibroadenoma (mass) and juvenile hypertrophy (excessive breast development). In this first stage the progression from ANDI to a disease state results in the formation of giant fibroadenomas and multiple fibroadenomas.
2. During the mature reproductive period (25 to 40 years) cyclic hormonal changes affect glandular tissue and stroma. In this second period the ANDI is an exaggeration of these cyclic effects, such as cyclic mastalgia and generalized nodularity.
3. The third phase is involution of lobules and ducts or epithelia turnover, which occurs during ages 35 to 55 years. The ANDI associated with lobular involution are macrocysts (lumps) and sclerosing lesions (mammographic abnormalities). Those associated with ductal involution are duct dilation (nipple discharge) and periductal fibrosis (nipple retraction), and those with epithelial turnover are mild hyperplasia (pathologic description).

With ductal involution, progression to disease states during this period results in periductal mastitis with bacterial infections and abscess formation. Disease conditions with increased epithelial turnover are epithelial hyperplasias with atypia. Hughes feels that this framework allows the clinician to understand the pathogenesis of these conditions and to understand that these disorders are aberrations of a normal process that does not usually require any specific treatment (72).

Fibrocystic Change

Fibrocystic change, the most common lesion of the breast, is an imprecise term that covers a spectrum of clinical signs and symptoms and histologic changes (66). Macroscopic cysts occur in approximately 7% of women and microscopic, nonpalpable cysts in close to 40% of women (74). The term refers to a histologic picture of fibrosis, cyst formation, and epithelial hyperplasia (73). It is common in women 35 to 55 years of age but rare in postmenopausal women not taking hormone replacement therapy. The presence of estrogen seems necessary for the clinical symptoms to occur. This is supported by the observation that it is present bilaterally, increased in the perimenopausal age group, and responsive to endocrine therapy (75). In essence, a diagnosis of fibrocystic change is of little clinical significance as long as malignancy is excluded. These lesions are always associated with benign changes in the breast epithelium.

Cysts arise from the breast lobules and are an aberration of normal breast involution. The potassium-to-sodium ratio is a convenient marker to distinguish cyst subtypes (76). Cysts are either lined by apocrine epithelium with a high potassium-to-sodium ratio and a higher hormone or steroid concentration (type I); or by flattened lobule epithelium with a low potassium-to-sodium ratio and a higher concentration of albumin, CEA, CA125, and steroid hormone-binding globulin (type II) (75,77). A recent study has demonstrated that apocrine cysts produce and secrete large amounts of prostate-specific antigen (PSA) (78). The role of this serine protease in proliferative breast disease is not fully understood.

Clinical Findings

Fibrocystic changes may produce an asymptomatic mass but more often are accompanied by pain or tenderness and sometimes nipple discharge. In many cases, discomfort coincides with the premenstrual phase of the cycle, when the cysts tend to enlarge. Fluctuation in size and rapid appearance or disappearance of a breast mass are common. Multiple or bilateral masses appear frequently, and many patients have a history of a transient mass in the breast or cyclic breast pain. Cyclic breast pain is the most common symptom of fibrocystic changes.

Differential Diagnosis

Pain, fluctuation in size, and multiplicity of lesions are the features most helpful for differentiation from carcinoma. If a dominant mass is present, however, the diagnosis of cancer should be suspected until it is disproved by biopsy. Final diagnosis of the mass usually depends on biopsy.

Diagnostic Tests

Patients with cystic disease may have a discrete fibrocystic mass that is frequently indistinguishable from carcinoma on the basis of clinical findings. Mammography may be helpful, but there are no mammographic signs diagnostic of fibrocystic change. Ultrasonography is useful in differentiating a cystic from a solid mass. The finding of a simple cyst rules out carcinoma. **Any suspicious lesion should be biopsied.** Microscopic findings include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia (79).

When the diagnosis of fibrocystic change has been established by previous biopsy or is practically certain because the history is classic, aspiration of a discrete mass suggestive of a cyst is indicated. Aspiration may be performed with ultrasonographic guidance, but this usually is not necessary (80). Benign cyst fluid is straw colored to dark green to brownish and does not need to be submitted for cytologic evaluation (5). The patient is reexamined at intervals thereafter. Further cysts will occur in 30% of patients, cause anxiety, and require repeated evaluations (74). Biopsy should be performed if no cyst fluid is obtained, if the fluid is bloody, if a mass persists after aspiration, or if at any time during follow-up a persistent mass is noted. Even if a needle biopsy is performed and results are negative for malignancy, a suspicious mass that does not resolve over several months should be excised. Surgery should be conservative, because the primary objective is to exclude cancer. Simple mastectomy or extensive removal of breast tissue is rarely, if ever, indicated for fibrocystic disease. Most patients do not require treatment.

Mastalgia

Mastalgia is a recognized organic condition (81,82). Approximately 70% of women experience severe breast pain at some time in their lives (83). More than 30% of women seen in surgical breast clinics suffer from mastalgia (84). In 15% of the patients the mastalgia is so severe that it alters lifestyle and requires treatment (83). Mastalgia interferes with sexual (48%), physical (37%), social (12%), and work or school activities (8%) (85).

Cyclic mastalgia is related to exaggerated premenstrual symptoms associated with breast engorgement, pain, and tenderness (86). Noncyclic mastalgia is independent of menstrual cycles and more difficult to treat. Breast pain associated with generalized fibrocystic changes is best treated by avoiding trauma and by wearing (night and day) a brassiere that gives good support and protection (87). Hormone therapy is not advisable because it does not relieve symptoms and has undesirable side effects. Recognized treatments include bromocriptine, danazol, evening primrose oil, and tamoxifen, although tamoxifen is not approved for this use (88,89,90 and 91). A survey of surgeons in Great Britain revealed that 75% prescribed danazol as first-line therapy (81). Other treatments included analgesia (21%),

diuretics (18%), local excision (18%), bromocriptine (15%), evening primrose oil (13%), tamoxifen (9%), a well-fitting bra (3%), and no treatment (10%) (81). In this study, breast specialists were more likely to initiate therapy with evening primrose oil, tamoxifen, vitamin B₆, and analgesia. In another study the first-line therapy was evening primrose oil containing essential fatty acids (g-linolenic acid [GLA]), with danazol and bromocriptine reserved for second-line treatment (83). In a prospective mastalgia trial, women were given eight capsules of evening primrose oil daily for 4 months (320 mg GLA) (92). Those who responded had a lower level of essential fatty acids at the time of initiation when compared with poor responders, suggesting that evening primrose oil increases essential fatty acids and that this increase may be associated with the improvement in symptoms in the responders. Danazol (100 to 200 mg twice daily orally), a synthetic androgen, has been used for patients with severe pain (89). This treatment suppresses pituitary gonadotropins, and its androgenic effects (acne, edema, hirsutism) are usually intolerable; therefore, it probably should not be used. A recent study was conducted to evaluate the response to administration of danazol (200 mg daily) during the luteal phase (93). This approach to therapy reduces the premenstrual mastalgia with virtually no side effects. In one study, taking progesterone agents for birth control reduced cyclic breast pain to 2.3% of women compared with 4.9% who did not take such medication (84). Further studies may be warranted to see whether medroxyprogesterone acetate suppresses cyclic mastalgia in reproductive-age women. Bromocriptine (2.5 mg twice daily) given for 3 to 6 months was effective in women with an abnormal thyrotropin-releasing hormone (TRH) level (90). Patients who have normal TRH levels or are resistant to bromocriptine responded favorably to progesterone and systemic nonsteroidal antiinflammatory drugs.

The role of caffeine consumption in the aggravation of fibrocystic change is controversial (94,95,96 and 97). Results of some studies suggest that eliminating caffeine from the diet is associated with improvement of symptoms (96,97). Many patients are aware of these studies and report relief of symptoms after discontinuing intake of coffee, tea, and chocolate. Similarly, many women find vitamin E (150 to 600 IU daily) or B₆ (200 to 800 mg/day) helpful (98,99). However, observations about these effects have been difficult to confirm and are anecdotal (100,101 and 102). A recent review of nutritional interventions for fibrocystic breast conditions that evaluated evening primrose oil, vitamin E, or pyridoxine suggested that there are insufficient data to draw clear conclusions about their effectiveness (103). Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms usually subside unless patients are taking estrogen. A patient with fibrocystic changes should be advised to examine her own breasts each month just after menstruation and to inform her physician if a mass appears.

Fibrocystic Change and Cancer

Fibrocystic change is not associated with an increased risk of breast cancer unless there is histologic evidence of epithelial proliferative changes, with or without atypia (104,105,106,107,108 and 109). The common coincidence of fibrocystic disease and malignancy in the same breast reflects that one in every nine women will develop breast cancer, and as many as 80% of biopsies show fibrocystic changes. Page and Dupont (107) evaluated the relationship between fibrocystic change and breast cancer in 10,366 women who underwent biopsy from 1950 until 1968 and were followed for a median of 17 years. Approximately 70% of the biopsies showed nonproliferative breast disease, whereas 30% showed proliferative breast disease. Cytologic atypia were present in 3.6% of cases. Women with nonproliferative disease had no increased risk of breast cancer, whereas women with proliferative breast disease and no atypical hyperplasia had a twofold higher risk of breast cancer. **Patients whose biopsy results showed atypical ductal or lobular hyperplasia had an approximately fivefold higher risk than women with nonproliferative disease to develop invasive breast cancer in either breast.** Patients with carcinoma *in situ* have an 8- to 10-fold risk of developing breast cancer. This risk is bilateral for lobular lesions and local for ductal lesions. A family history of breast cancer added little risk for women with nonproliferative disease, but family history plus atypia increased breast cancer risk 11-fold. The presence of cysts alone did not increase the risk of breast cancer, but cysts combined with a family history of breast cancer increased the risk about threefold (66,104,105,106,107,108 and 109). Women with these risk factors (family history of breast cancer and proliferative breast disease) should be followed carefully with physical examination and mammography. For such women, age-specific probability of developing invasive breast carcinoma in the next 10 years is 1 in 2,000 (age 20), 1 in 256 (age 30), 1 in 67 (age 40), 1 in 39 (age 50) and 1 in 29 (age 60) (105). The relative risk changes with the type of proliferative lesion diagnosed.

Benign Tumors

Fibroadenoma

Fibroadenomas are the most common benign tumors of the breast. In one series, they account for 50% of all breast biopsies (110). They usually occur in young women (age 20 to 35 years) and may occur in teenagers (111). In women younger than 25 years, fibroadenomas are more common than cysts. They rarely occur after menopause, although occasionally they are found, often calcified, in postmenopausal women. For this reason, it is postulated that fibroadenomas are responsive to estrogen stimulation. A recent study reports the *de novo* occurrence of fibroadenoma in 51 women over age 35 years, who had no evidence of a palpable or mammographic visualized lesion in well-documented prior visits (112).

Although the presence of a fibroadenoma does not increase the risk of breast carcinoma, this subject still generates controversy (113). Because transformation of a fibroadenoma into cancer is rare and regression is frequent, current management recommendations are conservative (110).

On gross examination, fibroadenomas appear encapsulated and sharply delineated from the surrounding breast parenchyma. Microscopically, they have an epithelial and a stromal component. In longstanding lesions and in postmenopausal patients, calcifications may be observed within the stroma. Fibroadenomas may appear in multiples. Clinically, a young patient usually notices a mass while showering or dressing. Most masses are 2 to 3 cm in diameter when detected, but they can become extremely large (i.e., the giant fibroadenoma). On physical examination, they are firm, smooth, and rubbery. They do not elicit an inflammatory reaction, are freely mobile, and cause no dimpling of the skin or nipple retraction. They are often bilobed, and a groove can be palpated on examination. Mammographically, they have typical benign-appearing features with smooth, clearly defined margins.

A suspected fibroadenoma should be confirmed by either excisional biopsy or fine-needle aspiration cytology. Complete excision of a fibroadenoma with local anesthesia can be performed to treat the lesion and confirm the absence of malignancy. However, a young woman with a clinical fibroadenoma can undergo needle cytology and observation of the mass (114). Rarely will the fibroadenoma increase to more than 2 to 3 cm in size. Large or growing fibroadenomas must be excised.

Multiple Fibroadenomas

Multiple fibroadenomas have been reported in premenopausal women undergoing immunosuppression for transplant (115,116,117 and 118). It is an uncommon syndrome that raises issues regarding appropriate treatment. Excision of all lesions through separate incisions could leave significant scarring and deformity. Excision of these mobile lesions through a single periareolar incision has been suggested, but this approach can lead to significant ductal disruption (119). Alternatively, these lesions can be treated with observation based on triple-test concordance of a classic clinical examination with histologic corroboration with FNA and ultrasonographic diagnostic criteria consistent with a fibroadenoma (116).

Phyllodes Tumor

Cystosarcoma phyllodes, which is perhaps best referred to as a *phyllodes tumor*, may occur at any age but tends to be more common in women who are in their late thirties, forties, and fifties (120,121,122 and 123). These lesions are rarely bilateral and usually appear as isolated masses that are difficult to distinguish clinically from a fibroadenoma. Patients often relate a long history of a previously stable nodule that suddenly increases in size. Size is not a diagnostic criterion, although phyllodes tumors tend to be larger than fibroadenomas, probably because of their rapid growth. There are no good clinical criteria by which to distinguish a phyllodes tumor from a fibroadenoma.

The histologic distinction between fibroadenoma, benign phyllodes tumor, and malignant phyllodes tumor can be very difficult (124). Tumors judged by the pathologist to be benign tend to recur locally in up to 10% of patients (121,122 and 123). Malignant phyllodes tumors tend to recur locally and usually metastasize to the lung, although brain, pelvic, and bone metastases have also been reported (121,123). The stromal component of the tumor is malignant and metastasizes, behaving like a sarcoma. Axillary involvement is extremely unusual. Often, the appearance of metastasis is the first sign that a phyllodes tumor is malignant.

Treatment is wide local excision (120,121,122 and 123,125). Primary excision or reexcision with normal breast margins is recommended (122). Massive tumors, or large tumors in relatively small breasts, may require mastectomy; otherwise, mastectomy should be avoided and axillary lymph node dissection is not indicated. Typically, a patient will undergo excisional biopsy of a mass believed to be fibroadenoma, but histologic examination will reveal a phyllodes tumor. When the pathologic diagnosis is phyllodes tumor, complete reexcision of the area should be undertaken so that the prior biopsy site and any residual tumor are removed. Recurrence is associated with margin involvement, whereas death correlates with size and grade (126). Chemotherapy for metastatic phyllodes tumors should be based on regimens for sarcoma, not adenocarcinoma (122). Radiation therapy has generally not been used in the treatment of phyllodes tumors. When there is bulky

tumor, positive margins, recurrence, or malignant histology radiation therapy may be of some benefit ([127](#)).

Breast Conditions Requiring Evaluation

Nipple Discharge

Nipple discharge is the breast symptom in 4.8% of patients seeking evaluation of a breast complaint, with 2.6% spontaneous and 2.2% provoked ([128](#)). Nipple discharge is infrequently found to be associated with carcinoma, with only 4 of 104 cases (3.8%) being due to malignancy ([129](#)). The most common causes of nipple discharge in nonlactating women are solitary intraductal papilloma, carcinoma, papillomatosis, and fibrocystic change with ectasia of the ducts ([130](#)). **Following are the important characteristics of the discharge and other factors to be evaluated by history and physical examination ([130](#)):**

1. Nature of discharge (serous, bloody, or milky)
2. Association with a mass
3. Unilateral or bilateral
4. Single or multiple ducts
5. Discharge that is spontaneous (persistent or intermittent) or expressed by pressure at a single site or on entire breast
6. Relation to menses
7. Premenopausal or postmenopausal
8. Hormonal medication (contraceptive pills or estrogen).

Unilateral, spontaneous, bloody, or serosanguinous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal cancer. In either case, a mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple and at the margin of the areola. Bloody discharge is more suggestive of cancer but is usually caused by a benign papilloma in the duct. Cytologic examination is usually of no value but may identify malignant cells ([129](#)). Negative findings do not rule out cancer, which is more likely in women over 50 years of age. In any case, the involved duct—and a mass, if present—should be excised ([129,130](#) and [131](#)). Although ductography may identify a filling defect prior to excision of the duct system, this study is of little value ([129](#)). A new technology, fiberoptic ductoscopy, is emerging to evaluate patients with nipple discharge ([132](#)). In 259 patients with nipple discharge, it successfully detected intraductal papillary lesions in 92 patients (46%). Further experience and understanding of this technology may guide breast surgery for nipple discharge, and is being used for the assessment of margins in breast cancer value.

In premenopausal women, spontaneous multiple-duct discharge, unilateral or bilateral, is most marked just before menstruation. It often is caused by fibrocystic change. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually seen on biopsy. If a mass is present, it should be removed. Milky discharge from multiple ducts in nonlactating women presumably reflects increased secretion of pituitary prolactin; serum prolactin and thyroid-stimulating hormone levels should be evaluated to detect a pituitary tumor or hypothyroidism. Hypothyroidism may cause galactorrhea. Alternatively, phenothiazines may cause milky discharge that disappears when medication is discontinued. Oral contraceptive agents may cause clear, serous, or milky discharge from multiple ducts or, less often, from a single duct. The discharge is more evident just before menstruation and disappears when the medication is stopped. If discharge does not stop and is from a single duct, surgical exploration should be performed.

When localization is not possible and no mass is palpable, the patient should be reexamined every week for 1 month. When unilateral discharge persists, even without definite localization or tumor, surgical exploration must be considered. The alternative is careful follow-up at intervals of 1 to 3 months. Mammography should be performed. Chronic unilateral nipple discharge, especially if it is bloody, is an indication for resection of the involved ducts. Purulent discharge may originate in a subareolar abscess and requires excision of the abscess and related lactiferous sinus ([133](#)).

Erosive Adenomatosis of the Nipple

Erosive adenomatosis is a rare benign condition of the nipple that mimics Paget's disease ([134](#)). Patients seek treatment for pruritus, burning, and pain. On clinical examination the nipple can appear ulcerated, crusting, scaling, indurated, and erythematous. The nipple can be enlarged and more prominent during menstrual cycles ([135](#)). The differential diagnosis includes squamous cell carcinoma, psoriasis, contact dermatitis, seborrheic keratosis, adenocarcinoma metastatic to the skin, and unusual primary tumors of the nipple ([134](#)). Biopsy should be performed to diagnose the lesion. Local excision is curative ([134](#)).

Fat Necrosis

Fat necrosis of the breast is rare but clinically important because it produces a mass, often accompanied by skin or nipple retraction, which is indistinguishable from carcinoma. Trauma is presumed to be the cause, although only about one-half of patients have a history of injury to the breast. Ecchymosis is occasionally seen near the tumor. Tenderness may or may not be present. If untreated, the mass associated with fat necrosis gradually disappears. Fat necrosis often has a confusing clinical picture. Diagnostic imaging studies are usually insufficient ([136](#)). As a rule, the safest course is needle core or excisional biopsy of the entire mass to rule out carcinoma ([136](#)). Fat necrosis is common after segmental resection and radiation therapy or transverse rectus abdominis musculocutaneous (TRAM) flap ([137](#)).

Breast Abscess

Lactational Abscesses

Infection in the breast is rare unless the patient is lactating. During lactation, an area of redness, tenderness, and induration frequently develops in the breast. The organism most commonly found in these abscesses is *Staphylococcus aureus* ([138](#)). In its early stages, the infection can often be reversed while nursing is continued from that breast by administering an antibiotic such as *dicloxacillin* 250 mg 4 times daily, or *oxacillin*, 500 mg 4 times daily for 7 to 10 days. If the lesion progresses to a localized mass with local and systemic signs of infection, an abscess is present. It should be drained, and nursing should be discontinued.

Nonlactational Abscess

Rarely, infections or abscesses may develop in young or middle-aged women who are not lactating ([139](#)). The current approach to nonlactational abscess is conservative ([140](#)). A suspected abscess should be evaluated with preliminary ultrasonography to assess the presence of an inflammatory mass, frank pus, solitary cavity, or a multiloculated abscess ([141](#)). Aspiration of pus, if present, and antibiotic therapy is instituted with reaspiration if necessary ([140](#)). Bacteriologic analysis of 22 abscesses in nonlactating women shows a preponderance of gram-positive cocci including *Staphylococcus epidermidis* (11 women), *Staphylococcus aureus* (3 women), *Proteus mirabilis* (3 women), *Pseudomonas aeruginosa* (1 woman), and sterile abscess (4 women) ([141](#)). If these infections recur after multiple aspirations, incision and drainage followed by excision of the involved lactiferous duct(s) at the base of the nipple may be necessary during a quiescent interval. In virtually all cases, mamillary sinus can be demonstrated as the cause of reinfection or persistent infection ([142](#)). Because inflammatory carcinoma must always be considered in the presence of erythema of the breast, findings suggestive of abscesses are an indication for incision and biopsy of any indurated tissue. Patients should not undergo prolonged treatment for an apparent infection unless biopsy has eliminated the possibility of inflammatory carcinoma.

Disorders of Breast Augmentation

Estimates indicate that nearly 4 million women in the United States have undergone augmentation mammoplasty. Breast implants are usually placed under the pectoralis muscle or, less desirably, in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel or saline.

The complications of breast implantation are significant. About 15% to 25% of patients develop capsule contraction or scarring around the implant, leading to a firmness and distortion of the breast that can be painful and sometimes requires removal of the implant and capsule. Implant rupture may occur in as many as 5% to 10% of women, and bleeding of gel through the capsule is even more common ([143](#)). In April 1992, the FDA concluded that the safety and effectiveness of silicone gel breast implants had not been established and called for additional preclinical and clinical studies ([144](#)). The FDA advised symptomatic women with ruptured implants to discuss the need for surgical removal with their physicians. When there is no evidence of associated symptoms or rupture, implant removal is generally not indicated because the risks of removal are probably greater than those of retention. If screening ultrasonography shows no rupture, the probability of rupture is

2.2% (145). If ultrasonography shows rupture, true rupture is present in 37.8%. In this setting a large number of women would have normal implants removed. When MRI is used in addition to ultrasonography, the probability of rupture increases to 86%.

A suggested association between silicone gel and autoimmune disease has been poorly documented (146,147). A retrospective cohort study from the Mayo Clinic showed no increased incidence of autoimmune disorders among women with silicone implants (148). Subsequent studies have demonstrated no clinical data proving an increased incidence of connective tissue disorders in patients with silicone gel breast implants (149,150 and 151). Even so, patients who have symptoms suggestive of an autoimmune disorder should discuss with their physician the risks and benefits of implant removal.

Any association between implants and an increased incidence of breast cancer is unlikely (152). However, breast cancer may develop in any patient with a silicone gel prosthesis.

The successful outcome of gynecologic surgery is based on thorough evaluation, careful preoperative preparation, and attentive postoperative care. Approaches to the general perioperative management of patients undergoing major gynecologic surgery who have specific medical problems that could complicate the surgical outcome are presented in this chapter.

Medical History and Physical Examination

The hazards of undertaking surgery without a thorough understanding of a patient's medical history and performing a complete physical examination cannot be overstated. The preoperative medical history should include any significant medical illnesses that might be aggravated by surgery or anesthesia.

- 1. Inquiry should be made regarding medications currently being taken as well as those discontinued within the months prior to surgery.** This inquiry should include notation of nonprescription drugs being taken and the use of oral contraceptives, which many patients consider a routine part of their lives rather than a medication. In addition, information on the use of alternative therapies, herbs, and vitamins should be elicited. Specific instructions must be given to the patient regarding the need to discontinue any medications prior to surgery (e.g., *aspirin* or oral contraceptives) as well as those medications that should be continued (e.g., cardiac or antihypertensive medications).
- 2. The patient should be questioned regarding known allergies to medications (e.g., sulfa and penicillin), foods, or environmental agents.** A history of sensitivity to shellfish may be the only clue to an iodine sensitivity, which may be significant because iodinated intravenous contrast material is used for intravenous pyelography (IVP), enhanced computed tomography (CT) scanning, and venography and arteriography. A history of hypersensitivity to intravenously administered iodine-containing compounds or shellfish should be clearly noted, and the patient should not be exposed to iodine-containing compounds unless such exposure is absolutely mandatory. When intravenous contrast material must be used, administration of a glucocorticoid preparation may prevent life-threatening anaphylactic reactions.
- 3. Previous surgical procedures, and the patient's course following those surgical procedures, should be reviewed to identify complications of previous operations that might be avoided.** Pertinent medical records from prior surgery should be obtained and reviewed. Reactions and response to anesthetic techniques should be evaluated with the anesthesiologist in charge. The patient should be asked about specific complications, such as excessive bleeding, wound infection, deep vein thrombosis, peritonitis, or bowel obstruction. A history of pelvic surgery should alert the gynecologist to the possibility of distorted surgical anatomy and possible preexisting injury to adjacent organ systems, such as small bowel adhesions in the pelvis or ureteral stenosis from previous periureteral scarring. Intravenous pyelography may be helpful in such cases to establish ureteral anatomy and patency and to identify any preexisting abnormality. Many patients may not be entirely clear about the extent of the previous surgical procedure or the details of intraoperative findings. Therefore, operative notes from previous pelvic operations should be obtained and reviewed to determine the details of the procedure and findings. This is particularly important in patients who have had surgery for pelvic inflammatory disease, pelvic abscess, endometriosis, or pelvic malignancy.
- 4. Family history may identify familial traits that might complicate planned surgery.** A family history of excessive intraoperative or postoperative bleeding, malignant hyperthermia, and other potentially inherited conditions should be sought. A general review of systems should also be included in the questioning in an effort to identify any coexisting medical or surgical conditions. Inquiry about gastrointestinal and urologic function is particularly important before undertaking pelvic surgery, and many gynecologic diseases also involve adjacent nongynecologic viscera.
- 5. Although many women undergoing gynecologic surgical procedures are otherwise healthy, with pathology identified only on pelvic examination, other major organ systems should not be neglected in the physical examination.** Identification of abnormalities such as a heart murmur or pulmonary compromise should lead the surgeon to obtain additional testing and consultation in order to minimize intraoperative and postoperative complications. Decisions regarding additional testing or consultation should be made in conjunction with the anesthesiologist.

Laboratory Evaluation

The selection of appropriate preoperative laboratory studies will depend on the extent of the anticipated surgical procedure and the patient's medical status.

1. For patients undergoing general anesthesia, a blood count, including hematocrit, white blood cell count, and platelet count, should be obtained routinely.
2. The results of serum chemistry and liver function tests are rarely abnormal in asymptomatic patients who have no significant factors in their medical history and who are not taking medications.

3. Coagulation studies are of little value unless the patient has a significant risk factor in her medical history (1).
4. In women under 40 years of age, a chest radiograph and electrocardiography are of very low yield in identifying asymptomatic cardiopulmonary disease and thus may not be necessary (2,3). However, women over 40 years of age and those undergoing major gynecologic surgical procedures should have a chest radiograph, electrocardiography, and serum electrolyte analysis preoperatively. If the results of these studies are normal, they will serve as baseline data for comparison to other studies that may be required in the evaluation of a postoperative complication.

Radiographic evaluation of adjacent organ systems should be undertaken based on patients' needs.

1. Intravenous pyelography is helpful to delineate ureteral patency and course, especially in the presence of a pelvic mass, gynecologic cancer, or congenital müllerian anomaly. **However, an IVP is not of significant value in the evaluation of most patients undergoing pelvic surgery (4).**
2. A barium enema or upper gastrointestinal studies with small bowel assessment may be of significant value in evaluating some patients before pelvic surgery. Because of the proximity of the female genital tract to the lower gastrointestinal tract, the rectum and sigmoid colon may be involved with benign (endometriosis or pelvic inflammatory disease) or malignant gynecologic conditions. Conversely, a pelvic mass could have a gastrointestinal origin such as a diverticular abscess or a mass of inflamed small intestines (Crohn's disease). Clearly, any patient with gastrointestinal symptoms should be further evaluated.
3. Other imaging studies, including ultrasonography, CT scanning, or magnetic resonance imaging (MRI), are useful only in selected patients.

Preoperative Discussion and Informed Consent

The verbal and nonverbal rapport and trust that exist between the patient and her gynecologist begin on the initial office visit and should be built on during each subsequent visit. During the initial discussion, the physician should explain in sufficient detail to the patient the findings of the examination, the results of testing, the natural history of the disease process, and the goals of the surgical procedure. Because most gynecologic surgery is elective, the gynecologist has the opportunity to evaluate the patient from a medical point of view, as well as to allow the patient to develop psychological coping mechanisms and to answer questions that may not have been discussed initially. The surgeon should be available to discuss in person or by phone any questions that arise before actual hospital admission.

The goals of the preoperative discussion are to allay the patient's anxiety and fears and to answer any questions. The discussion should serve as the basis to expand further on issues relative to the surgery, its expected outcome, and risks as well as to obtain signed informed consent (5). Informed consent is an educational process for the patient and her family and fulfills the physician's need to convey information in understandable terms. The following items should be discussed and, after each item, the patient and family should be invited to ask questions:

1. The nature and extent of the disease process
2. The extent of the actual operation proposed and the potential modifications of the operation, depending on intraoperative findings
3. The anticipated benefits of the operation, with a conservative estimate of successful outcome
4. The risks and potential complications of the surgery
5. Alternative methods of therapy and the risks and results of those alternative methods of therapy
6. The results likely if the patient is not treated.

A discussion of the nature and the extent of the disease process should include an explanation in lay terms of the significance of the disease. Is it life-threatening, or will it likely result in significant disability or dysfunction? To what extent does the disease process alter the patient's daily living? If untreated, could the disease resolve spontaneously, or could it potentially worsen? What is the time course and natural history of the disease?

The goals of surgery should be discussed in detail. Some gynecologic surgical procedures are performed purely for diagnostic purposes (e.g., dilation and curettage, cold knife conization, a diagnostic laparoscopy, or staging laparotomy), while most are clearly aimed at correcting an anatomic defect or a specific disease process. The extent of the surgery should be outlined, including which organs will be removed. Most patients like to be informed regarding the type of surgical incision and the estimated duration of anesthesia.

The expected outcome of the surgical procedure should be explained. If the procedure is being performed for diagnostic purposes, the outcome will depend on surgical or pathologic findings that are not known before surgery. When treating anatomic deformity or disease, the expected success of the operation should be discussed, as well as the potential for failure of the operation. This discussion should include the probability of failure (i.e., failure of tubal sterilization or the possibility that stress urinary incontinence may not be alleviated). When treating cancer, the possibility of finding more advanced disease and the potential need for adjunctive therapy (e.g., postoperative radiation therapy or chemotherapy) should be mentioned. Other issues of importance to the patient include discussion of loss of fertility or loss of ovarian function. These issues should be raised by the physician to ensure that the patient adequately understands the pathophysiology that may result from the surgery and to allow her to express her feelings regarding these emotionally charged issues.

The risks and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular procedure. For most major gynecologic surgery, the risks include intraoperative and postoperative hemorrhage, postoperative infection, venous thrombosis, and injury to adjacent viscera. If the patient has a preexisting medical problem, what additional risks might be encountered? Unanticipated findings at the time of surgery should also be mentioned. For example, if the ovaries are found unexpectedly to be diseased, it may be the best surgical judgment that they should be removed.

The usual postoperative course should be discussed in enough detail to allow the patient to understand what to expect in the days following surgery. Information regarding the need for a suprapubic catheter or prolonged central venous monitoring helps the patient accept her postoperative course and avoids surprises to the patient that may be very disconcerting. The expected duration of the recovery period, both in and out of the hospital, should be noted.

Alternative methods of therapy should be mentioned as part of the preoperative discussion. Other medical management or surgical approaches should be discussed, along with their potential benefits and complications. Finally, the patient should have an understanding of the outcome of the disease if nothing is done. Following this discussion, it should be clear to the patient why the proposed surgery is the appropriate next step in her care. The preoperative discussion and signing of the consent form should include witnesses—a family member and another member of the health care team. The informed consent discussion detailing the information given to the patient should be documented in the patient's chart.

The anesthesiologist responsible for the surgical procedure should also have the opportunity to examine the patient, review her laboratory findings, and discuss the proposed anesthetic method with the patient. In many institutions, the consent to the administration of anesthetic is included in the surgical consent form, whereas in other institutions it is a separate form that should be obtained by the anesthesiologist after appropriate preoperative discussion.

General Considerations

Nutrition

In general, patients undergoing elective gynecologic surgery have adequate nutritional stores and, for the most part, do not require nutritional support. However, **all patients should have a nutritional assessment, especially those undergoing surgery for gynecologic cancer and other major gynecologic procedures in which a prolonged postoperative recovery is expected.** Reassessment of nutritional status should also be performed at regular intervals postoperatively until the patient has successfully returned to a regular diet.

A nutritional assessment includes a careful history and physical examination, which are the most useful, reliable, and cost-effective methods of assessing a patient's nutritional status. In particular, information about recent weight loss as well as the patient's dietary history should be noted. Evidence of malnutrition that can be detected on physical examination includes temporal wasting, muscle wasting, ascites, and edema. Accurate height and weight measurements should be obtained and an ideal body weight, percent ideal body weight, and percent usual body weight may be calculated. Patients who have lost less than 6% of their ideal body weight do not need preoperative nutritional intervention. However, **patients who have lost more than 12% of their ideal body weight should be considered for preoperative intervention.** Patients who have lost between 6% and 12% of their body weight should undergo further studies to determine if preoperative intervention is needed. In addition to routine preoperative laboratory tests, data on albumin, transferrin, zinc, lipids, and liver function may be obtained. In selected patients,

additional laboratory assessments such as vitamin B₁₂, folate, copper, manganese, prothrombin time, and creatinine values may be useful in the nutritional assessment.

A variety of techniques have been developed to determine nutritional state, including isotope dilution, g neutron activation, and anthropometric measurements. Anthropometric measurements of skin-fold thickness and arm-muscle circumference provide an estimate of total body fat and lean muscle mass. Isotope dilution techniques have been used to determine the ratios of exchangeable sodium and potassium, which can determine body cell mass and thus give another parameter for chronic malnutrition. Whole body counters that can measure radioactive intracellular calcium can also be used to determine skeletal muscle mass. More recently, g neutron activation has been used to measure total body nitrogen, which is currently considered the state-of-the-art method for the determination of total body protein (6,7). Unfortunately, these measurements have not been reproducible and traditionally have been poor predictors of nutritional status and clinical outcome (8,9).

The degree of malnutrition can in part be determined by serum concentrations of albumin, transferrin, prealbumin, and retinal binding protein (RBP). The levels of these serum proteins are greatly influenced by the patient's level of hydration. Prealbumin and RBP have the shortest half-lives, and levels are depressed very early in comparison with serum transferrin and albumin, which have half-lives of 8 and 20 days, respectively (10). A quick assessment of malnutrition can be performed based on the patient's weight, appetite, and serum albumin levels. **An unintentional weight loss of 35 pounds over 3 weeks, anorexia, or a serum albumin level <3.5 g/dl are indicative of malnutrition.** Serum albumin was determined to be a decent substitute for the Prognostic Nutritional Index (PNI), which is a time-consuming calculation, in assessing malnutrition in women with gynecologic malignancies (11).

No single test accurately predicts the outcome in malnourished surgical patients. A number of formulas incorporating a variety of nutritional indices have been proposed to assess the perioperative risk secondary to malnutrition. Mullen and co-workers have prospectively evaluated a model that incorporates albumin (ALB), triceps skin-fold thickness (TSF), transferrin (TFN), and delayed hypersensitivity (DH). By a step-wise regression analysis, a linear predictive model called the PNI was developed to relate these factors. It is calculated as follows:

$$\text{PNI (\%)} = 158 - 16.6(\text{ALB}) - 0.78(\text{TSF}) - 0.20(\text{TFN}) - 5.8(\text{DH}).$$

This model was tested on 100 patients undergoing elective surgery and was shown to be valid (12).

Despite the variety of tests and calculations, the decisions regarding the need for nutritional support should be based on several individualized factors. These factors include the patient's prior nutritional state, the anticipated length of time in which the patient will not be able to eat, the severity of surgery, and the likelihood of complications. The nutritional assessment should also determine whether the cause of the malnutrition is increased enteral loss (malabsorption, intestinal fistula), decreased oral intake, increased nutritional requirements as a result of hypermetabolism (sepsis, malignancy), or a combination of these factors. Moderate to severe malnutrition occurs either as a consequence of the patient's diagnosis or possibly from the therapeutic modality used to treat her disease (13,14). Severe malnutrition, if not corrected, can contribute to further postoperative complications by causing altered immune function, chronic anemia, impaired wound healing and, eventually, multiple organ system failure and death.

The patient's nutritional requirements are also increased by surgery. Indices of nutrition were abnormal in 50% of patients who were hospitalized for more than 1 week after surgery (14). Surgery increases the nutritional requirements for several reasons. First, there is a period following surgery during which oral intake is not allowed or is very limited. In addition, the operation itself causes increased protein catabolism, increased energy requirements, and a negative nitrogen balance. If the surgery is uncomplicated and the patient is without food for less than 7 days, this response is limited and patients usually recover without the need for nutritional support. An adequate diet is defined as providing 75% of estimated caloric and protein needs. Therefore, if an adequate oral diet is not expected for 7 to 10 days, perioperative nutritional support may be required to avoid progressive malnutrition and its associated complications. Perioperative nutritional support can reduce operative morbidity and decrease hospitalization when it is commenced early in the postoperative course. Therefore, in patients with either normal nutritional indices or mild or moderate malnutrition who will be undergoing surgical procedures likely to require a prolonged catabolic period of more than 7 to 10 days, total parenteral nutrition (TPN) should be instituted in the early postoperative period as soon as the patient is hemodynamically stable. This type of management should be strongly considered in patients undergoing pelvic exenterations, urinary diversions, or multiple enterectomies (15).

Preoperative nutritional support is indicated for patients who have significant preexisting malnutrition or who require major elective surgery. Preoperative nutritional support is recommended for at least 5 to 7 days prior to surgery to correct electrolyte imbalances and nutritional deficits. Starker and others recommended the following markers to determine adequate nutritional support: weight, fluid status, and serum albumin. In this study patients who exhibited weight loss, diuresis, and a rise in serum albumin after initiation of TPN had an extremely low risk of postoperative morbidity. In contrast, patients who exhibited additional fluid retention, weight gain, and a decline in serum albumin had a significantly higher risk of postoperative complications. In this group of patients, an additional 5 to 7 days of TPN was recommended before proceeding with surgical interventions (16). Nutritional support should be tapered and stopped at midnight prior to surgery and then restarted 24 to 72 hours after the procedure and continued until the patient is able to meet nutritional requirements.

Calculation of Caloric Requirements

The most precise method for calculating a patient's daily caloric requirements is indirect calorimetry. This method is very costly, however, and is not used routinely in clinical practice. Caloric requirements can be calculated based on Long's modification of the Harrison-Benedict formula for actual energy expenditure (AEE) (17). This is the most accurate available method to calculate an individual's AEE.

$$\text{AEE (women)} = (655.10 + 9.56 \text{ weight [kg]} + 4.85 \text{ height [cm]} - 4.68 \text{ age [yr]}) \times \text{activity factor} \times \text{injury factor}$$

- Activity factor: confined to bed (1.2), out of bed (1.3)
- Injury factor: minor surgery (1.2), skeletal trauma (1.3), major sepsis (1.6), severe burn (2.1)

1. **The daily caloric requirements can be met by providing 1,000 calories more than the patient's basal energy expenditure.** Alternatively, daily caloric requirements can be met by giving the patient 35 kcal/kg per day for maintenance and 45 kcal/kg per day for anabolic states. Daily nitrogen requirements may be met by providing 1 g of nitrogen (6.25 g of protein) for every 125 to 150 calories.
2. **The maximal rate of glucose oxygenation in adults is approximately 7 g/kg per day.** Patients with very high caloric requirements or diabetes mellitus should receive calories in excess of this in the form of lipids. *Insulin* should be used to maintain serum glucose concentration between 150 and 250 mg/dl, and it may be added directly to the TPN solution. Glucose administration in excess of the caloric requirements can lead to fatty infiltration of the liver and other metabolic complications.
3. **Lipid in a 10% to 20% emulsion can be given as further caloric supplement.** More calories can be given in the form of free fatty acids, which are the major source of energy for most peripheral tissues. When lipids are used as a major source of calories, a minimum of 50 to 150 g/day of glucose should also be given to provide a substrate for the central nervous system. Most patients can tolerate up to 2 g of fat/kg per day, and daily dosages should not exceed 4 g of fat/kg per day. These lipid emulsions are isotonic and can be delivered simultaneously with the protein and carbohydrate mixture in a 3-liter bag for infusion over 24 hours. In general, 30% to 50% of nonprotein calories should be supplied in lipid form. Serum triglyceride levels should be monitored to ensure that the patient can metabolize the fat.
4. **In addition to calories and protein, nutritional support should be maintained in terms of electrolytes, vitamins, and trace elements.** Daily maintenance requirements for electrolytes are as follows: sodium, 60 to 120 mEq; potassium, 30 to 40 mEq; chloride, 60 to 120 mEq; magnesium, 8 to 10 mEq; calcium, 200 to 400 mg; and phosphorous, 300 to 400 mg. A number of vitamins and trace elements must also be supplied to ensure that the patient is eumetabolic.

Route of Administration

After the decision has been made that nutritional support is required, the appropriate route of administration must be determined. Enteral nutrition should be considered primarily because it is easy to deliver, associated with the fewest complications, linked to enhanced wound healing, and relatively inexpensive (18). Contraindications to this route of delivery include intestinal obstruction, gastrointestinal bleeding, and diarrhea. Many different types are commercially available and can be chosen based on their caloric content, fat content, protein content, osmolality, viscosity, and price. Depending on the patient's problem, the route of delivery may be through a Dobhoff feeding tube, a gastrostomy tube, or a feeding jejunostomy tube. If the gastrointestinal tract is unusable for more than 7 days postoperatively, TPN should be implemented.

Total parenteral nutrition must be delivered through a central vein and has gained wide acceptance as a means of providing nutritional support for surgically ill patients. It must be delivered through a subclavian or internal jugular vein, and the catheter must be placed using meticulous sterile surgical technique. Proper daily care is required to avoid infectious complications, and a eumetabolic state may be obtained if multivitamins (including folate and B₁₂) and trace metals (cobalt, iodine, manganese, and zinc) are used to supplement the 2 to 3 L/day of TPN solution. Essential fatty acids are supplied weekly, and iron may be added if hyperalimentation is prolonged and bone marrow stores have become depleted. Appropriate adjustments in the contents of the TPN are required for patients with liver, renal, or cardiac dysfunction. When managed by an experienced team, the most frequent complication, infection, can be reduced to a very reasonable level (5% to 10%) (19).

Postoperative Outcome

A number of retrospective clinical studies, mostly from the general surgical literature, have demonstrated that nutritional support improves postoperative outcome in a variety of categories, including surgical complications, sepsis, wound infections, and mortality. A number of prospective randomized trials, however, have failed to demonstrate that the widespread use of preoperative TPN improves clinical outcome (20,21,22,23 and 24). The largest, most carefully executed, prospective, randomized trial evaluating perioperative TPN use was reported by the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group (24). The study evaluated a series of 395 malnourished patients who were randomly assigned to receive TPN for 7 to 15 days before surgery and 3 days postoperatively (treatment arm) or no perioperative TPN (control arm). The patients were then followed for 90 days after the surgery and were evaluated in terms of morbidity and mortality. Major complications during the first 30 days, as well as the overall 90-day mortality rates, were then analyzed and were similar in both the treated and control arms. However, in a small group of patients with extremely severe malnutrition, the incidence of noninfectious complications was significantly less common in the group given TPN. In this study, severe malnutrition was defined as a nutritional risk index score of less than 83. The authors of that study concluded that preoperative TPN should be limited to patients who were severely malnourished unless there were other specific indications.

The effect of postoperative TPN on outcome was evaluated in patients undergoing major surgery, regardless of their nutritional status. Three hundred patients were randomized to either TPN or prolonged glucose administration for up to 15 days. There were no significant differences among the two groups with respect to mortality rate or complications. Sixty percent of patients were tolerating enteral intake by 8 to 9 days after surgery, signifying that the majority of patients do not require nutritional support. However, 20% of patients in the glucose-only arm were unable to tolerate oral intake within 15 days of their operations. For these patients, institution of TPN represented a life-saving therapy. Unfortunately, a method of preoperative identification of this group has not been established. Interestingly 20% of the TPN-only arm could not tolerate the nutritional therapy and required treatment modifications. This group had a higher mortality rate than the glucose arm that subsequently required parenteral nutrition (36% versus 21%, P < 0.10). Therefore, suboptimal nutrition includes not only too little nutrition, but also too much nutritional support (25).

In summary, clinical trials have demonstrated that TPN can improve nutritional status as measured by biochemical assays, immune function, and nitrogen balance. The effect of TPN on clinical outcome, however, is less well established. Despite what would seem reasonable based on common sense as well as preoperative nutritional parameters, the data do not support TPN for mild to moderately malnourished patients. With severe malnutrition, preoperative TPN would seem to be beneficial and should be instituted.

Fluid and Electrolytes

Water constitutes approximately 50% to 55% of the body weight of the average woman. Two-thirds of this water is contained in the intracellular compartment. One-third is contained in the extracellular compartment, of which one-fourth is contained in plasma, and the remaining three-fourths is in the interstitium.

Osmolarity, or tonicity, is a property derived from the number of particles in a solution. Sodium and chloride are the primary electrolytes contributing to the osmolarity of the extracellular compartment. Potassium and, to a lesser extent, magnesium and phosphate are the major intracellular electrolytes. Water flows freely between the intracellular and the extracellular spaces to maintain osmotic neutrality throughout the body. Any shifts in osmolarity in any fluid spaces within the body are accompanied by corresponding shifts in free water from spaces of lower to higher osmolarity, thus maintaining equilibrium.

The average adult daily fluid maintenance requirement is approximately 30 ml/kg per day, or 2,000 to 3,000 ml/day (26). This is offset partially by insensible losses of 1,200 ml/day, which includes losses from the lungs (600 ml), skin (400 ml), and gastrointestinal tract (200 ml). Urinary output from the kidney will provide the remainder of the fluid loss, and this output will vary depending on total body intake of water and sodium. Approximately 600 to 800 mOsm of solute are excreted by the kidney per day. Healthy kidneys can concentrate urine up to approximately 1,200 mOsm and, therefore, the minimum output can range between 500 and 700 ml/day. The maximal urine output of the kidney can be as high as 20 L/day, as seen in patients with diabetes insipidus. In healthy individuals, the kidney adjusts output commensurate with daily fluid intake.

The major extracellular buffer used in the acid-base balance is the bicarbonate-carbonic acid system: $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$ (27). Typically, the body will maintain a bicarbonate-to-carbonic acid ratio of 20:1 in order to maintain an extracellular pH of 7.4. Both the lung and the kidney play integral roles in the maintenance of normal extracellular pH via retention or excretion of carbon dioxide and bicarbonate. Under conditions of alkalosis, minute ventilation decreases and renal excretion of bicarbonate increases to restore the normal ratio of bicarbonate to carbonic acid. The opposite occurs with acidosis.

Ultimately, the kidney plays the most important role in fluid and electrolyte balance through excretion and retention of water and solute. Circulating antidiuretic hormone and aldosterone help modulate the process. Serum osmolarity affects hypothalamic release of antidiuretic hormone and aldosterone secretion in response to renal perfusion. Under states of dehydration or hypovolemia, serum antidiuretic hormone levels increase, leading to increased resorption of water in the distal tubule of the kidney. In addition, increased aldosterone release promotes increased sodium and water retention. The opposite occurs in states of fluid excess. As a result, individuals with normal renal function and circulating antidiuretic hormone and aldosterone levels maintain normal serum osmolarity and electrolyte composition, despite daily fluctuations of fluid and electrolyte intake.

Various disease states can alter the normal fluid and electrolyte homeostatic mechanisms, making perioperative fluid and electrolyte management more difficult. Patients with intrinsic renal disease are unable to excrete solute and to maintain acid-base balance. In patients undergoing the stress of chronic starvation or severe illness, there may be an inappropriately high level of circulating antidiuretic hormone and aldosterone, resulting in fluid and sodium retention. With severe cardiac disease, secondary renal hypoperfusion can lead to increased aldosterone synthesis and, therefore, increased sodium and water retention by the kidney. Finally, patients with severe diabetes can have significant osmotic diuresis as well as acid-base dysfunction secondary to circulating ketoacids. Correction and optimization of renal, cardiac, or endocrine disorders preoperatively are imperative and will often rectify fluid and electrolyte abnormalities.

Fluid and electrolyte management in the preoperative and perioperative periods requires knowledge of the daily fluid and electrolyte requirements for maintenance, replacement of ongoing fluid and electrolyte losses, as well as correction of any existing abnormalities.

Fluid and Electrolyte Maintenance Requirements

The body adjusts to higher and lower volumes of intake by changes in plasma tonicity. Alterations in plasma tonicity induce adjustments in circulating antidiuretic hormone levels, which ultimately regulate the amount of water retained in the distal tubule of the kidney. In the preoperative and the early postoperative periods, it is usually only necessary to replace sodium and potassium. Chloride is automatically replaced, concomitant with sodium and potassium, because chloride is the usual anion used to balance sodium and potassium in electrolyte solutions. There are various commercially available solutions containing 40 mmol of sodium chloride, with smaller amounts of potassium, calcium, and magnesium designed to meet the requirements of a patient who is receiving 3 L of intravenous fluids per day. The daily requirement, however, can be met by any combination of intravenous fluids. For example, 2 liters of D5 (5% dextrose)/0.45 normal saline (7 mEq sodium chloride each), supplemented with 20 mEq of potassium chloride, followed by 1 liter of D5W (5% dextrose in water) with 20 mEq of potassium chloride, would suffice.

Fluid and Electrolyte Replacement

Fluid and electrolyte losses beyond the daily average must be replaced by appropriate solutions. The choice of solutions for replacement depends on the composition of the fluids lost. Often, it is difficult to measure free water loss, particularly in patients who have high losses from the lungs, skin, or the gastrointestinal tract. Weighing these patients daily can be very useful. Up to 300 g of weight loss daily can be attributable to weight loss from catabolism of protein and fat in the patient

who is taking nothing by mouth (26). Anything beyond this, however, would be due to fluid loss and should be replaced accordingly.

Patients with a high fever can have increased pulmonary and skin loss of free water, sometimes in excess of 2 to 3 L/day. These losses should be replaced with free water in the form of D5W. Perspiration typically has one-third the osmolarity of plasma and can be replaced with D5W or, if excessive, with D5/0.25 normal saline.

The patient with acute blood loss needs replacement with appropriate isotonic fluid or blood or both. There are a wide range of plasma volume expanders, including albumin, dextran, and hetastarch solutions, which contain large-molecular-weight particles (>50,000 molecular weight). These particles are slow to exit the intravascular space, and about one-half of the particles remain after 24 hours. These solutions are expensive, however, and for most cases, simple replacement with 0.9 normal saline or lactated Ringer's solution will suffice. One-third of the volume of lactated Ringer's solution or normal saline typically will remain in the intravascular space, and the remainder goes to the interstitium.

Appropriate replacement of gastrointestinal fluid loss depends on the source of fluid loss in the gastrointestinal tract. Gastrointestinal secretions beyond the stomach and up to the colon are typically isotonic with plasma, with similar amounts of sodium, slightly lower amounts of chloride, slightly alkaline pH, and more potassium (in the range of 10 to 20 mEq/L). Under normal conditions, stool is hypotonic. However, under conditions of increased flow (i.e., severe diarrhea), stool contents are isotonic with a composition similar to that of the small bowel contents. Gastric contents are typically hypotonic, with one-third the sodium of plasma, increased amounts of hydrogen ion, and low pH.

In patients who have gastric outlet obstruction, nausea, and vomiting, or who undergo nasogastric suction, appropriate replacement of gastric secretions can be provided with a solution such as D5/0.45 normal saline with 20 mEq/L of potassium. Potassium supplementation is particularly important to prevent hypokalemia in these patients, whose kidneys attempt to conserve hydrogen ions in the distal tubule of the kidney in exchange for potassium ions.

In patients with bowel obstruction, 1 to 3 liters of fluid can be sequestered daily in the gastrointestinal tract. This fluid should be replaced with isotonic saline or lactated Ringer's solution. Similarly, patients with enterocutaneous fistulas or new ileostomies should receive replacement with isotonic fluids.

Correction of Existing Fluid and Electrolyte Abnormalities

Patients who have fluid or electrolyte abnormalities preoperatively can pose a diagnostic challenge. The correct diagnosis and therapy is contingent on a correct assessment of total body fluid and electrolyte status. The management of hyponatremia, for example, may be either fluid restriction or fluid replacement. The choice of treatment depends on whether there is overall extracellular fluid excess and normal body sodium stores or decreased overall total body sodium stores and extracellular fluid. A detailed history is necessary to disclose any underlying medical illness and to assess the amount and duration of any abnormal fluid losses or intake. Initial evaluation should include an assessment of hemodynamic, clinical, and urinary parameters in order to determine the overall level of hydration as well as the fluid status of the extracellular fluid compartment. The patient who has good skin turgor, moist mucosa, stable vital signs, and good urinary output is well hydrated. Nonpitting edema is indicative of extracellular fluid excess, whereas patients with orthostasis, sunken eyes, parched mouth, and decreased skin turgor clearly have extracellular volume contraction. A patient's overall extracellular fluid status does not always reflect the hydration status of the intravascular compartment, however. A patient can have increased interstitial fluid and yet be intravascularly dry, requiring replacement with isotonic fluid.

The laboratory workup for patients who may have preexisting fluid problems should include assessment of blood hematocrit, serum chemistry, glucose, blood urea nitrogen (BUN) and creatinine, urine osmolarity, and urine electrolyte levels. Serum osmolarity is mainly a function of the concentration of sodium and is given by the following equation:

$$2 \times \text{Na}^+ + \text{glucose (mg/dl)/18} + \text{BUN (mg/dl)/2.8}.$$

Normal serum osmolarity is typically 290 to 300 mOsm. Blood hematocrit will rise or fall inversely at a rate of 1% per 500-ml alteration of extracellular fluid volume. The BUN-to-creatinine ratio is typically 10:1 but will rise to a ratio of greater than 20:1 under conditions of extracellular fluid contraction. Under conditions of extracellular fluid deficit, urine osmolarity will typically be high (>400 mOsm), whereas urine sodium concentration is low (<15 mEq/L) indicative of an attempt by the kidney to conserve sodium. Under conditions of extracellular fluid excess or in cases of renal disease in which the kidney has impaired ability to retain sodium and water, urine osmolarity will be low and urine sodium will be high (>30 mEq/L). Finally, changes in sodium can give insight into the degree of extracellular fluid excess or deficit. In the average person, the serum sodium rises by 3 mmol/L for every liter of water deficit and falls by 3 mmol/L for each liter of water excess. One must be careful in making these estimates, however, because patients with prolonged water and electrolyte loss can have low serum sodium levels and marked water deficits.

Specific Electrolyte Disorders

Hyponatremia

Because sodium is the major extracellular cation, shifts in serum sodium levels are usually inversely correlated with the hydration state of the extracellular fluid compartment. The pathophysiology of hyponatremia, then, is usually expansion of body fluids leading to excess total body water (27,28). Symptomatic hyponatremia usually does not occur until the serum sodium is below 120 to 125 mEq/L. The severity of the symptoms (nausea, vomiting, lethargy, seizures) is related more to the rate of change of serum sodium than to the actual serum sodium level.

Hyponatremia in the form of extracellular fluid excess can be seen in patients with renal or cardiac failure as well as in conditions such as nephrotic syndrome, in which total body salt and water are increased, with a relatively greater increase in the latter. Administration of hypertonic saline to correct the hyponatremia would be inappropriate in this setting. The treatment should include, in addition to correcting the underlying disease process, water restriction with diuretic therapy. Inappropriate secretion of antidiuretic hormone (ADH) can occur with head trauma, pulmonary or cerebral tumors, and states of stress. The abnormally elevated ADH results in excess water retention. Treatment includes water restriction and, if possible, correction of the underlying cause. *Demeclocycline* has been shown to be effective in this disorder via its action in the kidney.

Inappropriate replacement of body salt losses with water alone will result in hyponatremia. This will typically occur in patients losing large amounts of electrolytes secondary to vomiting, nasogastric suction, diarrhea, or gastrointestinal fistulas, and who received replacement with hypotonic solutions. Simple replacement with isotonic fluids and potassium will usually correct the abnormality. Rarely, rapid correction of the hyponatremia is necessary, in which case hypertonic saline (3%) can be administered. Hypertonic saline should be administered very cautiously in order to avoid a rapid shift in serum sodium, which will induce central nervous system dysfunction.

Hypertremia

Hypertremia is an uncommon condition that can be life-threatening if severe (serum sodium >160 mEq/L). The pathophysiology is extracellular fluid deficit. The resultant hyperosmolar state leads to decreased water volume in cells in the central nervous system, which, if severe, can cause disorientation, seizures, intracranial bleeding, and death. The causes include excessive extrarenal water loss, which can occur in patients who have a high fever, have undergone tracheostomy in a dry environment, or have extensive thermal injuries; who have diabetes insipidus, either central or nephrogenic; and who have iatrogenic salt loading. The treatment involves correction of the underlying cause (correction of fever, humidification of the tracheostomy, administration of pitressin for control of central diabetes insipidus) and replacement with free water either by the oral route or intravenously with D5W. As with severe hyponatremia, marked hypertremia should be corrected slowly.

P>Hypokalemia

Hypokalemia may be encountered preoperatively in patients with significant gastrointestinal fluid loss (prolonged emesis, diarrhea, nasogastric suction, intestinal fistulas) and marked urinary potassium loss secondary to renal tubular disorders (renal tubular acidosis, acute tubular necrosis, hyperaldosteronism, prolonged diuretic use). It can also arise from prolonged administration of potassium-free parenteral fluids in patients who are restricted from ingesting anything by mouth. The symptoms associated with hypokalemia include neuromuscular disturbances, ranging from muscle weakness to flaccid paralysis, and cardiovascular abnormalities, including hypotension, bradycardia, arrhythmias, and enhancement of digitalis toxicity. These symptoms rarely occur unless the

serum potassium is <3 mEq/L. The treatment is potassium replacement. Oral therapy is preferable in patients who are on an oral diet. If necessary, potassium replacement can be given intravenously in doses that should not exceed 10 mEq/hr.

Hyperkalemia

Hyperkalemia is encountered infrequently in preoperative patients. It is usually associated with renal impairment but can also be seen in patients who have adrenal insufficiency, are taking potassium-sparing diuretics, and have marked tissue breakdown such as that occurring with crush injuries, massive gastrointestinal bleeding, or hemolysis. The clinical manifestations are mainly cardiovascular. Marked hyperkalemia (potassium >7 mEq/L) can result in bradycardia, ventricular fibrillation, and cardiac arrest. The treatment chosen depends on the severity of the hyperkalemia and whether there are associated cardiac abnormalities detected with electrocardiography. *Calcium gluconate* (10 ml of a 10% solution), given intravenously, can offset the toxic effects of hyperkalemia on the heart. One ampule each of sodium bicarbonate and D50, with or without insulin, will cause a rapid shift of potassium into cells. Over the longer term, cation exchange resins such as *sodium polystyrene sulfate* (*Kayexalate*), taken orally or by enema, will bind and decrease total body potassium. Hemodialysis is reserved for emergent conditions in which other measures are not sufficient or have failed.

Postoperative Fluid and Electrolyte Management

Several hormonal and physiologic alterations in the postoperative period may complicate fluid and electrolyte management. The stress of surgery induces an inappropriately high level of circulating ADH. Circulating aldosterone levels also are increased, especially if sustained episodes of hypotension have occurred either intraoperatively or postoperatively. The elevated levels of circulating ADH and aldosterone make patients prone to sodium and water retention postoperatively.

Total body fluid volume may be altered significantly postoperatively. First, 1 ml of free water is released for each gram of fat or tissue that is catabolized and, in the postoperative period, several hundred milliliters of free water is released daily from tissue breakdown, particularly in the patient who has undergone extensive intraabdominal dissection and who is restricted from ingesting food and fluids by mouth. This free water is often retained in response to the altered levels of ADH and aldosterone. Second, fluid retention is further enhanced by third spacing, or sequestration of fluid in the surgical field. **The development of an ileus may result in an additional 1 to 3 liters of fluid per day being sequestered in the bowel lumen, bowel wall, and peritoneal cavity.**

In contrast to renal sodium homeostasis, the kidney lacks the capacity for retention of potassium. In the postoperative period, the kidneys will continue to excrete a minimum of 30 to 60 mEq/L of potassium daily, irrespective of the serum potassium level and total body potassium stores (27). If this potassium loss is not replaced, hypokalemia may develop. Tissue damage and catabolism during the first postoperative day usually result in the release of sufficient intracellular potassium to meet the daily requirements. However, beyond the first postoperative day, potassium supplementation is necessary.

Correct maintenance of fluid and electrolyte balance in the postoperative period starts with the preoperative assessment, with emphasis on establishing normal fluid and electrolyte parameters prior to surgery. Postoperatively, close monitoring of daily weight, urine output, serum hematocrit, serum electrolytes, and hemodynamic parameters will yield the necessary information to make correct adjustments in crystalloid replacement. The normal daily fluid and electrolyte requirements must be met, and any unusual fluid and electrolyte losses, such as from the gastrointestinal tract, lungs, or skin, must be replaced. After the first few postoperative days, third-space fluid begins to mobilize back into the intravascular space, and ADH and aldosterone levels revert to normal. The excess fluid retained perioperatively is thus mobilized and excreted through the kidneys, and exogenous fluid requirements decrease. The patient with inadequate cardiovascular or renal reserve is prone to fluid overload during this time of third-space reabsorption, especially if intravenous fluids are not appropriately reduced.

The most common fluid and electrolyte disorder in the postoperative period is fluid overload. The fluid excess can occur concomitant with normal or decreased serum sodium. Large amounts of isotonic fluids are usually infused intraoperatively and postoperatively to maintain blood pressure and urine output. Because the infused fluid is often isotonic with plasma, it will remain in the extracellular space. Under such conditions, serum sodium will remain within normal levels. Fluid excess with hypotonicity (decreased serum sodium) can occur if large amounts of isotonic fluid losses (e.g., blood and gastrointestinal tract) are inappropriately replaced with hypotonic fluids. Again, the predisposition toward retention of free water in the immediate postoperative period compounds the problem. An increase in body weight occurs concomitant with the fluid expansion. In the patient who is not allowed anything by mouth, catabolism should induce a daily weight loss as great as 300 g/day. Clearly, the patient who is gaining weight in excess of 150 g/day is in a state of fluid expansion. Simple fluid restriction will correct the abnormality. When necessary, diuretics can be used to increase urinary water excretion.

States of fluid dehydration are uncommon but will occur in patients who have large daily fluid losses that are not replaced. Gastrointestinal losses should be replaced with the appropriate fluids. Patients with high fevers should be given appropriate free water replacement, because up to 2 L/day of free water can be lost through perspiration and hyperventilation. Although these increased losses are difficult to monitor, a reliable estimate can be obtained by monitoring body weight.

Postoperative Acid-base Disorders

A variety of metabolic, respiratory, and electrolyte abnormalities in the postoperative period can result in an imbalance in normal acid-base homeostasis, leading to alkalosis or acidosis. Changes in the respiratory rate will directly affect the amount of carbon dioxide that is exhaled. *Respiratory acidosis* will result from carbon dioxide retention in patients who have hypoventilation from central nervous system depression. This condition can result from oversedation with narcotics, particularly in the presence of concurrent severe chronic obstructive pulmonary disease. *Respiratory alkalosis* can result from hyperventilation caused by excitation of the central nervous system by drugs, pain, or excess ventilator support. Numerous metabolic derangements can result in *alkalosis* or *acidosis*. Proper fluid and electrolyte replacement as well as maintenance of adequate tissue perfusion will help prevent most acid-base disorders that occur during the postoperative period.

Alkalosis

The most common acid-base disorder encountered in the postoperative period is alkalosis (27). Alkalosis is usually of no clinical significance and resolves spontaneously. Several etiologic factors may include hyperventilation associated with pain; posttraumatic transient hyperaldosteronism, which results in decreased renal bicarbonate excretion; nasogastric suction, which removes hydrogen ions; infusion of bicarbonate during blood transfusions in the form of citrate, which is converted to bicarbonates; administration of exogenous alkali; and use of diuretics. Alkalosis can usually be corrected easily with removal of the inciting cause, as well as with correction of extracellular fluid and potassium deficits (Table 19.1). Full correction can usually be safely achieved over 1 to 2 days.

Disorder	Source of Alkali	Cause of Renal HCO ₃ ⁻ Retention
Gastric alkalosis Nasogastric suction Vomiting	Gastric mucosa	↓ECF, ↓K
Renal alkalosis Diuretics Respiratory acidosis and diuretics	Renal epithelium	↓ECF, ↓K ↓ECF, ↓K, ↑Pco ₂
Exogenous base	NaHCO ₃ , Na citrate, Na lactate	Coexisting disorder of ECF, K, Pco ₂

↓ECF, extracellular fluid depletion; ↓K, potassium depletion; ↑Pco₂, carbon dioxide retention; NaHCO₃, sodium bicarbonate; Pco₂, partial pressure of carbon dioxide, arterial.

Table 19.1. Causes of Metabolic Alkalosis

Marked alkalosis, with serum pH higher than 7.55, can result in serious cardiac arrhythmias or central nervous system seizures. Myocardial excitability is particularly pronounced with concurrent hypokalemia. Under such conditions, fluid and electrolyte replacement may not be sufficient to correct the alkalosis rapidly. *Acetazolamide* (250 to 500 mg), orally or intravenously, can be given 2 to 4 times daily to induce renal bicarbonate diuresis. Treatment with an acidifying agent is rarely necessary and should be reserved for acutely symptomatic patients (i.e., those with cardiac or central nervous system dysfunction) or for patients with

advanced renal disease. Under such conditions, HCl (5 to 10 mEq/hr of a 100-mmol solution) can be given via a central intravenous line. Ammonium chloride can also be given orally or intravenously but should not be given to patients with hepatic disease.

Acidosis

Metabolic acidosis is less common than alkalosis during the postoperative period, but acidosis can potentially be serious because of its effect on the cardiovascular system. Under conditions of acidosis, there are decreased myocardial contractility, a propensity for vasodilation of the peripheral vasculature leading to hypotension, and refractoriness of the fibrillating heart to defibrillation (27). These effects promote decompensation of the cardiovascular system and can hinder attempts at resuscitation.

Metabolic acidosis results from a decrease in serum bicarbonate levels caused by the consumption and replacement of bicarbonate by circulating acids or the replacement by other anions such as chloride. The proper workup includes a measurement of the anion gap:

$$\text{Anion gap} = (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-) = 10 \text{ to } 14 \text{ mEq/L (normal)}.$$

The anion gap is also composed of circulating protein, sulfate, phosphate, citrate, and lactate (29).

With metabolic acidosis, the anion gap can be increased or normal. An increase in circulating acids will consume and replace bicarbonate ion, thus increasing the anion gap. The causes include an increase in circulating lactic acid secondary to anaerobic glycolysis, such as that seen under conditions of poor tissue perfusion; increased ketoacids, as with cases of severe diabetes or starvation; exogenous toxins; and renal dysfunction, which leads to increased circulating sulfates and phosphates (30). The diagnosis can be established via a thorough history and measurement of serum lactate (normal <2 mmol/L), serum glucose, and renal function parameters. Metabolic acidosis in the face of a normal anion gap is usually the result of an imbalance of the ions chloride and bicarbonate, which occurs under conditions leading to excess chloride and decreased bicarbonate. Hyperchloremic acidosis can be seen in patients who have undergone saline loading. Bicarbonate loss will be seen in patients with small bowel fistulas, new ileostomies, severe diarrhea, or renal tubular acidosis. Finally, in patients with marked extracellular volume expansion, which often occurs postoperatively, the relative decrease in serum sodium and bicarbonate will result in a mild acidosis. A summary of the various causes of metabolic acidosis is shown in Table 19.2.

High Anion Gap	Normal Anion Gap	
	Hypokalemic	Hypokalemic
Uremia	Hypoproteinemia	Diarrhea
Ketacidosis	Primary adrenal failure	Renal tubular acidosis
Lactic acidosis	NH ₄ Cl	Ileal and sigmoid fistulas
Aspirin	Sulfur poisoning	Hyperalimentation
Paraldehyde	Early chronic renal failure	
Methanol	Obstructive uropathy	
Ethylene glycol		
Methyl malonic aciduria		

NH₄Cl, chloramine.

Table 19.2. Causes of Metabolic Acidosis

The treatment of metabolic acidosis depends on the cause. In patients with lactic acidosis, restoration of tissue perfusion is imperative. This can be accomplished through cardiovascular and pulmonary support as needed, oxygen therapy, and aggressive treatment of systemic infection wherever appropriate. Ketosis from diabetes can be corrected gradually with *insulin* therapy. Ketosis resulting from chronic starvation or from lack of caloric support postoperatively can be corrected with nutrition. In patients with normal anion gap acidosis, bicarbonate losses from the gastrointestinal tract should be replaced, excess chloride administration can be curtailed and, where necessary, a loop diuretic can be used to induce renal clearance of chloride. Dilutional acidosis can be corrected with mild fluid restriction.

Bicarbonates should not be given unless serum pH is lower than 7.2 or severe cardiac complications secondary to acidosis are present. Furthermore, close monitoring of serum potassium levels is mandatory. Under states of acidosis, potassium will exit the cell and enter the circulation. The patient with a normal potassium concentration and metabolic acidosis is actually depleted of intracellular potassium. Treatment of the acidosis without potassium replacement will result in severe hypokalemia with its associated risks. A summary of the various acid-base abnormalities and associated therapies is shown in Table 19.3.

Primary Disorder	Effect	Common Causes	Compensation	Treatment
Respiratory acidosis	Carbon dioxide Retention	Central nervous system depression Anxiety and lung impairment	Renal excretion of acid salts Respiratory alkalosis Chemical shift to the right Mild alkali	Respiratory stimulation Control of anxiety Fluids production
Respiratory alkalosis	Hyperventilation	Central nervous system Excitation Excite respiratory center	Renal excretion of sodium, potassium Respiratory acidosis Absorption of hydrogen and chloride ions Lactate release from red blood cells	Control Hyperventilation
Metabolic acidosis	Excess base of base Increased nonvolatile acids	Excess chloride Excess potassium Increased bicarbonate ion Lactic, formic, uric, uric, lactic acidosis Diarrhea Excess acidosis	Respiratory alkalosis Renal excretion of hydrogen and chloride ions Retention of potassium bicarbonate	Increase sodium load Give bicarbonate Serum pH < 7.2
Metabolic alkalosis	Excess base of chloride and potassium Increased bicarbonate	Contraction of Excess intake of Excess intake of Diuretics Hypokalemia Extracellular fluid Volume contraction	Respiratory acidosis Hypokalemia Renal excretion of bicarbonate and potassium Absorption of hydrogen and chloride ions	Increase chloride control Potassium replacement Hypokalemia Control to reach Intracellular Urgent volume replacement Chloride 0.11 NaCl as needed

NaCl, sodium chloride.

Table 19.3. Acid-Base Disorders and Their Treatment

Perioperative Pain Management

Although satisfactory analgesia is easily achievable with currently available methods, patients continue to suffer unnecessarily from postoperative pain. Studies have consistently shown that 30% to 40% of patients suffer moderate to severe pain in the postoperative period (31). There are several reasons for the existing inadequacies in pain management. First, patient expectations of pain relief are low and they are not aware of the extent of analgesia that they should expect. In a study of the perception of pain relief after surgery, 86% of patients had moderate to severe pain after surgery, but 70% felt that the pain was as severe as they had expected (32). Second, there is a lack of formal physician training in pain management. This lack is epitomized by the commonly written order prescribing a range of narcotic to be given intramuscularly every 3 to 4 hours as needed, leaving pain management decisions to the nursing staff, with no attempt made to titrate the dose of the prescribed narcotic commensurate with individual patient requirements. Third, attitudes continue to be influenced by the common misconception that the use of narcotics in the postoperative period can result in opioid dependence. In one review, 20% of nurses responding to a staff questionnaire expressed concern that the use of opioid analgesics during the postoperative period could cause addiction (32). Studies have confirmed that nurses will administer less than one-fourth of the total dose of narcotic that is prescribed on an as-needed basis. In order to facilitate acute pain management and reduce the number of adverse outcomes, the American Society of Anesthesiologists has established practice guidelines for acute pain management (33).

minimal effective analgesic concentration (MEAC) refers to the serum concentration of a drug below which very little analgesia is achieved. At the MEAC, receptor and plasma concentrations of a drug are in equilibrium. Steady-state drug concentrations above the MEAC are difficult to achieve with intramuscular depot injection (34). In one study, patients receiving intramuscular injections with *meperidine hydrochloride* (*Demero*) every 4 hours experienced marked intra- and interpatient variations in narcotic drug peak concentrations as well as in the time required to reach these peaks. As a result, serum concentrations of drug were above the MEAC an average of only 35% of each 4-hour dosing interval (35). Variable pain control following intermittent intramuscular injections is the result of inadequate, highly variable, and unpredictable blood concentrations (36). Adequate analgesia can be achieved through intramuscular or subcutaneous modes of administration,

but unpredictable absorption can make titration difficult. Small intravenous boluses can be more easily titrated but may be shorter acting, requiring more frequent injections and thus intensive nursing care, whereas larger intravenous boluses may be associated with a higher incidence of central nervous system and respiratory depression. **The *patient-controlled analgesia (PCA) technique, which allows patients to self-administer small doses of narcotic on demand, allows titration of measured boluses of narcotic as needed to relieve pain and can provide a more thorough analgesia with maintenance of steady-state drug concentrations above the MEAC.***

Irrespective of the route of administration, analgesics must be front loaded in order to provide prompt analgesia from the start. Without front loading, attainment of the MEAC will not occur for at least three elimination half-lives of the narcotic agent that is used. After front loading, additional small boluses of narcotic can be administered until analgesia is achieved. From the total dose of drug required to achieve analgesia, maintenance drug dosages can then be determined and administered either as a continuous infusion or on a scheduled basis, so that the dose of drug administered offsets the amount that is cleared ([Table 19.4](#)). Thereafter, prescribed doses of narcotic can be adjusted as needed.

Drug	Total Front-Loaded Dose	Increments	Cautions
Morphine	0.08-0.12 mg/kg	0.02 mg/kg q 10 min	Histaminic effects; nausea; biliary colic; reduce dose for elderly
Meperidine	1.0-1.5 mg/kg	0.20 mg/kg q 10 min	Reduce dose or change drug for impaired renal function
Codeine	0.5-1.0 mg/kg	0.1 mg/kg q 15 min	Nausea
Fentanyl	0.4-1.0 µg/kg	0.2-0.5 µg/kg q 6 min	Bradycardia; minimal hemodynamic alterations

Table 19.4. Guidelines for Front-Loading IV Analgesics for Relief of Postoperative Pain

Patient-controlled Analgesia

PCA devices are electronically controlled infusion pumps that deliver a preset dose of narcotic into a patient's indwelling intravenous catheter upon patient request. The devices all contain delay intervals or lockout times during which patient demands for more narcotic are not met. These devices eliminate the delay between the onset of pain and the administration of analgesic agents, a common problem inherent with on-demand analgesic orders in busy hospital wards. Patient-controlled analgesia has enjoyed excellent patient acceptance. Compared with conventional intramuscular injections, serum narcotic levels have significantly lower variability in patients using PCA ([34](#)). Patients using PCA have been shown to have improved analgesia, a lower incidence of postoperative pulmonary complications, and less confusion than those given intramuscular narcotics ([37](#)). Furthermore, the total dose of narcotic used has been lower with PCA than with conventional intramuscular depot injection.

The use of PCA does not by any means eliminate the adverse side effects of narcotics. Potentially life-threatening respiratory depression is seen in as many as 0.5% of patients using PCA. The use of a continuous narcotic infusion in addition to demand dosing has been associated with a fourfold increase in respiratory depression. Elderly patients and those with preexisting respiratory compromise also are at risk for respiratory depression ([34](#)).

Carefully supervised regimens using continuous infusions, on-demand intramuscular therapy, or fixed dosage schedules (every-4-hour dosing) with on-demand supplementation can have analgesic efficacy comparable with PCA. Nonetheless, the type of close supervision required to achieve adequate on-demand analgesia without PCA is difficult to maintain. Use of PCA shortens the time between the onset of pain and the administration of pain medication, provides more continuous access to analgesics, and allows for an overall steadier state of pain control.

Epidural and Spinal Analgesia

Anesthetics and narcotics administered either in the epidural space or intrathecally are among the most potent analgesic agents available; the efficacy of these agents is greater than that provided by intravenous PCA techniques. These drugs can be administered in one of several ways, including a single-shot dose given by epidural or intrathecal injection, intermittent injection given either on schedule or on demand, and continuous infusion.

Because of the risk of central nervous system infections and headaches, intrathecal administration is usually limited to a single dose of narcotic, local anesthetic, or both. In comparison with epidural administration, duration of action for a single dose is increased via the intrathecal route as a result of the high concentrations of drug attained in the cerebrospinal fluid. However, the risk of central nervous system and respiratory depression, as well as systemic hypotension, also is increased. Even the low doses of opioids required for intrathecal analgesia have been associated with an increased risk of respiratory depression ([38](#)). Therefore, some investigators have warned against the use of intrathecal spinal analgesia outside the intensive care setting.

Epidural administration is the preferred approach and provides extended (>24 hours) pain control during the postoperative period. Relative contraindications are the presence of coagulopathy, sepsis, and hypotension. Both anesthetic and narcotic agents have been used with excellent efficacy. Among the anesthetic agents, *bupivacaine* has been the most popular, providing excellent analgesia with minimal toxicity. Epidural analgesia is most suited for pain control in the lower abdomen and extremities. Potential adverse effects of epidural anesthetic agents include urinary retention, motor weakness, hypotension, and central nervous system and cardiac depression. In contrast to anesthetic agents, opioids offer excellent analgesia without accompanying sympathetic blockade. Epidural opioids tend to have a much longer duration of action, and hypotension is a rare complication. Compared with epidural anesthetics, however, there is a higher incidence of nausea and vomiting, respiratory depression, and pruritus ([39](#)).

Compared with analgesics administered intramuscularly or intravenously, epidural analgesia has been shown to be associated with improved pulmonary function postoperatively, a lower incidence of pulmonary complications, a decrease in postoperative venous thromboembolic complications (most likely secondary to earlier ambulation), fewer gastrointestinal side effects, a lower incidence of central nervous system depression, and shorter convalescence ([39](#)). Severe respiratory depression is the most serious potential complication, seen in fewer than 1% of patients. A lower incidence of respiratory depression is seen with the more lipophilic drugs such as *fentanyl*, which is quickly absorbed within the spinal cord and is therefore less likely to diffuse to the central nervous system respiratory control centers. Pruritus, nausea, and urinary retention are common but can be easily managed and are usually of little clinical significance. Cost is perhaps the main and most limiting drawback of epidural analgesia.

Close monitoring by nursing staff is required for safe administration of epidural analgesia. However, an intensive care setting is not necessary. Epidural analgesics can be administered safely in a hospital ward setting under close nursing supervision, using respiratory monitoring with hourly ventilatory checks during the first 8 hours of epidural analgesia.

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are becoming increasingly popular for the postoperative treatment of pain in patients undergoing major and minor surgical procedures. The NSAID *ketorolac* is a potent drug that can be given intravenously or intramuscularly. *Ketorolac* has a slightly slower onset of activity than *fentanyl* but has an analgesic potency comparable to *morphine*. The theoretical advantages of NSAIDs over opioids include absence of respiratory depression, lack of abuse potential, decreased sedative effects, decreased nausea, early return of bowel function, and faster recovery. In clinical studies, *ketorolac* has been found to have analgesic effects similar to those of morphine in postoperative orthopedic patients and, when used in conjunction with PCA, significantly reduced opioid requirements ([40,41](#)). Studies in gynecologic populations have been less positive. One study found no differences in pain scores, *morphine* consumption, or side effects between patients given *ketorolac* intravenously compared with placebo following hysterectomy ([42](#)). Because of the potential advantages, many advocate the addition of NSAIDs to opioid therapy for perioperative pain management.

Potential adverse effects associated with the use of NSAIDs include an increased risk of renal compromise (particularly in patients suffering from acute hypovolemia), gastrointestinal side effects, hypersensitivity reactions, and bleeding. Although NSAIDs cause a modest increase in bleeding time, this does not appear to be clinically significant. Controlled prospective studies have not demonstrated a significant increase in blood loss in patients who receive NSAIDs perioperatively. These agents should be used with extreme care, if at all, in patients with asthma, because 5% to 10% of adult patients with asthma are sensitive to *aspirin* and other NSAID preparations. *Ketorolac* is active when administered both intravenously and orally, making it easy to administer in the perioperative setting for patients undergoing minor procedures.

Antibiotic Prophylaxis

Infection at the operative site is a common cause of morbidity in patients undergoing gynecologic surgery. Procedures such as vaginal hysterectomy, abdominal hysterectomy, surgical drainage of pelvic abscess, selected cases of pregnancy termination, and radical surgery for gynecologic malignancy carry a significant risk of postoperative infection. Other risk factors for the development of wound infection include prolonged operative time, prolonged preoperative admission, concurrent infection, and presence of malignancy. Such infections result in considerable morbidity as well as prolonged hospitalization, increased rates of readmission, and substantial cost. Prophylactic antibiotics have been used in an effort to reduce these problems.

Pathogens that can cause contamination during gynecologic surgery are organisms indigenous to the vaginal tract, including gram-positive and gram-negative aerobes and anaerobes ([Table 19.5](#)). The primary pathogenic bacteria include coliforms, streptococci, fusobacteria, and *Bacteroides*.

Lactobacillus	Esterobacter agglomerans
Diphtheroids	Klebsiella pneumoniae
Staphylococcus aureus	Proteus mirabilis
Staphylococcus epidermidis	Proteus vulgaris
Streptococcus agalactiae	Morganella morganii
Streptococcus faecalis	Citrobacter diversus
α -Hemolytic streptococci	
Group D streptococci	Bacteroides species
Peptostreptococci	<i>E. bivius</i>
Peptococcus	<i>E. disiens</i>
Clostridium	<i>E. fragilis</i>
Gally anaerobia	<i>E. melanogenicus</i>
Escherichia coli	
Fusobacterium	
Esterobacter cloacae	

Table 19.5. Bacteria Indigenous to the Lower Genital Tract

Prophylactic antibiotic use in patients undergoing vaginal hysterectomy is highly effective and widely accepted as the standard of care. A review of the placebo-controlled trials in the literature regarding antibiotic prophylaxis in vaginal and abdominal hysterectomy included 48 studies of 5,524 patients who underwent vaginal hysterectomy and 30 studies of 3,752 patients who underwent abdominal hysterectomy ([43](#)). In vaginal hysterectomy, prophylactic antibiotics decreased febrile morbidity from 40% in control patients to 15% in treated patients and lowered pelvic infection rates from 25% in control patients to 5% in treated patients. In this analysis the benefits of prophylaxis were less pronounced with abdominal hysterectomy; prophylactic antibiotics reduced febrile morbidity from 28% in control patients to 16% in treated patients, pelvic infections from 10% to 5%, and wound infections from 8% to 3%. More recently, a metaanalysis of 25 randomized controlled trials revealed that use of antibiotic prophylaxis reduced the incidence of serious infections after abdominal hysterectomy from 21.1% (373 of 1,768) to 9% (166 of 1,836) ([44](#)). The authors concluded that because preoperative antibiotics are highly effective in prevention of serious infections associated with total abdominal hysterectomy, they should be used routinely.

The antibiotic chosen for prophylaxis for gynecologic surgery should have activity against the broad range of vaginal organisms. The first- and second-generation cephalosporins are well suited for this purpose because of their activity against gram-positive, gram-negative, and anaerobic organisms. Most classes of antibiotics (including *penicillin*, *tetracycline*, *sulfonamide*, broad-spectrum *penicillin*, and cephalosporins) and anaerobic drugs (clindamycin, *metronidazole*) have been shown to be effective prophylactically, but none has been shown to be consistently more effective than first-generation cephalosporins ([45,46,47](#) and [48](#)).

The timing of administration of the prophylactic antibiotic agent is important. Antibiotics given for prophylaxis are most active if present in tissues prior to contamination with an inoculum of bacteria ([49](#)). **For patients who undergo hysterectomy, the antibiotic should be present in the tissues prior to opening of the vaginal cuff, at which time vaginal organisms enter the pelvic cavity. Infusion of an antibiotic within 30 minutes of surgery is ideal for this purpose.** For long surgical procedures, particularly when there is a large blood loss or when an antibiotic agent with a short half-life is used, a second antibiotic dose should be given intraoperatively.

Many prospective studies have shown that short courses of prophylactic antibiotics (24 hours or shorter) are as efficacious as longer ones ([49](#)). Moreover, several clinical trials have found that one perioperative dose of prophylactic antibiotics is sufficient ([50,51](#) and [52](#)). The use of one dose of a prophylactic antibiotic has many advantages, including decreased cost, decreased toxicity, minimal alteration of host flora, and decreased induction of pathogen resistance.

Despite the advantages of using prophylactic antibiotics, the importance of good surgical technique must be emphasized. Delicate handling of tissues, good hemostasis, adequate drainage, and avoidance of unnecessarily large pedicles in ligatures promote healing and lower the risk of complications.

Postoperative Infections

Infections are a major source of morbidity in the postoperative period. Risk factors for infectious morbidity include the absence of perioperative antibiotic prophylaxis, contamination of the surgical field from infected tissues or from spillage of large bowel contents, an immunocompromised host, poor nutrition, chronic and debilitating severe illness, poor surgical technique, and preexisting focal or systemic infection. Sources of postoperative infection can include the lung, urinary tract, surgical site, pelvic side wall, vaginal cuff, abdominal wound, and sites of indwelling intravenous catheters. Early identification and treatment of infection will result in the best outcome from these potentially serious complications.

Although infectious morbidity is an inevitable complication of surgery, the incidence of infections can be decreased by the appropriate use of simple preventive measures. In cases that involve transection of the large bowel, spillage of fecal contents inevitably occurs. A thorough preoperative mechanical and antibiotic bowel preparation in combination with systemic antibiotic prophylaxis will help decrease the incidence of postoperative pelvic and abdominal infections in these patients. The surgeon can further decrease the risk of postoperative infections by using meticulous surgical technique. Blood and necrotic tissue are excellent media for the growth of aerobic and anaerobic organisms. In cases in which there is higher-than-usual potential for serum and blood to collect in spaces that have been contaminated by bacterial spill, closed-suction drainage may reduce the risk of infection. Antibiotic therapy, rather than prophylaxis, should be initiated during surgery in patients who have frank intraabdominal infection or pus.

Elective surgical procedures should be postponed in patients who have infections preoperatively. In an epidemiologic study conducted by the Centers for Disease Control and Prevention, the incidence of nosocomial surgical infections ranged from 4.3% in community hospitals to 7% in municipal hospitals ([53](#)). Urinary tract infections accounted for approximately 40% of these nosocomial infections. Infections of the skin and wound accounted for approximately one-third of the infections, and respiratory tract infections accounted for approximately 16%. In patients who had any type of infection prior to surgery, the risk of infection at the surgical wound site was increased fourfold. Rates of infection were higher in older patients, in patients with increased length of surgery, and in those with increased length of hospital stay prior to surgery. The relative risk was 3 times higher in patients with a community-acquired infection prior to surgery. These community-acquired infections included infections of the urinary and respiratory tracts.

Historically, the standard definition of febrile morbidity for surgical patients has been the presence of a temperature higher than or equal to 100.4°F (38°C) on two occasions at least 4 hours apart during the postoperative period, excluding the first 24 hours. However, other **sources have defined fever as two consecutive**

temperature elevations greater than 101.0°F (38.3°C) (54,55). Febrile morbidity has been estimated to occur in as many as one-half of patients; however, it is often self-limited, resolving without therapy, and is usually noninfectious in origin (56). Overzealous evaluations of postoperative fever, especially during the early postoperative period, are time consuming, expensive, and sometimes uncomfortable for the patient (55). **The value of 101.0°F is more useful than 100.4°F to distinguish an infectious cause from an inconsequential postoperative fever.**

The assessment of a febrile surgical patient should include a review of the patient's history with regard to risk factors. Both the history and the physical examination should focus on the potential sites of infection (Table 19.6). The examination should include inspection of the pharynx, a thorough pulmonary examination, percussion of the kidneys to assess for costovertebral angle tenderness, inspection and palpation of the abdominal incision, examination of sites of intravenous catheters, and an examination of the extremities for evidence of deep venous thrombosis or thrombophlebitis. In gynecologic patients, an appropriate workup may also include inspection and palpation of the vaginal cuff for signs of induration, tenderness, or purulent drainage. A pelvic examination should also be performed in order to identify a mass consistent with a pelvic hematoma or abscess and to look for signs of pelvic cellulitis.

Operative Site	Nonoperative Site
Vaginal cuff	Urinary tract
Pelvic cellulitis	Asymptomatic bacteremia
Pelvic abscess	Cystitis
Supravaginal, extraperitoneal	Pyelonephritis
Intraperitoneal	Respiratory
Adhesia	Atelectasis
Cellulitis	Pneumonia
Abscess	Vascular
Abdominal incision	Phlebitis
Cellulitis	Septic pelvic thrombophlebitis
Simple	
Progressive bacterial synergistic	
Necrotizing fasciitis	
Mycetozis	

Table 19.6. Posthysterectomy Infections

Patients with fever in the early postoperative period should have an aggressive pulmonary toilet, including incentive spirometry (55). If the fever persists beyond 72 hours postoperatively, additional laboratory and radiologic data may be obtained. The evaluation may include complete and differential white blood cell counts and a urinalysis. In one study, a routine urine culture had a yield of only 9%; therefore, culture should not be analyzed unless indicated by the urinalysis results or symptoms (54). Routine chest radiographs have a yield of 12.5% and should be obtained in asymptomatic patients as well as those with signs and symptoms localizing to the lung (54). Blood cultures can also be obtained but will most likely be of little yield unless the patient has a high fever (102°F). In patients with costovertebral angle tenderness, IVP may be indicated to rule out the presence of ureteral damage or obstruction from surgery, particularly in the absence of laboratory evidence of urinary tract infection. Patients who have persistent fevers without a clear localizing source should undergo CT scanning of the abdomen and pelvis to rule out the presence of an intraabdominal abscess. Finally, if fever persists in patients who have had gastrointestinal surgery, a barium enema or upper gastrointestinal series with small bowel assessment may be indicated late in the course of the first postoperative week to rule out an anastomotic leak or fistula.

Urinary Tract Infections

Historically, the urinary tract has been the most common site of infection in surgical patients (53). However, the incidence reported in the more recent gynecologic literature has been less than 4% (56,57). This decrease in urinary tract infections is most likely the result of increased perioperative use of prophylactic antibiotics. The incidence of postoperative urinary tract infection in gynecologic surgical patients not receiving prophylactic antibiotics has been confirmed to be as high as 40% (58), and **even a single dose of perioperative prophylactic antibiotic has been shown to decrease the incidence of postoperative urinary tract infection from 35% to 4% (59).**

Symptoms of a urinary tract infection may include urinary frequency, urgency, and dysuria. In patients with pyelonephritis, other symptoms include headache, malaise, nausea, and vomiting. A urinary tract infection is diagnosed on the basis of microbiology and has been defined as the growth of 10^5 organisms/ml of urine cultured. Most infections are caused by coliform bacteria, with *Escherichia coli* being the most frequent pathogen. Other pathogens include *Klebsiella*, *Proteus*, and *Enterobacter* species. *Staphylococcus* organisms are the causative bacteria in fewer than 10% of cases.

Despite the high incidence of urinary tract infections in the postoperative period, few of these infections are serious. Most are confined to the lower urinary tract, and pyelonephritis is a rare complication (60). Catheterization of the urinary tract, either intermittently or continuously with the use of an indwelling catheter, has been implicated as a main cause of urinary tract contamination (61). In fact, more than 1 million catheter-associated urinary tract infections occur yearly in the United States, and **catheter-associated bacteria remains the most common etiology of gram-negative bacteremia in hospitalized patients.** Bacteria adhere to the surface of urinary catheters and grow within bile films, which appear to protect embedded bacteria from antibiotics, making treatment less effective. Therefore, the use of urinary tract catheters should be minimized. An indwelling catheter should be removed or replaced in a patient undergoing treatment for catheter-related infections.

The treatment of urinary tract infection includes hydration and antibiotic therapy. Commonly prescribed and effective antibiotics include penicillin, sulfonamides, cephalosporins, fluoroquinolones, and nitrofurantoin. The choice of antibiotic should be based on knowledge of the susceptibility of organisms cultured at a particular institution. In some institutions, for example, more than 40% of *E. coli* strains are resistant to *ampicillin*. For uncomplicated urinary tract infections, an antibiotic that has good activity against *E. coli* should be given in the interim while awaiting results of the urine culture and sensitivity data.

Patients who have a history of recurrent urinary tract infections, those with chronic indwelling catheters (Foley catheters or ureteral stents), and those who have urinary conduits should be treated with antibiotics that will be effective against the less common urinary pathogens such as *Klebsiella* and *Pseudomonas*. Chronic use of the fluoroquinolones for prophylaxis is not advised, because these agents are notorious for inducing antibiotic-resistant strains of bacteria.

The respiratory tract is an uncommon site for infectious complications in gynecologic surgical patients. Hemsell noted only six cases of pneumonia in more than 4,000 women who underwent elective hysterectomy (56). This low incidence is probably a reflection of the young age and good health status of gynecologic patients in general. In acute care facilities, pneumonia is a frequent hospital-acquired infection, particularly in elderly patients (62). Risk factors include extensive or prolonged atelectasis, preexistent chronic obstructive pulmonary disease, severe or debilitating illness, central neurologic disease causing an inability to clear oropharyngeal secretions effectively, and nasogastric suction (62). In surgical patients, early ambulation and aggressive management of atelectasis are the most important preventive measures. The role of prophylactic antibiotics remains unclear.

A significant proportion (40% to 50%) of hospital-acquired pneumonias are caused by gram-negative organisms. These organisms gain access to the respiratory tract from the oral pharynx. Gram-negative colonization of the oral pharynx has been shown to be increased in patients in acute care facilities and has been associated with the presence of nasogastric tubes, preexisting respiratory disease, mechanical ventilation, tracheal intubation, and paralytic ileus, as a result of microbial overgrowth in the stomach (63). Interestingly, the use of antimicrobial drugs seems to significantly increase the frequency of colonization of the oral pharynx with gram-negative bacteria.

A thorough lung examination should be included in the assessment of all febrile surgical patients. In the absence of significant lung findings, a chest radiograph is probably of little benefit in patients at low risk for postoperative pulmonary complications. In patients with pulmonary findings or with risk factors for pulmonary complications, a chest radiograph should be obtained. A sputum sample should also be obtained for Gram stain and culture. The treatment should include postural drainage, aggressive pulmonary toilet, and antibiotics. The antibiotic chosen should be effective against both gram-positive and gram-negative organisms, and in patients who are receiving assisted ventilation, the antibiotic spectrum should include drugs that are active against *Pseudomonas* organisms.

Phlebitis

Intravenous catheter-related infections are common; the reported incidence is from 25% to 35% (64). The intravenous site should be inspected daily, and the catheter

should be removed if there is any associated pain, redness, or induration. Unfortunately, phlebitis can occur even with close surveillance of the intravenous site. In one study, more than 50% of the cases of phlebitis became evident more than 12 hours after discontinuation of intravenous catheters (65). In addition, fewer than one-third of patients had symptoms related to the intravenous catheter site 24 hours prior to the diagnosis of phlebitis.

Intravenous catheters should be inserted using sterile technique, and they should be changed frequently. The institution of intravenous therapy teams has decreased the incidence of phlebitis by as much as 50% (64). This decrease is related not so much to surveillance of the intravenous catheter site as it is to frequent changing of intravenous catheters. The incidence of catheter-related phlebitis increases significantly after 72 hours. Therefore, intravenous catheters should be changed at least every 3 days.

Phlebitis can be diagnosed based on the presence of fever, pain, redness, induration, or a palpable venous cord. Occasionally, suppuration will be present. Phlebitis is usually self-limited and resolves within 3 to 4 days. The treatment includes application of warm, moist compresses and prompt removal of any catheters from the infected vein. Antibiotic therapy with antistaphylococcal agents should be instituted for catheter-related sepsis. Excision or drainage of an infected vein is rarely necessary.

Wound Infections

The results of a prospective study of more than 62,000 wounds were revealing in regard to the epidemiology of wound infections (66). The wound infection rate varied markedly, depending on the extent of contamination of the surgical field. The wound infection rate for clean surgical cases (infection not present in the surgical field, no break in aseptic technique, no viscus entered) was lower than 2%, whereas the incidence of wound infections with dirty, infected cases was 40% or higher. Preoperative showers with *hexachlorophene* slightly lowered the infection rate for clean wounds, whereas preoperative shaving of the wound site with a razor increased the infection rate. A 5-minute wound preparation immediately before surgery was as effective as preparation for 10 minutes. The wound infection rate increased with the duration of preoperative hospital stay as well as with the duration of surgery. In addition, incidental appendectomy increased the risk of wound infection in patients undergoing clean surgical procedures. The study concluded that the incidence of wound infections could be decreased by short preoperative hospital stays, hexachlorophene showers prior to surgery, minimizing shaving of the wound site, use of meticulous surgical technique, decreasing operative time as much as possible, bringing drains out through sites other than the wound, and dissemination of information to surgeons regarding their wound infection rates. A program instituting these conclusions led to a fall in the clean wound infection rate from 2.5% to 0.6% over an 8-year period. The wound infection rate in most gynecologic services has been lower than 5%, reflective of the clean nature of most gynecologic operations.

The symptoms of wound infection often occur late in the postoperative period, usually after the fourth postoperative day, and may include fever, erythema, tenderness, induration, and purulent drainage. Wound infections which occur on postoperative days 1 through 3 are generally caused by streptococcal and *Clostridia* infections. The management of wound infections is mostly mechanical and involves opening the infected portion of the wound above the fascia, with cleansing and debridement of the wound edges as necessary. Wound care, consisting of debridement and dressing changes 2 to 3 times daily with mesh gauze, will promote growth of granulation tissue, with gradual filling in of the wound defect by secondary intention. Clean, granulating wounds can often be secondarily closed with good success, shortening the time required for complete wound healing.

The technique of delayed primary wound closure can be used in contaminated surgical cases to lower the incidence of wound infection. Briefly, this technique involves leaving the wound open above the fascia at the time of the initial surgical procedure. Vertical interrupted mattress sutures through the skin and subcutaneous layers are placed 3 cm apart but are not tied. Wound care is instituted immediately after surgery and continued until the wound is noted to be granulating well. Sutures may then be tied and the skin edges further approximated using sutures or staples. **Using this technique of delayed primary wound closure, the overall wound infection rate has been shown to be decreased from 23% to 2.1% in high-risk patients (67).**

Pelvic Cellulitis

Vaginal cuff cellulitis is present to some extent in most patients who have undergone hysterectomy. It is characterized by erythema, induration, and tenderness at the vaginal cuff. Occasionally, a purulent discharge from the apex of the vagina may also be present. The cellulitis is often self-limited and does not require any treatment. Fever, leukocytosis, and pain localized to the pelvis may accompany severe cuff cellulitis and most often signifies extension of the cellulitis to adjacent pelvic tissues. In such cases, broad-spectrum antibiotic therapy should be instituted with coverage for gram-negative, gram-positive, and anaerobic organisms. If purulence at the vaginal cuff is excessive or if there is a fluctuant mass noted at the vaginal cuff, the vaginal cuff should be gently probed and opened with a blunt instrument. The cuff can then be left open for dependent drainage or, alternatively, a drain can be placed into the lower pelvis through the cuff and removed when drainage, fever, and symptoms in the lower pelvic region have resolved.

Intraabdominal and Pelvic Abscess

The development of an abscess in the surgical field or elsewhere in the abdominal cavity is an uncommon complication after a gynecologic surgery. It is most likely to occur in contaminated cases in which the surgical site is not adequately drained or as a secondary complication of hematomas. The causative pathogens in patients who have intraabdominal abscesses are usually polymicrobial in nature. The aerobes most commonly identified include *E. coli*, *Klebsiella*, *Streptococcus*, *Proteus*, and *Enterobacter*. Anaerobic isolates are also common, usually from the *Bacteroides* group. These pathogens arise mainly from the vaginal tract but also can be derived from the gastrointestinal tract, particularly when the colon has been entered at the time of surgery.

Intraabdominal abscess is sometimes difficult to diagnose. The evolving clinical picture is often one of persistent febrile episodes with a rising white blood cell count. Findings on abdominal examination may be equivocal. If an abscess is located deep in the pelvis, it may be palpable by pelvic or rectal examination. For abscesses above the pelvis, the diagnosis will depend on radiologic confirmation.

Ultrasonography can occasionally delineate fluid collections in the upper abdomen as well as in the pelvis. However, bowel gas interference makes visualization of fluid collections or abscesses in the midabdomen difficult to distinguish. **CT scanning is therefore much more sensitive and specific for diagnosing intraabdominal abscesses and often is the radiologic procedure of choice.** Occasionally, if conventional radiologic methods fail to identify an abscess and the index of suspicion for an abscess remains high, labeled leukocyte scanning may be useful for locating the infected focus.

Standard therapy for intraabdominal abscess is evacuation and drainage combined with appropriate parenteral administration of antibiotics. Abscesses located low in the pelvis, particularly in the area of the vaginal cuff, can often be reached through a vaginal approach. In many patients, the ability to drain an abscess by placement of a drain percutaneously under CT guidance has obviated the need for surgical exploration. With CT guidance, a pigtail catheter is placed into an abscess cavity via either transperineal, transrectal, or transvaginal approaches. The catheter is left in place until drainage decreases. Transperineal and transrectal drainage of deep pelvic abscesses has been successful in 90% to 93% of patients, obviating the need for surgical management (68,69). **For those patients in whom radiologic drainage is not successful, however, surgical exploration and evacuation are indicated.** The gold standard of initial antibiotic therapy has been the combination of *ampicillin*, *gentamicin*, and *clindamycin*. Adequate treatment can also be achieved with currently available broad-spectrum single agents (including the broad-spectrum *penicillin*), second- and third-generation cephalosporins, *levofloxacin* and *metronidazole*, and the *sulbactam-clavulanic acid*-containing preparations (70,71,72 and 73).

Necrotizing Fasciitis

Necrotizing fasciitis is an uncommon infectious disorder; approximately 1,000 cases occur annually in the United States (74). The disorder is characterized by a rapidly progressive bacterial infection that involves the subcutaneous tissues and fascia while characteristically sparing underlying muscle. Systemic toxicity is a frequent feature of this disease, as manifested by the presence of dehydration, septic shock, DIC, and multiple organ system failure.

The pathogenesis of necrotizing fasciitis involves a polymicrobial infection of the dermis and subcutaneous tissue. Hemolytic streptococcus was initially believed to be the primary pathogen responsible for the infection in necrotizing fasciitis (75). However, it is now evident that numerous other organisms are often cultured in addition to streptococcus, including other gram-positive organisms, coliforms, and anaerobes (75,76,77,78 and 79). Bacterial enzymes such as hyaluronidase and lipase released in the subcutaneous space destroy the fascia and adipose tissue and induce a liquefactive necrosis. In addition, noninflammatory intravascular coagulation or thrombosis subsequently occurs. Intravascular coagulation results in ischemia and necrosis of the subcutaneous tissues and skin (76,77). Late in the course of the infection, destruction of the superficial nerves produces anesthesia in the involved skin. The release of bacteria and bacterial toxins into the systemic circulation can

cause septic shock, acid-base disturbances, and multiple organ impairment.

The diagnostic criteria for necrotizing fasciitis include extensive necrosis of the superficial fascia and subcutaneous tissue with peripheral undermining of the normal skin, a moderate to severe systemic toxic reaction, the absence of muscle involvement, *Clostridia* in wound and blood culture and major vascular occlusion, intensive leukocytic infiltration, and necrosis of subcutaneous tissue (80).

Most patients with necrotizing fasciitis suffer pain, which in the early stages of the disease is often disproportionately greater than that expected from the degree of cellulitis present. Late in the course of the infection, the involved skin may actually be anesthetized secondary to necrosis of superficial nerves. Temperature abnormalities, both hyperthermia and hypothermia, are common concomitant with the release of bacterial toxins as well as with bacterial sepsis, which is present in up to 40% of patients (81). The involved skin is initially tender, erythematous, and warm. Edema develops and the erythema spreads diffusely, fading into normal skin, characteristically without distinct margins or induration. Subcutaneous microvascular thrombosis induces ischemia in the skin, which becomes cyanotic and blistered. Eventually, as necrosis develops, the skin becomes gangrenous and may slough spontaneously. Most patients will have leukocytosis and acid-base abnormalities. Finally, subcutaneous gas may develop, which can be identified by palpation and by radiograph. The finding of subcutaneous gas by radiograph is often indicative of clostridial infection, although it is not a specific finding and may be caused by other organisms. These organisms include *Enterobacter*, *Pseudomonas*, anaerobic streptococci, and *Bacteroides* (82) which, unlike clostridial infections, spare the muscles underlying the affected area. A tissue biopsy specimen for Gram stain and aerobic and anaerobic culture should be obtained from the necrotic center of the lesion in order to identify the etiologic organisms (77). Although necrotizing fasciitis is often diagnosed during surgery, a high index of suspicion as well as liberal use of frozen-section biopsy can often provide an early life-saving diagnosis and minimize morbidity (83).

Predisposing risk factors for necrotizing fasciitis include diabetes mellitus, alcoholism, an immunocompromised state, hypertension, peripheral vascular disease, intravenous drug abuse, and obesity (74,76,79,82,84). The most frequent site of infection has been in the extremities (77), but the infection can occur anywhere in the subcutaneous tissues, including the head and neck, trunk, and perineum. Necrotizing fasciitis has been known to occur after trauma, surgery, burns, and lacerations; as a secondary complication in perirectal infections or Bartholin duct abscesses; and *de novo* (74,75,76 and 77,83). Increased age, delay in diagnosis, inadequate debridement during initial surgery, extensive disease at the time of diagnosis, and the presence of diabetes mellitus are all factors that have been associated with an increased likelihood of mortality from necrotizing fasciitis (74,81). Clearly, early diagnosis and aggressive management of this lethal disease have led to improved survival. In an earlier series, the mortality rate was consistently higher than 30%; in more recent series, the mortality rate has decreased to less than 10% (82,85,86).

Successful management of necrotizing fasciitis involves early recognition, immediate initiation of resuscitative measures (including correction of fluid, acid-base, electrolyte, and hematologic abnormalities), aggressive surgical debridement and redebridement as necessary, and broad-spectrum antibiotic therapy. Many patients will benefit from central venous monitoring, as well as from high-caloric nutritional support.

During surgery, the incision should be made through the infected tissue down to the fascia. An ability to undermine the skin and subcutaneous tissues with digital palpation often will confirm the diagnosis. Multiple incisions can be made sequentially toward the periphery of the affected tissue until well-vascularized, healthy, resistant tissue is reached at all margins. The remaining affected tissue must be excised. The wound can then be packed and sequentially debrided on a daily basis as necessary until healthy tissue is displayed at all margins.

Hyperbaric oxygen therapy may be of some benefit, particularly in patients for whom culture results are positive for anaerobic organisms. Retrospective nonrandomized studies (74,87) have demonstrated that the addition of hyperbaric oxygen therapy to surgical debridement and antimicrobial therapy appear to significantly decrease both wound morbidity and overall mortality in patients with necrotizing fasciitis. The demonstrated benefit of hyperbaric therapy in one study (74) was remarkable, given that patients receiving hyperbaric oxygen were sicker and had a higher incidence of diabetes mellitus, leukocytosis, and shock.

After the initial resuscitative efforts and surgical debridement, the primary concern is the management of the open wound. Allograft and xenograft skin can be used to cover open wounds, thus decreasing heat and evaporative water loss. Interestingly, temporary biologic closure of open wounds also seems to decrease bacterial growth (88). Amniotic membranes have also been shown to be an effective wound covering in patients with necrotizing fasciitis (84). Recently a new technology has been developed to expedite wound healing. The vacuum-assisted closure (VAC) method is a subatmospheric pressure technique that has been demonstrated in laboratory and clinical studies to significantly improve wound healing. The VAC device as a method for wound control has demonstrated significant promotion of wound healing in laboratory and clinical studies (89,90). In situations in which spontaneous closure is not likely, the VAC device may allow for the development of a suitable granulation bed and prepare the tissue for graft placement, thereby increasing the probability of graft survival. Finally, skin flaps can be mobilized to help cover open wounds once the infections have resolved and granulation has begun.

Gastrointestinal Preparation

Preparation of the lower gastrointestinal tract prior to elective gynecologic surgery has several goals. In most gynecologic surgery, when the gastrointestinal tract is not entered, mechanical preparation of the bowel reduces gastrointestinal contents and thus allows more room in the abdomen and pelvis, facilitating the surgical procedure. If a rectosigmoid colon enterotomy occurs, the mechanical bowel preparation eliminates formed stool and reduces the risk of bacterial contamination, thus reducing infectious complications. Mechanical bowel preparation may be accomplished by several methods (Table 19.7). The traditional use of laxatives and enemas requires at least 12 to 24 hours and generally causes moderate abdominal distention and crampy pain. In addition, nursing supervision of enema administration and the need for intravenous fluid replacement makes this regimen relatively expensive. Randomized trials comparing traditional mechanical bowel preparation with oral gut lavage (*PEG electrolyte solution [GoLYTELY]*) have found that the use of approximately 4 liters of *GoLYTELY* (administered until the rectal effluent is clear) provides more complete, faster, and more comfortable bowel preparation (91). Furthermore, the fluid loss following gut lavage with *GoLYTELY* appears to be clinically insignificant. Gut lavage can usually be performed at home the day prior to scheduled surgery. If the patient cannot drink the 4 liters, the *GoLYTELY* may be administered through a small-caliber nasogastric tube. The ingestion of 4 liters of fluid is problematic for many patients. An alternative mechanical preparation method is the use of oral *sodium phosphate (Phospho-Soda)*. When evaluated in a randomized trial comparing the 4 liters of *GoLYTELY* with oral *sodium phosphate*, colonoscopic examination disclosed that both methods were equally effective in colonic cleansing and more patients preferred the sodium phosphate method (92).

Time	Mechanical Prep	Antibiotic Prep
Preoperative day 2	Clear liquid diet	
Preoperative day 1	Clear liquid diet	
12 noon	Magnesium citrate (240 or PO), or ColElyse (1 L, PO over 2 hrs)	
1 pm		Erythromycin base 500 mg PO, plus Neomycin 5 gm PO Aminosalicylic 500 mg PO may be substituted
2 pm		Repeat PO antibiotics
8 pm	Enemas until clear (V OSMO 5 NS + 20 mlq KC1 at 123 cc/hr regimen)	
11 pm		Repeat PO antibiotics
Operative day	Nothing by mouth	
12 midnight	Surgery	Preoperative IV antibiotic

PO, per os; OSMO, oral sodium phosphate; NS, normal saline; PO, per os.

Table 19.7. Bowel Preparation Regimens to Begin Day Prior to Surgery

High infection rates after colonic surgery have led to investigation of methods aimed at reducing these significant complications. Although mechanical bowel preparation is an essential part of all colonic surgery preparation regimens, it does not reduce the infection rate satisfactorily. Reduction of the number of pathogenic flora in the colon is the primary strategy to reduce infection after colonic surgery. The colon has the greatest concentration of bacteria in the body, including both aerobes and anaerobes. Anaerobes outnumber aerobes by 1,000:1. After reducing the bacterial load by mechanical preparation, the administration of antibiotics can further reduce the bacterial count in the colon. Of the many trials reported, the most widely accepted regimen combines *erythromycin* base and *neomycin* administered orally (Table 19.7) (93,94 and 95). Many surgeons substitute *metronidazole* for the *erythromycin*; there is no significant difference in infection rates, but patients tolerate *metronidazole* better than *erythromycin*. **The use of oral antibiotics 24 hours prior to colonic resection has reduced the infection rate from approximately 40%, to 5% to 10%, in randomized trials.** Because these oral antibiotics are poorly absorbed and many do little to reduce infection from vaginal contamination, an intravenous antibiotic (first-generation cephalosporin) can be added to the preoperative regimen. **Antibiotic bowel prophylaxis should be used**

for patients who are likely to undergo colorectal surgery (pelvic exenteration, ovarian cancer debulking) and those who are at high risk for rectal injury (such as severe cases of endometriosis or pelvic inflammatory disease).

Postoperative Gastrointestinal Complications

Ileus

Following abdominal or pelvic surgery, most patients will experience some degree of intestinal ileus. The exact mechanism by which this arrest and disorganization of gastrointestinal motility occurs is unknown, but it appears to be associated with the opening of the peritoneal cavity and is aggravated by manipulation of the intestinal tract and prolonged surgical procedures. Infection, peritonitis, and electrolyte disturbances may also result in ileus. For most patients undergoing common gynecologic operations, the degree of ileus is minimal and gastrointestinal function returns relatively rapidly, allowing the resumption of oral intake within a few days of surgery. Patients who have persistently diminished bowel sounds, abdominal distention, and nausea and vomiting require further evaluation and more aggressive management.

Ileus is usually manifested by abdominal distention and should be evaluated initially by physical examination. Pertinent points of the abdominal examination include assessment of the quality of bowel sounds and palpation in search of tenderness or rebound. The possibility that the patient's signs and symptoms may be associated with a more serious intestinal obstruction or other intestinal complication must be considered. Pelvic examination should be performed to evaluate the possibility of a pelvic abscess or hematoma that may contribute to the ileus. **Abdominal radiograph to evaluate the abdomen in the flat (supine) position as well as in the upright position usually will aid in the diagnosis of an ileus. The most common radiographic findings include dilated loops of small and large bowel as well as air-fluid levels while the patient is in the upright position.** Sometimes, massive dilation of the colon or stomach may be noted. The remote possibility of distal colonic obstruction suggested by a dilated cecum should be excluded by rectal examination, proctosigmoidoscopy, or barium enema. In the postoperative gynecology patient, especially in the upright position, the flat plate of the abdomen may also show evidence of free air. This is a common finding following surgery, which lasts 7 to 10 days in some instances and is not indicative of a perforated viscus in most patients.

The initial management of a postoperative ileus is aimed at gastrointestinal tract decompression and maintenance of appropriate intravenous replacement fluids and electrolytes.

1. **A nasogastric tube should evacuate the stomach of its fluid and gaseous contents.** Prolonged nasogastric suction continues to remove swallowed air, which is the most common source of air in the small bowel. Some clinicians prefer to use a longer small intestinal tube (Cantor or Miller-Abbott tube) (96). This tube, which usually has a mercury-filled bag on its distal tip, may be propelled by peristalsis through the pylorus and into the small bowel, thus allowing a better evacuation of the small bowel. The disadvantage of long tubes is that they take a longer time to become positioned and may not enter the small bowel as a result of the decreased intestinal motility associated with ileus.
2. **Fluid and electrolyte replacement must be adequate to keep the patient well perfused.** Significant amounts of third-space fluid loss occur in the bowel wall, the bowel lumen, and the peritoneal cavity during the acute episode. Gastrointestinal fluid losses from the stomach may lead to a metabolic alkalosis and depletion of other electrolytes as well. Careful monitoring of serum chemistry levels and appropriate replacement are necessary.
3. **Most cases of severe ileus will begin to improve over a period of several days.** In general, this is recognized by reduction in the abdominal distention, return of normal bowel sounds, and passage of flatus or stool. Follow-up abdominal radiographs should be obtained as necessary for further monitoring.
4. **When the gastrointestinal tract function appears to have returned to normal, the nasogastric tube may be removed and a liquid diet may be instituted.**
5. **If a patient shows no evidence of improvement during the first 48 to 72 hours of medical management, other causes of ileus should be sought.** Such cases may include ureteral injury, peritonitis from pelvic infection, unrecognized gastrointestinal tract injury with peritoneal spill, or fluid and electrolyte abnormalities such as hypokalemia. With persistent ileus, the use of water-soluble upper gastrointestinal contrast studies may assist in the resolution, but prospective randomized data regarding this maneuver are lacking.

Small Bowel Obstruction

Obstruction of the small bowel following major gynecologic surgery occurs in approximately 1% to 2% of patients (97). The most common cause of small bowel obstruction is adhesions to the operative site. If the small bowel becomes adherent in a twisted position, partial or complete obstruction may result from distention, ileus, or bowel wall edema. Less common causes of postoperative small bowel obstruction include entrapment of the small bowel into an incisional hernia and an unrecognized defect in the small bowel or large bowel mesentery. **Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate.** Because of the potential for mesenteric vascular occlusion and resulting ischemia or perforation, worsening symptoms of abdominal pain, progressive distention, fever, leukocytosis, or acidosis should be evaluated carefully because immediate surgery may be required.

In most cases of small bowel obstruction following gynecologic surgery, the obstruction is only partial and the symptoms usually resolve with conservative management.

1. **Further evaluation after several days of conservative management may be necessary.** Evaluation of the gastrointestinal tract with barium enema and an upper gastrointestinal study with small bowel assessment are appropriate. In most cases, complete obstruction is not documented, although a narrowing or tethering of the segment of small bowel may indicate the site of the problem.
2. **Further conservative management with nasogastric decompression and intravenous fluid replacement may allow time for bowel wall edema or torsion of the mesentery to resolve.**
3. **If resolution is prolonged and the patient's nutritional status is marginal, the use of total parenteral nutrition may be necessary.**
4. **Conservative medical management of postoperative small bowel obstruction usually results in complete resolution.** However, if persistent evidence of small bowel obstruction remains after full evaluation and an adequate trial of medical management, exploratory laparotomy may be necessary to surgically evaluate and manage the obstruction. In most cases, lysis of adhesions is all that is required, although a segment of small bowel that is badly damaged or extensively sclerosed from adhesions may require resection and reanastomosis.

Colonic Obstruction

Postoperative colonic obstruction following surgery for most gynecologic conditions is exceedingly rare. It is almost always associated with a pelvic malignancy, which in most cases will have been known at the time of the initial operation. Advanced ovarian carcinoma is the most common cause of colonic obstruction in postoperative gynecologic surgery patients, and it is caused by extrinsic impingement on the colon by the pelvic malignancy. Intrinsic colonic lesions may be undetected, especially in a patient with some other benign gynecologic condition. When colonic obstruction is manifested by abdominal distention and abdominal radiographs reveal a dilated colon and enlarging cecum, further evaluation of the large bowel is required by barium enema or colonoscopy. **Dilation of the cecum to more than 10 to 12 cm in diameter as viewed by abdominal radiograph requires immediate evaluation and surgical decompression by performing colectomy or colostomy.** Surgery should be performed as soon as the obstruction is documented. Conservative management of colonic obstruction is not appropriate because the complication of colonic perforation has an exceedingly high mortality rate.

Diarrhea

Episodes of diarrhea often occur following abdominal and pelvic surgery as the gastrointestinal tract returns to its normal function and motility. However, prolonged and multiple episodes may represent a pathologic process such as impending small bowel obstruction, colonic obstruction, or pseudomembranous colitis. Excessive amounts of diarrhea should be evaluated by abdominal radiographs and stool samples tested for the presence of ova and parasites, bacterial culture, and *Clostridium difficile* toxin. Proctoscopy and colonoscopy may also be advisable in severe cases. Evidence of intestinal obstruction should be managed as outlined previously. Infectious causes of diarrhea should be managed with the appropriate antibiotics as well as fluid and electrolyte replacement. *C. difficile*-associated pseudomembranous colitis may result from exposure to any antibiotic. Discontinuation of these antibiotics (unless they are needed for another severe infection) is advisable, along with the institution of appropriate therapy. Oral *metronidazole* is a suitable agent for instituting therapy and is less expensive than vancomycin. Therapy should be continued until the diarrhea abates, and several weeks of oral therapy may be required in order to obtain complete resolution of the pseudomembranous colitis.

Fistula

Gastrointestinal fistulas are relatively rare following gynecologic surgery. They are most often associated with malignancy, prior radiation therapy, or surgical injury to the large or small bowel that was improperly repaired or unrecognized. Signs and symptoms of gastrointestinal fistula are often similar to those of small bowel obstruction or ileus, except that a fever is usually a more prominent component of the patient's symptoms. When fever is associated with gastrointestinal dysfunction postoperatively, evaluation should include early assessment of the gastrointestinal tract to confirm its continuity. **When fistula is suspected, the use of water-soluble gastrointestinal contrast material is advised to avoid the complication of barium peritonitis.** Evaluation with abdominal pelvic CT scan may also assist in identification of a fistula and associated abscess. **Recognition of an intraperitoneal gastrointestinal leak or fistula formation usually requires immediate surgery, unless the fistula has drained spontaneously through the abdominal wall or vaginal cuff.**

An enterocutaneous fistula arising from the small bowel and draining spontaneously through the abdominal incision may be managed successfully with medical therapy. Therapy should include nasogastric decompression, replacement of intravenous fluids as well as TPN, and appropriate antibiotics to treat an associated mixed bacterial infection. If the infection is under control and there are no other signs of peritonitis, the surgeon may consider allowing potential resolution of the fistula over a period of up to 2 weeks. Some authors have suggested the use of somatostatin to decrease intestinal tract secretion and allow earlier healing of the fistula. In some cases, the fistula will close spontaneously with this mode of management. If the enterocutaneous fistula does not close with conservative medical management, surgical correction with resection, bypass, or reanastomosis will be necessary.

A *rectovaginal fistula* that occurs following gynecologic surgery is usually the result of surgical trauma that may have been aggravated by the presence of extensive adhesions in the rectovaginal septum associated with endometriosis, pelvic inflammatory disease, or pelvic malignancy. **A small rectovaginal fistula may be managed with a conservative medical approach, in the hope that decreasing the fecal stream will allow closure of the fistula.** A small fistula that allows continence except for an occasional leak of flatus may be managed conservatively until the inflammatory process in the pelvis resolves. At that point, usually several months later, correction of the fistula is appropriate. Large rectovaginal fistulas for which there is no hope of spontaneous closure are best managed by performing an initial diverting colostomy followed by repair of the fistula after inflammation has resolved. After the fistula closure is healed and deemed successful, the colostomy can be closed.

Thromboembolism Prophylaxis

Risk Factors

Deep venous thrombosis and pulmonary embolism, although largely preventable, are significant complications in postoperative patients. The magnitude of this problem is relevant to the gynecologist, because 40% of all deaths following gynecologic surgery are directly attributed to pulmonary emboli (98). Pulmonary embolism is also the second leading cause of death in women who undergo a legally induced abortion (99) and the most frequent cause of postoperative death in patients with uterine (100) or cervical carcinoma (101).

The causal factors of venous thrombosis were first proposed by Virchow in 1858 and include the following: a hypercoagulable state, venous stasis, and vessel intima injury. Two prospective studies have evaluated risk factors associated with the postoperative occurrence of deep venous thrombosis in patients undergoing gynecologic surgery. In one study, the risk factors of 124 patients undergoing vaginal and abdominal surgery for benign gynecologic disease were studied (102). Five factors were identified to be associated with postoperative deep venous thrombosis: (a) increasing age, (b) presence of varicose veins, (c) being overweight, (d) prolonged euglobulin lysis time, and (e) presence of serum fibrin-related antigen. In another prospective study, the risk factors associated with venous thromboembolic complications were also assessed in 411 patients undergoing major abdominal and pelvic surgery (103). Preoperative risk factors identified in this study include advanced age; nonwhite race; increasing stage of malignancy; history of deep venous thrombosis, lower extremity edema, or venous stasis changes; presence of varicose veins; being overweight; and a history of radiation therapy. Intraoperative factors associated with postoperative deep venous thrombosis included increased anesthesia time, increased blood loss, and the need for transfusion in the operating room. It is important to recognize these risk factors in order to provide the appropriate level of venous thrombosis prophylaxis.

Prophylactic Methods

During the past 2 decades, a number of prophylactic methods have undergone clinical trials that showed significant reduction in the incidence of deep venous thrombosis, and a few studies have demonstrated a reduction in fatal pulmonary emboli (100,101,102,103,104,105,106,107,108,109,110,111,112,113,114,115,116,117,118,119,120,121,122,123,124,125,126,127,128,129,130,131,132 and 133). The ideal prophylactic method would be effective, free of significant side effects, well accepted by the patient and nursing staff, widely applicable to most patient groups, and inexpensive.

Low-dose Heparin

The use of small doses of subcutaneously administered *heparin* for the prevention of deep venous thrombosis and pulmonary embolism is the most widely studied of all prophylactic methods. More than 25 controlled trials have demonstrated that *heparin*, given subcutaneously 2 hours preoperatively and every 8 to 12 hours postoperatively, is effective in reducing the incidence of deep venous thrombosis. The value of low-dose *heparin* in preventing fatal pulmonary emboli was established by a randomized, controlled, multicenter international trial that showed a significant reduction in fatal postoperative pulmonary emboli in general surgery patients receiving low-dose *heparin* every 8 hours postoperatively (104). Trials of low-dose *heparin* use in gynecologic surgery patients are limited, and a clear consensus regarding the value of low-dose *heparin* in all groups of patients has not been established because of differences in patient selection and length of follow-up. Three randomized controlled studies used the same regimen of low-dose *heparin* administration: 5,000 units subcutaneously 2 hours preoperatively and every 12 hours for 7 days postoperatively. Two trials were conducted in patients with benign gynecologic conditions (98%); all patients were older than 40 years of age, and follow-up was discontinued at the time of discharge from hospital (105,106). One trial showed a 23% incidence of deep venous thrombosis in the control group, compared with a 6% incidence of deep venous thrombosis in the patients treated with low-dose *heparin* (106). This difference was statistically significant ($P = 0.05$). Although this was a randomized trial, the control group contained a larger number of patients with malignancy and, when the cancer patients were excluded from the trial analysis, there was no significant value to the use of low-dose *heparin* in patients with benign conditions. In the other study, the nontreated control group had a 29% incidence of deep venous thrombosis compared with a 3.6% incidence in the group treated with low-dose *heparin* ($P = 0.001$) (105). A third trial evaluated a larger group of patients receiving treatment in gynecologic oncology unit, only 16% of whom had benign gynecologic conditions; follow-up included the first 6 weeks postoperatively (107). In this trial, there was no difference in the incidence of thromboembolic complications between the control group (12.4%) and the group treated with low-dose *heparin* (14.8%) (107).

In a subsequent trial (108), two more intense *heparin* regimens were evaluated in high-risk gynecologic oncology patients. *Heparin* was given either in a regimen of 5,000 units subcutaneously 2 hours preoperatively and every 8 hours postoperatively, or 5,000 units subcutaneously every 8 hours preoperatively (a minimum of three preoperative doses) and every 8 hours postoperatively. Both of these prophylaxis regimens were effective in significantly reducing the incidence of postoperative deep venous thrombosis in patients with gynecologic cancers.

Although low-dose *heparin* is considered to have no measurable effect on coagulation, most large series have noted an increase in the bleeding complication rate, especially a higher incidence of wound hematoma. Up to 10% to 15% of otherwise healthy patients develop a transiently prolonged activated partial thromboplastin time (APTT) after 5,000 units of *heparin* is given subcutaneously (109). Retrospective studies have suggested that low-dose *heparin* contributed to an increased occurrence of lymphocysts (110,111). A prospective study demonstrated an increase in retroperitoneal lymph drainage volume in patients treated with low-dose *heparin*, but there was no increase in the incidence of lymphocysts (109). Although relatively rare, thrombocytopenia is associated with low-dose *heparin* use and has been found in 6% of patients after gynecologic surgery (109). If patients remain on low-dose *heparin* therapy for greater than 4 days, it is reasonable to perform a platelet count to assess the possibility of heparin-induced thrombocytopenia.

Low-molecular-weight Heparin

Low-molecular-weight heparin (LMWH) consists of fragments of unfractionated *heparin* that vary in size from 4,500 to 6,500 daltons. When compared with unfractionated *heparin*, *LMWH* has more anti-Xa and less antithrombin activity, leading to less effect on partial thromboplastin time. Decreased platelet inhibition and microvascular bleeding has been noted with *LMWH* use, which may also lead to fewer bleeding complications (112). An increased half-life of 4 hours (in both intravenous and subcutaneous administrations) leads to increased bioavailability when compared with unfractionated *heparin*. The increase in half-life of *LMWH*

allows the convenience of once-a-day dosing. Several commercially available *LMWH* preparations are internationally available but only two (i.e., *enoxaparin* and *dalteparin*) have been approved by the Food and Drug Administration for deep venous thrombosis prophylaxis in the United States.

Four randomized controlled trials have compared *LMWH* with unfractionated *heparin* in patients undergoing gynecologic surgery. All studies showed a similar incidence of deep venous thrombosis. Bleeding complications ([113,114](#) and [115](#)) were also similar between the unfractionated *heparin* and *LMWH* groups. In a trial evaluating *LMWH* (*dalteparin*) in a gynecologic cancer population, the *LMWH* was associated with fewer bleeding complications than would have been expected. The rate of thromboembolism was approximately 2% in this collective group of 521 operative patients, with deep venous thrombosis diagnosed in 7 patients receiving unfractionated *heparin* and 3 patients receiving *LMWH* prophylaxis. A recent metaanalysis of patients undergoing general surgery and gynecologic surgery from 32 trials likewise indicated that daily *LMWH* administration is as effective as unfractionated *heparin* in deep venous thrombosis prophylaxis without any difference in hemorrhagic complications ([116](#)). Caution should be maintained in interpretation of assimilated data involving *LMWH*, because different anti-Xa activities are associated with the different preparations ([117](#)). In a comparison of prophylactic methods of deep venous thrombosis treatment, *LMWH* has been suggested by some investigators to be more cost effective than unfractionated *heparin* because of the convenience of once-daily dosing ([118,119](#)).

Mechanical Methods

Stasis in the veins of the legs while the patient is undergoing surgery has been clearly demonstrated and continues postoperatively for varying lengths of time. Stasis occurring in the capacitance veins of the calf during surgery, in addition to the hypercoagulable state induced by surgery, are the prime factors contributing to the development of acute postoperative deep venous thrombosis. Prospective studies of the natural history of postoperative venous thrombosis have shown that the calf veins are the predominant site of thrombi and that most thrombi develop within 24 hours of surgery ([120](#)). Reduction of venous stasis in the perioperative period by various mechanical methods has been less extensively investigated than pharmacologic methods such as low-dose *heparin*. However, mechanical prophylactic methods may play an important role in the prevention of postoperative deep vein thrombosis.

Although probably of only modest benefit, reduction of stasis by short preoperative hospital stays and early postoperative ambulation should be encouraged for all patients. Elevation of the foot of the bed, raising the calf above heart level, allows gravity to drain the calf veins and should further reduce stasis. More active forms of mechanical prophylaxis include elastic gradient compression stockings and external pneumatic leg compression.

Elastic Stockings In a survey of general surgeons in the United States, gradient elastic stockings were second only to low-dose *heparin* as the prophylactic method of choice in high-risk and moderately high-risk surgical patients ([121](#)). The simplicity of elastic stockings and the absence of significant side effects are probably the two most important reasons that they are often included in routine postoperative care. Controlled studies of graduated pressure stockings are limited but do suggest modest benefit when they are carefully fitted ([122](#)). Poorly fitted stockings may be hazardous to some patients who develop a tourniquet effect at the knee or mid thigh ([99](#)). Variations in human anatomy do not allow perfect fit of all patients to available stocking sizes.

External Pneumatic Compression The largest body of literature dealing with the reduction of postoperative venous stasis deals with intermittent external compression of the leg by pneumatically inflated sleeves placed around the calf or leg during intraoperative and postoperative periods. Various pneumatic compression devices and leg sleeve designs are available, and currently one method has not been shown to be superior to others. Single-chambered calf compression devices have been studied most extensively in gynecologic surgery and appear to significantly reduce the incidence of deep venous thrombosis on a level similar to that of low-dose *heparin*. In addition to increasing venous flow and pulsatile emptying of the calf veins, external pneumatic compression also appears to augment endogenous fibrinolysis, which may result in lysis of very early thrombi before they become clinically significant ([123](#)).

The duration of postoperative external pneumatic compression has differed in various trials. External pneumatic compression may be effective only when used in the operating room or for the first 24 hours postoperatively ([124,125](#)), although they should remain in use in patients who are not ambulatory.

Used in patients undergoing major surgery for gynecologic malignancy, external pneumatic compression has been found to reduce nearly threefold the incidence of postoperative venous thromboembolic complications ([126](#)). To determine the effectiveness of this approach, calf compression was applied intraoperatively and continued for the first 5 postoperative days. In a subsequent trial of similar patients that was designed to evaluate whether external pneumatic compression might achieve similar benefits when used only intraoperatively and for the first 24 hours postoperatively, there was no reduction of deep venous thrombosis when compared with the control group ([127](#)). Because of stasis and their hypercoagulable states, patients with gynecologic malignancies may remain at risk for a longer period than general surgical patients and therefore appear to benefit from longer use of external pneumatic compression.

External pneumatic leg compression has no significant side effects or risks. Although patient intolerance has been cited as a drawback to its use, anecdotal experience does not support this perception. However, we have had only 5 patients of nearly 900 treated with external pneumatic compression request removal because of discomfort. The equipment is easily managed by the nursing staff, and although the initial capital outlay for external pneumatic compressors may seem large, the cost per patient is slightly less than that of low-dose *heparin* given for 7 days postoperatively ([128](#)).

The risk factors associated with the failure of external compression to prevent deep venous thrombosis has been investigated in a retrospective analysis of 1,862 consecutive gynecologic surgery patients who received postoperative intermittent pneumatic compression at Duke University between 1992 and 1997. A history of prior deep venous thrombosis, diagnosis of cancer, and age greater than 60 years were factors independently associated with the development of deep venous thrombosis despite external pneumatic compression prophylaxis ($P < 0.05$). Patients having two or more of these factors had a 16-fold increased risk of postoperative deep vein thrombosis despite prophylaxis ($P < 0.05$) ([129](#)). In these extremely high-risk patients, combined methods of prophylaxis ought to be considered.

Combination Prophylaxis

Combination therapy using *heparin* and compression stockings has been utilized in other high-risk surgical patients in an attempt to diminish both the hypercoagulability and venous stasis that can be found in postoperative patients at high risk for thromboembolism. The prophylactic use of low-dose *heparin* has been compared with low-dose *heparin* combined with graduated compression stockings in deep vein thrombosis prophylaxis among general surgery patients. Willie-Jorgensen and associates ([130](#)), in an investigation involving 245 patients undergoing acute extensive abdominal operations, demonstrated that the rate of postoperative deep vein thrombosis was significantly lower among 79 patients receiving a combination regimen of graduated compression stockings and low-dose *heparin* (i.e., 5,000 units subcutaneously 1 hour preoperatively and 12 hours postoperatively) than patients receiving only the low-dose *heparin* regimen ($P = 0.013$). A statistically significant improvement ($P < 0.05$) in postoperative deep vein thrombosis was similarly noted by the same investigators in the evaluation of 176 patients undergoing elective abdominal surgery ([131](#)). A metaanalysis of six studies involving 898 general surgery patients has shown that combination therapy with low-dose *heparin* and graduated compression stockings provides significantly better deep vein thrombosis prophylaxis postoperatively than either single modality (odds ratio 0.40; 95% CI 0.27 to 0.59) ([132](#)). Recently, a multicenter prospective randomized clinical trial demonstrated that combination prophylaxis consisting of graduated compression stockings and *LMWH* was more effective in deep vein thrombosis prevention than graduated compression stockings alone (relative risk 0.52; 95% CI 0.17 to 0.95, $P = 0.04$) ([133](#)). Such combination prophylaxis might be considered in the highest risk gynecologic oncology patients, although the efficacy, risks, and costs have not been studied.

Management of Postoperative Deep Venous Thrombosis and Pulmonary Embolism

Because pulmonary embolism is the leading cause of deaths following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic venous thromboembolism regimens is an essential part of management ([98,100,101](#)). In addition, the early recognition of deep vein thrombosis and pulmonary embolism and immediate treatment are critical. Although pulmonary emboli arise from the deep venous system of the leg, following gynecologic surgery the pelvic veins are a known source of fatal pulmonary emboli as well.

The signs and symptoms of deep vein thrombosis of the lower extremities include pain, edema, erythema, and prominent vascular pattern of the superficial veins. These signs and symptoms are relatively nonspecific; 50% to 80% of patients with these symptoms will not actually have deep vein thrombosis ([134](#)). Conversely, approximately 80% of patients with symptomatic pulmonary emboli have no signs or symptoms of thrombosis in the lower extremities ([135](#)). Because of the lack of specificity when signs and symptoms are recognized, additional diagnostic tests should be performed to establish the diagnosis of deep vein thrombosis.

Venography Although venography has been the gold standard for diagnosis of deep vein thrombosis, other diagnostic studies are accurate when performed by a skilled technologist and, in most patients, may replace the need for routine contrast venography. Venography is moderately uncomfortable, requires the injection of a contrast material that may cause allergic reaction or renal injury, and may result in phlebitis in approximately 5% of patients ([136](#)). Fortunately, newer diagnostic tests

have been developed that are less invasive yet have a high accuracy rate in most patients.

Doppler Ultrasound B-mode duplex Doppler imaging is currently the most common technique used in the diagnosis of symptomatic venous thrombosis, especially when it arises in the proximal lower extremity. With duplex Doppler imaging, the femoral vein can be visualized and clots may be seen directly (137). Compression of the vein with the ultrasonographic probe tip allows assessment of venous collapsibility; the presence of a thrombus diminishes vein wall collapsibility. Doppler imaging is less accurate when evaluating the calf venous system and the pelvic veins.

Impedance Plethysmography Impedance plethysmography is a noninvasive study that measures the change in electrical impedance of the lower extremities when venous blood flow and volume are altered by an occlusive cuff on the thigh. This study may be performed at the patient's bedside and repeated as often as necessary without any risk to the patient. Correlation with venography in symptomatic patients approaches 95% (138,139). The test is effective in the identification of deep venous thrombi in the popliteal, femoral, and external iliac segments. It is less accurate (30%) in identifying calf vein thrombosis and does not identify thrombi occurring in the internal iliac venous system. False-positive results are primarily due to extrinsic venous compression. In gynecology, this might include a large pelvic mass compressing the external iliac or common iliac vein.

Magnetic Resonance Imaging MRI has a sensitivity and specificity comparable to venography. In addition, MRI may detect thrombi in pelvic veins which are not imaged by venography (140). The primary drawback to MRI is the time involved in examining the lower extremity and pelvis as well as the expense of this technology.

Deep Venous Thrombosis

The treatment of postoperative deep venous thrombosis requires the immediate institution of anticoagulant therapy. Treatment may be with either unfractionated *heparin* or LMWHs, followed by 3 to 6 months of oral anticoagulant therapy with *warfarin*.

Unfractionated Heparin After venous thromboembolism is diagnosed, unfractionated *heparin* should be initiated to prevent proximal propagation of the thrombus and allow physiologic thrombolytic pathways to dissolve the clot. After an initial bolus of 5,000 units intravenously, a continuous infusion of 30,000 units per day should be implemented and dosage adjusted to maintain APTT levels at a therapeutic range of 1.5 to 2.5 times the control value. Patients having subtherapeutic APTT levels in the first 24 hours have a risk of recurrent thromboembolism 15 times the risk of patients with appropriate levels. Administration of subcutaneous *heparin* also results in a higher likelihood of subtherapeutic prophylaxis when compared with continuous intravenous infusion. Thus management should entail aggressive use of intravenous *heparin* to achieve prompt anticoagulation. Oral anticoagulant (*warfarin*) should be started on the first day of *heparin* infusion. International normalized ration (INR) should be monitored daily until a therapeutic level is achieved. The change in the INR resulting from *warfarin* administration often precedes the anticoagulant effect by approximately 2 days, during which time low protein C levels are associated with a transient hypercoagulable state. Therefore, *heparin* should be administered until the INR has been maintained in a therapeutic range for at least 2 days, confirming the proper *warfarin* dose. Intravenous *heparin* may be discontinued in 5 days if an adequate INR level has been established. Patients experiencing a thromboembolic event for the first time should take *warfarin* for approximately 3 to 6 months to prevent recurrent thromboembolism. Longer periods of anticoagulation should be considered in patients experiencing a recurrence. Indefinite anticoagulation has not been shown to decrease the risk of deep venous thrombosis recurrence, and the risks of bleeding are increased in patients who maintain prolonged therapy.

Low-molecular-weight Heparin LMWH has been shown to be effective in the treatment of venous thromboembolism and has a cost-effective advantage over intravenous *heparin* in that it may be administered in the outpatient setting. The dosages used in treatment of thromboembolism are unique and weight adjusted according to each LMWH preparation. Because LMWH has a minimal effect on APTT, serial laboratory monitoring of APTT levels is not necessary. Similarly, monitoring of anti-Xa activity has not been shown to be of benefit in a dose adjustment of LMWH. The increased bioavailability associated with LMWH allows for once- or twice-daily dosing, potentially making outpatient management for a subset of patients an option. A metaanalysis involving more than 1,000 patients from 19 trials suggests that LMWH is more effective in preventing recurrent thromboembolism, safer, and less costly when compared with unfractionated *heparin*.

Pulmonary Embolism

Many of the signs and symptoms of pulmonary embolism are associated with other, more commonly occurring pulmonary complications following surgery. The classic findings of pleuritic chest pain, hemoptysis, shortness of breath, tachycardia, and tachypnea should alert the physician to the possibility of a pulmonary embolism. Many times, however, the signs are much more subtle and may be suggested only by a persistent tachycardia or a slight elevation in the respiratory rate. Patients suspected of pulmonary embolism should be evaluated initially by chest radiography, electrocardiography, and arterial blood gas assessment. Any evidence of abnormality should be further evaluated by ventilation-perfusion lung scan, searching for evidence of decreased perfusions in areas of adequate ventilation. Unfortunately, a high percentage of lung scans may be interpreted as indeterminate. In this setting, careful clinical evaluation and judgment are required to decide whether pulmonary arteriography should be obtained to document or exclude the presence of a pulmonary embolism.

The treatment of pulmonary embolism is as follows:

1. Immediate anticoagulant therapy, identical to that outlined for the treatment of deep vein thrombosis, should be initiated.
2. Respiratory support, including oxygen and bronchodilators and an intensive care setting, may be necessary.
3. Although massive pulmonary emboli are usually quickly fatal, pulmonary embolectomy has been performed successfully on rare occasions.
4. Pulmonary artery catheterization with the administration of thrombolytic agents bears further evaluation and may be important in patients with massive pulmonary embolism.
5. A vena cava interruption may be necessary in situations in which anticoagulant therapy is ineffective in the prevention of rethrombosis and repeated embolization from the lower extremities or pelvis. A vena cava umbrella or filter may be situated percutaneously or a large clip can be used to obstruct the vena cava above the level of the thrombosis. In most cases, however, anticoagulant therapy is sufficient to prevent repeat thrombosis and embolism and to allow the patient's own endogenous thrombolytic mechanisms to lyse the pulmonary embolus.

Management of Medical Problems

Endocrine Disease

The three most frequent endocrine disorders that occur in patients undergoing gynecologic surgery are diabetes mellitus, thyroid disease, and adrenal abnormalities. The pathophysiology of these disorders aids in understanding the effects of surgery on patients with these problems.

Diabetes Mellitus

It is estimated that approximately six million people in the United States (2.5% of the population) have diabetes mellitus (DM) and that about one-half of these individuals will undergo surgery at some point in their lives. Approximately 75% of individuals with DM will have surgery after they are 50 years of age. Many of these procedures are a direct result of the complications of DM: retinopathy, nephropathy, large- and small-vessel occlusive disease, and coronary artery disease. It is the direct effect of DM on the end organs that determines the risk of surgery rather than the type or duration or the control of the condition itself.

Diabetes mellitus is a complicated medical disorder of glucose metabolism that is related to a lack of production of or resistance to *insulin*. Patients with DM experience exaggerated hyperglycemia during surgery. This hyperglycemia is multifactorial in origin and is secondary to increased catecholamine production, which inhibits pancreatic release of insulin and causes increased *insulin* resistance at the end organs. Elevations in instrumental hormones such as cortisol, growth hormone, and glucagon also enhance gluconeogenesis and glycogenolysis. Goals of the preoperative assessment and perioperative management are to ensure metabolic homeostasis and to anticipate problems arising from preexisting complications.

Preoperative Risk Assessment

Large- and small-vessel arterial occlusive disease is the single most important risk factor in the preoperative setting. A careful history and physical examination should be performed to determine the presence or absence of coronary artery or cerebral vascular disease. Assessment of end-organ disease in the retina, kidney, and carotid arteries, or evidence of peripheral vascular disease by the presence of foot ulcers, should alert the clinician to the possibility of small- or large-vessel

disease. When extended surgery is possible, as with surgery for gynecologic cancer, exercise stress testing or *dipyridamole-thallium imaging* should be considered to rule out occult coronary artery disease. Diabetic nephropathy should be documented carefully preoperatively. Imaging studies using contrast dye should be avoided, and alternative testing should be performed to reduce the incidence of acute tubular necrosis. If a contrast study must be performed, adequate hydration both before and after the procedure is essential.

Preoperative evaluation should include examination of the skin and urine sediment to detect asymptomatic infection. There is a known predisposition for patients with DM to have gram-negative and staphylococcal pneumonia as well as an increased incidence of gram-negative and group B streptococcal sepsis ([141](#)). Seven percent of individuals with diabetes will have postoperative gram-negative sepsis, a rate approximately 7 times higher than in the nondiabetic population. These complications occur more often in patients with poor glucose control, probably due to impaired leukocyte function in the presence of hyperglycemia ([142,143](#)). Patients with DM have an increased risk of wound dehiscence and wound infection as well as decreased amounts of collagen formation, fibroblast growth, and capillary growth, presumably secondary to the pathophysiology of small-vessel disease ([144,145](#) and [146](#)).

Autonomic neuropathy has been documented in patients with DM, and these autonomic impairments can lead to intraoperative hypotension, cardiac arrhythmias, and sudden death as well as abnormal motility of the esophagus, stomach, and small intestine ([147](#)). Peripheral sensory and motor neuropathies may or may not be present. The presence of any manifestations of autonomic neuropathy intraoperatively should prompt close monitoring of the affected organ system during the postoperative period ([148](#)).

Perioperative Management

The general goal for glucose control during surgery is to maintain the glucose level between 150 and 200 mg/dl. Perioperative hyperglycemia (>250 mg/dl) is associated with increased susceptibility to infection and poor wound healing. Extreme hyperglycemia predisposes patients to metabolic acidosis, and surgery should be canceled until normal acid-base balance has been documented. Hyperosmolar hyperglycemic nonketotic states must be recognized before surgery. Electrolyte disturbances, especially those related to sodium and potassium, should be corrected preoperatively. Hypoglycemia should be avoided at all costs during the perioperative period.

The history and type of DM are important factors to consider when devising a perioperative management plan. Patients with non-*insulin*-dependent diabetes (type II) whose condition is controlled with oral hypoglycemic agents or diet are best treated with intravenous fluids containing no dextrose and generally should not be given insulin intraoperatively. Oral administration of hypoglycemic agents should be discontinued approximately 24 hours prior to the surgery. Hyperglycemic episodes in the perioperative period are treated with regular *insulin* only for blood sugar levels in excess of 250 mg/dl.

Insulin-dependent or type I diabetes poses a more difficult problem. Preoperatively, the goals include avoiding ketoacidosis and hypoglycemia as well as, but to a lesser extent, hyperglycemia. Traditionally, approximately one-third to one-half of the patient's usual daily dose of *NPH insulin* (intermediate acting) is given subcutaneously the morning of surgery. An infusion of 5% dextrose is then given intraoperatively, and additional regular *insulin* can be administered in the operating room and every 6 hours afterward if necessary ([141](#)). Alternatively, the continuous infusion of *insulin* and glucose in a fixed ratio has been advocated ([149,150](#)). The patient is much more prone to significant hypoglycemia, however, when a continuous infusion of *insulin* is given. Because of the severe implications associated with intraoperative hypoglycemia, this method may pose risks and has not been shown to improve the surgical outcome or lessen morbidity. There is no single regimen that is clearly superior for the intraoperative management of type I diabetics. However, a continuous intravenous *insulin* infusion is indicated for patients with unstable type I diabetes, those who require emergency surgery while in ketoacidosis, and those undergoing long, complex procedures ([142](#)).

Postoperative monitoring of patients with DM includes careful monitoring of serum glucose levels approximately every 6 hours until the patient is eating and her condition is stable on preoperative regimens. The serum glucose level should be maintained at less than 250 mg/dl, and regular *insulin* should be given on a sliding scale in carefully defined increments of the glucose level. It is essential to prevent the development of severe hypoglycemia or hyperglycemia and the associated complications of diabetic ketoacidosis or a hyperosmolar state. Compulsive perioperative management may obviate some of the infectious and wound healing complications that are more common in these patients ([144](#)).

Hyperthyroidism

Thyroid dysfunction should be suspected in any patient who has a history of hyperthyroidism, uses thyroid replacement medication or antithyroid medication, has had prior thyroid surgery, or is undergoing radioactive iodine therapy. Diffuse toxic goiter (Graves' disease), is the most common cause of hyperthyroidism. Any physical findings suggestive of weight loss, tachycardia, proptosis, or myxedema should initiate a more extensive laboratory evaluation of thyroid function. Total thyroxin, free T₃, free thyroxin (T₄), and thyroid-stimulating hormone (TSH) tests are useful in diagnosis.

Because of the risk of thyroid storm, a new diagnosis of hyperthyroidism necessitates postponement of elective surgery until adequate treatment with antithyroid medication can be initiated. Ideally, a euthyroid state should be maintained for 3 months prior to elective surgery. In emergent situations, b-blockers can be used to counter sympathomimetic drive such as palpitations, diaphoresis, and anxiety. Antithyroid medications such as *propylthiouracil* (PTU) or radioactive iodine do not render patients euthyroid quickly enough for urgent surgery. At best, PTU (100 to 200 mg every 6 hours) and a b-blocker can be implemented for 2 weeks prior to surgery; with careful monitoring, optimal results can be achieved ([151](#)).

When thyroid dysfunction is corrected and maintained for several months, surgery can proceed without additional perioperative monitoring. Antithyroid medications should be resumed with return of bowel function. In the emergent setting however, close monitoring of the patient for tachycardia, arrhythmias, and hypertension is necessary. b-Blockade can control these symptoms until definitive therapy can be initiated after recovery from surgery. Any signs suggestive of the development of thyroid storm, including hemodynamic instability, tachycardia, arrhythmias, hyperreflexia, diarrhea, or congestive heart failure, mandate transfer to an intensive care setting for optimal monitoring and management in consultation with a medical endocrinologist. Such thyroid instability can be triggered by underlying infection, which requires prompt diagnosis and treatment to facilitate management of this medical emergency.

Hypothyroidism

The prevalence of subclinical hypothyroidism is approximately 1% in the adult population ([152](#)). Many such cases are secondary to previous antithyroid therapy (radioactive iodine or thyroidectomy) for hyperthyroidism. A history of lethargy, cold intolerance, lassitude, weight gain, fluid retention, constipation, dry skin, hoarseness, periorbital edema, and brittle hair can be indicative of inadequate thyroid function. In this setting, physical findings of increased relaxation phase of deep tendon reflexes, cardiomegaly, pleural or pericardial effusions, or peripheral edema should stimulate further investigation of thyroid function by assessment of TSH levels. Temporal elevation of TSH can occur in the postoperative setting.

When elective surgery is planned for patients with hypothyroidism, it should be postponed until thyroid replacement therapy has been initiated ([153](#)). *Thyroxin* dosage (0.025 mg/day) should be doubled every 2 weeks until the patient is taking a dose of 0.15 mg daily. Dosage levels can ultimately be titrated against TSH levels. In the urgent surgical setting, thyroid replacement should be initiated postoperatively with return of bowel function. Close postoperative monitoring is essential. In severely myxedematous patients in whom surgery cannot be avoided, *thyroxin* (0.3 to 0.5 mg) given intravenously will saturate the carrier protein-binding sites. Standard replacement therapy can then be given until the thyroid function tests and TSH levels determine the optimal dose. In these patients, additional measures are usually necessary because of the severe hypothyroid state. With major abdominal surgery, free water restriction, ventilatory support, diuretics, and nasogastric suction are usually necessary until the patient's condition is stabilized after surgery. Additionally, *hydrocortisone* should be given intravenously (100 to 300 mg every 8 hours) to avoid the possibility of decreased adrenal reserve.

Adrenal Insufficiency

Adrenal insufficiency may result in catastrophic postoperative complications, including death. In patients undergoing surgery, insufficiency most often occurs secondary to the exogenous use of glucocorticoids. Therefore, the physician should ascertain whether a patient has used exogenous steroids for asthma, malignant conditions, arthritis, or irritable bowel syndrome. The type of steroid use, the route, the dose, the duration, and the temporal relationship to the timing of the surgical procedure must be determined. The classification of the surgical procedure and its associated stress should also be taken into consideration. High doses of exogenous steroids for prolonged periods can cause circulatory collapse, and they have adverse effects on wound healing and immunocompetence.

The daily replacement dose of cortisol is approximately 5 to 7.5 mg of *prednisone*. Suppression of the hypothalamic–pituitary–adrenal axis for more than a few weeks may produce relative adrenal insufficiency. When systemic steroids are used for longer periods, adrenal insufficiency may persist for up to 1 year (154). A number of biochemical tests have been recommended to preoperatively evaluate the function of the adrenal gland. The easiest and safest test to assess hypothalamic–pituitary–adrenal function is the *cosyntropin* stimulation test. *Cosyntropin*, a synthetic analog of adrenocorticotropic hormone, is given in a dose of 250 µg, intravenously, and a blood sample is collected 30 minutes after the injection and assayed for plasma cortisol. A plasma cortisol value of >500 nmol/L (18 to 20 µg/dl) indicates adequate adrenal function (155). If the history regarding exogenous steroid use is unclear, then the *cosyntropin* stimulation test should be performed preoperatively to determine if the patient will need perioperative glucocorticoid coverage.

Guidelines for perioperative steroid coverage have been recommended by Salem and co-workers based on clinical and research findings (155). The amount of glucocorticoid replacement should be equivalent to the normal physiologic response to surgical stress. In response to major surgical procedures, adults secrete 75 to 150 mg glucocorticoid a day. In contrast, during minor procedures only 50 mg of glucocorticoid is released (156). For minor surgical stress, the glucocorticoid target is approximately 25 mg of *hydrocortisone* equivalent. Therefore, the patient should receive 25 mg of *hydrocortisone* preoperatively and then resume the normal glucocorticoid dose the next day. For moderate surgical stress (i.e., as with abdominal hysterectomy) the glucocorticoid target is 50 to 75 mg of *hydrocortisone* equivalent per day for 1 to 2 days. The patient should receive her normal daily dose preoperatively, followed by 50 mg of *hydrocortisone* intravenously administered during surgery. Salem and co-workers recommended that patients should receive 60 mg *hydrocortisone* (20 mg every 8 hours) intravenously on postoperative day 1 and then return to their preoperative dose, given either enterally or parenterally on postoperative day 2. For major surgical stress, the glucocorticoid target range is 100 to 150 mg *hydrocortisone* equivalent per day for 2 to 3 days. The patient should receive her normal daily dose within 2 hours preoperatively, followed by 50 mg of *hydrocortisone* intravenously every 8 hours after the initial dose for the first 2 to 3 days after surgery (155).

Whether patients need even this amount of perioperative steroids is unknown. A randomized blinded trial evaluating perioperative steroid use in patients with secondary adrenal insufficiency was performed at the Veterans Affairs Medical Center. Patients who had been taking at least 7.5 mg of *prednisone* daily and had secondary adrenal insufficiency were randomized to two groups. The subjects underwent major surgical procedures; one group received perioperative saline injections and the other received cortisol. All patients received their usual daily steroid dose. Two patients had hypotension, one from each group, which was reversible with fluid replacement. When given their daily dose of steroids for surgical procedures, patients with secondary adrenal insufficiency do not experience serious hypotension secondary to insufficient glucocorticoid levels (157). Therefore, perioperative glucocorticoid coverage should be individualized, based on the patient's preoperative dosage requirements and the type of surgical procedure (155).

Administration of high-dose steroids should be stopped as soon as possible postoperatively because it can inhibit wound healing and promote infection. Hypertension and glucose intolerance also can develop. It is safe to abruptly discontinue steroid use after a few days of therapy. Addison's disease is uncommon but should be considered in the differential diagnosis if the patient develops perioperative hypotension. In addition to blood and isotonic fluid replacement, a "stress" dose of steroids should be given if adrenal insufficiency is suspected and sepsis and hypovolemia have been excluded.

When a prolonged or involved procedure is performed and longer steroid use is necessary, careful tapering will be required. The recommended approach is to halve the dose of *hydrocortisone* on a daily basis until a dose of 25 mg is reached. Eliminating one dose each day until the drug has been stopped is the safest method of withdrawal.

Cardiovascular Diseases

The incidence of perioperative cardiovascular complications has decreased markedly as a result of improvements in preoperative detection of high-risk patients, preoperative preparation, and surgical and anesthetic techniques (158).

Preoperative Evaluation

The goal of a preoperative cardiac evaluation is to determine the presence of heart disease, its severity, and the potential risk to the patient during the perioperative period. Every patient should be questioned about symptoms of cardiac disease including chest pain, dyspnea on exertion, peripheral edema, wheezing, syncope, claudication, or palpitations. Patients with a history of cardiac disease should be evaluated for worsening of symptoms, which indicates progressive or poorly controlled disease. Records of previous treatment should be obtained. Prescriptions for antihypertensive, anticoagulant, antiarrhythmic, antilipid, or antianginal medications may be the only indication of cardiac problems. In patients without known heart disease, the presence of DM, hyperlipidemia, hypertension, tobacco use, or a family history of heart disease identifies a group of patients at higher risk for heart disease who should be more carefully screened.

On physical examination, the presence of findings such as hypertension, jugular venous distention, laterally displaced point of maximum impulse, irregular pulse, third heart sound, pulmonary rales, heart murmurs, peripheral edema, or vascular bruits should prompt a more complete evaluation. Laboratory evaluation of patients with known or suspected heart disease should include a blood count and serum chemistry analysis. Patients with heart disease tolerate anemia poorly. Serum sodium and potassium levels are particularly important in patients taking diuretics and digitalis. Blood urea nitrogen and creatinine values provide information on renal function and hydration status. Assessment of blood glucose levels may detect undiagnosed DM. Chest radiograph and electrocardiography are mandatory as part of the preoperative evaluation, and the results may be particularly helpful when compared with those of previous studies.

Coronary Artery Disease

Coronary artery disease is a major risk factor for patients undergoing abdominal surgery. In an adult population without a prior history of myocardial infarction, the incidence of myocardial infarction following surgery is 0.1% to 0.7% (159). In patients who have had a prior myocardial infarction, however, the reinfarction rate is 2.8% to 7% (160). The risk of reinfarction is inversely proportional to the length of time between infarction and surgery. At 3 months or less, the risk of reinfarction is 5.7%, and from 3 to 6 months, the rate falls to 2.3%. Six months after myocardial infarction, the reinfarction rate is 1.5% (159). Fortunately, careful perioperative management can lower the reinfarction rate even in patients who have had recent infarctions. Perioperative myocardial infarction is associated with a mortality rate of 26% to 70% (160).

Because of the high mortality and morbidity associated with perioperative myocardial infarction, much effort has been made to predict perioperative cardiac risk. **A prospective evaluation of preoperative cardiac risk factors using a multivariate analysis identified independent cardiac risk factors for patients undergoing noncardiac surgery (161).** Using these factors, a cardiac risk index was created that placed a patient in one of four risk classes. High-risk clinical factors included age over 70 years, myocardial infarction within 6 months prior to surgery, congestive heart failure, and atrial and ventricular arrhythmias. More recent studies have added to and modified the commonly accepted list of risk factors, which are listed in [Table 19.8 \(160\)](#). Additional risk factors include unstable angina, DM, uncontrolled hypertension, history of stroke, and abnormal electrocardiogram.

Major
Unstable or severe angina
Recent myocardial infarction (>7 days but <30 days)
Decompensated congestive heart failure
Symptomatic arrhythmias
Intermediate
Mild angina
Prior myocardial infarction by history or ECG
Compensated or prior congestive heart failure
Diabetes mellitus
Minor
Advanced age
Abnormal ECG (LVT, LBBB, ST-T abnormalities)
Rhythm other than sinus
Low functional capacity
History of stroke
Uncontrolled systemic hypertension

ECG, electrocardiogram; LVT, left ventricular hypertrophy; BBB, bundle branch block.

Table 19.8. Risk Factors for Perioperative Cardiovascular Risk (160)

In addition to clinical predictors, cardiac risk is also determined by the risk level of the proposed operation and the functional capacity of the patient. High-risk procedures include emergent major operations, aortic and vascular procedures, and prolonged surgical procedures associated with large fluid shifts or blood loss. Intermediate-risk procedures include other intraperitoneal operations, whereas low-risk procedures include endoscopic surgery, breast surgery, and superficial procedures. The patient's functional status is assessed by a thorough history; risk classification is summarized in [Table 19.9](#). Patients with poor functional capacity have higher perioperative cardiac risk and should be considered for preoperative cardiac function testing ([160](#)).

Excellent
Carry 24 lb up eight steps Carry objects that weigh 80 lb Outdoor work (shovel snow, spade soil) Recreation (ski, basketball, squash, handball, jog or walk 5 mph)
Moderate
Have sexual intercourse without stopping Walk at 4 mph on ground level Outdoor work (garden, rake, weed) Recreation (roller skate, dance)
Poor
Shower and dress without stopping Basic housework Walk 2.5 mph on level ground Recreation (golf, bowl)

Table 19.9. Functional Capacity Assessment from Clinical History ([160](#))

In an effort to quantitate preoperative cardiac risk, several tests have been used to assess cardiovascular function. *Exercise stress testing* prior to surgery can identify patients who have ischemic heart disease not apparent at rest. These patients have been shown to be at increased risk of developing cardiac complications in the perioperative period. In a study of patients undergoing peripheral vascular surgery, a high-risk group of patients was identified who had ischemic electrocardiographic changes when they exercised to less than 75% of their maximal predicted heart rate. In this group, the incidence of perioperative myocardial infarction was 25% and the overall cardiac mortality rate was 18.5%. Conversely, no perioperative infarctions occurred in patients who were able to exercise to more than 75% of their maximal predicted heart rate and who had no electrocardiographic evidence of ischemia ([162](#)). However, the prognostic value of stress testing was not supported in another prospective study that found that only an abnormal preoperative resting electrocardiogram was an independent risk factor ([163](#)). The exercise stress test must be selectively applied to a high-risk population because its predictive value is dependent upon the prevalence of the disease. Therefore, it is not prudent to screen all patients preoperatively; it is preferable to rely on a careful history to identify patients with symptoms of cardiac disease for whom the test would be most predictive.

Exercise stress testing is limited in some patients who cannot exercise because of musculoskeletal disease, pulmonary disease, or severe cardiac disease. *Dipyridamole-thallium scanning* may be used to overcome the limitations of exercise stress testing. This study has a high degree of sensitivity and specificity, and it relies on the ability of dipyridamole to dilate normal coronary arteries but not stenotic vessels. Normally perfused myocardium readily takes up thallium when it is given intravenously. Conversely, hypoperfused myocardium does not demonstrate good uptake of thallium when scanned 5 minutes after injection. Reperfusion and uptake of thallium 3 hours after injection identify viable but high-risk myocardium. Old infarctions are identified as areas without uptake. Several studies have shown a risk of perioperative myocardial infarction in patients with areas of reperfusion of thallium uptake ranging from 20% to 33% ([164,165](#)). The dipyridamole-thallium scan is applicable for patients who are unable to exercise because it uses a medically induced "stress."

Dobutamine stress echocardiography is another test to evaluate cardiac risk in patients who are unable to exercise. This method identifies regional cardiac wall motion abnormalities after dobutamine infusion to identify patients at high risk for cardiac events. Positive and negative predictive values are similar to those of dipyridamole-thallium testing ([166,167](#)).

It is rare for patients who are younger than 50 years and who do not have diabetes, hypertension, hypercholesterolemia, or coronary artery disease to suffer a perioperative myocardial infarction. However, patients with coronary artery disease are at increased risk of myocardial infarction in the postoperative period. Prevention, early recognition, and treatment are important, because myocardial infarctions that occur in the postoperative period have mortality rates of approximately 50% and are more lethal than those that are not associated with surgery.

Nearly two-thirds of postoperative myocardial infarctions occur during the first 3 days postoperatively. Although the pathophysiologic factors are complex, the causes of postoperative myocardial ischemia and infarction are related to decreased myocardial oxygen supply coupled with increased myocardial oxygen requirements. In postoperative patients, conditions that decrease oxygen supply to the myocardium include tachycardia, increased preload, hypotension, anemia, and hypoxia ([168](#)). Conditions that increase myocardial oxygen consumption are tachycardia, increased preload, increased afterload, and increased contractility. Tachycardia and increased preload are the most important causes of ischemia, because both conditions decrease oxygen supply to the myocardium while simultaneously increasing myocardial oxygen demand. Tachycardia decreases the diastolic time which, when the coronary arteries are perfused, decreases the volume of oxygen available to the myocardium. Increased preload increases the pressure exerted by the myocardial wall on the arterioles within it, thus decreasing myocardial blood flow.

Other factors associated with perioperative myocardial ischemia include physiologic responses to the stress of intubation, intravenous or intraarterial line placement, emergence from anesthesia, pain, and anxiety. This stress results in catecholamine stimulation of the cardiovascular system, resulting in increased heart rate, blood pressure, and contractility, which may induce or worsen myocardial ischemia. Loss of intravascular volume because of third spacing of fluids or postoperative hemorrhage can also induce ischemia.

Postoperative myocardial infarction is often difficult to diagnose. Chest pain, which is present in 90% of nonsurgical patients with myocardial infarction, may be present in only 50% of patients with postoperative infarction, because of the masking of myocardial pain by coexisting surgical pain and the use of analgesia ([159](#)). Thus, it is important to maintain a high level of suspicion for postoperative infarction in patients with coronary artery disease. The presence of arrhythmia, congestive heart failure, hypotension, dyspnea, or elevations of pulmonary artery pressure may indicate infarction and should prompt a thorough cardiac investigation and electrocardiographic monitoring. **Measurement of creatinine phosphokinase myocardial band (CPK-MB) isoenzyme and troponin T levels are the most sensitive and specific indicators of myocardial infarction, and assessments should be obtained for all patients suspected of myocardial infarction.**

Despite the high incidence of silent myocardial infarction, routine use of postoperative electrocardiography (ECG) for all patients with cardiovascular disease is controversial. Many patients will exhibit P-wave changes that spontaneously resolve and do not represent ischemia or infarction. Conversely, patients with proven myocardial infarctions may show few, if any, ECG abnormalities. If routine screening of asymptomatic patients is desired, ECGs should be obtained 24 hours following surgery, because it has been shown that significant ECG changes that occur immediately postoperatively will persist for 24 hours. It is prudent to continue serial ECG assessments for at least 3 days postoperatively.

Postoperative management of patients with coronary artery disease is based on maximizing delivery of oxygen to the myocardium as well as decreasing myocardial oxygen utilization. Most patients benefit from supplemental oxygen in the postoperative period, although special care should be exercised in patients with chronic obstructive pulmonary disease. Oxygenation can be easily monitored by pulse oximetry. Anemia is detrimental because of loss of oxygen-carrying capacity as well as resultant tachycardia and should, therefore, be carefully corrected in high-risk patients.

Patients with coronary artery disease may benefit from pharmacologic control of hyperadrenergic states that result from increased postoperative catecholamine production. β -Blockers decrease heart rate, myocardial contractility, and systemic blood pressure, all of which are increased by adrenergic stimulation. Perioperative β -blockade with atenolol has been shown to significantly reduce perioperative ischemia, myocardial infarction, and overall mortality caused by cardiac death and congestive heart failure in the perioperative period ([169,170](#)). For patients receiving β -blockade therapy prior to surgery, that therapy should be continued in the perioperative period because abrupt withdrawal results in a rebound hyperadrenergic state.

Although prophylactic nitrates have been used in the perioperative period for many years, this practice remains controversial. *Nitroglycerin* enhances blood flow to ischemic areas, increases collateral flow, increases myocardial oxygenation, and reduces angina ([171,172,173](#) and [174](#)). The route of administration, dosage, and duration of therapy are controversial; thus, perioperative treatment with nitrates should be initiated in consultation with a cardiologist. Likewise, calcium-channel

blockers have not proved useful in the prophylaxis of perioperative myocardial ischemia (175).

Congestive Heart Failure

Patients with congestive heart failure (CHF) face a substantially increased risk of myocardial infarction during and after surgery (161). The postoperative development of pulmonary edema is a grave prognostic sign and results in death in a high percentage of patients (176). Because patients with heart failure at the time of surgery are significantly more likely to develop pulmonary edema perioperatively, every effort should be made to diagnose and treat CHF before surgery (177). The signs and symptoms of CHF are listed in [Table 19.10](#) and should be assessed based on preoperative history and physical examination. Patients who are able to perform usual daily activities without developing CHF are at limited risk of perioperative heart failure.

-
1. Presence of an S₃ gallop
 2. Jugular venous distention
 3. Lateral shift of the point of maximal impulse
 4. Lower extremity edema
 5. Basilar rales
 6. Increased voltage on electrocardiogram
 7. Evidence of pulmonary edema or cardiac enlargement on chest radiograph
 8. Tachycardia
-

Table 19.10. Signs and Symptoms of Congestive Heart Failure

To prevent severe postoperative complications, congestive heart failure must be corrected preoperatively. Treatment usually relies on aggressive diuretic therapy, although care must be taken to avoid dehydration, which may result in hypotension during the induction of anesthesia. Hypokalemia can result from diuretic therapy and is especially deleterious to patients who are also taking digitalis. In addition to diuretics and digitalis, treatment often includes the use of preload- and afterload-reducing agents. Optimal use of these drugs and correction of CHF may be aided by consultation with a cardiologist. In general, it is preferable to continue the usual regimen of cardioactive drugs throughout the perioperative period. In patients with severe or intractable CHF, the perioperative measurement of left ventricular filling (wedge) pressure with a pulmonary artery catheter (Swan-Ganz) may be extremely helpful to guide perioperative fluid management.

Postoperative CHF results most frequently from excessive administration of intravenous fluids and blood products. Other common postoperative causes are myocardial infarction, systemic infection, pulmonary embolism, and cardiac arrhythmias. The cause of postoperative heart failure must be diagnosed because, to be successful, treatment should be directed simultaneously to the underlying cause.

Postoperative diagnosis of CHF is often more difficult than preoperative diagnosis because the signs and symptoms of CHF are not specific and may result from other causes ([Table 19.10](#)). The most reliable method of detecting CHF is chest radiography, in which the presence of cardiomegaly or evidence of pulmonary edema is a helpful diagnostic feature.

Acute postoperative CHF frequently manifests as pulmonary edema. Treatment of pulmonary edema may include the use of intravenous furosemide, supplemental oxygen, including morphine sulfate, and elevation of the head of the bed. Intravenous aminophylline may be useful if cardiogenic asthma is present. Electrocardiography, in addition to laboratory evaluation, including arterial blood gas, serum electrolyte, and renal function chemistry measurements, should be obtained expeditiously. If the patient's condition does not improve rapidly, she should be transferred to an intensive care unit.

Arrhythmias

Nearly all arrhythmias found in otherwise healthy patients are asymptomatic and of limited consequence. In patients with underlying cardiac disease, however, even brief episodes of arrhythmias may result in significant cardiac morbidity and mortality.

Preoperative evaluation of arrhythmias by a cardiologist and anesthesiologist is important because many anesthetic agents as well as surgical stress contribute to the development or worsening of arrhythmias. In patients undergoing continuous electrocardiographic monitoring during surgery, a 60% incidence of arrhythmias, excluding sinus tachycardia, has been reported (178). Patients with heart disease have an increased risk of arrhythmias, most commonly ventricular arrhythmias (178). Conversely, patients without cardiac disease are more likely to develop supraventricular arrhythmias during surgery. Patients taking antiarrhythmic medications prior to surgery should continue taking those drugs during the perioperative period. Initiation of antiarrhythmic medications is rarely indicated preoperatively, but consultation with a cardiologist is recommended for patients in whom arrhythmias are detected prior to surgery.

Patients with first-degree atrioventricular (AV) block or asymptomatic Mobitz I (Wenckebach) second-degree AV block require no preoperative therapy. Conversely, a pacemaker is appropriate in patients with symptomatic Mobitz II second- or third-degree AV block before elective surgery (179). In emergency situations, a pacing pulmonary artery catheter can be used. Prior to performing surgery on patients with a permanent pacemaker, the type and location of the pacemaker should be determined because electrocautery units may interfere with demand-type pacemakers (180). When performing gynecologic surgery on patients with pacemakers, it is preferable to place the electrocautery unit ground plate on the leg to minimize interference. In patients with a demand pacemaker in place, the pacemaker should be converted preoperatively to the fixed-rate mode.

Surgery is not contraindicated in patients with bundle branch blocks or hemiblocks. Complete heart block rarely develops during noncardiac surgical procedures in patients with conduction system disease (181,182 and 183). However, the presence of a left bundle branch block may indicate the presence of aortic stenosis, which can increase surgical mortality if it is severe.

Valvular Heart Disease

Although there are many forms of valvular heart disease, primarily two types—aortic and mitral stenosis—are associated with significantly increased operative risk (184). Patients with significant aortic stenosis appear to be at greatest risk, which is further increased if atrial fibrillation, congestive heart failure, or coronary artery disease is also present. Significant stenosis of aortic or mitral valves should be repaired prior to elective gynecologic surgery (160).

Severe valvular heart disease is usually evident during physical exertion. Common findings in such patients are listed in [Table 19.11](#). The classic history presented by patients with severe aortic stenosis includes exercise dyspnea, angina, and syncope, whereas symptoms of mitral stenosis are paroxysmal and effort dyspnea, hemoptysis, and orthopnea. Most patients have a remote history of rheumatic fever. Severe stenosis of either valve is considered to be a valvular area of less than 1 cm², and diagnosis can be confirmed by echocardiography or cardiac catheterization.

Aortic stenosis
1. Systolic murmur at right sternal border, which radiates into carotids
2. Decreased systolic blood pressure
3. Apical heave
4. Chest radiograph with calcified aortic ring, left ventricular enlargement
5. Electrocardiogram with high R waves, depressed T waves in lead I and precordial leads
Mitral stenosis
1. Precordial heave
2. Diastolic murmur at apex
3. Mitral opening snap
4. Suffused face and lips
5. Chest radiograph with left atrial dilation
6. Electrocardiogram with large P waves and right axis deviation

Table 19.11. Signs and Symptoms of Valvular Heart Disease

Patients with valvular abnormalities have been subdivided by the American Heart Association into risk groups for the development of subacute bacterial endocarditis following surgery (185). Patients with prosthetic valves are classified as high risk, whereas patients with mitral valve prolapse with regurgitation, history of rheumatic heart disease, or bicuspid aortic valve are considered at moderate risk. **Patients in both high- and moderate-risk groups should receive prophylactic antibiotics immediately preoperatively to prevent subacute bacterial endocarditis.** Table 19.12 outlines the American Heart Association recommendations for antibiotic prophylaxis (185).

High-Risk Patients	Agents	Regimen
Standard regimen	Ampicillin and Gentamicin	2.0 g (4 or 6) IV within 30 min of starting procedure; 1.0 g (2 or 3) IV for ear 1.5 mg/kg (not to exceed 120 mg) within 30 min of starting procedure
	Vancomycin and Gentamicin	1.0 g IV over 1–2 hr completed within 30 min of starting procedure 1.5 mg/kg (not to exceed 120 mg) within 30 min of starting procedure
Penicillin-allergic	Vancomycin and Gentamicin	1.0 g IV over 1–2 hr completed within 30 min of starting procedure 1.5 mg/kg (not to exceed 120 mg) within 30 min of starting procedure
	Moderate-Risk Patients	Agents
Standard regimen	Ampicillin or Amoxicillin	2.0 g (4 or 6) IV within 30 min of starting procedure 2.0 g orally 1 hr before procedure
	Vancomycin	1.0 g IV over 1–2 hr completed within 30 min of starting procedure

Table 19.12. Recommendations for Prophylaxis of Bacterial Endocarditis for Genitourinary and Gastrointestinal Procedures (185)

Patients with aortic and mitral stenosis tolerate sinus tachycardia and other *tachyarrhythmias* poorly. In patients with aortic stenosis, sufficient digitalization should be provided to correct preoperative tachyarrhythmias, and *propranolol* may be used to control sinus tachycardia. Patients with mitral valve stenosis often have atrial fibrillation and, if present, digitalis should be used to reduce rapid ventricular response.

Patients with mechanical heart valves usually tolerate surgery well (186). Management of these patients requires antibiotic prophylaxis (Table 19.12) and discontinuation of anticoagulant therapy during the perioperative period. Usually, *warfarin* (*Coumadin*) is withheld several days prior of surgery and anticoagulation is obtained by intravenous administration of *heparin* (187). The *heparin* is discontinued 6 to 8 hours prior to surgery and resumed a few days postoperatively (188). The patient is returned to oral *warfarin* maintenance therapy. Alternatively, *warfarin* can be stopped 1 to 3 days perioperatively and restarted several days postoperatively. Perioperative heparinization is indicated in patients who have more thrombogenic valves, such as the Starr-Edwards valve, and valves in the tricuspid position (179). Both methods of management have essentially no risk of thromboembolic complications and bleeding complication rates of approximately 15%.

In the postoperative period, patients with mitral stenosis should be carefully monitored for pulmonary edema because they may not be able to compensate for the amount of intravenous fluid administered during surgery. Patients with mitral stenosis also frequently have pulmonary hypertension and decreased airway compliance. Therefore, they may require more pulmonary support and therapy postoperatively, including prolonged mechanical ventilation.

For patients with significant aortic stenosis, it is imperative that a sinus rhythm be maintained during the postoperative period. Even sinus tachycardia can be deleterious because it shortens the diastolic time. Bradycardia less than 45 beats per minute should be treated with atropine. Supraventricular dysrhythmias may be controlled with *verapamil* or direct-current cardioversion. Particular attention should be provided to the maintenance of proper fluid status, digoxin levels, electrolyte levels, and blood replacement.

Hypertension

Patients with controlled essential hypertension have no increased risk of perioperative cardiac morbidity or mortality (177). However, patients with concomitant heart disease are at elevated risk and should be completely evaluated by a cardiologist preoperatively. Laboratory studies should include an ECG, chest radiograph, blood count, urinalysis, and serum electrolytes and creatinine measurement. Antihypertensive medications should be continued perioperatively. Of note, b-blockers should be continued, parenterally if necessary, to avoid rebound tachycardia, hypercontractility, and hypertension.

Patients with diastolic pressures higher than 110 mmHg or systolic pressures higher than 180 mmHg should receive medication to control their hypertension prior to surgery. Chronically hypertensive patients are very susceptible to intraoperative hypotension because of impaired autoregulation of blood flow to the brain and, therefore, require a higher mean arterial pressure to maintain adequate perfusion (189). Conversely, during induction of anesthesia episodes of hypertension occur, and such episodes are seen more frequently in patients with baseline hypertension.

Postoperative hypertension is usually treated parenterally because gastrointestinal absorption may be diminished, and transdermal absorption can be erratic in patients who are cold and rewarming. Commonly used parenteral antihypertensives are listed in Table 19.13.

Drug	Route	Initial Dose	Onset	Duration	Side Effects
Nitroglycerin	IV infusion	0.5 µg/min	Immediate	2–5 minutes	Tachycardia, nausea
Labetalol	IV infusion	20 mg	5–10 minutes	4 hours	Bronchospasm, dizziness, nausea
Esmolol	IV infusion	50 µg/min	2 hours	9 minutes	Headache, somnolence, dizziness, hypotension
Nifedipine	Sublingual	10 mg	5 minutes	2 minutes	Hypotension, headache, dizziness, nausea, peripheral edema
Verapamil	IV infusion	5–10 mg	3–5 minutes	2–5 hours	Nausea, headache, hypotension, dizziness, pulmonary edema

IV, intravenous.

Table 19.13. Common Parenteral Antihypertensives

Hemodynamic Monitoring

Hemodynamic monitoring has become integral to the perioperative management of patients with cardiovascular and pulmonary disease. The major impetus for this advancement resides in the need for the quantitative estimate of cardiac function, resulting in the development of bedside pulmonary artery catheterization. The impact of monitoring of cardiac function is demonstrated by the significant reduction of myocardial infarctions in high-risk patients who are aggressively monitored for 72 to 96 hours postoperatively ([190](#)).

Before the development of the pulmonary artery catheter, central venous pressure (CVP) measurement was used to assess intravascular volume status and cardiac function. To measure the CVP, a catheter is placed in the central venous system, most frequently the superior vena cava. A water manometer or a calibrated pressure transducer is connected to the CVP line, thus allowing an estimation of right atrial pressure to be obtained. Right atrial pressure is determined by the balance between cardiac output and venous return. Cardiac output is determined by heart rate, myocardial contractility, preload, and afterload. Thus, if the pulmonary vascularity and left ventricular function are normal, the CVP accurately reflects the left ventricular end-diastolic pressure (LVEDP). The LVEDP reflects cardiac output or systemic perfusion and has been considered the standard estimator of left ventricular pump function. Venous return is determined primarily by the mean systemic pressure, which propels blood toward the heart, balanced against resistance to venous return, which acts in the opposite direction. Thus, if right ventricular function is normal, the CVP accurately reflects intravascular volume.

Left and right ventricular function is frequently abnormal or discordant; therefore, the relationship of CVP to cardiac function and to intravascular volume is not maintained. When this occurs, measurement of pulmonary artery occlusion pressure is required to accurately assess volume status and cardiovascular function. The use of a pulmonary artery catheter also allows detection of changes in cardiovascular function with more sensitivity and rapidity than clinical observation.

The balloon-tipped pulmonary artery catheter (Swan-Ganz catheter) can provide measurement of pulmonary artery and pulmonary artery occlusion pressures ([191](#)). The catheter can measure cardiac output, be used to perform intracavitary electrocardiography, and provide temporary cardiac pacing. The standard pulmonary artery occlusion catheter is a 7-French, radiopaque, flexible, polyvinyl chloride, 4-lumen catheter with a 1.5-ml latex balloon at its distal tip. Most often, a right internal jugular cannulation is used for placement of the catheter, because this site provides the most direct access into the right atrium and has fewer complications when compared with a subclavian route of placement. After the catheter is placed into the right atrium, the balloon is inflated and the catheter is pulled by blood flow through the right ventricle into the pulmonary artery. The position of the catheter can be identified and followed by the various pressure waveforms generated by the right atrium, right ventricle, and pulmonary artery. As the catheter passes through increasingly smaller branches of the pulmonary artery, the inflated balloon eventually occludes the pulmonary artery. **The distal lumen of the catheter, which is beyond the balloon, measures left atrial pressure (LAP) and, in the absence of mitral valvular disease, LAP approximates LVEDP. Thus, pulmonary–capillary wedge pressure (PCWP) equals the LAP, which equals LVEDP and is normal at 8 to 12 mm Hg.** Additionally, because the standard pulmonary artery catheter has an incorporated thermistor, thermodilution studies can be performed to determine cardiac output. This thermodilution method is performed by injecting cold 5% dextrose in water through the proximal port of the catheter, which cools the blood entering the right atrium. The change in temperature measured at the more distal thermistor (4 cm from the catheter tip) generates a curve proportional to cardiac output. Knowledge of the cardiac output is helpful in establishing cardiovascular diagnoses. For example, a patient with hypotension, low-to-normal wedge pressure, and a cardiac output of 3 L/min is most likely hypovolemic. Conversely, the same patient with a cardiac output of 8 L/min is probably septic with resultant low systemic vascular resistance.

Pulmonary artery catheters are associated with a small but significant complication rate. The complications can be grouped into those occurring during venous cannulation and those resulting from the catheter or its placement. The most common problems encountered during venous access are cannulation of the carotid or subclavian artery and introduction of a pneumothorax. Problems resulting from the catheter itself include dysrhythmias, sepsis, and disruption of the pulmonary artery. Pulmonary artery catheters should be placed under the supervision of experienced personnel in a setting in which complications can be rapidly diagnosed and treated.

The effect of pulmonary artery catheter use on patient outcome has become controversial. In 1996 Dalen and Bone recommended a reevaluation of pulmonary artery catheters and initiation of randomized clinical trials to assess their benefit ([192](#)). At that time, Connors and others published a large study demonstrating a higher mortality rate in patients who received a pulmonary artery catheter than those that did not have a pulmonary artery catheter ([193](#)). The design of this study was questionable, however, and it was retrospective and not randomized. A recent metaanalysis evaluating 12 randomized clinical trials demonstrated a statistically significant reduction in morbidity (63% versus 74%, $P < 0.01$) in the pulmonary artery catheter group, but no significant difference in mortality ([194](#)). Future large randomized clinical trials comparing pulmonary artery catheters to central venous catheters for the treatment of critical care patients are currently under way, and it is hoped a consensus regarding who will benefit from pulmonary artery catheters will eventually be established.

Hematologic Disorders

The presence of hematologic disorders, although uncommon in gynecologic patients, significantly affects operative morbidity and mortality and therefore should be considered routinely in preoperative evaluation. Preoperative assessment should include consideration of anemia, platelet and coagulation disorders, white blood cell function, and immunity.

Anemia

Moderate anemia is not in itself a contraindication to surgery because it can be corrected by transfusion. If possible, surgery should be postponed until the cause of the anemia can be identified and the anemia corrected without resorting to transfusion. **Current anesthetic and surgical practice ideally recommend a hemoglobin level of >10 g/dl or a hematocrit of >30%. Such numbers are only guidelines, and should be applied on an individual basis.** Oxygen-carrying capacity and tissue oxygenation is provided by the circulating blood volume. Usually this capacity is reflected by the hemoglobin level and hematocrit. Under certain circumstances, however, this is not the case. After an acute blood loss or before plasma expansion by extracellular fluid has occurred, hematocrit measurements may be normal despite a low circulating blood volume. Conversely, overhydration may result in low hematocrit and hemoglobin levels despite adequate red blood cell mass.

Individual tolerance of anemia depends on overall physical fitness and cardiovascular reserve. The effects of anemia depend on its magnitude, the rate at which it occurs, the oxygen requirement of the patient, and the ability of physiologic mechanisms to compensate ([195](#)). Maintenance of adequate tissue perfusion requires an increase in cardiac output as hemoglobin concentration falls ([196](#)). A patient with ischemic heart disease will not tolerate anemia as well as a healthy young patient. Therefore, the presence of cardiac, pulmonary, or other serious illness justifies a more conservative approach to the management of anemia. Conversely, patients with longstanding anemia may have normal blood volume levels and tolerate surgical procedures well. There is no evidence that mild to moderate anemia increases perioperative morbidity or mortality ([197](#)).

Patients with normal hematocrit levels may store three or more units of autologous blood preoperatively to reduce the need for allogenic blood transfusion and minimize the risk of infections and immunologic problems ([198](#)). *Recombinant human erythropoietin* may increase collection and reduce preoperative anemia in these patients ([199](#)). Further, intraoperative blood collection and homologous transfusion can be employed to limit need for allogenic blood transfusion.

Platelet and Coagulation Disorders

Surgical hemostasis is provided by platelet adhesion to injured vessels, which plugs the opening as the coagulation cascade is activated, resulting in the formation of fibrin clots. Thus, functional platelets and coagulation pathways are necessary to prevent excessive surgical bleeding. Platelet dysfunction is encountered more frequently preoperatively than coagulation disorders.

Platelets may be deficient in both number and function. The normal peripheral blood count is 150,000 to 400,000 per mm^3 , and the normal lifespan of a platelet is approximately 10 days. Although there is no clear-cut correlation between the degree of thrombocytopenia and the presence or amount of bleeding, several generalizations can be made. If the platelet count is higher than $100,000/\text{mm}^3$ and the platelets are functioning normally, there is little chance of bleeding during surgical procedures. Patients with a platelet count higher than $75,000/\text{mm}^3$ almost always have normal bleeding times, and a platelet count higher than $50,000/\text{mm}^3$ is probably adequate. **A platelet count lower than $20,000/\text{mm}^3$ will often be associated with severe and spontaneous bleeding.** Platelet counts higher than $1,000,000/\text{mm}^3$ are often, paradoxically, associated with bleeding.

If the patient's platelet count is lower than 100,000/mm³, an assessment of bleeding time should be obtained. If the bleeding time is abnormal and surgery must be performed, an attempt should be made to raise the platelet count by administering platelet transfusions immediately before surgery. In patients with immune destruction of platelets, human leukocyte antigen (HLA)–matched donor-specific platelets may be required to prevent rapid destruction of transfused platelets. If surgery can be postponed, a hematology consultation should be obtained to identify and treat the cause of the platelet abnormality.

Abnormally low platelet counts result from either decreased production or increased consumption of platelets. Although there are numerous causes of thrombocytopenia, most are exceedingly uncommon. Decreased platelet production may be drug induced and has been associated with the use of *sulfonamides*, *cinchona alkaloids*, *thiazide diuretics*, *nonsteroidal antiinflammatory drugs (NSAIDs)*, gold salts, *penicillamine*, *anticonvulsants*, and *heparins* (200). Decreased platelet count is a feature of several diseases, including vitamin B₁₂ and folate deficiency, aplastic anemia, myeloproliferative disorders, renal failure, and viral infections. Inherited congenital thrombocytopenia is extremely rare. More commonly, thrombocytopenia results from immune destruction of platelets by diseases such as idiopathic thrombocytopenia purpura and collagen vascular disorders. Consumptive thrombocytopenia is a feature of disseminated intravascular coagulation (DIC), which is encountered most frequently in conjunction with sepsis or malignancy in the preoperative population.

Platelet dysfunction is most often acquired, but may be inherited. Occasionally, a patient with von Willebrand's disease, the second most common inherited disorder of coagulation, may be encountered in the preoperative setting. More commonly, however, platelet dysfunction results from the use of drugs (e.g., *aspirin* and *amitriptyline*), and patients with resulting prolonged bleeding times should have the drug withheld for 7 to 10 days before surgery. Uremia and hepatic diseases can also affect platelet function.

Platelet dysfunction is more difficult to diagnose than abnormalities of platelet count. A history of easy bruising, petechiae, bleeding from mucous membranes, or prolonged bleeding from minor wounds may signify an underlying abnormality of platelet function. Such dysfunction can be identified with the help of a bleeding time, but full characterization of the underlying etiology should be carried out with hematologic consultation. If at all possible, surgery should be postponed until therapy has been instituted.

Similarly, disorders of the coagulation cascade are often diagnosed through a personal or family history of excessive bleeding during minor surgery, childbirth, or menses. Deficiency of factor VIII (hemophilia) and factor IX (Christmas disease) are the most commonly encountered inherited disorders of coagulation. There are few commonly prescribed drugs that affect coagulation factors, the exceptions being *warfarin* and *heparin*. Disease states that may be associated with decreased coagulation factor levels are primarily liver disease, vitamin K deficiency (secondary to obstructive biliary disease, intestinal malabsorption, or antibiotic reduction of bowel flora), and DIC.

Preoperative laboratory screening for coagulation deficiencies is controversial. Routine screening in patients without historical evidence of a bleeding problem is not warranted (201). However, patients who are seriously ill or who will be undergoing extensive surgical procedures should undergo testing preoperatively to determine prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count.

White Blood Cells and Immune Function

Abnormally high or low white blood cell counts are not an absolute contraindication to surgery; however, they should be considered relative to the need for surgery. Evaluation of an elevated or decreased white blood cell count should be undertaken prior to elective surgery. Clearly, **patients with absolute granulocyte counts lower than 1,000/mm³ are at increased risk of severe infection and perioperative morbidity and mortality, and should undergo surgery only for life-threatening indications** (202).

Blood Component Replacement

Most hematologic problems observed in the postoperative period are related to perioperative bleeding and blood component replacement. Although the primary cause of the bleeding is usually lack of surgical hemostasis, other factors, including deranged coagulation, may compound the problem. Such coagulopathy can result from massive transfusion (less than one blood volume) and is thought to be due to dilution of platelets and labile coagulation factors by platelet- and factor-poor packed red blood cells (PRBCs), fibrinolysis, and DIC.

Reports of massive transfusions in soldiers reveal that for those in whom thrombocytopenia developed following red blood cell replacement, bleeding diatheses that responded to infusion of fresh blood but not fresh-frozen plasma (FFP) also developed (203). The investigators concluded that dilutional thrombocytopenia is a major cause of posttransfusion bleeding. However, more recently, in a prospective, randomized, double-blind study, prophylactic platelet administration during massive transfusion was not helpful (204). Although it seems that these studies are contradictory, they demonstrate the need for obtaining platelet counts during transfusion of large amounts of blood. If clinical evidence of excessive bleeding exists and the platelet count is lower than 100,000/mm³, platelets should be transfused, because they are consumed during surgery and higher levels are required to maintain hemostasis following surgery.

Packed red blood cells, which may be stored for several weeks, are used for most postoperative transfusions. Most clotting factors are stable for long periods. The exceptions are factors V and VIII, which decrease to 15% and 50% of normal, respectively. Despite this loss, these factors rarely decrease below levels required for hemostasis. In 1985, a National Institutes of Health consensus conference concluded that there was little or no scientific evidence to support the use of FFP for bleeding diatheses following multiple blood transfusions except in the presence of clinical bleeding, platelet count higher than 100,000/mm³, and a partial thromboplastin time greater than 1.5 times control. A task force of the American Society of Anesthesiologists (205) recently **recommended critical values for replacement in patients with massive transfusion and microvascular bleeding:**

1. Platelet counts <50,000/mm³ (with intermediate platelet counts, i.e., 50,000/mm³ to 100,000/mm³ the transfusion of platelet concentrates should be based on the risk for more significant bleeding)
2. Elevated (>1.5 times normal) prothrombin or activated partial thromboplastin time values
3. Coagulation factor concentrations less than 30%
4. Fibrinogen concentrations less than 80 to 100 mg/dl.

Donor blood is stored in the presence of citrate, which chelates calcium to prevent clotting, raising the theoretical risk of hypocalcemia following massive transfusion. However, citrate is metabolized at a rate equivalent to 20 units of blood transfused per hour; thus, routine supplementation of calcium is unnecessary. Close monitoring of calcium levels is required in patients with hypothermia, liver disease, or hyperventilation, because citrate metabolism may be slowed. Hepatic metabolism of citrate to bicarbonate can result in metabolic alkalosis following transfusion, resulting in subsequent hypokalemia, despite the high level of extracellular potassium in stored blood.

Pulmonary Disease

In patients undergoing abdominal surgery, several pulmonary physiologic changes occur secondary to immobilization, anesthetic irritation of the airways, and the splinting of breathing that inevitably occurs with incisional pain. Pulmonary physiologic changes include a decrease in the functional residual capacity (FRC) and vital capacity (VC), an increase in ventilation–perfusion mismatching, and impaired mucociliary clearance of secretions from the tracheobronchial tree. These changes result in transient hypoxemia and atelectasis that, untreated, can progress to pneumonia in the postoperative period (206,207). Postoperative pulmonary dysfunction is more pronounced in patients with advanced age, preexisting lung disease, obesity, a significant history of smoking, and upper abdominal surgery (206).

Most postoperative pulmonary complications occur in patients who have preexisting pulmonary disease. In these patients, the incidence of pulmonary complications is higher than 70%, as compared with the low incidence (2% to 5%) that occurs in individuals with healthy lungs (206,208). The risk of postoperative pulmonary complications is lower in patients undergoing lower abdominal surgery as compared with upper abdominal surgery and in those undergoing nonthoracic, nonabdominal surgery as compared with abdominal operations. The presence of chronic obstructive pulmonary disease markedly increases the risk (206,209).

Preoperative spirometry is of unproved value in patients undergoing abdominal surgery in whom the risk of postoperative pulmonary complications is low (210,211,212 and 213). In high-risk patients, preoperative spirometry should be performed with and without bronchodilators in order to identify patients who may

benefit from preoperative treatment with inhaled b_2 agonists and steroids. These patients include those with a history of chronic cough or dyspnea, evidence of pulmonary abnormalities by either physical examination or chest radiograph, and a history of chronic obstructive pulmonary disease, as well as patients with a significant history of smoking. In addition to the preoperative spirometric evaluation, an arterial blood gas assessment should be performed. The spirometric abnormalities most often associated with postoperative atelectasis and pneumonia are shown in [Table 19.14](#).

Parameter	Value
Maximal breathing capacity	<50% predicted
FEV ₁	<1 L
FVC	<70% predicted
FEV ₁ /FVC	<65% predicted
Pao ₂	<60 mm Hg
Paco ₂	>45 mm Hg

FEV₁, forced expiration volume; FVC, forced vital capacity; Pao₂, partial pressure of oxygen, arterial; Paco₂, partial pressure of carbon dioxide, arterial.

^aComplication defined as atelectasis or pneumonia.

From Moser SA, Rack P. Asthma and chronic obstructive lung disease. In: Breslow MJ, Miller CJ, Rogon NC, eds. *Perioperative management*. St Louis: Mosby, 1990:218-230.

Table 19.14. Predictors of Postoperative Pulmonary Complications^a

Young, healthy patients rarely have abnormal chest radiographic examination results. Therefore, chest radiographs should not be performed routinely in these patients. Most patients with abnormal chest radiographs have history or physical examination findings suggestive of pulmonary disease ([214](#)). Chest radiographs should be limited to patients older than 40 years, patients with a history of smoking, patients with a history of pulmonary disease, and patients who have evidence of cardiopulmonary disease.

Asthma

The prevalence of bronchial asthma is increasing worldwide, and approximately 10% of people have suffered an asthma attack ([215](#)). Asthma is a disease that is characterized by a history of episodic wheezing, physiologic evidence of reversible obstruction of the airways, either spontaneously or following bronchodilator therapy, and pathologic evidence of chronic inflammatory changes in the bronchial submucosa. Asthma is not a disease of airway physiology in which hypertrophy and increased contractility of bronchial smooth muscle is the dominant lesion; rather, it is an inflammatory disease affecting the airways that secondarily results in epithelial damage, leukocytic infiltration, and increased sensitivity of the airways to a number of different stimuli. The treatment of asthma is directed toward relaxing the airways and alleviating inflammation with glucocorticoids.

Despite advances in pharmacologic management, morbidity and mortality from asthma have been increasing in recent years ([216](#)). This most likely cause has been the result of underdiagnosis and undertreatment of this disease ([217](#)). Multiple stimuli have been noted to precipitate or exacerbate asthma, including environmental allergens or pollutants, respiratory tract infections, exercise, cold air, emotional stress, use of β -adrenergic blockers, and aspirin ([218](#)). Management of asthma includes removal of the inciting stimuli as well as use of appropriate pharmacologic therapy.

The severity of clinical asthma correlates with measurements of the severity of the inflammatory response in the lung ([219](#)). Some investigators have referred to asthma as a chronic eosinophilic bronchitis ([217](#)). Numerous mediators, including interleukin-3, interleukin-5, granulocyte-macrophage colony-stimulating factors, tumor necrosis factor- α , and interferon- γ , are released in the lungs by eosinophils, macrophages, and T cells. The mediators induce microvascular leakage, bronchoconstriction, and epithelial damage, which block the distal airways. The optimal therapy for asthma involves not only managing the acute symptoms but also long-term management of the inflammatory component of the disease.

Pharmacotherapy of Asthma

The recognition of asthma as an inflammatory condition that should be treated with antiinflammatory agents has led to the use of glucocorticoids for treatment. Glucocorticoids have become the first-line therapy for chronic asthma because they inhibit mediator release from eosinophils and macrophages, inhibit the late response to allergens, and reduce hyperresponsiveness of the bronchioles ([217](#)). Inhaled steroids have greatly reduced the steroid dose required to achieve optimal results. The steroid effect is dose related, but many patients with asthma can achieve control using low-dose inhaled steroids (1,000 g/day). Onset of action is slow (several hours), and up to 3 months of steroid therapy may be required for optimal improvement of bronchial hyperresponsiveness. Even with acute exacerbation of asthma, steroid treatment can enhance the beneficial effect of β -adrenergic treatment.

During acute exacerbations of asthma, a short course of oral steroids may be necessary in addition to inhaled steroids. For adults with chronic asthma, however, only a minority will require chronic oral steroid therapy. Patients taking oral steroids should receive intravenous steroid support perioperatively.

Until recently, b_2 -adrenergic agonists were considered the first-line drugs for asthma. These drugs, inhaled 4 to 6 times daily, rapidly relax smooth muscle in the airways and are effective for up to 6 hours. Studies of b_2 agonists in chronic asthma, however, have failed to show any influence of these agents on the inflammatory component of asthma. Furthermore, it has been suggested that the long-term use of this class of drugs can lead to a worsening of asthma ([217](#)). Thus b_2 agonists are now recommended for use for short-term relief of bronchospasm or as first-line treatment for patients with very infrequent symptoms or symptoms provoked solely by exercise ([220](#)).

Methylxanthines, such as *theophylline*, have been relegated to third-line status in the management of asthma. It is doubtful whether these drugs have any additional benefit in patients who are using maximal inhaled therapy. The xanthines are limited by their narrow therapeutic window. It is necessary to achieve a serum concentration of at least 10 g/ml; at levels higher than 20 g/ml significant toxicity develops, including nausea, tremor, and central nervous system excitation. Xanthines have a limited antiinflammatory effect and no effect on bronchial hyperresponsiveness or eosinophilic degranulation. In addition, plasma concentrations can be altered by drugs or environmental factors, requiring an adjustment in the *theophylline* dose. Smoking and *phenobarbital* use, for example, increase clearance of theophylline by the liver, whereas clearance of *theophylline* is decreased with hepatic disease and cardiac failure or with the concomitant use of certain drugs, including *ciprofloxacin*, *cimetidine*, *erythromycin*, and *troleandomycin*.

Anticholinergic agents are weak bronchodilators that work via inhibition of muscarinic receptors in the smooth muscle of the airways. The quaternary derivatives such as *ipratropium bromide* (*Atrovent*) are available in an inhaled form that is not absorbed systemically. Anticholinergic drugs may provide additional benefit in conjunction with standard steroid and bronchodilator therapy but should not be used as single-agent therapy because they do not inhibit mast cell degranulation, do not have any effect on the late response to allergens, and do not have an antiinflammatory effect.

Cromolyn sodium is highly active in the treatment of seasonal allergic asthma in children and young adults. It is usually not as effective in older patients or in patients in whom asthma is not caused by allergy ([220](#)). The drug is taken by inhalation but has a relatively short duration of action (3 to 4 hours). It has a mild antiinflammatory effect but is less effective than inhaled corticosteroids, and its role as a single agent is limited.

Perioperative Management of Asthma

In patients with asthma, elective surgery should be postponed whenever possible until pulmonary function and pharmacotherapeutic management are optimized. The preoperative evaluation may include pulmonary function testing and arterial blood gas assessment, depending on the severity of the symptoms and concern regarding ventilation and oxygenation. Preoperative chest physiotherapy, bronchodilator therapy, systemic hydration, and appropriate antibiotics will improve the reversible components of asthma ([221](#)). For mild asthma, the use of inhaled β -adrenergic agonists preoperatively may be all that is required. For chronic asthma, optimization of steroid therapy will greatly decrease alveolar inflammation and bronchiolar hyperresponsiveness. Inhaled b_2 agonists should be added to therapy as needed for further control of asthma. Each drug prescribed should be used in maximal dosage before adding an additional agent. For patients undergoing emergent surgery who

have significant bronchoconstriction, a multimodal approach should be instituted, including aggressive bronchodilator inhalation therapy, intravenous *aminophylline*, as well as steroid therapy. Ideally, steroid therapy can be instituted 3 to 6 days preoperatively. In all patients with asthma, pharmacotherapeutic response can be demonstrated by an improvement in the peak expiratory flow rate based on pulmonary function testing (220).

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is the greatest risk factor for the development of postoperative pulmonary complications. The term *COPD* has been used to encompass both chronic bronchitis and emphysema, disease entities that often occur in tandem. Cigarette smoke is implicated in the pathogenesis of both, and any treatment plan must include cessation of smoking (222). *Chronic bronchitis* is defined as the presence of productive cough on most days for at least 3 months per year and for at least 2 successive years (223). It is characterized by chronic airway inflammation and excessive mucus production. The histologic changes of emphysema include destruction of alveolar septa and distension of airspaces distal to terminal alveoli. The destruction of alveolar septa is most likely caused by serine elastase, released by neutrophils exposed to cigarette smoke (222). The destruction of alveoli results in air trapping, loss of pulmonary elastic recoil, collapse of the airways in expiration, increased work of breathing, significant ventilation–perfusion mismatching, and an ineffective cough (219). The impaired ability to cough effectively and clear secretions predisposes patients with COPD to atelectasis and pneumonia in the postoperative period.

COPD and a history of heavy smoking account for the majority of postoperative pulmonary complications in gynecologic surgical patients. The severity of COPD can be determined preoperatively via a thorough history, physical examination, pulmonary function tests, and arterial blood gas assessments. Preoperative evaluation should be performed to assess reversible components of COPD, such as bronchospasm or infection. Several studies have suggested that preoperative pulmonary preparation of patients with preexisting lung disease can decrease the incidence of postoperative pulmonary complications by 50% to 70% (224,225,226 and 227).

The severity of COPD can be quantitated with pulmonary function testing (206,208,228). Typically, patients with COPD demonstrate impaired expiratory air flow, manifested by diminished forced expiratory volume (FEV₁), forced vital capacity (FVC), FEV₁/FVC, and maximal expiratory flow rate (MEFR). In one study, patients with abnormal pulmonary function test results had a 70% incidence of postoperative pulmonary complications, as compared with a 3% incidence of complications in patients who had normal spirometry results (208). In patients considered to be at high risk, the incidence of complications was highest in those undergoing abdominal surgery (92%) or thoracic surgery (78%) and lowest in those undergoing surgery outside the abdomen (26%). Guidelines for preoperative spirometry include the following: lung resection; coronary artery bypass or upper abdominal surgery in a patient with a positive smoking history or dyspnea; lower abdominal surgery in a patient with uncharacterized pulmonary symptoms or history of pulmonary disease without recent spirometry within 60 days, especially if the surgery will be extensive, prolonged, or require strenuous postoperative rehabilitation (229).

Arterial blood gas measurement may show varying degrees of hypoxemia and hypercapnia and can be used for prognostic purposes; Pa O₂ levels lower than 70 mm Hg and PaCO₂ levels higher than 45 mm Hg are associated with an increase in the risk of postoperative pulmonary complications and the need for mechanical ventilation postoperatively (230). PaCO₂ levels higher than 50 mm Hg are associated with increased postoperative respiratory failure and should caution against elective surgery (221).

The preoperative preparation of the patient at risk for postoperative pulmonary complications should include cessation of smoking for as long as possible preoperatively. Whereas 2 to 3 days of smoking abstinence are sufficient for carboxyhemoglobin levels to return to normal (231), 2 months of smoking abstinence is required to significantly lower the risk of postoperative pulmonary complications (232). Longer periods of abstinence can thus be considered in patients undergoing elective surgery.

In patients with severe COPD, maximal improvement in airflow limitation can be achieved with a therapeutic trial of high-dose oral glucocorticoids followed by a 2-week trial of high-dose inhaled steroid (*beclomethasone* 1.5 mg/day or the equivalent) in addition to inhaled bronchodilator therapy. Ideally, oral and inhaled steroid therapy should be initiated 1 to 2 weeks preoperatively. Inhaled steroids, in particular, address the inflammatory component of COPD. Oral steroid therapy initiated preoperatively should be maintained throughout the perioperative period and then tapered postoperatively. β -Adrenergic agonist therapy can be initiated at least 72 hours preoperatively and is beneficial in patients who have demonstrated either clinical or spirometric improvement with bronchodilator therapy.

Patients with COPD and an active bacterial infection, as suggested by purulent sputum, should undergo a full course of antibiotic therapy prior to surgery. The antibiotic used should cover the most likely etiologic organisms, *Streptococcus pneumoniae* and *Haemophilus influenzae*. In any patient with acute upper respiratory infection, surgery should be delayed if possible. In the absence of evidence of an acute infection, the use of antibiotics to sterilize the sputum should be avoided because this practice may lead to bacterial resistance.

Instruction in deep breathing maneuvers and chest physical therapy are easily instituted, and these measures can be started the evening before surgery (232). Steps to improve skeletal muscle strength include good nutrition and treatment of hypokalemia (221). Prophylactic measures, such as smoking cessation, pharmacotherapy administration, and aggressive pulmonary toilet, should be instituted preoperatively and continued postoperatively to minimize the incidence of atelectasis and pneumonia.

Postoperative Pulmonary Management

Atelectasis

Atelectasis accounts for more than 90% of all postoperative pulmonary complications. The pathophysiology involves a collapse of the alveoli resulting in ventilation–perfusion mismatching, intrapulmonary venous shunting, and a subsequent drop in the Pa O₂. Collapsed alveoli are susceptible to superimposed infection, and if managed improperly atelectasis will progress to pneumonia. Patients with atelectasis have a decreased FRC as well as decreased lung compliance, resulting in increased work during breathing. Despite the decrease in Pa O₂, the PCO₂ remains unaffected unless atelectatic changes progress to large volumes of the lung or there is preexisting lung disease.

Physical findings associated with atelectasis may include a low-grade fever. Auscultation of the chest may reveal decreased breath sounds at the bases or dry rales upon inspiration. Percussion of the posterior thorax may suggest elevation of the diaphragm. Radiologic findings include the presence of horizontal lines or plates noted on the posteroanterior chest radiographs, occasionally with adjacent areas containing hyperinflation. These changes are most pronounced during the first 3 postoperative days.

Therapy for atelectasis should be aimed at expanding the alveoli and increasing the functional residual capacity. The most important maneuvers are those that promote maximal inspiratory pressure, which is maintained for as long as possible. This exercise promotes not only an expansion of the alveoli but also secretion of surfactant, which stabilizes alveoli. It can be achieved with aggressive supervised use of incentive spirometry, deep breathing exercises, coughing and, in some cases, the use of positive expiratory pressure with a mask (continuous positive airway pressure). Oversedation should be avoided, and patients should be encouraged to ambulate and change positions frequently. Fiberoptic bronchoscopy for removal of mucopurulent plugs should be reserved for patients who fail to improve with the usual measures.

Cardiogenic (High-pressure) Pulmonary Edema

Cardiogenic pulmonary edema can result from myocardial ischemia, myocardial infarction, or from intravascular volume overload, particularly in patients who have low cardiac reserve or renal failure. The process usually begins with an increase in the fluid in the alveolar septa and bronchial vascular cuffs, ultimately seeping into the alveoli. Complete filling of the alveoli impairs secretion and production of surfactant. Concomitant with alveolar flooding, there is a decrease in lung compliance, impairment of the oxygen diffusion capacity, and an increase in the arteriolar–alveolar oxygen gradient. Ventilation–perfusion mismatching in the lung results in a decrease in the PaO₂, resulting eventually in decreased oxygenation of the tissues and impairment of cardiac contractility.

Symptoms may include tachypnea, dyspnea, wheezing, and use of the accessory muscles of respiration. Clinical signs may include distention of the jugular veins, peripheral edema, rales upon auscultation of the lungs, and an enlarged heart. Radiographic findings may include the presence of bronchiolar cuffing as well as increased interstitial fluid markings extending to the periphery of the lung. The diagnosis can be further confirmed with the use of central hemodynamic monitoring,

which will denote an elevated central venous pressure and, more specifically, an elevation in the pulmonary–capillary wedge pressure.

The patient's volume status should be evaluated thoroughly. In addition, myocardial ischemia or infarction should be ruled out by performing ECG and analyzing cardiac enzyme levels. The management of cardiogenic pulmonary edema includes oxygen support, aggressive diuresis, and afterload reduction to increase the cardiac output. In the absence of myocardial infarction, an inotropic agent may be used. Mechanical ventilation should be reserved for cases of acute respiratory failure.

Noncardiogenic Pulmonary Edema (Adult Respiratory Distress Syndrome)

In contrast to cardiogenic pulmonary edema, in which alveolar flooding is a result of an increase in the hydrostatic pressure of the pulmonary capillaries, alveolar flooding in patients with adult respiratory distress syndrome (ARDS) is the result of an increase in pulmonary capillary permeability. The primary pathophysiologic process is one of damage to the capillary side of the alveolar–capillary membrane. This damage results in rapid movement of fluid containing high concentrations of protein from the capillaries to the pulmonary parenchyma and alveoli. Lung compliance decreases and oxygen diffusion capacity is impaired, resulting in hypoxemia. If not managed aggressively, respiratory failure may result. Even if managed aggressively, the mortality rate associated with ARDS is 60% to 70% (221). There are a number of causes as well as several distinct states of ARDS. The causes of ARDS include shock, sepsis, massive nonlung trauma (as from fractures or burns), multiple red blood cell transfusions, aspiration injury, inhalation injury, pneumonia, pancreatitis, DIC, and fat emboli (221). Irrespective of the cause, which should be identified and treated if possible, the evolving clinical findings and management are very similar.

Clinically, ARDS passes through several stages. Initially, patients develop tachypnea and dyspnea with no remarkable findings on clinical evaluation or on chest radiograph. Chest radiographs will eventually reveal bilateral diffuse pulmonary infiltrates. As lung compliance becomes impaired, functional residual capacity, tidal volume, and vital capacity decrease. The PaO₂ decreases and, characteristically, increases only marginally with oxygen supplementation. An attempt should be made to maintain the arterial oxygen level above 90%. This may be achievable initially by administering oxygen by mask. For patients with severe hypoxemia, endotracheal intubation with positive-pressure ventilation should be instituted. Guidelines for initial ventilatory support are changing, and new lung-protective ventilation strategies are being advocated. One strategy advocates the use of high positive end-expiratory pressure (PEEP), low tidal volume, permissive hypercapnia, and pressure-limited ventilatory modes. The low-tidal-volume strategy may confer a survival advantage, and available data support its use in patients with ARDS (233). Multicenter trials are currently under way to assess differences in PEEP and FIO₂ levels, and the use of glucocorticoids.

Attempts to manage and treat the cause of ARDS also must include aggressive efforts toward hemodynamic and circulatory resuscitation in patients with shock. Nosocomial pneumonia is present in 50% of patients with ARDS, and broad-spectrum antibiotic therapy should be administered as appropriate for patients with suspected pneumonia or sepsis. Patients who have DIC may require replacement with cryoprecipitate or FFP. Other measures for general care should include the placement of a nasogastric tube, gastric acid suppression with H² blockers, and administration of steroids in patients with the fat emboli syndrome.

Hemodynamic monitoring is invaluable and should be initiated early in the course of the disease process. Patients with any evidence of fluid overload should receive aggressive diuresis, whereas others may require fluid resuscitation for maintenance of tissue perfusion while the pulmonary–capillary wedge pressure is maintained below 15 mm Hg. Pulmonary wedge pressure may be falsely elevated when PEEP is being applied. The goal of management is to maintain the lowest pulmonary–capillary wedge pressure, with acceptable cardiac output and blood pressure. In the presence of hypotension and oliguria, inotropic support with *dopamine* or *dobutamine* is helpful.

With aggressive management, particularly if the inciting cause is identified and treated, ARDS can be reversed during the first 48 hours with few sequelae. After the first 48 hours, however, progression of the ARDS will cause lung damage that may leave residual pulmonary fibrosis. With progression beyond 10 days, multiple organ system failure occurs and the mortality rate is higher than 80% (234).

Renal Disease

The need for surgical intervention in patients with renal impairment has resulted in the development of a very specialized medical approach to their care. Special precautions are necessary to compensate for the kidney's impaired ability to regulate fluids and electrolytes and excrete metabolic waste products. Equally important are the unique problems that develop in patients with chronic renal impairment, including an increased risk of sepsis, coagulation defects, impaired immune function and wound healing, and a propensity to develop specific acid-base abnormalities. Special consideration must be given to a variety of different medications, anesthetic agents, and numerous hematologic and nutritional factors that are important in the successful surgical care of patients with renal insufficiency.

Management of fluid levels and cardiovascular hemodynamics in patients with acute or chronic renal impairment is paramount. Intravascular fluid volume changes that lead to hypertension or hypotension are very common in these patients and are often difficult to manage secondary to autonomic dysfunction, acidosis, and other problems that are inherent to the underlying kidney disease. Patients undergoing dialysis for whom major abdominal or pelvic surgery is contemplated should be treated using a Swan-Ganz catheter intraoperatively and postoperatively. The results of physical examination and central venous pressure monitoring correlate poorly with left cardiac filling pressures. Swan-Ganz catheter measurements will help guide fluid replacement and avoid volume overload. Invasive hemodynamic monitoring should be continued as needed throughout the first postoperative week because third spacing will occur during this period.

Postoperative dialysis is usually necessary to avoid problems associated with fluid overload and hyperkalemia. Dialysis-dependent patients should undergo dialysis approximately 24 hours following surgery. A short-lived but rather significant fall in the number of platelets occurs during dialysis, and *heparin* is used in hemodialysis equipment to prevent clotting. Because of these factors and concerns about postoperative bleeding, dialysis is usually avoided during the first 12 to 24 hours following surgery. Although ischemic heart disease is the most common cause of death in patients with renal insufficiency, it is not a major cause of perioperative mortality (235). A large percentage of perioperative deaths of patients with renal insufficiency are associated with hyperkalemia that is controlled most effectively by dialysis (236).

Patients with chronic renal failure are at an increased risk for postoperative infections resulting from abnormalities in neutrophil and monocyte function (237). Appropriate preoperative antibiotic prophylaxis and an accurate assessment of nutritional status will lower the incidence of postoperative infectious complications.

The major hematologic concern in patients with chronic renal insufficiency is the increased incidence of bleeding. These bleeding problems are secondary to abnormal bleeding times and, in particular, disorders of platelet function related to a decreased amount of factor VIII and von Willebrand antigen in the serum of uremic patients. Anemia, which is common in patients with renal insufficiency, can contribute to prolonged bleeding times (238).

Abnormalities in arachidonic acid metabolism, acquired platelet storage pool deficiency, and disturbed regulation of platelet calcium content all account for an increased tendency for uremic patients to have significant bleeding during surgery (239). Therefore, the bleeding time should be routinely checked preoperatively in these patients and abnormalities should be corrected before surgery. Options for the correction of bleeding time in uremic patients include infusion of *desmopressin* or *cryoprecipitate*, both of which act to increase plasma levels of factor VIII and von Willebrand antigen (240,241).

Normal renal function is essential for maintenance of acid-base balance in the body. Patients with renal insufficiency can have a normal anion gap or an elevated anion gap acidosis. When mild renal insufficiency develops, a normal anion gap can be seen, whereas in more significant and severe renal dysfunction, an elevated anion gap acidosis occurs. Hemodialysis corrects metabolic acidosis. If a patient is severely acidotic (pH less than 7.15) and emergency surgery is planned, correction of the blood pH to 7.25 using intravenous sodium bicarbonate is indicated. Correction of metabolic acidosis should be carried out slowly, however, because in patients with hypocalcemia seizures may be precipitated (241). It is also important to exclude other causes of elevated anion gap acidosis, such as ketoacidosis secondary to diabetes, lactic acidosis secondary to infection or, in rare instances, poisoning with *ethylene glycol*, *methanol*, or *aspirin*.

Impaired kidney function causes phosphate retention by the kidney and impaired vitamin D metabolism. Therefore, hypocalcemia is common in patients with renal insufficiency, but tetany and other signs of hypocalcemia are relatively uncommon because metabolic acidosis raises the level of ionized calcium. Oral phosphate binders such as *aluminum hydroxide* (1 to 2 g per meal) and dietary phosphate restriction (1 g per day) is the usual treatment for hypocalcemia-hyperphosphatemia in patients with renal insufficiency. In chronic situations, because of central nervous system toxicity associated with elevated aluminum levels, it is preferable to treat hypocalcemia-hyperphosphatemia with large doses of *calcium carbonate* (6 to 12 g per day) rather than with the standard aluminum-containing antacids (242).

Approximately 20% of patients with renal insufficiency will exhibit clinical evidence of protein calorie malnutrition. Vitamin deficiencies, most notably with water-soluble

vitamins, also occur with dialysis. Nutritional disturbances in patients with chronic renal insufficiency arise secondary to deficiencies in protein intake, and studies have shown that, in patients with chronic renal insufficiency, their kidneys are hyperfiltrating (243). Postoperatively, both protein and caloric intake may need to be increased dramatically to meet catabolic demands in surgical patients. As much as 1.5 g/kg of protein and 45 kcal/kg of calories may be needed (243).

Wound healing is impaired in patients with chronic renal failure, and wound dehiscence and evisceration are potential problems. Wound healing is most appropriately aided by nutritional assessment preoperatively and maintenance of adequate caloric and protein intake in the perioperative setting. Antibiotic prophylaxis should be used in these patients, and uremia should be treated with dialysis as indicated. A running mass-closure of the midline vertical incision with continuous monofilament sutures should be used to further decrease the risk of wound dehiscence and evisceration (244).

Patients with chronic renal disease have an altered ability to excrete drugs and are prone to significant metabolic derangements secondary to the altered bioavailability of many commonly used medications. Because of this, as well as the effect of dialysis on drug pharmacokinetics, the gynecologic surgeon and nephrologist must be aware of the lowered metabolism and bioavailability of narcotics, barbiturates, muscle relaxants, antibiotics, and other drugs that require renal clearance. Of particular note is the inability of patients with renal insufficiency to clear the neuromuscular blockade caused by *pancuronium* (245). Care must be taken with *D-tubocurarine*, especially if repeated doses are given (246). *Midazolam*, *propofol*, *vecuronium*, and *atracurium* have been safely used in patients with renal failure (241). *Succinylcholine* has been reported to cause significant hyperkalemic responses in patients with renal failure (247). *Succinylcholine* can be used safely in patients with chronic renal insufficiency. Careful monitoring of the serum potassium level is necessary (248).

Perioperative acute renal failure in previously normal patients may be caused by decreased renal perfusion, nephrotoxins, or both. Patients with impaired cardiac function, intravascular volume depletion, sepsis, or hypotension fall under the first category. Nephrotoxic medications such as *aminoglycosides*, chemotherapeutic agents such as *cisplatin*, or iodinated contrast agents fall under the second category (249,250 and 251). The risk of renal impairment becomes cumulative if more than one of these factors exist at the same time, and especially if a variety of factors are associated with intravascular volume depletion (252). Several measurements should be used to avoid acute renal failure. All nephrotoxic drugs should be discontinued when possible; when it is not practical to withdraw medication, strict attention should be paid to the pharmacokinetic characteristics of each drug as well as to the regular measurements of the serum creatinine. Patients with diabetes should be given reduced doses of radiocontrast agents and should be well hydrated because they are particularly susceptible to renal injury from these materials (253). Volume repletion is essential to lower the incidence of renal impairment (254).

Liver Disease

Management of perioperative problems in gynecologic patients with liver disease requires a comprehensive understanding of normal liver physiology and the pathophysiology underlying diseases of the liver that may complicate surgery or recovery. Patients with liver disease often have numerous complicated problems involving nutrition, coagulation, wound healing, encephalopathy, and infection.

History and Physical Examination

Patients with a history of alcohol abuse, drug use, hepatitis, jaundice, blood product exposure, or a family member with liver disease should undergo biochemical evaluation. During the physical examination, note should be made of any jaundice, signs of muscle wastage, ascites, right upper quadrant tenderness, or hepatomegaly.

Laboratory Testing

The biochemical profile (alkaline phosphatase, calcium, lactic acid dehydrogenase, bilirubin, serum glutamic-oxaloacetic transaminase, cholesterol, uric acid, phosphorous, albumin, total protein, and glucose) has not been shown to be useful for routine preoperative evaluation (255). Mild abnormalities lead to further extensive testing that require consultation, delays in surgery, and increased cost without net benefit. A possible exception is selected use of biochemical testing when the history or physical examination reveals abnormalities. Patients with known liver disease should undergo albumin and bilirubin testing using the Child's risk classification (Table 19.15). This system was originally designed to predict mortality following portosystemic shunt surgery. It divides patients into three classes of severity based on five easily assessed clinical parameters. Measurement of prothrombin time may also be helpful in patients with significant histories of liver disease. If a history of hepatitis is ascertained, the patient should be tested for serum aminotransferase, alkaline phosphatase, bilirubin, and albumin levels. Serologic documentation of hepatitis is also important. If a patient has a known malignancy, there may be some benefit from biochemical testing of the liver as a screen for metastatic disease, although this has not been proved conclusively.

Parameter	Child Classification		
	A	B	C
Bilirubin	<2.0	2.0-3.0	>3.0
Albumin	>3.5	3.0-3.5	<3.0
Ascites	None	Easily controlled	Poorly controlled
Encephalopathy	None	Mild	Advanced
Nutritional status	Excellent	Good	Poor

Table 19.15. Child's Classification of Liver Dysfunction

Anesthesia

With few exceptions, most anesthetic agents, including those administered by epidural or spinal routes, reduce hepatic blood flow and decrease oxygenation of the liver. Other perioperative factors—hemorrhage, intraoperative hypotension, hypercarbia, congestive heart failure, and intermittent positive pressure ventilation, especially in critically ill patients—lead to decreased hepatic perfusion and hypoxia (256).

Drug Metabolism

Patients with altered liver function should be carefully monitored because of the prolonged action of many medications used during surgery. In addition to impaired metabolism, hypoalbuminemia decreases drug binding, which alters serum levels and biliary clearance rates. The degree of hepatic metabolism varies greatly, depending on the type of medication being considered. For inhalation anesthetics, *isoflurane* is preferred because it undergoes minimal hepatic metabolism in comparison with *halothane* or *enflurane*. Narcotics, induction agents, sedatives, and neuromuscular blocking agents all undergo abnormal metabolism in patients with decompensated liver disease. *Diazepam*, *meperidine*, and *phenobarbital* cause prolonged depression of consciousness and may precipitate hepatic encephalopathy because of their altered rates of clearance. *Sufentanil* and *oxazepam* are the preferred narcotics, and *benzodiazepine* should be used for patients with altered liver function. Muscle relaxants, such as *D-tubocurarine*, *pancuronium*, and *vecuronium*, cause prolonged neuromuscular blockade in patients with impaired liver function and are not ideal drugs to use in this situation. *Atracurium* is not metabolized by the liver and, therefore, is the preferred muscle relaxant for patients with abnormal hepatic function. *Succinylcholine* metabolism is greatly prolonged in patients with hepatic dysfunction and must be used with great caution (257).

Determination of Operative Risk

Although it is well known that acute hepatobiliary damage results in increased morbidity and mortality in the surgical patient, estimating the operative risk in patients with hepatic dysfunction is troublesome, because it is often difficult to determine which patients are at risk based on the history and physical examination. The most accurate method for risk assessment of surgery in patients with hepatic dysfunction is Child's classification (Table 19.15). Using this system, accurate assessment of

morbidity and mortality can be directly related to the degree of liver dysfunction (258). The Child's classification has been shown to be useful for patients undergoing a variety of different types of abdominal surgery. Operative mortalities of 10%, 31%, and 76% have been reported for each of the three Child's classifications, respectively (259). The major cause of perioperative death was sepsis. This classification correlated significantly with postoperative complications such as bleeding, renal failure, wound dehiscence, and sepsis.

Acute Viral Hepatitis

Acute viral hepatitis poses an increased risk of operative complications and perioperative mortality and, therefore, elective surgery is contraindicated (260). Elective surgery should be delayed for approximately 1 month after the results of all biochemical tests have returned to normal (261). In patients with ectopic pregnancy, hemorrhage, or bowel obstruction secondary to malignancy, however, surgical intervention must take place before normalization of serum transaminase (260). In these situations, the perioperative morbidity (12%) and mortality (9.5%) rates are much higher than when they are performed under ideal situations (257).

Chronic Hepatitis

Chronic hepatitis is a group of disorders characterized by inflammation of the liver for at least 6 months. The disease is divided by morphologic and clinical criteria into chronic persistent hepatitis and chronic active hepatitis. A liver biopsy is usually required to establish the extent and type of injury. The surgical risk in these patients correlates most closely with the disease severity. The risk of surgery in patients with asymptomatic or mild disease is minimal, in contrast to a significant risk for those patients who have symptomatic chronic active hepatitis (262). Elective surgery is contraindicated in symptomatic patients, and nonelective surgery is associated with significant morbidity (261). In the nonelective situation, patients taking long-term glucocorticoid therapy should be given appropriate stress coverage with a higher dose of glucocorticoids during the perioperative period. Preoperatively, patients who are not taking steroids should receive prednisone and azathioprine, which have been shown to reduce the perioperative risk of complications and may result in remission in up to 80% of patients (263). More recently, a controlled randomized trial of prednisone and interferon- α has documented regression of the hepatitis B core antigen and hepatitis B viral DNA replication in approximately 30% of patients (264). Interferon- α has also been used in the treatment of hepatitis C. Consideration should be given to using these medications for patients in whom surgery cannot be avoided but is not emergent.

Asymptomatic carriers of the hepatitis B virus (individuals who test positive for the hepatitis B surface antigen) are not at increased risk for postoperative complications in the absence of elevated aminotransferase levels and liver inflammation. There is, however, a significant risk to the health care professional when operating on these individuals. In cases of needle stick in which the patient's hepatitis status is unknown, both the health care worker and the patient should be tested for HCV antibody and HBV serologic markers. If markers for HBV infection are present, hepatitis B immune globulin should be administered to unvaccinated medical personnel. A vaccination series should then be initiated during the early postoperative period. If the health care worker is immune (surface antibody positive), no treatment is necessary (257). All medical personnel, and especially those in the surgical subspecialties, should receive a full course of recombinant hepatitis B vaccine as recommended by the Centers for Disease Control and Prevention (265).

Alcoholic Liver Disease

Alcoholic liver disease encompasses a spectrum of diseases including fatty liver, acute alcoholic hepatitis, and cirrhosis. Elective surgery is not contraindicated in patients with fatty liver because liver function is preserved. If nutritional deficiencies are discovered, they should be corrected prior to elective surgery. Acute alcoholic hepatitis is characterized on biopsy by hepatocyte edema, polymorphonuclear leukocyte infiltration, necrosis, and the presence of Mallory bodies. Elective surgery in these patients is contraindicated (266). Abstinence from alcohol for approximately 6 to 12 weeks along with clinical resolution of the biochemical abnormalities are recommended before surgery is considered. Severe alcoholic hepatitis may persist for several months despite abstinence and, if any question of continued activity exists, a liver biopsy should be repeated (267). In cases of urgent or emergent surgery on patients with alcohol dependence, a benzodiazepine taper is appropriate as prophylaxis against alcohol withdrawal.

Cirrhosis

Cirrhosis is an irreversible liver lesion characterized histologically by parenchymal necrosis, nodular degeneration, fibrosis, and a disorganization of hepatic lobular architecture. The most serious complication of cirrhosis is portal venous hypertension that ultimately leads to bleeding from esophageal varices, ascites, and hepatic encephalopathy. Conventional liver biochemical test results correlate poorly with the degree of liver impairment in patients with cirrhosis. Hepatic dysfunction, however, may be somewhat quantitated by low albumin levels and prolonged prothrombin times.

Surgical risk is clearly increased in patients with cirrhosis, although it is substantially greater in emergency surgery than in elective surgery. Perioperative mortality correlates with the severity of cirrhosis and can be estimated through the use of the Child's classification (Table 19.15). Surgery in patients with Child's class A cirrhosis can usually be performed without significant risk, whereas surgery in patients with Child's class B or C poses a major risk and requires careful preoperative consideration. Meticulous preoperative preparation may improve the surgical outcome (268).

The genital and urinary tracts are intimately associated anatomically and embryologically from the earliest stages of their development. The bladder is located directly above the anterior vaginal wall, and the urethra is fused to it. Both of these structures, as well as other structures of the pelvic floor, are placed at risk during pregnancy and childbirth. Each organ system in the pelvic floor—urinary, genital, intestinal—traverses the pelvis and exits through its own orifice. Thus, these systems are intricately related in function and anatomic support ([1](#)). Disorders of each of these components should be evaluated in light of their impact on the function of the surrounding structures and the functional anatomy of the pelvic floor. The term *urogynecology* has been coined to describe the area of gynecology that deals with disorders of the female lower urinary tract; however, it has become apparent that urinary tract disorders are only one facet of a wide range of pelvic floor disorders that afflict women. As part of this growing recognition, the American Board of Obstetrics and Gynecology and the American Board of Urology have recently agreed to begin the process of jointly accrediting fellowship programs in Female Pelvic Medicine and Reconstructive Surgery. This effort to train both urologists and gynecologists in the treatment of all aspects of pelvic floor dysfunction is a positive step toward improving the care of patients afflicted with these common conditions.

Pelvic Floor Anatomy

The striated muscles of the pelvic floor, in combination with their fascial attachments, work together across the entire pelvis to prevent pelvic organ displacement, to maintain continence, and to control expulsive activities. An appreciation of the fact that these organ systems have complex interrelationships should help clinicians realize that patients' problems are not necessarily limited to a single organ; rather, each disturbance of pelvic support or continence exists within a complex pelvic "ecosystem" and, as a result, may be linked to problems in other organ systems.

Pelvic Support

The bony pelvis surrounds and protects its contents but, by itself, actually provides them with little support. The pelvic organs are supported primarily by the muscular activity of the pelvic floor, aided by ligamentous attachments. Rather than functioning as a rigid structure, the pelvic floor muscles provide dynamic support through constant activity, functioning more like a self-regulating trampoline that continually adjusts its tension in response to changing circumstances ([2,3](#)).

The functional anatomy of the muscles of the pelvic floor (the levator ani) has been studied for many years but remains poorly understood ([4](#)). The pelvic floor muscles contract to maintain urinary and fecal continence and relax to permit bowel and bladder emptying. The pelvic floor plays a role in normal female sexual responsiveness ([5](#)). It must distend tremendously to allow the delivery of a term infant but must contract again during the postpartum period to allow its varied functions to continue. Because the urethra, bladder, rectum, and supporting structures of the pelvis are all part of the pelvic floor, the functions of these organs cannot really be understood without an understanding of the pelvic musculature (see [Chapter 5](#)) ([6,7](#)).

Levator Ani Muscle

The nomenclature of the pelvic muscles has long been subject to debate. The levator ani muscle (the broad general term for most of the muscles of the pelvic floor) has been described as consisting of a diaphragmatic portion (iliococcygeus) and the more important pubovisceral portion ([8](#)). The iliococcygeus portion of the levator ani consists of a thin muscular sheet that arises from the pelvic sidewall on either side of the arcus tendineus and ischial spine and inserts into a midline raphe behind the rectum. The pubovisceral (pubococcygeus) portion of the levator ani muscle consists of a thick U-shaped band of muscle arising from the pubic bone and attaching to the lateral walls of the vagina and rectum ([Fig. 20.1](#)). Therefore, the rectum is supported by a muscular sling that pulls it toward the pubic bones when these muscles contract. This muscular band is often called the *puborectalis* or the *pubococcygeus* muscle, but a more accurate term is the *pubovisceral* muscle because these muscles arise from the pubic bone and insert directly onto pelvic viscera or provide a supporting sling for them.

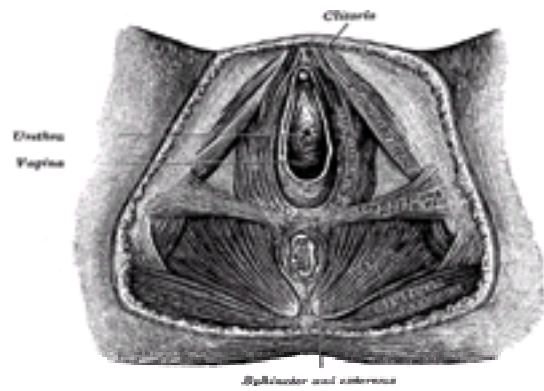

Figure 20.1 The levator ani muscles, as seen from below. (From Goss CM, ed. *Gray's anatomy of the human body*. 28th ed. Philadelphia, Lee & Febiger, 1966:447, with permission.)

When the pubovisceral muscle contracts, it pulls the rectum, vagina, and urethra anteriorly toward the pubic bone and constricts the lumens of these pelvic organs (Fig. 20.2). It is this contractile property that is so important in maintaining urinary and fecal continence and in providing support for the genital organs (vagina, cervix, uterus) that lie upon and are supported by the levator plate. The medial portions of the pubovisceral muscle (levator ani) pass laterally to the arcus tendineus fasciae of the pelvis and attach to the endopelvic fascia surrounding the vaginal wall at a point opposite the upper half of the urethra (9,10 and 11) (Fig. 20.3). The pubovisceral muscle attaches to a web of endopelvic fascia rather than directly to the urethra in this area. This portion of the muscle (puborectalis) contains large quantities of type I (“slow-twitch”) muscle fibers that are tonically contracted. This baseline level of muscular activity provides constant resilient support for the urethra. At the same time, type II (“fast-twitch”) fibers allow the pubovisceral muscle to respond quickly to rapid changes in intraabdominal pressure (coughing, sneezing) and to maintain urethral closure under such conditions (12). Reflex contraction of both types of muscle fibers helps support all of the contents of the pelvis.

Figure 20.2 A: The “pubovisceral” muscle at rest. B: Contraction of the pubovisceral muscle constricts the lumens of the urethra, vagina, and rectum, augmenting closure of all three organs.

Figure 20.3 Frontal section of the cadaver of a 21-year-old woman at the vesical neck showing the supportive layer formed by the vaginal wall (VW) and the endopelvic fascia (E) attached to the pelvic wall at the arcus tendineus fasciae pelvis (ATFP) on the inner surface of the levator ani (LA) at the level of the proximal urethral and internal urinary meatus (IUM). The area where the pubic bones were removed is shaded (PB). The image is reconstructed from a specimen made from the left side of the body by reflecting it across the midline. (From Delancey J. Structural support of the urethra as it relates to stress urinary incontinence: the hammock hypothesis. *Am J Obstet Gynecol* 1994;170:1715, with permission.)

As with the external anal sphincter, the levator ani muscles exhibit constant baseline tone in addition to their ability to contract and offset increases in intraabdominal pressure that would force pelvic contents downward. The phenomenon of constant baseline tone is separate from the ability of these muscles to contract forcefully. This aspect of pelvic muscle function is poorly understood, but it is critical for proper pelvic support because closure of the pelvic floor allows the pelvic viscera to rest on a muscular shelf. The constant adjustments in muscle activity maintain pelvic floor closure in response to changing circumstances and keep the pelvic ligaments from stretching.

Pelvic Ligaments

It is often erroneously believed that the various pelvic ligaments are the most important factors in pelvic support. Ligaments are poorly suited to maintaining support over time because fibrous tissues elongate when subjected to constant tension. The pelvic ligaments serve mainly to keep structures in positions where they can be supported by muscular activity rather than acting as weight-bearing structures themselves. The loss of normal muscular support leads to sagging and widening of the urogenital hiatus and predisposes patients to the development of pelvic organ prolapse (13) (Fig. 20.4).

Figure 20.4 Supportive role of the levator plate. Note how muscle tone in the levator muscle complex keeps the urogenital hiatus constricted and relatively closed

(top). As muscle tone is lost, the levator plate sags, gradually widening the levator hiatus and predisposing the patient to the development of prolapse (bottom).

Although fascia and ligaments are believed to be essential for support of the pelvic organs, this belief comes more from the amount of attention given to these structures in the performance of gynecologic surgery than from any empiric evidence regarding their role in pelvic support. However, the pelvic ligaments (i.e., the round, infundibulopelvic, and cardinal) are loose condensations of areolar tissue, blood vessels, and muscle fibers. By themselves, they have little supportive strength; rather, they function as “moorings” to hold the uterus and vagina in place. The pelvic ligaments and the endopelvic fascia attach the uterus and vagina to the pelvic sidewalls so that these structures can be supported by the muscles of the pelvic floor. The entire complex then rests on the levator plate, where it can be closed by increases in intraabdominal pressure by a flap-valve effect (14).

Connective Tissue

Connective tissue is the “glue” of the body. It is composed primarily of elastin and collagen fibers in a polysaccharide ground substance. The composition of connective tissue is not constant but varies in different sites throughout the body. Connective tissue forms capsules to help maintain the structural integrity of organs. It forms the fascia that covers muscles and the tendons and allows them to attach to other structures in the body. If connective tissue fails, muscular support is weak because the attachments that permit muscles to exercise their functions are unreliable (15). Connective tissue is not static; instead, it is a dynamic tissue that undergoes constant turnover and remodeling in response to stress. Connective tissue turnover and repair are especially important in relation to wound healing and recovery from surgery. Hormonal changes appear to have significant effects on collagen, and these effects are probably of great importance during pregnancy and parturition, as well as in aging (16,17 and 18). Exercise appears to increase collagen turnover, as measured by increased proline hydroxylase activity in 69-year-old women who exercised for 8 weeks (19). Nutrition has an important role in the maintenance of connective tissue integrity. Vitamin C deficiency (scurvy) produces defects in collagen synthesis and repair that can result in the breakdown of seemingly normal connective tissue, even including the reopening of old, previously healed wounds (20).

Studies suggest that connective tissue abnormalities are a significant factor contributing to prolapse and related conditions. For example, joint hypermobility is a common clinical marker for abnormal collagen levels. Several studies have now shown an association between joint hypermobility and pelvic floor prolapse (21,22). Studies evaluating patients with a history of Ehlers-Danlos syndrome, a disorder of collagen synthesis, have revealed an increased incidence of urinary incontinence associated with this disorder (23,24). Fibroblasts grown in tissue culture from the fascia of women with recurrent genital prolapse have an imbalance of collagen types, with excessive synthesis of weaker type III collagen (25). Both collagen content and collagen strength appear to be decreased in the fascia of women with stress incontinence (26,27). However, pelvic support defects are affected by many different factors, and the ultimate clinical presentation (and perhaps the surgical solution) may be different for each patient (28).

Lower Urinary Tract Function

The bladder is a complex organ that has a relatively simple function: to store urine effortlessly, painlessly, and without leakage and to discharge urine voluntarily, effortlessly, completely, and painlessly. To meet these demands, the bladder must have normal anatomic support as well as normal neurophysiologic function.

Normal Urethral Closure

Normal urethral closure is maintained by a combination of intrinsic and extrinsic factors. The extrinsic factors include the levator ani muscles, the endopelvic fascia, and their attachments to the pelvic sidewalls and the urethra. This forms a hammock beneath the urethra that responds to increases in intraabdominal pressure by remaining tense, allowing the urethra to be closed against the posterior supporting shelf (Fig. 20.5). When this supportive mechanism becomes faulty for some reason—the endopelvic fascia has detached from its normal points of fixation, muscular support has weakened, or a combination of these two processes—normal support is lost, and anatomic hypermobility of the urethra and bladder neck develops. For many women, this loss of support is severe enough to cause loss of closure during periods of increased intraabdominal pressure, and stress incontinence results. However, many women remain continent in spite of loss of urethral support (11).

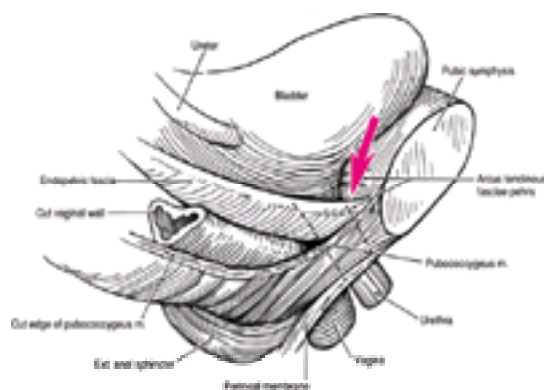

Figure 20.5 Lateral view of the pelvic floor drawn from a three-dimensional reconstruction with the urethra, vagina, and fascial tissues transected at the level of the vesical neck. Note how the urethra is compressed against the underlying supportive tissues by the downward force (arrow) generated by a cough or sneeze. (From Delancey J. Structural support of the urethra as it relates to stress urinary incontinence: the hammock hypothesis. *Am J Obstet Gynecol* 1994;170:1718, with permission.)

The intrinsic factors contributing to urethral closure include the striated muscle of the urethral wall, vascular congestion of the submucosal venous plexus, the smooth muscle of the urethral wall and associated blood vessels, the epithelial coaptation of the folds of the urethral lining, urethral elasticity, and the tone of the urethra as mediated by α -adrenergic receptors of the sympathetic nervous system. The intrinsic competence of the urethral closure mechanism can be affected by congenital developmental defects, scarring from trauma or multiple unsuccessful surgical procedures, estrogen deficiency, and neurologic injury. Stress incontinence resulting from intrinsic sphincteric deficiency is more difficult to correct than that occurring from loss of proper anatomic support. Urethral support alone, however, is not responsible for ensuring the integrity of the closure mechanism. The bladder is an autonomic organ under voluntary control, and neurophysiology plays a role in its function, although our understanding of these complex processes is limited (29).

The Bladder

The bladder is a bag of smooth muscle that stores urine and contracts to expel urine under voluntary control. It is a low-pressure system that expands to accommodate increasing volumes of urine without an appreciable rise in pressure. This function appears to be mediated primarily by the sympathetic nervous system. During bladder filling, there is an accompanying increase in outlet resistance. This action is manifest as increasing muscle fiber recruitment, as seen with electromyography of the pelvic floor and urethra while performing filling cystometry. The bladder muscle (the detrusor) should remain inactive during bladder filling, without involuntary contractions. When the bladder has filled to a certain volume, fullness is registered by tension-stretch receptors, which signal the brain to initiate a micturition reflex. This reflex is permitted or not permitted by cortical control mechanisms, depending on the social circumstances and the state of the patient's nervous system. Normal voiding is accomplished by voluntary relaxation of the pelvic floor and urethra, accompanied by sustained contraction of the detrusor muscle, leading to complete bladder emptying.

Innervation

The lower urinary tract receives its innervation from three sources: (a) the sympathetic and (b) parasympathetic divisions of the autonomic nervous system

and (c) the neurons of the somatic nervous system (external urethral sphincter). The *autonomic nervous system* consists of all efferent pathways with ganglionic synapses that lie outside the central nervous system. Although knowledge of the norepinephrine of the autonomic nervous system is incomplete, it appears that the sympathetic system primarily controls bladder storage and that the parasympathetic nervous system controls bladder emptying. The somatic nervous system plays only a peripheral role in neurologic control of the lower urinary tract through its innervation of the pelvic floor and external urethral sphincter.

The sympathetic nervous system originates in the thoracolumbar spinal cord, principally T11 through L2 or L3. The ganglia of the sympathetic nervous system are located close to the spinal cord and use acetylcholine as the preganglionic neurotransmitter. The postganglionic neurotransmitter in the sympathetic nervous system is norepinephrine, and it acts on two types of receptors: a receptors, located principally in the urethra and bladder neck, and b receptors, located principally in the bladder body. Stimulation of a receptors increases urethral tone and thus promotes closure. a-Adrenergic receptor blockers have the opposite effect. Stimulation of b receptors decreases tone in the bladder body.

The *parasympathetic nervous system* controls bladder motor function—bladder contraction and bladder emptying. The parasympathetic nervous system originates in the sacral spinal cord, primarily in S2 to S4, as does the somatic innervation of the pelvic floor, urethra, and external anal sphincter. Sensation in the perineum is also controlled by sensory fibers that connect with the spinal cord at this level. For this reason, examination of perineal sensation, pelvic muscle reflexes, and pelvic muscle or anal sphincter tone is relevant to clinical evaluation of the lower urinary tract. The parasympathetic neurons have long preganglionic neurons and short postganglionic neurons, which are located in the end organ. Both the preganglionic and postganglionic synapses use acetylcholine as their neurotransmitter, acting on muscarinic receptors. Because acetylcholine is the main neurotransmitter used in bladder muscle contraction, virtually all drugs used to control detrusor muscle overactivity have anticholinergic properties. Unfortunately, cholinergic stimulants appear to be ineffective in promoting bladder emptying, even though they cause bladder muscle strips to contract in a laboratory setting, thus making medical treatment of voiding dysfunction unsuccessful in most cases.

Bladder storage and bladder emptying involve the interplay of the sympathetic and parasympathetic nervous systems. The modulation of these activities appears to be influenced by a variety of nonadrenergic, noncholinergic neurotransmitters and neuropeptides, which fine-tune the system at various facilitative and inhibitory levels in the spinal cord and higher areas of the central nervous system (30,31 and 32). Thus, neuropathology at almost any level of the neurourologic axis can have an adverse effect on lower urinary tract function.

Micturition

Micturition is triggered by the peripheral nervous system controlled by the central nervous system. It is useful to consider this event as occurring at a micturition threshold, a bladder volume at which reflex detrusor contractions occur. The threshold volume is not fixed but instead is variable, and it can be altered depending on the contributions made by sensory afferents from the perineum, bladder, colon, and rectum as well as input from the higher centers of the nervous system. The micturition threshold is, therefore, a floating threshold that can be altered or reset by various influences.

The spinal cord and higher centers of the nervous system have complex patterns of inhibition and facilitation. The most important facilitative center above the spinal cord is the pontine-mesencephalic gray matter of the brain stem, often called the *pontine micturition center*, which serves as the final common pathway for all bladder motor neurons. Transection of the tracts below this level leads to disturbed bladder emptying, whereas destruction of tracts above this level leads to detrusor hyperreflexia. The cerebellum serves as a major center for coordinating pelvic floor relaxation and the rate, force, and range of detrusor contractions, and there are multiple interconnections between the cerebellum and the brain-stem reflex centers. Above this level, the cerebral cortex and related structures exert inhibitory influences on the micturition reflex. Thus, the upper cortex exerts facilitative influences that release inhibition, permitting the anterior pontine micturition center to send efferent impulses down the complex pathways of the spinal cord, where a reflex contraction in the sacral micturition center generates a detrusor contraction that causes bladder emptying.

Colorectal Function

The sigmoid (S-shaped) colon begins at the pelvic brim and straightens as it enters the pelvis to become the rectum. Below the cul-de-sac, it expands into the rectal ampulla, filling the posterior pelvis from the left side. An anorectal angle of 90 degrees is formed at this point by the action of the puborectalis portion of the levator ani muscle complex, separating the anal canal below from the rectum above. **The anorectal angle is believed to be one factor among several that are important in the maintenance of normal anal continence. The puborectalis muscle maintains this angle through its normal tone, and during normal defecation, it relaxes to depress the pelvic floor and then contracts to elevate the pelvic floor during and after bowel emptying.**

The anorectal continence mechanism consists of an *internal sphincter* composed of smooth muscle and an *external sphincter* composed of striated muscle. The internal sphincter is a visceral muscle under autonomic control and normally has a high resting tone. The external sphincter is a striated muscle under voluntary control. In addition, there are sensory nerves in the rectum and pelvic floor. Continence is maintained at the level of the internal anal sphincter by gradual increases in the level of tonic contraction of the internal anal sphincter. This seal works only if the anal lining is sufficiently bulky to permit closure, and it is maintained by a combination of vascularity and infolding of the anal lining. The contractile efficiency of the internal sphincter is aided by contraction of the external anal sphincter. Rapid rectal distention causes a reflex relaxation of the internal anal sphincter. Under these circumstances, continence is maintained by contraction of the external sphincter. The efficiency of this process is closely linked to rectal sensation. Afferent sensation from the rectum appears to travel with the parasympathetic nerves to sacral segments S2 to S4. Sensation from the anal canal also travels to these sacral segments through the inferior hemorrhoidal branches of the pudendal nerve. The sensory apparatus of the rectum allows patients to distinguish between solid feces, liquid stool, and flatus. Impairment of this ability can have serious social consequences.

Innervation

The innervation of the gut is similarly complex. There are two ganglionic complexes in the bowel wall: (a) a *myenteric plexus* between the longitudinal and circular muscle coats, and (b) a *submucosal plexus*. The innervation of the smooth muscle of the bowel involves excitatory and inhibitory nonadrenergic, noncholinergic neurotransmitters and cotransmitters, primarily acetylcholine, substance P, and vasoactive intestinal polypeptide. The sphincters appear to be under separate neuronal control from nonsphincteric smooth muscle of the bowel. Sympathetic stimulation (norepinephrine) appears to cause contraction of the internal anal sphincter, whereas parasympathetic stimulation causes relaxation of the internal anal sphincter. The internal anal sphincter receives sympathetic innervation by the hypogastric nerves from L5, and the parasympathetic innervation comes from sacral segments S1 to S3. The external anal sphincter is innervated by branches of the pudendal nerve, originating in the sacral segments S2 to S4, with some branches from the coccygeal nerve plexus (S4 to S5).

Like the bladder, the colon and rectum undergo a filling and emptying cycle; unlike the bladder, the lower end of the gastrointestinal tract is not a closed viscus but rather a one-way conduit through which waste matter passes (33). Like the bladder, colorectal function can be categorized into storage (continence) and emptying (defecation) components.

Anal Continence

Anal continence is maintained by a combination of colonic compliance and mechanisms for retention in the rectosigmoid that keep the distal rectum collapsed and empty. The forces of retention are both mechanical and physiologic. The mechanical forces promoting retention of stool involve the S-shaped anteroposterior angulations of the sigmoid colon and the spiral folds in the lumen formed by the valves of Houston. Also, the puborectalis muscle creates a sharp angulation of the anorectum, which is accentuated by contraction of this muscle. Increases in intraabdominal pressure accentuate these angulations. These pressure increases have been postulated to create a flap-valve effect, which helps occlude the upper anal canal during periods of increased intraabdominal pressure (34); however, the principal mechanism of action may actually be a sphincter-like function exerted by puborectalis contraction (35). A flutter-valve effect may also be created in the collapsed anorectum (33,36). Retention of stool is further helped by a reverse pressure gradient between the rectum and the rectosigmoid colon. Waves of muscle contraction are both more frequent and of higher amplitude in the rectum than they are in the sigmoid.

The most important factors in maintaining fecal continence are sphincteric factors. The anus has both internal and external sphincters. Both of these sphincters are tonically contracted in the resting state, with the internal sphincter more so than the external sphincter. The external sphincter contains both slow-twitch and fast-twitch fibers. It remains tonically contracted even during sleep. In addition to its tonic baseline contractility, the external anal sphincter can respond with a quick, forceful contraction during periods of stress to maintain anal control, and its degree of contraction varies with posture and activity. The internal sphincter is at or near its state of maximal contraction all of the time. It relaxes only to allow the passage of stool when the rectum reaches a threshold of distention. When this occurs, relaxation of

diuresis if glucose control is poor), vascular insufficiency (which can lead to incontinence at night when peripheral edema is mobilized into the vascular system, resulting in increased diuresis), chronic pulmonary disease (which can lead to stress incontinence from chronic coughing), or a wide variety of neurologic conditions that can affect the neurourogenic axis at any point from the cerebral cortex to the peripheral nervous system.

Many medications affect the lower urinary tract ([39,40](#)).

1. Sedatives such as the benzodiazepines may accumulate in the patient's system and cause confusion and secondary incontinence, particularly for elderly patients.
2. Alcohol may have similar effects to benzodiazepines and also impairs mobility as well as produces diuresis.
3. Anticholinergic drugs may impair detrusor contractility and may lead to voiding difficulty and overflow incontinence. Drugs with anticholinergic properties are widespread and include antihistamines, antidepressants, antipsychotics, opiates, antispasmodics, and drugs used to treat Parkinson's disease.
4. α -Adrenergic agents may have a profound effect on the lower urinary tract. α -Agonists, which are often found in over-the-counter cold remedies, increase outlet resistance and may lead to voiding difficulty.
5. α -Blockers, which are often used in the treatment of hypertension (e.g., prazosin, terazosin), may decrease urethral closure and lead to stress incontinence ([41](#)).
6. Calcium-channel blockers may reduce bladder smooth muscle contractility and lead to voiding problems or incontinence; they may also cause peripheral edema, which may lead to nocturia or nighttime urine loss.
7. Angiotensin-converting enzyme inhibitors may result in a chronic and bothersome cough that can result in increasing stress urinary incontinence in an otherwise asymptomatic patient ([42](#)).

Physical Examination

The physical examination of the patient with incontinence should include detection of general medical conditions that may affect the lower urinary tract. Such conditions include cardiovascular insufficiency, pulmonary disease, occult neurologic processes (e.g., multiple sclerosis, stroke, Parkinson's disease, and anomalies of the spine and lower back), as well as abnormalities of genitourinary development. The pelvic examination, including an evaluation of urethral support, is of crucial importance.

1. Patients with urinary incontinence should be examined with a full bladder, particularly if stress incontinence is a complaint.
2. The patient should stand with her feet separated to shoulder width and cough several times to see if the physical sign of stress incontinence can be demonstrated. If urine loss occurs, confirm with the patient that this is the problem that has been bothering her. Many multiparous women may lose a small amount of urine during such an examination but not be bothered by it.
3. Many women with urge incontinence caused by detrusor overactivity may demonstrate urine loss during a cough stress test, but this finding may not be relevant to their real complaint. The physical findings must be set within the context of the patient's history to be relevant.
4. The patient's complaint should be reproduced by the physician and confirmed with the patient, particularly if surgery is contemplated.

Urinalysis

Examination of the urine by dipstick testing and microscopy is necessary to exclude infection, metabolic abnormalities, and kidney disease.

1. Urine culture will help rule out infection, which can be associated with incontinence.
2. Urine cytology is useful as a screening test for urinary tract malignancy, but the utility of the test depends greatly on the accuracy of the laboratory performing the cytology. Routine urinary cytology is not helpful, but testing should be performed in women older than 50 years of age with irritative urinary tract symptoms, particularly if those symptoms are of sudden onset.
3. Hematuria should be evaluated with cytology, intravenous urography, and cystoscopy. Bladder biopsy should be performed by the surgeon who will treat the patient in the event that a malignancy is discovered.

Measurement of Postvoid Residual Urine

Incomplete bladder emptying is a frequent cause of incontinence. Patients with a large postvoid residual urine have a diminished functional bladder capacity because of the dead space occupied in the bladder by retained urine. This stagnant pool of urine is also a frequent source of urinary tract infections, because the major defense of the bladder against infection is frequent, complete emptying.

A large postvoid residual can contribute to urinary incontinence in two ways. If the bladder is overdistended, increases in intraabdominal pressure can force urine past the urethral sphincter, causing stress incontinence. In some cases, bladder overdistention may provoke an uninhibited contraction of the detrusor muscle, leading to incontinence. Both conditions may exist together, further complicating the problem.

Patients with an elevated postvoid residual urine should begin a regimen of clean, intermittent self-catheterization to improve bladder emptying. In many cases, this technique may be the only therapy needed to correct the incontinence and eliminate recurrent urinary tract infections. The recent development of sacral nerve root neuromodulation for nonobstructive voiding dysfunction now offers an additional treatment option for some of these women ([43](#)).

Frequency/Volume Bladder Chart

A frequency/volume bladder chart is an invaluable aid in the evaluation of patients with urinary incontinence, but use of this tool often is neglected ([44,45](#)). A frequency/volume chart is a voiding record kept by the patient for several days. Use of a plastic measuring "hat" that fits over the patient's toilet bowl is very helpful in keeping accurate records. Patients should be instructed to write down the time of every void on the chart and measure the amount of urine voided. The time of any incontinent episodes should be recorded, and it is also helpful to maintain an annotated record of symptoms or activities associated with urine loss. If desired, the patient can also be instructed to keep a record of fluid intake, although in most cases intake can be estimated with some accuracy from the amount of urine produced.

A frequency/volume bladder chart gives an accurate record of 24-hour urinary output, the total number of daily voids, the average voided volume, and the functional bladder capacity (largest volume voided in normal daily life). This information allows the clinician to confirm complaints of urinary frequency with objective data and to determine whether part of the patient's problem is an abnormally high (or low) urinary output. For example, incontinence is a common complaint of many patients with diabetes, and the first step in the management of such patients is to control their blood glucose levels and decrease their urinary output rather than using medications or surgery, which often is ineffective. Conversely, many patients with incontinence decrease their fluid intake dramatically in an attempt to control their urine loss, not realizing that the resulting highly concentrated urine is often much more irritating to their bladders than a higher volume of a more diluted urine. **As a rule, daily urine output should be 1,500 to 2,500 mL, with an average voided volume of about 250 mL, a functional bladder capacity (largest voided volume) of 400 to 600 mL, and seven or eight voids per day.** The frequency/volume chart is the foundation for conservative management of urinary incontinence based on fluid manipulation and behavioral management of voiding habits.

Urodynamic Studies

At its most basic level, a urodynamic study is anything that provides objective evidence about lower urinary tract function ([46](#)). In this sense, measurement of a patient's voided urine volume and catheterization to determine her postvoid residual urine are urodynamic studies. A frequency/volume chart is also a valuable urodynamic study. Obtaining clinically useful information does not always require the use of expensive, complex technology.

Bladder Filling Test If a patient with a complaint of urinary incontinence comes for her examination without a full bladder, a great deal of information can be obtained by a simple bladder filling test ([47](#)). The patient should urinate and measure the volume she voids. The residual urine can be measured by draining it through a 10- or 12-Fr. red rubber catheter placed into the bladder. Once the residual urine has been drained out, a bag of sterile water or saline attached to the catheter can be used to fill the patient's bladder at a rate of 60 to 75 mL/min until her functional bladder capacity is reached.

If the patient experiences urgency with accompanying urine loss during bladder filling, it is highly likely that she has motor urge incontinence caused by detrusor overactivity. If the patient leaks an isolated spurt of urine each time she coughs, and this leakage is demonstrated repetitively and confirmed as the problem for which she is seeking help, she has stress incontinence. Further evaluation is required for patients who exhibit mixed incontinence (the presence of both stress and urge

incontinence), who exhibit prolonged leakage with coughing (suggestive of a cough-induced detrusor contraction), who have marked incontinence with a nearly empty bladder or with minimal effort, who develop incontinence after their prolapse is treated, or who report incontinence that cannot be verified by simple testing.

Multichannel Urodynamic Studies Multichannel urodynamic studies produce a biophysical profile of a patient's bladder and urethral function, but such studies are helpful only if they are interpreted with reference to the patient's history and the results of her physical examination. Clinicians who recommend that patients undergo urodynamic studies without first taking a careful history and performing a thorough physical examination are likely to obtain useless or irrelevant information from these expensive investigations. A detailed history and a thorough physical examination often can predict reliably the type of incontinence when these findings are combined with those derived from some simple urodynamic tests (48,49 and 50).

A wide variety of sophisticated studies of bladder and urethral function have been developed to measure various aspects of bladder storage and bladder emptying. These studies include uroflowmetry, filling cystometry, pressure-flow voiding studies (with and without simultaneous electromyography of the pelvic floor), urethral pressure profilometry, and determination of leak-point pressure.

The bladder is affected by neural impulses running along afferent and efferent sensory pathways and generates a pressure–volume relationship in the cycle of micturition (Fig. 20.6). As bladder volume increases, tension-stretch receptors in the bladder wall are activated, and the afferent sensory impulses gradually lead to a desire to void. Normally, this occurs between 150 and 250 mL. Normally, a patient is able to suppress a micturition reflex until an appropriate time. She should then be able to relax the pelvic floor and generate a sustained contraction of the bladder detrusor muscle until emptying is complete, after which the detrusor relaxes and the cycle begins again.

Figure 20.6 Pressure–volume relationship of the micturition cycle. (1) The normal bladder accommodates increasing urine volumes without a significant increase in pressure. (2) At about 200 mL, the first sensation of bladder fullness is appreciated. (3) The micturition reflex can be suppressed until a socially acceptable time and place for urination presents itself. (4) At this time, a voluntary detrusor contraction is initiated, in conjunction with pelvic floor relaxation. (5) There is a brief isometric pressure rise before the bladder neck is open and flow starts. (6) Normal voiding is accomplished by a sustained detrusor contraction until bladder emptying is complete. (7) The detrusor muscle then relaxes and the process of filling begins anew. Cystometry Cystometry is the technique by which the pressure–volume relationship of the bladder is measured. It can be divided into two phases: (a) filling cystometry and (b) voiding cystometry (also called a **pressure-flow study**). Simple cystometry is carried out when bladder pressure only is measured during filling. Because the bladder is an intraabdominal organ, however, the pressure recorded in the bladder is a combination of several other pressures, most notably the pressure created by the activity of the detrusor muscle itself and the pressure exerted on the bladder by the weight of the surrounding intraabdominal contents (e.g., uterus, intestines, straining, or exertion). For this reason, the technique of subtracted cystometry is used.

Subtracted cystometry is an attempt to measure the pressure exerted in the bladder by the activity of the detrusor muscle. Subtracted cystometry is carried out by measuring *total intravesical pressure* (P_{ves}) with a bladder pressure catheter, approximating *intraabdominal pressure* (P_{abd}) by measuring either rectal or vaginal pressure, and using an electronic instrument to subtract the latter from the former to give the *true detrusor pressure* (P_{det}) or the subtracted pressure:

$$P_{det} = P_{ves} - P_{abd}$$

Measurements can be made using either expensive electronic microtip transducer pressure catheters or inexpensive fluid-filled pressure lines. The technique for such a study is shown in Figure 20.7.

Figure 20.7 Subtracted filling cystometry. Pressure catheters are in place in the bladder and rectum. An additional filling catheter has been placed in the bladder. Volume infused, total bladder pressure, rectal (abdominal) pressure, and subtracted detrusor pressure (intrinsic bladder pressure) are recorded. (From **Wall LL, Addison WA.** Basic cystometry in gynecologic practice. *Postgrad Obstet Gynecol* 1988;26(2):3).

1. Fluid (usually sterile water or saline, sometimes radiographic contrast dye) is infused at a rate of 50 to 100 mL/min. The volume infused and the pressure measurements are recorded continuously. The patient's bladder may be filled with her lying supine, in a modified lithotomy position, sitting, or standing. When possible, standing cystometry is usually preferable because most patients with incontinence complain of this problem when they are erect.
2. The point at which any leakage occurs should be noted carefully.
3. During filling, the point at which the first desire to void is experienced should be noted, along with the point at which the patient experiences a strong desire to void, urgency, and her cystometric capacity.
4. Provocative maneuvers are performed, such as coughing, heel-bouncing, and listening to the sound of running water in an attempt to produce urinary incontinence and to provoke any uninhibited detrusor contractions, which may be the cause of the patient's symptoms.

Normal cystometric values for women are shown in Table 20.3.

- Residual urine <30 mL
- First desire to void occurs between 150 and 250 mL infused
- Strong desire to void does not occur until after 250 mL
- Cystometric capacity between 400 and 600 mL
- Bladder compliance between 20 and 100 mL/cm H₂O measured 60 sec after reaching cystometric capacity
- No uninhibited detrusor contractions during filling, despite provocation
- No stress or urge incontinence demonstrated, despite provocation
- Voiding occurs due to a voluntarily initiated and sustained detrusor contraction
- Flow rate during voiding is >15 mL/sec with a detrusor pressure of less than 50 cm H₂O

Table 20.3. Approximate Normal Values of Female Bladder Function

At *cystometric capacity* (ideally, the same as the patient's functional bladder capacity), the filling catheter should be removed, leaving only the pressure measurement lines in place (Fig. 20.8). If the pressures are allowed to equilibrate for 1 minute, bladder compliance can be calculated by dividing the bladder volume in milliliters by the pressure of water in centimeters. The patient should then void. The urine flow rate can be measured and correlated with the detrusor pressure. This technique allows a better assessment of voiding function than measurement of urine flow rate alone.
