Figure 20.8 Pressure–flow voiding study. The filling catheter has been removed. Volume voided, urine flow rate, total bladder pressure, rectal (abdominal) pressure, and subtracted detrusor pressure are recorded. (From Wall LL, Addison WA. *Basic cystometry in gynecologic practice*. *Postgrad Obstet Gynecol* 1988;26[2]:3, with permission).

Urethral Pressure Profile

In addition to an assessment of filling and emptying, specific urodynamic tests allow some quantitative assessment of sphincteric integrity. The urethral pressure profile is a test designed to measure urethral closure. Because continence requires the pressure in the urethra to be higher than the pressure in the bladder, it was believed that measuring the pressure differential between the two would provide useful clinical information. The urethral pressure profile is generated by slowly pulling a pressure-sensitive catheter through the urethra from the bladder, which is usually filled with a standardized volume of fluid (Fig. 20.9). The urethral closure pressure (P_{close}) is the difference between the urethral pressure (P_{ure}) and the bladder pressure (P_{ves}):

$$P_{\text{close}} = P_{\text{ure}} - P_{\text{ves}}$$

Figure 20.9 Parameters normally measured during urethral pressure profile studies (International Continence Society).

Although this pressure can be used to differentiate groups of normal women from groups of those with stress incontinence (women with stress incontinence tend to have higher urethral pressure levels than those who do not), there is considerable overlap between the two groups. It has also been suggested that women with stress incontinence with low urethral closure pressure (<20 cm H₂O) have a poorer prognosis for surgical outcome than women who do not have this condition; however, there is considerable debate about this (51,52 and 53). Because stress incontinence, by definition, occurs during increases in intraabdominal pressure that are generated by some kind of physical activity, it is not obvious why measurement of resting urethral pressure should be relevant to stress-related leakage, which is a dynamic event. In general, the urethral pressure profile has been a disappointing test with questionable clinical utility.

Leak-Point Pressure Test

A more promising test appears to be the leak-point pressure test (54). The idea behind this test is quite simple: the amount of force that it takes to produce stress incontinence should be related to the severity of the stress incontinence and to the strength of the sphincteric unit. **The leak-point pressure is the intravesical (or sometimes intraabdominal) pressure measured at the moment that stress incontinence occurs.** It is usually determined at a bladder volume of 200 mL, but the technique has not been completely standardized. When the appropriate bladder volume has been reached, patients are asked to cough with gradually increasing force (cough leak-point pressure), and finally to strain slowly (Valsalva) to increase intravesical pressure gradually. The lowest pressure at which leakage occurs is recorded as the cough or the Valsalva leak-point pressure. If leakage is not demonstrated, the highest pressure that has been obtained can be recorded with the notation “no leakage” to the specified pressure as measured in cm H₂O. This figure appears to give a reasonable estimation of sphincteric strength. Standardization and interpretation of these tests are in early stages, and further research is required.

Extraurethral Causes of Incontinence

Involuntary urine loss can occur through two basic routes. Most urinary incontinence represents unwanted urine loss through the urethra (transurethral incontinence); however, urine loss can also occur through abnormal openings. These openings can be created by congenital causes or some form of trauma. The congenital causes of urinary incontinence are not common and usually are easy to diagnose. The most extreme cases are caused by bladder exstrophy, in which there is a congenital absence of the lower anterior abdominal wall and anterior portion of the bladder, resulting in the entire bladder opening directly to the outside

(55). Such cases are diagnosed at birth, and before the advent of modern reconstructive surgery, these infants usually died very early in life from sepsis.

Ectopic Ureter

The most common and most subtle congenital anomaly causing extraurethral urine loss is an ectopic ureter (56). Generally, ectopic ureters are detected early in life, but occasionally one may escape detection until adolescence or early adulthood. In infancy, an ectopic ureter should be suspected when a mother seeks care for her baby whom she says is never dry. Normally, infants have periods of dryness interspersed with periods of wetness. If a parent notes that every time the baby is checked her diaper is wet, this is the first clue that an ectopic ureter may exist because this ureter will most likely drain outside the bladder, causing continuous urinary leakage. Most commonly, the ectopic ureter drains into the vagina, but occasionally, it may drain into the urethra distal to the point of continence. Ectopic ureter has been reported as an uncommon cause of suburethral mass (57). This condition can be diagnosed easily by excretory urography.

Urinary Fistula

A traumatic opening between the urinary tract and the outside is called a fistula. Worldwide, the most common cause of fistulas is obstructed labor. This was also true in the Western world 150 years ago, but advances in the provision of basic obstetric services and advanced obstetric intervention have virtually eliminated this problem in developed countries. The rest of the world is not so fortunate.

Obstructed labor often occurs in rural areas where girls are married young (sometimes as early as 9 or 10 years of age) and where transportation is poor and access to medical services is limited. In such circumstances, pregnancy often occurs shortly after menstruation begins and before maternal skeletal growth is complete. When labor begins, cephalopelvic disproportion is common, and little can be done to correct fetal malpresentations. Women may be in labor as long as 5 to 6 days without intervention, and if they survive, they usually give birth to a stillborn infant. In such cases, the soft tissues of the pelvis have been crushed by constant pressure from the fetal head, leading to an ischemic vascular injury and subsequent tissue necrosis. When this tissue sloughs, a genitourinary or rectovaginal fistula develops. Many of these patients have complex or multiple fistulas, involving total destruction of the urethra and sloughing of the entire bladder base. Obstetric fistulas are frequently as large as 5 to 6 cm in diameter.

After such fistulas develop, the lives of these young women (most of whom are younger than 20 years of age) are ruined unless they can gain access to curative surgical services. The constant, uncontrolled dribble of urine makes them offensive to their husbands and family members. They can no longer live with their families. Most of them eventually become destitute social outcasts—and yet these are otherwise healthy functional young women. The social and economic costs of this problem are enormous, but the problem has largely been neglected by the world medical community. The morbidity associated with obstetric fistulas remains, along with the related problem of maternal mortality, one of the single most neglected issues in international women's health care (58).

In the industrialized world, the most common causes of genitourinary fistulas are surgery, malignancy, and radiation therapy or the interrelation of all three factors. Most often, a vesicovaginal fistula develops after an otherwise uncomplicated vaginal or abdominal hysterectomy in which a small portion of the bladder was inadvertently trapped in a surgical clamp or was transfixed by a suture. These fistulas most often occur at the vaginal apex and are no larger than 1 to 2 mm. The amount of urine that can leak through a fistula of any size, however, is enormous.

A wide variety of techniques are available for fistula repair (59,60). **Traditionally, fistula repair is has been performed after a waiting period to allow the resolution of inflammation and formation of scar tissue.** This is particularly important in the case of obstetric fistulas, in which the extent of the vascular injury to the soft tissues of the pelvis may not be apparent for many weeks. However, there has been a recent trend toward early closure of small gynecologic fistulas (61). The keys to closure of a vesicovaginal fistula include wide mobilization of tissue planes so that the fistula edges can be approximated without any tension, close approximation of tissue edges, closure of the fistula in several layers, and meticulous attention to postoperative bladder drainage for 10 to 14 days. The closure of large fistulas will be enhanced by the use of tissue grafts (e.g., Martius labial fat-pad grafts, gracilis muscle flaps) that bring an additional blood supply to nourish an area that has sustained vascular injury.

Stress Urinary Incontinence

Stress incontinence occurs during periods of increased intraabdominal pressure (e.g., sneezing, coughing, or exercise) when the intravesical pressure rises higher than the pressure that the urethral closure mechanism can withstand, and urine loss results. Stress urinary incontinence is the most common form of transurethral urinary incontinence in women. A community survey of 1,060 randomly selected women older than 18 years of age in South Wales, for example, revealed that 22% of women had this complaint (62). In a survey of 144 collegiate female varsity athletes, 27% complained of stress incontinence while participating in their sport (63). The activities most likely to produce urinary loss were jumping, high-impact landings, and running. Even in otherwise fit and vigorous women, the continence mechanism is particularly susceptible to stress incontinence.

The term *stress incontinence* refers to three distinct entities: a symptom, a sign, and a condition (37). Confusion can occur if the differences between these three entities are not appreciated.

Symptoms and Signs

The *symptom* of stress incontinence refers to the patient's complaint that she leaks urine when intraabdominal pressure is increased. Such urine leakage may result from a variety of conditions: genuine stress incontinence, a detrusor contraction provoked by coughing or change of position, incomplete bladder emptying, or a urethral diverticulum. The patient's complaint of stress incontinence makes it likely, but not certain, that she has this problem, but the complaint must be confirmed by some objective means. A patient should never undergo surgery for stress incontinence on the basis of symptoms alone.

The *sign* of stress incontinence refers to the physical demonstration of urine loss during conditions of increased intraabdominal pressure (e.g., coughing) while the patient is being examined. Mere demonstration of stress urinary leakage during a physical examination does not mean that the patient has a clinical problem with stress incontinence. According to the International Continence Society's definition, incontinence exists when urine loss becomes a social or hygienic problem (37). Many women experience occasional stress urinary leakage that is merely annoying or inconvenient. These women do not consider themselves incontinent, nor do they need surgery; however, studies have also shown that there is little relationship between the volume of urine lost and the distress that it causes a patient with incontinence (64).

Genuine Stress Incontinence

A specific technical term, *genuine stress incontinence*, is used to refer to the urodynamic diagnosis of stress incontinence (37). Genuine stress incontinence is said to exist when a patient has demonstrable urinary leakage when intravesical pressure exceeds the maximum urethral closure pressure in the absence of a detrusor contraction. This term can only be used for a patient who has undergone urodynamic testing and who has met these test criteria, which prove that her urine loss is caused by ineffective urethral closure during periods of increased intraabdominal pressure (Fig. 20.10). This urodynamic diagnosis must be analyzed with reference to the patient's complaint; one may have genuine stress incontinence that is nonetheless not a clinical problem or is a less severe problem than urge incontinence caused by detrusor muscle overactivity.

Figure 20.10 Subtracted cystometrogram showing a stable bladder with genuine stress incontinence. During the filling phase (A), there is no rise in detrusor pressure. When the patient stands (B), there is a rise in intravesical and rectal pressure as the position of the intraabdominal contents changes, but the subtracted detrusor pressure remains stable. When the patient coughs in the erect position (C), the detrusor remains stable. Coughs appear as sharp, isolated pressure spikes. The presence of leakage confirms that the patient has genuine stress incontinence owing to ineffective urethral closure rather than detrusor overactivity.

The clinical condition of stress incontinence includes a spectrum of symptoms ranging in severity. At one end of the spectrum is the female athlete who leaks only a tiny amount during vigorous physical activity; at the other end of the spectrum is the frail elderly woman who leaks large amounts of urine during minimal physical effort. The degree to which either woman is bothered by her leakage is influenced by her cultural values and expectations regarding urinary continence and incontinence.

Biobehavioral Model A biobehavioral model of stress incontinence can be created by examining the interaction of three variables: the biologic strength of the sphincteric mechanism, the level of physical stress placed on the closure mechanism, and the woman's expectations about urinary control (Fig. 20.11). This model explains the enormous variation that exists among the symptoms, the degree of demonstrable leakage, and a patient's response to her stress incontinence. Modification of any one of these factors may influence the patient's clinical status. For example, many patients give up certain physical activities (e.g., running, dancing, aerobics) when they experience stress incontinence. Limiting their activities may eliminate the incontinence problem, but it does so at a certain cost to their quality of life. Other women learn to cope with stress incontinence by adopting new body postures during physical activities that prevent them from leaking or by strengthening their pelvic muscles to compensate for increased exertion. Other women may be profoundly relieved to find out that the small amount of leakage they experience from time to time is not abnormal. In any case, the interaction of these three biopsychosocial factors opens up a variety of strategies for the management of stress incontinence. Surgical intervention is only one strategy, and it addresses only the biologic competence of the sphincteric mechanism rather than either of the other factors that interact to produce the clinical problem.

Figure 20.11 A biobehavioral model of stress incontinence. Clinical stress urinary incontinence results from the interaction of three distinct components: the inherent biologic strength of the urinary sphincter, the level of physical stress placed on the sphincter, and the psychosocial milieu in which the patient lives (i.e., her personal and cultural expectations concerning urinary control and urinary incontinence).

Interaction of Extrinsic and Intrinsic Urethral Support Effective urethral closure is maintained by the interaction of extrinsic urethral support and intrinsic urethral integrity, each of which is influenced by several factors (i.e., muscle tone and strength, innervation, fascial integrity, urethral elasticity, coaptation of urothelial folds, urethral vascularity). In the clinical setting, damaged urethral support is manifest clinically by urethral hypermobility, which often results in incompetent urethral closure during physical activity and presents as stress urinary incontinence. Intrinsic urethral functioning is more complicated and is not nearly as well understood as urethral support (65).

Clinical appreciation of the importance of extrinsic support and intrinsic urethral function have led surgeons to separate stress incontinence into two broad types:

1. That caused by anatomic hypermobility of the urethra, which produces faulty urethral closure under stress
2. That caused by intrinsic sphincteric weakness or deficiency

The former type is more prevalent, probably accounting for somewhere between 80% and 90% of stress urinary incontinence.

The latter type is less common and more challenging to treat. Although this concept is useful, in most cases, patients cannot be distinguished easily as belonging to one category or another but instead are affected to some degree by both factors that interact to produce the clinical condition of stress incontinence (Fig. 20.12). The challenge is deciding which factor predominates because this decision will have a direct bearing on the type of treatment chosen.

Figure 20.12 Interaction of anatomic urethral hypermobility with intrinsic sphincteric deficiency in patients with stress incontinence. The problem is not an "either-or" dichotomy, but rather one of degree.

Nonsurgical Treatment

Many extrinsic, as well as intrinsic, factors influence urethral closure, and surgery is not the only option, nor is it always the best choice, for this condition.

Nonsurgical approaches to stress incontinence are based on manipulation of the factors that contribute to the condition. These approaches may involve reducing factors that worsen the problem (e.g., obesity, smoking, or excessive fluid intake) or by intervening actively to enhance the ability of the patient's pelvic floor to compensate for increased intraabdominal pressure (e.g., making adaptive changes in posture, rehabilitating pelvic muscles, improving estrogen status, using α -adrenergic stimulants, or wearing a device to improve urethral support).

Muscle Strengthening By its connection with the endopelvic fascia, the musculature of the levator ani complex provides substantial support for the urethra, vagina, and rectum as they descend through the pelvic floor (66). The periurethral levator ani muscles contain both type I (slow-twitch) and type II (fast-twitch) muscle fibers, which allows them to maintain tone over a long period and to increase tone suddenly to compensate for the increased abdominal pressure that occurs with coughing, sneezing, and straining. These muscle groups can be rehabilitated through exercise and physical therapy (67). There are two possible ways in which this therapy

improves stress urinary incontinence. First, strengthening the striated urogenital sphincter could enhance its ability to constrict the urethral lumen, yielding a stronger closure force in the urethra at rest or increasing the forces of urethral closure generated during a cough or other stressful situations. Second, because the levator ani muscles play an important role in pelvic and urethral support, exercise could improve the support of the proximal urethra, generating improved continence during a cough, when the muscles are active, without producing a noticeable rise in resting urethral pressure measurements.

Kegel was the first person to investigate pelvic floor muscle strengthening. He developed the patient's awareness of the pubococcygeus muscle and instructed her in exercises to strengthen this muscle with a crude pneumatic biofeedback device called a perineometer. He stressed the importance of supervised instruction and encouragement in the performance of these exercises and reported good success rates in relieving symptomatic stress incontinence by his program. Although nearly all gynecologists are familiar with these exercises, they rarely are taught and used as Kegel did originally, and this form of therapy has often degenerated into a few brief words of oral instruction in which the patient is told to stop and start her urine stream a few times each day while voiding. Programs based on this approach are not only disappointing in their results but also can train women to become dysfunctional voiders.

For muscular rehabilitation of the pelvic floor to be effective, exercises must be supervised, performed regularly, and aided by some form of feedback so that the patient can judge her progress. Careful supervision makes a dramatic difference in the degree of success that can be obtained ([67,68](#)). Using an intensive program of physical therapy over 3 months with pretherapy and posttherapy urodynamic and radiographic evaluations, Benvenuti and colleagues cured 32% of their patients with genuine stress incontinence and brought about marked improvement in symptoms in the remaining 68%. Both tonic and phasic contractility of the pubococcygeus muscle were improved, and there was clear-cut improvement of bladder neck support, as seen on radiographic evaluation in 13 of 15 patients who underwent repeat studies. After 12 to 36 months of follow-up, 77% reported that they had maintained the functional level they had attained at the end of treatment ([69](#)).

Similarly, Peattie and co-workers trained 30 premenopausal women with genuine stress incontinence in pelvic muscle rehabilitation with an ingenious form of resistive therapy using a set of weighted vaginal cones ([70](#)). These cones are of the same size but of increasing weight (from 20 to 100 g). After inserting a cone into the vagina, it can only be retained in place by contracting the pelvic floor. As one cone is successfully retained for 15 minutes, the next heaviest cone is used, thus progressively increasing the retained weight. The feeling that the cone is slipping out of the vagina results in a form of sensory biofeedback that causes an increased contraction in the pelvic floor in an attempt to retain it. At the end of 1 month of therapy, 19 patients (70%) reported cure or significant improvement of symptoms, and only 11 (37%) opted for subsequent surgical intervention.

Physical therapy will not cure or improve all cases of stress incontinence; however, properly supervised and rigorously performed techniques for pelvic muscular rehabilitation can play a significant role in the treatment of genuine stress incontinence ([69](#)). Patients can expect improvement in their symptoms by tensing the musculature of the pelvic floor and holding these contractions for 5 seconds each, 15 to 20 times per session, three sessions per day. This will strengthen slow-twitch muscle fibers. Patients should also practice a similar number of rapid contractions to strengthen the fast-twitch muscle fibers. Pelvic muscle exercises should be taught to patients one-on-one during a pelvic examination because many patients contract the wrong muscles; teaching Kegel exercises to large groups in classrooms is not worthwhile. Because pelvic muscle rehabilitation is virtually without side effects, involves the patient in her own care, and may prevent the development of subsequent pelvic organ prolapse if used regularly, physicians should be encouraged to incorporate pelvic muscle exercises into routine health maintenance programs for women.

Drug Therapy The tone of the urethra and bladder neck is maintained in large part by α -adrenergic activity from the sympathetic nervous system. For this reason, many pharmacologic agents have been used with varying degrees of success to treat stress incontinence. These drugs include *imipramine* (which has a concomitant relaxing effect on the detrusor), *ephedrine*, *pseudoephedrine*, *phenylpropanolamine*, and *norepinephrine*. Unfortunately, many of these compounds also increase vascular tone and may, therefore, lead to problems with hypertension, a condition that afflicts many postmenopausal women with stress incontinence. These effects may preclude the use of α -agonists in such patients. A recent U.S. Food and Drug Administration (FDA) statement urged caution in the use of *phenylpropanolamine*, an α -agonist, in women because of an apparent increased epidemiologic risk for hemorrhagic cerebral vascular accidents. Although the risk remains very low, it is not possible to predict who is at risk for this complication ([71](#)). The use of these agents in the treatment of stress urinary incontinence appears to be more limited than originally thought. Of equal importance, however, is the role of α -blockers such as *prazosin* in causing stress incontinence. These drugs are commonly used in treating hypertension because of their relaxing effects on vascular smooth muscle; however, they may also relax the bladder neck and urethra to the point at which incontinence develops. For patients who have symptoms of stress incontinence while taking this or a related drug, their antihypertensive medication should be changed before surgery is considered because their incontinence may resolve spontaneously with a change of medication ([41](#)).

Postmenopausal women with urogenital atrophy resulting from estrogen deprivation and concurrent urinary incontinence should receive hormone replacement therapy as part of their therapeutic regimen unless such therapy is contraindicated. Not only will many complaints of urgency, frequency, and irritation often disappear, but evidence suggests that estrogen replacement enhances the effectiveness of α -adrenergic receptors in the urethra ([72,73](#)).

Electrical Stimulation In addition to physical therapy and selected pharmacologic agents, electrical stimulation therapy has been used to treat stress incontinence. This treatment may offer advantages to women with moderate to severe weakness of the pelvic floor muscles who have difficulty performing pelvic muscle exercises themselves. Electrical stimulation, particularly when used in conjunction with individual instruction by a pelvic floor physical therapist, also is useful in teaching the patient which muscles to exercise. Passage of an electrical current through the muscles of the pelvic floor causes them to contract and simultaneously causes a reflex inhibition of detrusor activity. The stimulus can be applied transvaginally or transrectally in either continuous or intermittent fashion. When compared with sham devices and pelvic floor exercises, electrostimulation has produced mixed results in the treatment of stress urinary incontinence ([74,75](#)). Although many authors have reported good success rates using these devices, patient acceptance of the technique is often poor, and the device may fail because of mechanical problems. Although this mode of therapy remains an option for patients with stress incontinence, it is unlikely to be used extensively at present outside a research setting. Recently, a new device using pulsed magnetic technology has been developed for strengthening the pelvic floor in the treatment of urinary incontinence. This device produces a rapidly pulsing magnetic field that passes through air, skin, fat, and bone with minimal attenuation. *Extracorporeal magnetic innervation* has been used to treat women with both stress and urge incontinence in a noninvasive treatment session (it does not require internal probes or electrodes). A typical treatment session lasts 20 minutes and includes both high- and low-frequency stimulation with the patient sitting fully clothed on the treatment chair. The recommended treatment course consists of twice weekly sessions for 6 to 8 weeks. The research is currently limited by short duration of follow-up and small numbers of patients, but the concept is attractive, and this therapy may offer a more acceptable form of treatment for many women with pelvic floor dysfunction ([76,77](#)).

Surgical Management

Operations for stress incontinence can be classified into four broad categories ([78,79](#) and [80](#)):

1. Traditional anterior vaginal colporrhaphy
2. Operations to correct stress incontinence resulting from anatomic hypermobility (retropubic bladder neck suspension operations, needle suspension procedures, tension-free vaginal tape, and some sling procedures)
3. Operations for stress incontinence resulting from intrinsic sphincteric weakness or dysfunction (sling operations and periurethral injections)
4. Salvage operations (intentionally obstructive sling operations, implantation of an artificial urinary sphincter, urinary diversion)

Anterior Colporrhaphy Anterior vaginal repair is the oldest operation for stress incontinence in gynecology. It was described by Howard Kelly in 1914 ([81](#)). He believed that stress incontinence was caused by an open vesical neck rather than from loss of urethral support, and he designed an operation to cure this condition by pulling the bladder neck closed using periurethral Kelly plication sutures. This operation remained the standard first approach to stress incontinence until the middle of the twentieth century and still is popular among many practitioners.

Many different operations have been lumped together under the term *anterior colporrhaphy*, including simple plication of the bladder neck, elevation of the bladder neck by plicating the fascia under the urethra, and elevation and fixation of the bladder neck by passing sutures lateral to the urethra and driving the needles anteriorly into the back of the pubic symphysis for fixation.

The mechanism of action of this operation, when it works, is preventing excessive displacement of endopelvic fascia beneath the urethra so that the urethra can be closed during coughing or sneezing. The main advantage of this operation is that it avoids an abdominal incision, which may not be well tolerated by older women. It also allows the operation to be performed in conjunction with other vaginal surgery, such as vaginal hysterectomy for uterine prolapse.

The problem with most techniques of anterior colporrhaphy is that they do not hold up well over time ([82,83 84](#)). In essence, this operation attempts to take

weak support from below and to push it back up from below, with hope that these structures will maintain their strength and position over time. Although there have been excellent long-term results shown with anterior colporrhaphy, most of these reports use specific techniques requiring skillful dissection of the endopelvic fascia, deep bold bites of suture, and fixation of permanent sutures to the pubic bone from below: in essence, a transvaginal retropubic bladder neck suspension (85,86). Most surgical series that have evaluated techniques of anterior colporrhaphy for stress incontinence show long-term success rates of only 35% to 65%, a figure that most would regard as unacceptably low. Anterior colporrhaphy should be reserved primarily for patients requiring cystocele repair who do not have significant stress incontinence.

Surgery to Correct Urethral Hypermobility

Retropubic Urethropexy The modern era of retropubic surgery for stress incontinence began in 1949, when Marshall, Marchetti, and Krantz described their technique for urethral suspension in a male with postprostatectomy incontinence (87). Since that time, a variety of modifications of this operation have been described, all of which share at least two characteristics: they are performed through an open low abdominal incision or with laparoscopically assisted exposure of the space of Retzius, and they all involve attachment of the periurethral or perivesical endopelvic fascia to some other supporting structure in the anterior pelvis (Fig. 20.13). In the Marshall-Marchetti-Krantz operation, the periurethral fascia is attached to the back of the pubic symphysis. Another approach, the Burch colposuspension, involves the attachment of the fascia at the level of the bladder neck to the iliopectineal ligament (Cooper's ligament) (88,89). With the paravaginal repair, the lateral endopelvic fascia along the urethra and bladder is reattached to the arcus tendinous fascia pelvis (90,91). In the Turner-Warwick vaginooobturator shelf procedure, the endopelvic fascia, vagina, or both are attached to the fascia of the obturator internus muscle (92,93). All of these operations cure stress incontinence by correcting anatomic hypermobility of the urethra and bladder neck. The long-term success rate for patients undergoing these operations as primary procedures for stress incontinence is in the range of 70% to 90% (94,95,96,97 and 98).

Figure 20.13 Points of reattachment of the endopelvic fascia during retropubic bladder neck suspension operations. A: Arcus tendineus fascia pelvis. **B:** Periosteum of the pubic symphysis. **C:** Iliopectineal ligament (Cooper's ligament). **D:** Obturator internus fascia. (From Wall LL. Stress urinary incontinence. In Rock JA, Thompson JD, eds. *TeLinde's operative gynecology*. 8th ed. Philadelphia: JB Lippincott, 1997, with permission.)

Retropubic urethropexy has had high success rates; however, the traditional route, which requires an abdominal incision, results in increased morbidity when compared with transvaginal corrective procedures. Presumably, laparoscopically assisted retropubic urethropexy would have a decreased recovery time when compared with the traditional open approach; however, the learning curve is prolonged with this technique, and the published results of the success rate of this operation to date are mixed (99,100 and 101). Many surgeons have made substantial modifications to the operation in an attempt to perform it laparoscopically, and these modifications may be a factor explaining these differences in outcome.

No operation is perfect, however (102,103). Depending on how high and tight the suspending sutures are tied, these operations may introduce an element of urethral kinking or obstruction, with subsequent voiding difficulty (104,105 and 106). This can be a significant long-term complication for patients undergoing this type of surgery. Operations that put sutures directly into the pubic symphysis may cause debilitating osteitis pubis, which can disable an otherwise healthy woman for several months. The normal vaginal axis is almost horizontal, with the vagina resting on top of the levator plate (Fig. 20.14). Because the vagina is a tubular structure, pulling up on the anterior vagina also elevates the posterior vagina. This can pull the posterior vagina up out of its normal position, opening the rectouterine pouch of Douglas and thereby predisposing patients to enterocele formation, uterine prolapse, and vaginal vault eversion. For this reason, culdoplasty can be performed at the time of bladder neck suspension to reduce the incidence of future prolapse (107).

Figure 20.14 Normal location of structures over the pelvic floor. Note that the normal vagina is almost horizontal, lying over the levator plate. Any operation that pulls the vagina forward, away from its normal location, increases the risk of enterocele formation and the development of rapidly progressive prolapse.

Transvaginal Urethropexy Needle suspension procedures are so named because they suspend the urethra and bladder neck through a technique that involves passage of sutures between the vagina and anterior abdominal wall using a specially designed long needle carrier. To perform these operations, a vaginal incision is typically made at the level of the bladder neck, the endopelvic fascia is perforated, the space of Retzius is entered from below, and a permanent suture is passed down through a low abdominal incision through the retropubic space, where it is fixed to the endopelvic fascia at the level of the bladder neck. The long needle is then passed back up through the retropubic space to the abdominal incision, where it is tied in place (Fig. 20.15). The first needle suspensions were performed by a gynecologist, Dr. Armand Pereyra, in the 1950s, but many urologic surgeons have since made modifications to the technique (108,109,110,111,112 and 113).

Figure 20.15 Guidance of the long needle through the space of Retzius using the surgeon's index finger. (From Wall LL. Stress urinary incontinence. In Rock

These operations are designed to correct stress incontinence resulting primarily from anatomic hypermobility of the bladder neck and urethra. If the suspending sutures are pulled too tight, an element of obstruction can be created. They are relatively simple and take less time to perform than open procedures, but this advantage is often offset by the fact that they are not as effective in curing stress incontinence. Initial cure rates are between 70% and 90%, but these rates appear to decrease significantly over time in many series, with 5-year success rates of 50% or less ([95114,115,116,117](#) and [118](#)). In addition to a lower success rate, other complications include perforation of the bladder or urethra by the long needles, infections, formation of granulation tissue around sutures and the synthetic bolsters often used in fixing the sutures to the fascia at the bladder neck or abdominal wall, development of prolapse as a result of changes created in the vaginal axis, chronic pulling pelvic pain created by the suspension sutures, and nerve entrapment syndromes ([119,120,121](#) and [122](#)). Because the long-term success rate of needle urethropexy is poor, this operation is falling out of favor. Surgeons performing needle urethropexy should know their long-term continence rates to make sure that they are offering their patients an appropriate treatment option.

Tension-free Vaginal Tape The poor success rates of needle urethropexy operations have led many surgeons to search for a similarly attractive, low-morbidity operation with better long-term success. Ulmson described a new technique for correcting stress urinary incontinence in 1996 ([123](#)). This technique involves the use of polypropylene mesh placed under the midurethra with minimal tension. To perform this operation, a small midurethral incision is made in the vaginal epithelium mucosa. A 40- × 1-cm mesh tape covered by a plastic sheath and attached to two 5 mm-curved trocars is passed lateral to the urethra and through the endopelvic fascia into the retropubic space. The trocar is then passed along the back of the pubic bone, through the rectus fascia, into two small suprapubic skin incisions. The tension on the tape is adjusted, the sheath is removed, and the remaining tape is cut off at the level of the skin. This technique has the advantage of being performed quickly using limited anesthesia (less than 30 minutes in experienced hands). The procedure requires the use of a catheter guide to deviate the urethra and cystoscopy to ensure that bladder or urethral perforations are recognized immediately because the trocar is passed blindly.

The short-term results reported to date by various authors are encouraging, but long-term data must be evaluated before the role of this operation in the treatment of stress incontinence can be determined ([124,125](#)). The complications reported appear to be similar to those occurring with needle urethropexies. Concern about the use of synthetic materials placed through a vaginal incision remain; reports of transvaginal sling operations performed using other types of synthetic materials have documented complications with this approach in the past ([126,127](#) and [128](#)).

Sling Procedures and Periurethral Injections

Sling Operations After reviewing reports that included patient follow-up for more than 48 months, the American Urological Association and the Female Stress Urinary Incontinence Guidelines Panel concluded that the two most effective surgical treatments for stress incontinence are retropubic bladder neck suspensions and sling procedures ([130](#)). This panel confirmed that the use of sling operations in women with complex or recurrent stress urinary incontinence is a safe and effective treatment. Given the high success rates with complex incontinence, many surgeons are now performing sling procedures as a primary procedure, rather than reserving such operations for patients who have failed previous operations. Traditionally, sling operations have been used principally for patients with complicated stress incontinence, usually resulting from intrinsic sphincteric damage or weakness. Probably no more than 15% to 20% of women with stress incontinence need a sling procedure to be cured. Patients requiring a sling typically have demonstrable stress incontinence with normal urethral support or stress incontinence with a low leak-point pressure. Other candidates might be women with stress incontinence who engage in very heavy occupational lifting, who have severe chronic obstructive lung disease, and who have posthysterectomy vaginal vault eversion. Such patients appear to have an increased risk for surgical failure if their stress incontinence is treated with an anterior colporrhaphy, retropubic operation, or needle suspension. Although sling operations do provide urethral support, they work primarily by compressing the urethral lumen at the level of the bladder neck to compensate for a faulty urethral closure mechanism; that is, they work by creating some degree of outlet obstruction ([Fig. 20.16](#)).

Figure 20.16 Mechanism of action of sling procedures for stress incontinence. **A:** Normal urethra. **B:** Incompetent urethra with intrinsic sphincteric deficiency. The lumen is gaping, scarred, and has lost its normal coaptation and pliability. **C:** Correction of intrinsic sphincteric deficiency using a sling operation. The urethra is supported and the urethral lumen is partially compressed by the sling. (From **Wall LL**. Stress urinary incontinence. In **Rock JA, Thompson JD**, eds. *TeLinde's operative gynecology*. 8th ed. Philadelphia: JB Lippincott, 1997, with permission.)

Sling operations have traditionally been performed using a combined vaginal and abdominal approach. The anterior vagina is opened, the space of Retzius is dissected on each side of the bladder neck, and a sling is passed around the bladder neck and urethra and is then attached to the anterior rectus fascia or some other structure to cradle the urethra in a supporting hammock. This both supports the urethra and allows it to be compressed during periods of increased intraabdominal pressure ([130,131,132,133,134,135,136,137,138,139](#) and [140](#)). The sling can be made of organic or inorganic materials. Organic materials can be autologous tissues harvested from the patient (e.g., fascia lata, rectus fascia, tendon, round ligament, rectus muscle, vagina), processed allografts from human donors (e.g., fascia lata, dermis), or heterologous tissues harvested from another species and processed for surgical use (e.g., ox dura mater, porcine dermis). Synthetic materials (e.g., Silastic, Gore-Tex, Marlex) are popular because of their consistent strength and easy availability, but these substances are often plagued by problems with erosion and infection when they are used around the urethra ([127,128](#) and [129](#)).

Technologic advances have made it possible to perform sling procedures completely through the vaginal approach using bone anchors, bone screws, and suture capturing devices. These devices decrease the morbidity resulting from an abdominal incision and may allow for earlier discharge and resumption of normal activity. The safety and efficacy of these modifications to the traditional sling procedure must be confirmed with comparative long-term outcome studies.

The most common problem encountered by patients for whom a sling procedure has been performed is obstructed voiding after surgery. The sling does not have to be pulled tight to work, but the common temptation of less experienced surgeons is to make the sling too tight in hopes of ensuring that the patient is cured. Not infrequently, patients with a sling require long-term bladder drainage using either a suprapubic catheter or clean intermittent self-catheterization. The symptoms of obstructed voiding—urgency, frequency, urge incontinence, incomplete emptying, low flow, intermittent stream, hesitancy, and increased residual urine—typically improve over time and often resolve. Some patients, however, require long-term self-catheterization. This possibility should be discussed with patients before surgery.

The number of sling procedures performed for stress urinary incontinence has increased markedly over the past several years. The use of donor allograft tissue for implantation has resulted in decreased morbidity and ease of performing these surgical procedures. The short-term results of surgery with these allografts have been promising; however, the concern over long-term results and reports of early failures necessitates additional research before human allografts can be recommended for most sling procedures ([139,140](#) and [141](#)). Sling procedures for simple and complex stress urinary incontinence continue to be an important treatment option with low morbidity when performed by experienced surgeons.

Periurethral Injections A less invasive treatment of intrinsic urethral failure is attempting to restore urethral closure by injecting a material around the periurethral tissues to facilitate their coaptation under conditions of increased intraabdominal pressure ([142,143,144,145,146](#) and [147](#)). This approach has been tried for years

with limited success, but advances in chemistry have allowed the development of materials better suited to the injection procedure, namely *polytetrafluoroethylene paste (Polytet)*, *glutaraldehyde cross-linked bovine collagen (Contigen)*, and *pyrolytic carbon-coated zirconium beads (Durasphere)*. A small-gauge needle is inserted into the periurethral tissues, and the material is injected along the urethra at the level of the bladder neck. This seems to work by bulking up the bladder neck, allowing enhanced urethral closure under stress, rather than by changing the resting urethral pressure. *Teflon* is harder to work with and requires the use of a power-injector. It also has been shown to migrate to other areas of the body under some circumstances. *Contigen* can be passed easily through small-bore needles under local anesthesia but requires preoperative skin testing to check for possible allergic reactions (3%). *Durasphere* is nonantigenic (thus no skin testing is required) and does not migrate. *Durasphere* appears to have similar reduction in leakage episodes as compared with collagen and is more likely to require only a single injection (147). This bulking agent does require a larger-gauge needle for injection and is somewhat more difficult to inject than collagen. These techniques may require several injections to achieve continence, and the long-term success of these operations remains poorly studied. The development of a bulking agent that is easy to inject, is nonantigenic, has a minimal inflammatory response, and does not degrade or migrate should result in increased efficacy in properly selected patients.

Salvage Operations

The best opportunity to cure stress incontinence occurs at the time of the initial operation. Subsequent surgeries have a lower success rate, and the chances of success seem to diminish with each subsequent operation (65). In some cases, the surgeon is faced with a scarred, fibrotic nonfunctional urethra in a hopelessly incontinent patient. This type of patient requires what can best be called “salvage” operations—a last ditch effort for cure. Such patients may benefit from periurethral collagen injections. Others may benefit from the placement of a deliberately obstructive sling, with the plan that the patient will drain her bladder by self-catheterization for the rest of her life. Still others may benefit from the implantation of an artificial urinary sphincter, a high-technology approach to incontinence that appears to work better for males than females (148,149). Finally, others may require urinary diversion. Only a small percentage of women with stress incontinence require such measures.

Urinary Incontinence Caused by Detrusor Overactivity

Although stress incontinence is the most common type of urinary continence in women, urge incontinence caused by detrusor overactivity is the most common form of incontinence in older women and the second most common form of urinary incontinence overall (150). In this condition, urine loss is caused not by failure of urethral support or closure but rather by uninhibited contractions of the detrusor muscle. Patients with this condition typically experience sudden, unexpected loss of large volumes of urine or leakage associated with a sudden urge to urinate that cannot be controlled. In both cases, urine loss occurs from an unsuppressed contraction of the bladder muscle, a failure to inhibit the micturition reflex. **When this occurs as the result of a known neuropathologic process relevant to bladder disorders (e.g., stroke, Parkinson's disease, multiple sclerosis), it is referred to as *detrusor hyperreflexia*. In cases in which there is no evidence of neuropathology (most cases), the condition is referred to as *detrusor instability*.** Both conditions can be called *detrusor overactivity* (65). Detrusor overactivity should be suspected in all cases in which the patient has symptoms of urgency, frequency, and urge incontinence. For patients who have frequency and urgency without incontinence, detrusor overactivity rarely is the cause of their problem. For most such cases, the cause of the symptoms is a disorder of bladder sensation (151,152).

Diagnosis

The diagnosis of incontinence caused by detrusor overactivity can be confirmed by cystometry. A rule for all incontinence evaluations is to demonstrate incontinence and confirm with the patient that what has been demonstrated reproduces her complaint. Subtracted filling cystometry for patients with an overactive detrusor should show phasic pressure waves that produce urgency and urge incontinence (Fig. 20.17). False-negative and false-positive results can occur. False-positive results occur for patients with asymptomatic detrusor activity, detrusor activity that is irrelevant to the complaint, or detrusor activity that is situational (e.g., caused by test anxiety). The false-negative results occur because 20-minute cystometry is not always an accurate measure of daily bladder activity. Looking for detrusor instability with such a test is like looking for an episodic cardiac arrhythmia using 12-lead electrocardiography, as opposed to looking for the arrhythmia using a 24-hour Holter monitor. The sensitivity of the latter test is far greater than that of the former. The same principles apply to stationary subtracted cystometry when compared with long-term ambulatory urodynamic studies (153,154 and 155). In most patients with a strong history of urge incontinence, a detrusor problem is the cause of leakage.

Figure 20.17 Subtracted cystometrogram showing detrusor overactivity. Notice that the rectal pressure stays relatively constant throughout bladder filling in the supine position, whereas there are phasic changes in intravesical pressure and subtracted detrusor pressure. These changes are diagnostic of uninhibited contractions of the detrusor muscle. In this patient, these contractions produced a large amount of urine loss. Note that the rise in rectal pressure that occurs when the patient stands (S) provokes an additional detrusor contraction.

Treatment

Detrusor overactivity can be treated using drugs or behavioral modification (150). The best initial choice is probably a combination of the two therapies. If possible, long-term management of this condition should be based on behavioral therapy for two main reasons. The first is that the drugs used in treating detrusor instability have unpleasant anticholinergic side effects. Most patients tire of these problems over time and discontinue medications. Second, the cure rates with behavioral treatment are comparable to those with drug therapy, and any drug therapy for this condition will be enhanced by modifying the behavior that contributes to detrusor overactivity.

Drug Therapy

The drugs used in treating detrusor muscle overactivity can be grouped into different categories according to their pharmacologic characteristics; however, for all practical purposes, these drugs are anticholinergic agents that exert their effects on the bladder by blocking the activity of acetylcholine at muscarinic receptor sites. Most of these drugs have a short half-life, which means that they must be taken frequently. All of these drugs have side effects, the most common of which are dry mouth resulting from decreased saliva production, increased heart rate because of vagal blockade, feelings of constipation resulting from decreased gastrointestinal motility, and occasionally, blurred vision caused by blockade of the sphincter of the iris and the ciliary muscle of the lens of the eye. Other drugs, such as *imipramine*, may produce orthostatic hypotension and cardiac arrhythmias. Patients should be encouraged to titrate their medication to their symptoms and to vary the dosage (within acceptable limits) according to their needs.

The introduction of two new medications for the treatment of detrusor overactivity has resulted in significant attention being given to urinary incontinence in the media—*tolterodine* and long-acting *oxybutynin*. *Tolterodine (Detrol)* is a muscarinic receptor antagonist with a long half-life, which means it can be taken once or twice daily. *Tolterodine* has demonstrated similar efficacy to immediate-release *oxybutynin* in the reduction of urinary frequency and episodes of urge-related urinary leakage. Significant reduction in the common complaint of a bothersome dry mouth was found in the *tolterodine* group compared with the group taking immediate-release *oxybutynin* and the placebo group (156,157). Long-acting *oxybutynin (Ditropan XL)* relies on a slow-release mechanism known as oral osmotic (OROS) technology to deliver a constant dose of *oxybutynin* throughout the day. By reducing fluctuations in serum levels through this constant-release mechanism, the new delivery system attempts to reduce the side-effect profile associated with traditional formulations. Long-acting *oxybutynin* appears to have better patient

compliance and reduced side-effects while maintaining efficacy similar to that of immediate-release *oxybutynin* (158,159).

A list of medications and the usual dosage ranges are given in Table 20.4. In general, it is best to start with a lower dose (particularly for elderly patients) and to increase it as needed to a higher, more frequent dosage. Patients with neuropathic detrusor hyperreflexia generally need more medication than patients with idiopathic detrusor instability. Patients should be warned of the anticholinergic side effects. Patients should be particularly advised about the symptom of a dry mouth and told that this is not due to thirst. Some patients increase their fluid intake to combat this problem, with a subsequent worsening of their incontinence. If dry mouth is a problem, patients should relieve it by chewing gum, sucking on a piece of hard candy, or eating a piece of moist fruit.

Drug	Dose
Tolterodine	1-2 mg PO b.i.d.
Tolterodine, long-acting	4 mg PO q.d.
Hyoscyamine sulfate	0.125-0.25 mg PO q. 4-6 hr
Hyoscyamine sulfate, extended release	0.375 mg PO b.i.d.
Oxybutynin chloride	5-10 mg PO t.i.d./q.i.d.
Oxybutynin chloride XL	5-15 mg PO q.d.
Dicyclanide hydrochloride	20 mg PO q.i.d.

Table 20.4. Drugs Useful in Treating Detrusor Overactivity

Behavioral Therapy

Behavioral therapy for detrusor instability is based on the assumption that the underlying pathophysiology is the escape of the detrusor from the cortical control over micturition that had previously been established during childhood toilet-training. The object of bladder retraining (or *bladder drill*, as it is sometimes called) is to reestablish the authority of the cerebral cortex over bladder function. This is performed through a regimen of timed voiding, gradually increasing the intervals between voids until the cycle of urgency, frequency, and urge incontinence is broken.

Behavioral therapy is carried out as follows:

1. The patient is instructed to void on a timed schedule, starting with a relatively frequent interval of every hour while she is awake.
2. When she wakes up in the morning, she voids at 6:00 AM, 7:00 AM, 8:00 AM, and so forth throughout the day. If it is 7:00 AM, and she does not feel the need to void, she must do so anyway. The object is to make her bladder do what she wants it to do, instead of responding to the whims of her bladder. If it is 7:55 AM and she is desperate to urinate, she cannot do so. She must wait until 8:00 AM, even if this means that she leaks some urine onto a pad. When the appropriate time arrives, she can empty her bladder.
3. At night, the patient is allowed to void only when she is awakened from sleep by the need to do so.
4. When she can maintain this schedule for 1 week, the voiding interval is increased by 15 minutes. It is increased gradually by 15 minutes every week until a normal voiding interval of 2.5 to 3 hours has been established.

This program works very well for patients with detrusor instability. The secret of success is gradual increases in the interval between voids. The best predictor of success is patient compliance; those who follow this program get excellent results. **Unfortunately, patients who have suffered a neurologic insult that has resulted in detrusor hyperreflexia do not respond very well to bladder retraining because the problem is actually one of neural pathway destruction rather than the need to reestablish cortical control mechanisms.** Frequently, these patients have a trigger volume of urine that sets off a contraction that they cannot control voluntarily. Such patients may benefit from a timed voiding schedule in which they void at regular intervals (such as every 2 hours) to keep their bladder volume below the trigger point. Attempting to lengthen the interval between voids often does not work well.

Functional Electrical Stimulation

Functional electrical stimulation similar to that used with stress urinary incontinence has also been used in treating overactive bladders that have not responded to other medical and behavioral therapy. Several prospective, double-blind studies have demonstrated cure or improvement in 50% of patients with overactive bladders (160,161) using this technology. Economic and reimbursement issues, as well as issues related to access, patient compliance, and acceptability of the therapy, have limited the use of electrical stimulation for the treatment of detrusor overactivity in the past, but many of these questions are being answered, opening up a whole new range of exciting treatment possibilities in the future.

Sacral Nerve Root Neuromodulation

Even with the development of newer anticholinergic medications with fewer side effects, there continues to be a select group of patients with overactive bladders who remain refractory to standard medical and behavioral treatment. Surgical treatment of this condition has traditionally involved substantial morbidity and major urinary denervation, reconstruction, or both in order to achieve therapeutic benefits. For example, augmentation cystoplasty for refractory urge incontinence has significant short-term operative morbidity and often results in long-term voiding dysfunction that requires clean intermittent catheterization to achieve bladder emptying. The development of implantable sacral nerve root stimulators has led to FDA approval of sacral root neuromodulation in patients with refractory urinary urgency and frequency, urge incontinence, and voiding dysfunction. This therapy offers patients with severe symptoms an alternative to urinary augmentation or diversion. Sacral nerve stimulation therapy is performed in two phases. In the first phase, a percutaneous nerve evaluation test (PNE) is performed to determine which patients respond to this type of therapy. This phase is followed by surgical implantation of a permanent electrode lead adjacent to the third sacral nerve root connected to a pulse generator in those patients who are identified as appropriate candidates after a successful test stimulation (this technique results in more than 50% improvement in symptoms).

A multicenter prospective study demonstrated that 63% of test patients responded to the initial procedure. After implantation, 47% of patients became completely dry, and 77% were successful in eliminating "heavy" leakage episodes. Despite substantial success in nearly 80% of patients who received implants, 30% of patients required further surgical revision because of pain or other complications at the generator or implant site. There were no permanent injuries or nerve damage in the initial trials (162,163). This therapy offers an alternative to radical surgery for many patients in whom other treatment options have been unsuccessful.

Mixed Incontinence

Patients are said to have mixed incontinence when they have motor urge incontinence as a result of detrusor overactivity along with stress incontinence. Because most patients have mixed symptoms, every effort should be made to confirm the diagnosis and to demonstrate stress and urge incontinence objectively before establishing such a diagnosis. Patients with mixed incontinence often pose complicated management problems, and controversy exists regarding the best method of treating them. In the confirmed presence of both types of urinary incontinence, one reasonable approach is to try to determine which symptom is more bothersome to the patient—stress incontinence or urge incontinence—and to proceed from that point (164). Others advocate using conservative therapy to treat urge incontinence first, proceeding with surgery only if stress incontinence persists. Because patients with mixed incontinence have a lower continence rate after surgery than patients with genuine stress incontinence alone, this approach is reasonable. However, some patients experience the *de novo* onset of detrusor overactivity after stress incontinence surgery, and detrusor instability resolves in some patients with mixed incontinence after surgery for stress incontinence. **Bladder neck suspension surgery is contraindicated for patients with detrusor instability alone as the cause of their incontinence. Patients with mixed incontinence, a small functional bladder capacity, and high-pressure detrusor contractions on filling cystometry should undergo operations for stress incontinence only after careful consideration of their individual circumstances and a comprehensive clinical and urodynamic evaluation.**

Functional or Transient Incontinence

In addition to stress incontinence and incontinence caused by detrusor overactivity, a variety of other conditions may cause involuntary urine loss that is a social or hygienic problem (Table 20.2). Among the most important of these causes are those that are loosely categorized as functional or transient. The factors leading to urinary incontinence of this type are medically reversible conditions. This gives them heightened importance (particularly for older women) because appropriate medical intervention can cure or improve the continence problem without resorting to other forms of treatment.

Resnick has invented the useful mnemonic DIAPPERS to help remember these factors (165,166) (Table 20.5). *Delirium* is an acute confusional state that may result in incontinence caused by disorientation. It is often associated with serious underlying pathology. *Infection* may lead to detrusor overactivity, which can be reversed by appropriate antimicrobial therapy. *Atrophic urethritis* and *vaginitis* can be a significant cause of urgency and frequency in older women. *Pharmacologic agents* of many types can have an adverse impact on urinary tract function. *Psychiatric diagnoses* may also be accompanied by incontinence. *Excessive urine production*, such as that found in diabetes, hypercalcemia, or excessive fluid intake, often leads to incontinence by overwhelming a bladder's capabilities to deal with large volumes of fluid. *Restricted mobility* often is associated with incontinence, particularly for elderly patients who, because of arthritis or unsteady gait, cannot reach toilet facilities or undress themselves quickly enough when the urge to urinate arises. Bowel disorders are often found in association with urinary tract problems, partly because of the shared innervation of these organ systems. *Stool impaction* is often found in elderly patients with urinary incontinence; relief of the impaction by prescribing a good bowel regimen to prevent the problem from recurring is often associated with improvement in the function of both organ systems. All of these factors argue strongly for the inclusion of a good medical evaluation as part of the workup of any patient with urinary incontinence.

Delirium
Infection
Atrophic urethritis and vaginitis
Pharmacologic causes
Psychological causes
Excessive urine production
Restricted mobility
Stool impaction

Table 20.5. Reversible Causes of Incontinence

Disorders of Bladder Emptying, Storage, and Contents

Voiding Difficulty

For women, disorders of urine storage (incontinence) are more common than disorders of bladder emptying (voiding difficulty), which tend to be the predominant problems in men because of the longer urethra and the presence of a potentially enlarged and obstructing prostate gland. Nonetheless, **women do suffer from voiding difficulties, which may be defined as emptying dysfunction resulting from a failure of pelvic floor relaxation or failure of the detrusor muscle to contract appropriately.** True outflow obstruction (defined as a detrusor pressure of more than 50 cm H₂O in association with a urine flow rate of less than 15 mL/sec) is rare in women and, when seen, is usually found in patients who have undergone obstructive bladder neck surgery for stress incontinence (106,167).

For normal voiding to occur, the pelvic floor and urethral sphincter must relax, which should occur in conjunction with a coordinated contraction of the detrusor muscle that leads to complete bladder emptying. Of course, the bladder may be emptied by other mechanisms, such as by abdominal straining in the absence of a detrusor contraction, or simply by relaxation of the pelvic floor if the closure mechanism is exceptionally weak; however, complete bladder emptying is not the same as normal voiding. Some women may empty their bladders completely, but only by expending great effort over several minutes. In such cases, voiding is clearly abnormal, even though the bladder is empty when voiding ceases. In the worst cases, voiding is both difficult and incomplete.

An example of voiding difficulty is the *detrusor-sphincter dyssynergia* that occurs in some patients with multiple sclerosis and other neuropathic conditions (168,169). With this condition, there is a lack of coordination between detrusor contraction and urethral relaxation, and the urethral sphincter contracts at the same time as the detrusor. This means that outlet resistance to voiding increases at the same time that intravesical pressure is increasing; hence, voiding becomes difficult if not impossible. Great effort is required to overcome urethral resistance; the patient voids with an interrupted stop-and-start stream and usually leaves a significant amount of residual urine.

Treatment

Voiding difficulty can be managed in several different ways, depending on the cause of the condition. Patients with pelvic floor spasticity (in the absence of a neurologic insult) can often be trained to relax the pelvic floor through biofeedback therapy and to void normally.

Drug Therapy

Mild sedatives are sometimes helpful in this process, as are α -blockers (e.g., prazosin, phenoxybenzamine), which reduce urethral tone. For patients who are unable to generate a detrusor contraction, attempts have been made to enhance detrusor contractility using a cholinergic agonist such as bethanechol chloride. Although cholinergic medications are successful in making strips of bladder muscle contract in a laboratory, there is little evidence that such drugs are helpful clinically (170).

Self-Catheterization

The mainstay in the treatment of voiding difficulty, therefore, is clean intermittent self-catheterization (171). The implementation of self-catheterization programs revolutionized the treatment of voiding difficulties and urinary retention by eliminating the use of chronic indwelling catheters for many patients. **The most important protection against urinary tract infection is frequent and complete bladder emptying rather than avoidance of the introduction of a foreign body into the bladder.** Self-catheterization allows the patient to accomplish this task using a small (14-Fr.) plastic catheter that she inserts through the urethra into the bladder, draining its contents. The catheter is then removed, washed with soap and water, dried, and stored in a clean, dry place. Elaborate sterile procedures are not necessary. Although bacteria are introduced into the bladder in this process, frequent emptying through self-catheterization greatly reduces the risk for urinary tract infection for these patients. The urine of women after self-catheterization regimens will always be colonized with bacteria; however, this condition should not be treated unless symptomatic infection occurs.

Sacral Nerve Root Neuromodulation

Even though self-catheterization can be used to treat women who have all types of voiding dysfunction, some women find this difficult or cumbersome to perform. Neuromodulation of the sacral nerve roots (S3 or S4) has proved to be an effective treatment option for some patients with nonobstructive urinary retention as well as for some patients with refractory urge incontinence. If test stimulation results in successful voiding, the implanted pulse generator results in clinical improvement in voiding symptoms in 70% of patients (163). Although this technology requires a major surgical procedure, many women favor this therapy over lifelong self-catheterization.

Suppressive Antibiotics

Voiding difficulty and stress incontinence pose special surgical problems, and many women with these conditions do not void normally after surgery, particularly if an

obstructive operation is performed. After surgery, voiding difficulty can be managed with self-catheterization and reassurance. If outflow obstruction is diagnosed on a pressure-flow voiding study (low flow in the presence of high pressure), however, it may be beneficial to take down the obstructive operative procedure and resuspend the bladder neck at a lower, less obstructed, level ([106](#)).

Chronic suppressive antibiotic therapy should not be used; instead, acute infections should be treated with an appropriate antibiotic for 3 days. This treatment prevents the selection of potentially dangerous drug-resistant bacteria, which pose a risk for these patients.

Acute Urinary Retention

Acute urinary retention exists when there is a sudden inability to void ([172](#)). The condition is painful, and, upon catheterization, a large volume of urine is released. Sometimes, the explanation is found readily, as in the case of a woman who develops urinary retention after the administration of an epidural anesthetic. A careful search should always be performed to determine the cause of the retention, particularly if any neurologic signs are present. The patient should be catheterized to decompress her bladder and prevent overdistention. Most patients should be taught self-catheterization. This procedure not only gives patients a better method of long-term bladder emptying than an indwelling catheter but also provides them with a “safety valve” in the event that the problem recurs unexpectedly in the future.

Disorders of Bladder Sensation

Most patients with disorders of bladder sensation experience pain rather than lack of bladder sensation. The cause of most painful bladder conditions is unknown, and the therapies currently used in treatment are only partially successful, similar to the treatment of most chronic pain syndromes. As a result, disorders of bladder sensation are among the most frustrating urogynecologic conditions.

Diagnosis

A careful history should be obtained, along with a sterile urine specimen for analysis and culture. Many women treated repetitively for chronic cystitis have taken multiple courses of antibiotics on the basis of symptoms without ever having had a culture-proven infection. Detrusor instability may be the cause of frequency, urgency, and urge incontinence but is not usually a factor in dysuria or painful urination. **Women older than 50 years of age (particularly smokers and workers exposed to chemicals) are at risk for bladder cancer, and this possibility must be considered, especially if hematuria is present. Urinary cytology is sometimes helpful in detecting early tumors of the urinary tract, and cystoscopy and intravenous urography are mandatory in the evaluation of patients with hematuria.**

Interstitial cystitis is a syndrome that presents as urgency, frequency, and bladder pain in the presence of a small bladder capacity, with bladder pain experienced on filling and relieved by voiding. Many different pathophysiologic processes factor into this condition, which complicates treatment ([173](#)). A number of possible causes must be considered in the differential diagnosis of painful voiding, including urethral diverticula; vulvar disease; endometriosis; chemical irritation from soaps, bubble bath, or feminine hygiene products; urinary stones; urogenital atrophy from estrogen deprivation; and sexually transmitted diseases ([174](#)).

The diagnosis of interstitial cystitis is largely one of exclusion; strict diagnostic guidelines have been developed for research protocols, but the criteria used to diagnose this condition in clinical practice are vague, shifting, and confusing. Hydrodistention of the bladder is believed to be of diagnostic value if Hunner's ulcers are seen; but this finding occurs infrequently in patients with irritative bladder symptoms. The cystoscopic findings of terminal hematuria and diffuse petechial hemorrhage or glomerulations are often seen on reinspection after filling to capacity. Bladder biopsies rarely assist in the diagnosis but may rule out other causes of the patient's symptoms. The use of a potassium chloride infusion test has been described in the evaluation of patients with painful bladder symptoms and is believed to be suggestive of interstitial cystitis in those patients with a positive response ([175](#)). The ideal diagnostic test for interstitial cystitis has not been determined.

Treatment

Typically, the clinician has no definitive diagnosis at the end of the evaluation and must rely on symptomatic treatment.

1. Frequency-urgency syndromes should be managed with a careful voiding regimen (similar to that used in the treatment of detrusor instability) and local care.
2. The use of urinary tract analgesics such as Urised is often helpful in reducing urethral irritation. Urised is a polypharmaceutical agent containing a mixture of *methenamine*, *methylene blue*, *phenyl salicylate*, *benzoic acid*, *atropine sulfate*, and *hyoscyamine*, which has a soothing effect on many irritative urethral symptoms.
3. Restricting the patient's intake of alcohol, caffeine, fruit juice, spices, artificial sweeteners, and food colorings often is helpful.
4. Instruction in the basics of vulvar and perineal hygiene is important (thorough drying; avoidance of most body powders, perfumes, or colored irritating soaps; avoidance of tight-fitting undergarments).
5. Hydrodistention of the bladder has been recommended as a treatment option and can result in clinical improvement in some patients.
6. *Pentosan polysulfate (Elmiron)* is an oral agent with *heparin*-like activity. This medication is designed to attempt to replacement of the glycoaminoglycan sulfate layer that is believed deficient in these patients.
7. Some patients benefit from the instillation of 50 mL of a 50% solution of *dimethylsulfoxide (DMSO)* for 20 to 30 minutes every other week for four or five sessions.
8. Because it has been theorized that bladder pain may result from increased histamine release, some patients benefit from medications that block these inflammatory mediators, such as *diphenhydramine hydrochloride*, 25 to 50 mg orally three times per day, in combination with 300 mg of *cimetidine* three times per day.

Pelvic Organ Prolapse

Pelvic support problems account for thousands of gynecologic surgical procedures each year, and yet our understanding of these conditions has advanced remarkably slowly over the past century. An increased appreciation of the various contributions of muscle, nerve, and connective tissue to pelvic organ support will probably change this situation within the next decade. Many basic questions have not yet been asked, and many basic clinical issues remain unresolved.

Definition and Classification

A prolapse is a downward or forward displacement of one of the pelvic organs from its normal location. Traditionally, prolapse has referred to displacement of the bladder, the uterus, or the rectum. These displacements have usually been graded on a scale of 0 to 3 (or 0 to 4); the grade increases with increasing severity of the prolapse, with 0 referring to no prolapse and 3 (or 4) referring to total prolapse (“prolapsed”) ([176](#),[177](#),[178](#) and [179](#)). All forms of female genital prolapse are described with reference to the vagina. True rectal prolapse (as contrasted to a rectocele) is discussed separately.

A variety of terms are used to describe female genital prolapse. Although these terms are generally unsatisfactory and somewhat inaccurate, they are so fixed in the literature that it is impossible to avoid discussing these terms.

- A *cystocele* is a downward displacement of the bladder.
- A *cystourethrocele* is a cystocele that includes the urethra as part of the prolapsing organ complex.
- A *uterine prolapse* is a descent of the uterus and cervix down the vaginal canal toward the vaginal introitus.
- A *rectocele* is a protrusion of the rectum into the posterior vaginal lumen.
- An *enterocele* is a herniation of the small bowel into the vaginal lumen.

Unfortunately, these descriptive terms are inaccurate and misleading. They prejudge the true nature of any prolapse by focusing attention on the bladder, rectum, or uterus rather than on the specific defects that are responsible for alterations in vaginal support. Furthermore, these terms are used in combination with an imprecise (and usually unspecified) system of grading, and they do not convey useful comparative information. The lack of an accurate system of classification of pelvic support

defects has hampered progress in the clinical evaluation and treatment of patients with prolapse.

What is observed during a pelvic examination of patients with these conditions is an alteration in vaginal anatomy: anterior vaginal wall descent, posterior vaginal wall descent, a lateral vaginal support defect, cervical descent, or descent of the vaginal apex (in patients who have had a hysterectomy). To name these areas of vaginal descent after the organs that are presumed to be responsible for them prejudices many clinical issues and can lead the surgeon into problems for which he or she may not be prepared; for example, when an “occult” enterocele is discovered during a rectocele repair or when vaginal eversion occurs after surgery because its apex was not believed to be involved in the support defect. Similarly, lumping defects of vaginal support into organ compartments or broad categories such as “cystocele” or “rectocele” draws attention from the precise nature and location of the defects of pelvic support that are present.

As a result of the deficiencies in the traditional classification, the International Continence Society standardization of terminology of female pelvic organ prolapse was developed and published in 1996 (180). The International Continence Society, the American Urogynecologic Society, and the Society of Gynecologic Surgeons have all adopted this standard system for the classification of female pelvic organ prolapse. In this system, anatomic descriptions of specific sites in the vagina replace the traditional terms (i.e., cystocele, rectocele, enterocele). This descriptive system contains a series of nine site-specific measurements. The classification uses six points along the vagina (two points on the anterior, middle, and posterior compartments) measured in relation to the hymen. The anatomic position of the six defined points should be measured in centimeters proximal to the hymen (negative number) or distal to the hymen (positive number), with the plane of the hymen representing zero. Three other measurements in the pelvic organ prolapse quantitative examination (POPQ) include the genital hiatus, perineal body, and the total vaginal length.

The genital hiatus is measured from the middle of the external urethral meatus to the posterior midline hymen. The perineal body is measured from the posterior margin of the genital hiatus to the midanal opening. The total vaginal length is the greatest depth of the vagina in centimeters when the vaginal apex is reduced to its full normal position (Fig. 20.18). All measurements except the total vaginal length are measured at maximal straining.

Figure 20.18 Standardization of terminology for female pelvic organ prolapse (POP-Q classification). This diagram demonstrates the anatomic position of the POP-Q sites including six sites involving the anterior (Aa, Ba), middle (C, D), and posterior (Ap, Bp) compartments with the genital hiatus (gh), perineal body (pb), and total vaginal length (TVL). (From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:12, with permission.)

The anterior vaginal wall measurements are termed Aa and Ba, with the Ba point moving depending on the amount of anterior compartment prolapse. Point Aa represents a point on the anterior vagina 3 cm proximal to the external urethral meatus, which corresponds to the bladder neck. By definition, the range of position of this point is -3 to $+3$. Point Ba represents the most distal or dependent point of any portion of the anterior vaginal wall from point Aa to just anterior to the vaginal cuff or anterior lip of the cervix. This point can vary depending on the nature of the patient’s support defect. For example, point Ba is -3 in the absence of any prolapse (it is never less than -3) to a positive value equal to the total vaginal length in a patient with total eversion of the vagina.

The middle compartment consists of points C and D. Point C represents the most depend edge of the cervix or vaginal cuff after hysterectomy.

Point D is the location of the posterior fornix; it is omitted if the cervix is absent. This point represents the level of the uterosacral ligament attachment to the posterior cervix. It is meant to differentiate suspensory failure from cervical elongation.

The posterior compartment is measured similarly to the anterior compartment; the corresponding terms are Ap and Bp. The nine measurements can be recorded as a simple line of numbers (i.e., -3 , -3 , -8 , -10 , -3 , -3 , 11 , 4 , 3 for points Aa, Ba, C, D, Ap, Bp, total vaginal length, genital hiatus, and perineal body). The six vaginal sites have possible ranges, which are dependent on the total vaginal length (Table 20.6). After collection of the site-specific measurements, stages are assigned according to the most dependent portion of the prolapse (Table 20.7). The POPQ examination often appears confusing on initial review; however, a measuring device (i.e., a marked ring forceps or marked cotton-tip applicator) can assist in instructing those unfamiliar with this staging system. The POPQ examination provides a standardized measurement system to allow for more accurate postoperative outcome assessments and to ensure uniform, reliable, and site-specific descriptions of pelvic organ prolapse. An inexpensive demonstration videotape describing the system and showing its use in several patients is available from the American Urogynecology Society.

Points	Description	Range
Aa	Anterior wall 3 cm from hymen	-3 cm to $+3$ cm
Ba	Most dependent portion of rest of anterior wall	-3 cm to $+TVL$
C	Cervix or vaginal cuff	$\pm TVL$
D	Posterior fornix (if no prior hysterectomy)	$\pm TVL$ or omitted
Ap	Posterior wall 3 cm from hymen	-3 cm to $+3$ cm
Bp	Most dependent portion of rest of posterior wall	-3 to $+TVL$

TVL, total vaginal length.
(Adapted from Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:11-12, with permission.)

Table 20.6. Possible Ranges of the Six Site-specific Pelvic Organ Prolapse Quantitative Examination Measurements

Stage 0	No prolapse is demonstrated. Points Aa, Ap, Ba, Bp are all at -3 cm, and point C is between total vaginal length (TVL) and $-(TVL - 2)$ cm.
Stage I	The most distal portion of the prolapse is >1 cm above the level of the hymen.
Stage II	The most distal portion of the prolapse is <1 cm proximal or distal to the plane of the hymen.
Stage III	The most distal portion of the prolapse is >1 cm below the plane of the hymen but no further than 2 cm less than the total vaginal length.
Stage IV	Complete to nearly complete eversion of the vagina. The most distal portion of the prolapse protrudes to at $\geq + (TVL - 2)$ cm.

Table 20.7. Stages of Pelvic Organ Prolapse

Symptoms of Prolapse

Asymptomatic pelvic prolapse generally does not require treatment, but the patient should be informed that she is losing some aspects of pelvic support, which may require treatment in the future. Symptomatic prolapse may manifest in several different ways. The most common symptom is a feeling of pressure or that something is protruding from the vagina. Patients often say they feel like they are sitting on an egg or they may complain of a dragging discomfort, which is described as a low backache or feeling of heaviness. Generally, this feeling is relieved by lying down, is less noticeable in the morning, and worsens as the day progresses, particularly if patients are on their feet for long periods. Specific types of prolapse may be associated with specific symptoms. Loss of anterior vaginal support often leads to urethral hypermobility, which in turn often (but not necessarily) results in stress urinary incontinence. A large anterior vaginal prolapse (or vaginal vault eversion) can produce symptoms of voiding difficulty. In such cases, the large prolapse comes out below the urethra, either compressing it from below or kinking it so that bladder emptying is incomplete or intermittent. An anterior protrusion of the rectum into the vaginal canal (rectocele) can cause symptoms of inefficient rectal emptying, often described by the patient as constipation. In severe cases, the patient may have to splint the posterior vagina with a finger during defecation, thereby reducing the pocket that is trapping stool back into its normal position. In most cases, however, constipation in women has causes other than a rectocele. The symptoms that result from a massive prolapse in which the entire uterus or vagina protrudes below the pelvic floor are self-explanatory.

Examination

In examining a patient with pelvic organ prolapse, all aspects of vaginal support should be carefully surveyed. Each area of vaginal anatomy should be described separately, and because **prolapse is almost invariably worse when the patient is upright, the clinician should become accustomed to examining patients in the standing position as well as in the standard dorsal lithotomy position.** The patient should stand on the floor with one foot elevated on a well-supported footstool. The examining gown can be lifted slightly to expose the genital region (Fig. 20.19). A standing pelvic examination allows the prolapse to be assessed when it is at its worst. A rectovaginal examination performed in this position is the best way of detecting an occult enterocele because the small bowel can be palpated easily in the cul-de-sac between the thumb and forefinger. A standing pelvic examination can be conducted quickly and efficiently.

Figure 20.19 Standing examination of the patient to detect the extent of pelvic organ prolapse. An enterocele is detected during a standing rectovaginal examination by palpating the small bowel between the thumb and index finger.

For a patient with prolapse, the traditional speculum examination of the vagina should be supplemented with a site-specific examination of the vagina using either a single-bladed speculum (such as a Sims speculum) or by taking a traditional Graves speculum apart and using the posterior blade as a single-sided retractor. This technique allows the clinician to perform the POPQ measurements by obtaining an adequate view of the anterior, posterior, and lateral vagina, looking for specific defects of vaginal support (Fig. 20.20A, Fig. 20.20B and Fig. 20.20C). This is important because a large prolapse of one side of the vagina may hold a smaller prolapse from the other side in place. This can result in misdiagnosis, such as when a large cystocele obscures the presence of a large rectocele, or when eversion of the vaginal apex is mistaken for a large cystocele.

Figure 20.20 Examination of a prolapse whose nature is unclear. **A:** Without more careful examination, the components of this prolapse are uncertain. When a speculum is placed posteriorly (**B**) and anteriorly (**C**) to inspect each vaginal wall separately, the prolapse goes away. This indicates that the patient has a prolapse of the vaginal apex, which has been elevated by the speculum in each instance. (From **Wall LL, Norton PA, DeLancey JOL.** Practical urodynamics. In: *Practical urogynecology*. Baltimore: Williams & Wilkins, 1993:307, with permission.)

As a general rule, any prolapse that lies within the vaginal lumen above the plane of the hymenal ring is of limited significance, particularly if the patient does not have symptoms.

Treatment

Asymptomatic prolapse does not need treatment. An exception is a woman with stress incontinence and prolapse who is about to undergo surgical bladder neck suspension. Most operations for stress incontinence elevate the anterior vagina and, in doing so, pull the posterior vagina forward. This opens the cul-de-sac, pulling it off the levator plate and thereby creating an opening for enterocele formation, the development of uterine prolapse, vaginal vault eversion, or worsening of an asymptomatic rectocele (108). Under these conditions, additional surgery in the form of a culdoplasty, rectocele or enterocele repair, or in some cases, hysterectomy, may be advisable.

Symptomatic prolapse can be treated conservatively or surgically, depending on the individual. Although pelvic muscle exercises may be of benefit to women with stress incontinence by strengthening urethral support, they have not proved beneficial for patients with significant prolapse. The pelvic muscles provide most of the support for the pelvic organs; after this support has become inefficient, increasing stress is placed on the connective tissue involved in pelvic support. When fascial attachments have been disrupted in the presence of poor muscular tone and clinically significant prolapse has developed, attempts to correct the problem by restoring muscular tone are not efficient. Pelvic muscle exercises are virtually never harmful, but under these circumstances, they are not likely to correct the problem.

P>

Pessary

Conservative management of prolapse usually involves fitting the patient with a pessary. A wide variety of shapes and sizes of pessaries are available. The use of pessaries is an important part of gynecologic practice that has been neglected in contemporary gynecologic residency training programs ([181](#)). Each patient should be fitted individually with her pessary, much as each individual is fitted for a contraceptive diaphragm. The patient who is using a pessary should have a well-estrogenized vagina. Postmenopausal women should be given hormone replacement therapy, or alternatively, they should use intravaginal estrogen cream on a regular basis. **For women who are past menopause, it is preferable to use intravaginal estrogen cream 4 to 6 weeks before the pessary is inserted because this makes the pessary more comfortable to wear, dramatically increases compliance, and promotes long-term use.**

Complications of pessary use include chronic irritation and erosion of a pessary into the bladder, creating a vesicovaginal fistula ([182,183](#)). All such cases are caused by neglect rather than the pessary itself. Patients who are using pessaries, particularly older women, should be examined on a regular basis. Some pessaries, such as the silicone doughnut pessary, can be left in place for months at a time without removal or inspection. Other pessaries, such as the cube pessary, which provides vaginal support through a gentle suction effect, ideally should be removed by the patient at bedtime each night and replaced in the morning to avoid erosions. The exact schedule of care should be based on individual circumstances. At the initial fitting, the patient should be encouraged to insert and remove the pessary herself. If the pessary fits and the patient is comfortable, it is helpful to reexamine her within 1 week and at least every 4 to 6 months thereafter.

Surgery

Traditionally, prolapse has been treated by surgery, the nature of which depends on the type of prolapse. The goal of surgery should be to relieve the patient of her symptoms by repairing each aspect of abnormal pelvic support in a durable and long-lasting manner. A detailed description of the various operations for managing pelvic support defects is beyond the scope of this chapter and can be obtained elsewhere ([184,185](#)); however, a few general remarks are in order.

Most patients with prolapse have defects in more than one location; thus, attention should be paid to correcting all defects during the same operation. Operations for prolapse are generally, but not always, carried out through the vaginal route rather than through the abdominal surgical route. Some conditions, such as stress urinary incontinence, are more reliably handled by an abdominal operation.

Operations for Vaginal Prolapse

Vaginal Hysterectomy Uterine prolapse is generally treated with vaginal hysterectomy, which may be accomplished by several different techniques. The advantage of vaginal hysterectomy is that it allows other vaginal surgery (e.g., anterior and posterior colporrhaphy or enterocele repair) to be performed at the same time, without the need for a separate incision or for repositioning the patient. At the time of hysterectomy for prolapse, special attention should be paid to closing the cul-de-sac using a McCall culdoplasty and to reattaching the endopelvic fascia and the uterosacral ligaments to the vaginal cuff to provide additional support ([186](#)). These same steps should be performed with abdominal hysterectomy ([187](#)). This reattachment to the uterosacral ligaments can be used both as a prophylactic procedure to prevent future posthysterectomy vaginal vault prolapse and as treatment for uterine prolapse. A modification to the standard plication, the high lateral fixation of the vaginal apex bilaterally without midline plication of the uterosacral ligaments, recreates normal anatomy with durable results ([188,189](#)). With any reconstructive procedure that requires plication or suspension to the uterosacral complex, care must be taken to avoid the ureters and ensure their postoperative patency ([190](#)).

Manchester/Fothergill Operation An alternative to hysterectomy for patients with uterine prolapse is the Manchester operation, originally described in 1888 by Donald and subsequently modified by Fothergill. In this operation, the bladder is dissected off the cervix, which is then amputated. The cardinal ligaments are sewn to the anterior cervical stump, and the posterior vagina is closed over the rest of the opening. This operation is usually performed in conjunction with an anteroposterior colporrhaphy, and it is usually done for the sake of expediency in patients who are poor surgical risks and who do not desire future fertility.

Uteropexy Occasionally, marked uterine prolapse may develop in a young nulliparous patient who desires to retain her fertility. If prolapse cannot be managed successfully with a pessary, such patients present a surgical challenge. The older abdominal uterine suspension operations (Baldy-Webster, Gilliam, ventrofixation, or hysteropexy) do not work for patients with significant uterine prolapse. There is anecdotal evidence of success in such patients using sacrospinous ligament fixation or retroperitoneal abdominal uterosacropexy, suturing mesh or fascia to the uterosacral ligaments and then to the anterior longitudinal ligament of the sacrum. There is little information available regarding long-term follow-up of such patients.

Paravaginal Defect Repair Operation Anterior vaginal prolapse has been treated with anterior colporrhaphy, plicating the endopelvic fascia in the midline under the bladder neck. If the anterior vaginal prolapse results from a lateral detachment of the endopelvic fascia from the lateral pelvic sidewall, however, better results will be obtained by performing a lateral repair. In this technique, the endopelvic fascia is reattached to the arcus tendineus fasciae pelvis through what is referred to as a *paravaginal defect repair* operation ([91,92,177,178](#)). Although generally this procedure is performed through an abdominal incision, operating in the space of Retzius, some surgeons are now performing it through a vaginal incision. In patients with severe or recurrent anterior defects, the traditional repair is now being reinforced with fascia lata or another graft material ([191,192](#)).

Posterior Colporrhaphy Repair of posterior vaginal prolapse for rectocele and enterocele is also performed vaginally using posterior colporrhaphy. In a rectocele repair, the posterior vagina is opened, the rectum is dissected away from the pararectal fascia, and the levator ani muscles are plicated over the rectum in the midline, after which the vaginal epithelium is closed. Because of concern over postoperative dyspareunia, recent modifications of posterior colporrhaphy have included site-specific repair. In this technique, the posterior vaginal epithelium is opened in the traditional fashion, and breaks in vaginal muscularis or Denonvillier's fascia are identified by using a finger in the rectum to demonstrate the defect. The traumatic separations may occur in various directions and be of varying magnitude; however, it is usually possible to identify and repair these defects ([193,194](#)). The site-specific repair technique for posterior compartment relaxation offers a more logical correction than the standard plication procedure and appears to have success rates similar to those of traditional approaches but with less vaginal narrowing.

An enterocele is a peritoneal hernia, usually seen over the rectum, often appearing as a second bump higher up in the vaginal canal on examination. The peritoneal sac should be carefully identified, opened, and closed with several pursestring sutures of permanent material; the sac should be excised, and the vagina should be closed once more over the defect. If the perineal body is noted to be deficient and the patient has a gaping introitus, this deficit may be repaired by a perineorrhaphy or perineoplasty, in which the vaginal fourchette is opened and the base of the levator ani muscle is pulled together in the midline, providing renewed support for the lateral vagina at its outlet.

Operations for Complete Eversion of the Vagina

Among the most challenging cases are those involving complete eversion of the vagina in patients who have had a previous hysterectomy. This condition virtually always requires surgical correction because of the large size of the prolapse, its propensity to enlarge over time because of increases in intraabdominal pressure, and the rare danger of vaginal evisceration if it is not treated.

Colpectomy and Colpocleisis For some patients, particularly elderly women who are not sexually active and who lead a sedentary lifestyle, the condition can be managed by surgically removing the vagina and closing off the space (colpectomy and colpocleisis). The correction of a significant and bothersome pelvic prolapse in elderly patients can often be completed using this technique with local anesthesia. These operations have proved very successful in preventing recurrent prolapse if patients are selected properly ([195](#)). The surgeon must consider both the patient's future coital activity as well as underlying issues relating to self-image if consideration is given to an obliterative procedure.

Colpopexy A different procedure is required for younger women and for women who wish to retain sexual function. For these women, the condition can be managed transvaginally or transabdominally. With the transvaginal approach, vaginal eversion is corrected by suturing one or both sides of the vaginal apex (usually the right side) to the sacrospinous ligament with one or two sutures—a transvaginal sacrospinous colpopexy. Other transvaginal reconstructive procedures for the management of advanced posthysterectomy vaginal vault prolapse (stage 3 to 4) include enterocele ligation and uterosacral ligament suspension or vaginal vault suspension using the iliococcygeal fascia on the pelvic sidewall. These procedures are performed transvaginally and have demonstrated effectiveness in restoring normal vaginal anatomy ([197,198](#)). In the transabdominal approach, the vaginal apex is suspended from the anterior longitudinal ligament along the sacrum using a graft of fascia or artificial mesh that is sutured to the vagina and to the sacrum in a retroperitoneal position—a transabdominal sacral colpopexy. The vaginal suspension should always be combined with a meticulous culdoplasty to repair the enterocele that coexists with vaginal eversion. All these operations are highly successful in resuspending the vaginal apex ([196,197,198](#) and [199](#)). Because the lines of force produced by increases in intraabdominal pressure are directed across the vagina differently after the two operations, patients who have recurrent prolapse postoperatively tend to have different problems. As a rule, recurrent anterior

vaginal prolapse is more common in patients with vaginal eversion if they have had a sacrospinous ligament fixation, whereas recurrent posterior vaginal prolapse is more common if they have undergone an abdominal sacral colpopexy. Some authors have suggested that recurrent posterior relaxation can be prevented by a colpoperineopexy in which mesh is attached all the way down to the perineal body during the suspension operation (200). It is unclear which is the best route for correcting posthysterectomy vaginal vault prolapse, and there are few clinical data comparing the vaginal or abdominal approaches (201,202). The most appropriate procedure must be individualized to each patient's clinical findings and the operating surgeon's expertise in reconstructive pelvic surgery.

Colorectal Dysfunction

Pelvic floor disorders span all three anatomic compartments of the pelvis: urinary, genital, and colorectal. Any approach to pelvic floor dysfunction that ignores colonic and rectal problems will not meet the needs of these women. Disorders of colonic and rectal function are disproportionately prevalent among women and represent a major area of continuing clinical neglect in women's health care (1). Although gynecologists and urologists have made great strides in jointly evaluating and treating urinary incontinence, to date neither specialty has done a creditable job of incorporating the treatment of posterior compartment problems into patient care. Because they are often the first physicians that women see for pelvic floor disorders, gynecologists have an obligation to become knowledgeable about common colorectal complaints. Not only can many of these problems be evaluated and treated initially by gynecologists, but a familiarity with colorectal conditions and a good working relationship with a colon and rectal surgeon or an interested gastroenterologist will also help educate practitioners of these specialties about the genitourinary complaints that frequently accompany disorders of the posterior pelvis. Among the more common conditions with which gynecologists should be familiar are anal incontinence, rectal prolapse, constipation, fecal impaction, and irritable bowel syndrome (see Chapter 14).

Anal Incontinence

Anal incontinence refers to involuntary passage of flatus or feces (either liquid or formed stool) through the anal canal. The term *anal incontinence* is therefore a more comprehensive term than *fecal incontinence*, which refers only to the involuntary passage of stool (203,204). Many women have disabling loss of gas, even though they are able to control feces. Although it is becoming more acceptable socially to talk about urinary incontinence, discussion of fecal loss still remains a taboo subject. Even patients with severe anal incontinence often will refuse to bring this problem to the attention of their doctor because of the extreme embarrassment involved. Physicians must ask patients directly (but sensitively) about loss of bowel control in order to elicit this complaint. The problem is more prevalent than most people realize: in one large household survey, 7.1% of the general population reported some degree of anal incontinence (205).

Diagnosis

Normal anal continence depends on the harmonious integration of many factors, including anal sphincter function, anorectal sensation and reflexes, colonic transit, rectal distensibility (compliance), stool consistency, stool volume, and the patient's level of mental functioning. As in the case of urinary incontinence, there are multiple potential causes of anal incontinence (203,204,205,206,207,208 and 209) (Table 20.8).

Table 20.8. Causes of Fecal Incontinence

History

A thorough history regarding bowel function should delineate the nature and frequency of anal loss. Loss of flatus alone is usually (but not necessarily) less troublesome than frequent loss of formed stool. The presence of liquid stool or diarrhea often represents a challenge that a decompensated sphincter cannot withstand, and this condition may respond favorably to bulking agents. If the history is uncertain, administration of a normal saline enema often is helpful in determining the diagnosis. The patient who can retain 1,000 to 1,500 mL of normal saline without leakage is unlikely to have a significant problem with anal incontinence (207). Important pieces of information include changes in stool frequency or consistency, history of blood in the stool, associated medical conditions (especially diabetes and related neurologic problems), medication use, obstetric history, and any history of pelvic or perianal surgery. It is also important to determine whether the patient ever notices anything protruding from the anus because rectal prolapse often is associated with anal incontinence.

Examination

The perineum should be carefully inspected to determine the state of hygiene, the presence of fissures, and the status of the anal sphincter. Pelvic muscle reflexes should be checked in all patients with anal incontinence, and a vaginal and bimanual examination should be performed. The possibility of a disrupted sphincter or a rectovaginal fistula must be considered. The patient should be examined while straining to check for the presence of rectal prolapse. All patients should undergo a digital rectal examination with testing of the stool for occult blood: at least 50% of rectal carcinomas lie within reach of the examiner's finger. Many patients with fecal incontinence have a fecal impaction, which should be removed (210,211). The puborectalis muscle should be palpated through the posterior rectum. When the patient contracts this muscle, the examiner's finger should move anteriorly. Poor sphincter tone is indicated by gaping of the rectum when the puborectalis muscle is depressed. Direct inspection of the large intestine through the use of flexible sigmoidoscopy or colonoscopy should be considered in all patients.

Tests

The American Gastroenterological Association has recently reviewed the major tests currently available for the evaluation of anorectal function (212). Anorectal manometry, endoanal ultrasonography, and evacuation proctography (defecography) are the most useful diagnostic tests; there are others, but they are less useful in clinical decision making.

Anorectal Manometry Anorectal manometry is a test performed to evaluate anorectal sensation, resting and squeeze pressures, compliance (distensibility), and reflexes. The test may be performed with solid-state transducers or water-perfusion techniques. In anorectal manometry, the pressure-measuring device is slowly withdrawn through the rectum and anal canal at rest and during intermittent squeeze maneuvers. Pressure gradients are calculated, and the response of the anus and rectum to distention with an air-filled balloon is evaluated. Specific resting and squeeze values cannot distinguish continent from incontinent patients, but patients with low squeeze pressures are more likely, as a group, to be incontinent than those who have higher values. Patients with low anal compliance (often due to radiation fibrosis or proctitis) tend to have urgency symptoms; when these patients undergo anorectal surgery, they tend to have less successful operative outcomes. Measurement of sensory thresholds is important in patients with anal incontinence because one of the most effective interventions is biofeedback training to improve anorectal sensation (213).

Endoanal Ultrasonography Endoanal ultrasonography is performed using a rotating ultrasound probe inserted into the anal canal that produces a circumferential view of the anatomy of the internal and external anal sphincters. It is currently the procedure of choice for evaluating sphincter damage, particularly from obstetric causes. Endoanal ultrasonography performed after vaginal childbirth has revealed a very high rate of occult sphincter injury in women who did not have a known perineal laceration at delivery (214). Although many of these women do not have symptoms in the immediate postpartum period, the long-term consequences of

occult sphincter injury are unclear. Such an injury may play an important role in the development of anal incontinence in later life. Endoanal ultrasonography is important in helping the clinician decide whether surgical repair will aid patients who have anal incontinence.

Evacuation Proctography Evacuation proctography is a radiographic test in which stoollike contrast material (usually a barium paste) is instilled into the rectum. The utility of the test can be enhanced by putting additional contrast in the bladder and vagina and by having the patient ingest contrast material before the study to opacify the small bowel. Cinefluoroscopic images are then taken with the patient sitting on a radiolucent commode so that the mechanism of rectal evacuation can be studied. The test is useful for evaluating puborectalis muscle function, detecting the presence of occult enteroceles, and evaluating patients for the presence of rectal prolapse and intussusception. These studies are most useful if done collaboratively by a pelvic floor physician and radiologist with special interest in this area (215).

Because the external anal sphincter is innervated by the pudendal nerve, assessment of pudendal nerve function would appear to have a role in the evaluation of patients with anal incontinence. Unfortunately, the pudendal nerve is hidden in the pelvis and traverses a tortuous pathway from the sacral spinal cord to the perineum, which varies significantly among different individuals. To date, it has not been possible to measure the length of the pudendal nerve accurately in individual patients; therefore, precise measurement of pudendal nerve conduction velocity (time of impulse transmission/length of pudendal nerve) is not possible. Numerous attempts have been made to correlate the time (latency) between a stimulus applied to the pudendal nerve at the ischial spine and its appearance at the anal sphincter, but the studies that correlate these results with clinical findings and surgical outcome are conflicting and their utility is questionable. The American Gastroenterology Association does not recommend this test in the evaluation of patients with fecal incontinence (212).

Treatment

Effective treatment of anal incontinence depends on its cause (204). The first step in treating fecal incontinence is usually bowel management, especially in patients with fecal impaction and resulting “overflow” incontinence. These patients respond well to disimpaction and the subsequent regular use of stool softeners and laxatives. Diarrhea can be evaluated and treated with bulking agents, often with surprisingly successful results. Antiflatulence preparations such as *Beano* (AK Pharma, Pleasantville, NJ) are often very helpful. High-fiber diets and stool-bulking agents will help the patient develop a more consistent stool that can be controlled more easily by the sphincter muscles. Antidiarrheal agents, such as loperamide or diphenoxylate with atropine, are also helpful. Daily tap water enemas can be used to help keep the rectum empty and to schedule predictable daily bowel movements. Biofeedback training is useful in helping patients regain control of sphincteric activity, especially when they have impaired rectal sensation. This technique allows patients to strengthen the muscles of the pelvic floor, to sense smaller volumes of stool in the rectum, and to improve their control over the anal sphincter mechanism, often with surprisingly good results (216).

Surgical repair should be considered in patients who have a demonstrable sphincter defect. The best results appear to be obtained using an overlapping sphincteroplasty rather than an end-to-end reapproximation of the torn sphincter (217). Although restoration of complete continence in most patients with an old sphincter injury is unlikely, the chance for substantial improvement is great enough that all patients should be offered the option of surgical repair if they are otherwise suitable candidates, irrespective of age (204). Patients with a rectovaginal fistula will obviously benefit from fistula closure. For some patients, construction of an anal neosphincter using transplanted gracilis muscle driven by an implanted pacemaker may be of benefit (218). Patients who have severe persistent incontinence after biofeedback therapy, medical management, and surgical treatment may be candidates for colostomy. An algorithm for the evaluation and treatment of fecal incontinence is given in Fig. 20.21 (204).

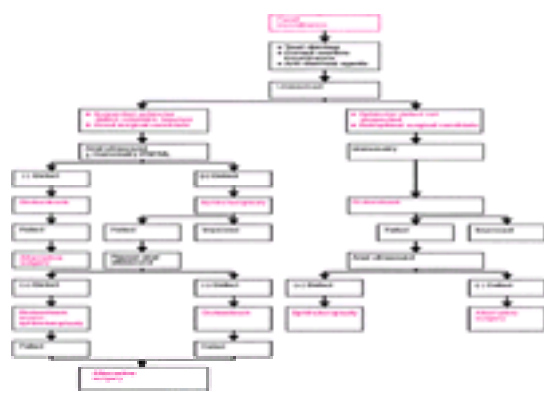

Figure 20.21 Treatment algorithm for fecal incontinence. (From Soffer EE, Hull T. Fecal incontinence: a practical approach to evaluation and treatment. *Am J Gastroenterol* 2000;95:1879, with permission.) PNTML, pudendal nerve terminal motor latency

Rectal Prolapse

Rectal prolapse is relatively uncommon but nonetheless is a significant clinical problem for those unfortunate enough to experience it. About 90% of patients with rectal prolapse are women (219). Normally, the rectum is attached firmly to the levator ani muscle complex through an extensive interweaving of longitudinal muscle fibers. This attachment is important because the rectum undergoes multiple changes in position and location during the normal act of defecation. Without this attachment, the rectum would slip down through the levator muscle hiatus during defecation. In rectal prolapse, this actually occurs. An intussusception of the rectum develops (for reasons not totally clear). Gradually, over time, the intussusception pulls the rectum away from its sacral attachments, ultimately allowing it to appear at or beyond the anal verge. Predisposing factors associated with rectal prolapse are summarized in Table 20.9 (219).

Poor bowel habits (especially constipation)
Neurologic disease (e.g., congenital anomaly, cauda equina lesion, spinal cord injury, syphilis)
Female sex
Nulliparity
Redundant rectosigmoid
Deep pouch of Douglas
Patulous anus (weak internal sphincter)
Distasis of levator ani muscle (defect in pelvic floor)
Lack of fixation of rectum to sacrum
Intussusception (also, secondary to colonic lesions)
Operative procedure (e.g., hemicolectomy, fistulectomy, abdominal perineal pull-through)

(From Corman ML. Rectal prolapse. In: *Gilbert and rectal surgery*. 2nd ed. Philadelphia: JB Lippincott, 1991:209-247, with permission.)

Table 20.9. Factors Associated with or Predisposing to Rectal Prolapse

Diagnosis

Most patients with rectal prolapse consider the presence of the prolapse itself as the major problem. Many patients have constipation; however, fecal incontinence also is commonly associated with rectal prolapse. Stretch injury of the pudendal and pelvic nerves may cause denervation injury to the rectum and resultant incontinence, but this finding is not always present. As the prolapse worsens, patients must replace the rectum manually to defecate. Occasionally, a rectal prolapse may become incarcerated; rarely, there is a transanal evisceration of small bowel from a ruptured rectal prolapse.

Patients with rectal prolapse should be examined while straining. If their sphincter tone is poor and the anus is patulous, subsequent surgical repair may not be satisfactory. If the tone of the pelvic muscles is good, however, the prognosis is more favorable. An important point is whether the prolapse is a full-thickness prolapse of the rectum or whether it is only a prolapse of the rectal mucosa. Examination of patients with rectal prolapse should include both digital examination and a thorough proctosigmoidoscopic or colonoscopic examination because a colonic cancer or sigmoidal polyp may form at the point at which an intussusception develops. Changes associated with the solitary rectal ulcer syndrome are frequently seen in patients with early rectal prolapse. The value of evacuation proctography in the evaluation of

(227,228 and 229). Many of these women appear to have disordered colonic motility of unknown etiology, and many of them exhibit paradoxical contraction (rather than relaxation) of the pelvic floor during defecation, resulting in fecal outflow obstruction. This condition has been termed the spastic pelvic floor syndrome. Although they are refractory to treatment by fiber supplementation and laxatives, some of these patients appear to benefit from biofeedback therapy that enables them to learn normal patterns of defecation and to relax the pelvic floor during a bowel movement (230). The possibility that they may have been victims of sexual abuse should always be considered in the differential diagnosis of such patients.

Endoscopy is a procedure that uses a narrow telescope to view the interior of a viscus space. Although the first medical endoscopic procedures were performed more than 100 years ago, the potential of this method has only recently been realized. Endoscopes are currently used to perform a variety of operations. In gynecology, endoscopes are used most often to diagnose conditions by direct visualization of the peritoneal cavity (laparoscopy) or the inside of the uterus (hysteroscopy).

When used appropriately, endoscopic surgery offers the benefits of reduced pain, improved cosmesis, lower cost, and faster recovery. The indications for endoscopic surgery are outlined here and detailed in the appropriate chapters. The technology, potential uses, and complications of laparoscopy and hysteroscopy are summarized here.

Laparoscopy

The past three decades have witnessed rapid progress and technologic advances in laparoscopy ([1,2,3,4,5,6,7,8,9,10,11](#) and [12](#)). Operative laparoscopy was developed in the 1970s; and in the early 1980s, laparoscopy was first used to direct the application of electrical or laser energy for the treatment of advanced stages of endometriosis ([6](#) and [7](#)). The use of high-resolution, lightweight video cameras in operative laparoscopy has made it easier to view the pelvis during the performance of complex procedures ([7,8,9](#) and [10](#)). Subsequently, many other procedures that were previously performed using traditional techniques, such as hysterectomy, became feasible with the laparoscope ([11](#)). However, the endoscopic approach may have drawbacks in some patients. Although some laparoscopic procedures appear to reduce the cost and morbidity associated with surgery, others have not been shown to be effective replacements for more traditional operations. The techniques and indications for operative endoscopy are evolving.

Diagnosis

The objective lens of a laparoscope can be positioned to allow wide-angle or magnified views of the peritoneal cavity. Laparoscopy is the standard method for the diagnosis of endometriosis and adhesions because no other imaging technique provides the same degree of sensitivity and specificity.

There are limitations to laparoscopy, however. The view is restricted, and if tissue or fluid becomes attached to the lens, vision may be obscured. Also, soft tissues or the inside of a hollow viscus cannot be palpated. For assessment of soft tissue, an imaging modality, such as ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) scans, is superior. Because of its ability to view soft tissue, ultrasonography is more accurate than laparoscopy for the evaluation of the inside of adnexal masses. The intraluminal contour of the uterus can be demonstrated only by hysteroscopy or contrast imaging. Ultrasonography, in combination with serum assays of b-human chorionic gonadotropin (b-hCG) and progesterone, can be used to diagnose ectopic pregnancy, usually allowing medical therapy to be given without laparoscopic confirmation ([12](#)). As a result of the advances in blood tests and imaging technology, laparoscopy is more often used to confirm a clinical impression than for initial diagnosis.

Laparoscopy may disclose abnormalities that are not necessarily related to the patient's problem. Although endometriosis, adhesions, leiomyomas, and small cysts in the ovaries are common, they are frequently asymptomatic. Thus, diagnostic laparoscopy must be performed prudently, interpreting findings in the context of the clinical problem and other diagnoses.

Therapy

The role of laparoscopy in the operative management of gynecologic conditions is still being defined. Many procedures previously in the domain of traditional abdominal and vaginal operations are feasible with laparoscopy. In addition to the benefits of endoscopic procedures in general, laparoscopic surgery is less likely than laparotomy to form adhesions. Because sponges are not used, the amount of direct peritoneal trauma is reduced substantially, and contamination of the peritoneal cavity is minimized. The lack of exposure to air allows the peritoneal surface to remain more moist and, therefore, less susceptible to injury and adhesion formation.

Despite these advantages, there are potential limitations: exposure of the operative field can be reduced, manipulation of the pelvic viscera is limited, and the caliber of the suture required may be larger than otherwise desired. In many cases, the cost of hospitalization increases, despite a shortened stay, because of prolonged operating room time and the use of more expensive surgical equipment and supplies. Efficacy may be reduced because surgeons may not adequately replicate the abdominal operation. In some patients, there is an increased risk for complications, which can be attributed to the innate limitations of laparoscopy, the level of surgical expertise, or both. With an adequate combination of ability, training, and experience, however, operative time and complications are comparable to those of traditional abdominal surgery.

Tubal Surgery

Sterilization Laparoscopic sterilization has been extensively used since the late 1960s and can be performed under local or general anesthesia. The tubes may be occluded by suture, clips, or Silastic rings, but electrosurgical desiccation with bipolar energy is the technique used most often (see [Chapter 10](#)). If an operative laparoscope is used, only one incision is required. Otherwise, a second port is needed for the introduction of the occluding instrument. Patients remain in the hospital

for several hours, even when general anesthesia is used. Postoperative pain is usually minor and related to the effects of the anesthesia, gas that remains in the peritoneal cavity (shoulder pain, dyspnea), and in the case of occlusive devices, pain at the surgical site. These effects normally disappear within a few days. The failure rate is about 5.4 per 1,000 woman-years ([13,14](#)).

Ectopic Gestation Ectopic gestation can be managed using laparoscopy to perform the same procedures done with laparotomy, including salpingostomy, salpingectomy, and segmental resection of a portion of the oviduct (see [Chapter 17](#)) ([15](#)). Salpingostomy is performed with scissors, a laser, or an electro-surgical electrode after carefully injecting the mesosalpinx with a dilute *vasopressin*-containing solution (20 units per 100 mL of normal saline). For salpingectomy, the vascular pedicles are usually secured with electro-surgical desiccation, ligatures, clips, or a combination thereof. Tissue is removed from the peritoneal cavity through one of the laparoscopic ports.

When salpingostomy is performed by any route, there is about a 5% chance that trophoblastic tissue remains. In such instances, medical treatment with *methotrexate* is considered appropriate (see [Chapter 17](#)). Consequently, b-hCG levels should be measured weekly until there is confidence that complete excision has occurred ([16,17](#)).

Ovarian Surgery

Ovarian Masses Laparoscopic removal of selected ovarian masses is a well-established procedure ([18,19](#)). However, controversy exists regarding the selection of tumors that can be removed by laparoscopy, because of concerns about an adverse effect on prognosis with malignant tumors ([20](#)). Preoperative ultrasonography is mandatory. Sonolucent lesions with thin walls and no solid components are at very low risk for malignancy and, therefore, are suitable for laparoscopic removal. For postmenopausal women, the measurement of CA125 may be useful in identifying candidates for laparoscopic management ([21,22](#)). Lesions with ultrasonographic findings suggestive of mature teratoma (dermoid) may also be suitable for endoscopic management ([23](#)). The ovarian tumors should be assessed by frozen histologic section, and any malignancy should be managed expeditiously by laparotomy ([22,24](#)).

Oophorectomy and cystectomy are performed similar to those for laparotomy ([16](#)). For cystectomy, scissors are used to separate the cyst from the ovary; if oophorectomy is performed, the vascular pedicles are ligated with sutures, clips, linear cutting staplers, electro-surgical desiccation, or a combination thereof. Most cysts are drained before extraction, through either a laparoscopic cannula or a posterior colpotomy. If there is concern about the impact of spilled cyst contents, the specimen can be removed in a retrieval bag inserted into the peritoneal cavity.

Although in the past the ovary has routinely been closed after cystectomy, this practice may be unnecessary and could contribute to the formation of adhesions ([25](#)). However, complete disruption of the ovarian cortex may make closure necessary. If so, the edges of the ovarian incision can be sutured.

Other Ovarian Surgery

Many cases of ovarian torsion previously treated by laparotomy and oophorectomy can be managed laparoscopically ([26,27](#)). If there is no apparent necrosis, the adnexa should be untwisted. Otherwise, adnexectomy is indicated.

Polycystic ovarian syndrome can be treated laparoscopically using electro-surgery and laser vaporization ([28,29](#) and [30](#)). Although such procedures have been shown to be successful, the occurrence of postoperative adhesions in 15% to 20% of patients underscores the need first to exhaust medical treatment ([31,32](#)).

Uterine Surgery

Myomectomy

Laparoscopic myomectomy, although feasible, is rarely performed, in part because its efficacy is yet to be established, especially as it relates to the treatment of infertility and menorrhagia ([33,34](#)). Also, laparoscopic myomectomy requires more technical skills than many other endoscopic procedures.

Unless the myoma involves the endometrial cavity, it is unlikely to contribute to heavy menstrual bleeding. Leiomyomas that cause pressure are often large and located in or near vital vascular structures. Myomectomy should be performed only when indicated (as opposed to expectant or medical management), and laparotomy should be used if there are technical limitations ([35](#)). **The only leiomyomas that are clearly appropriate candidates for laparoscopic excision are those pedunculated or subserosal lesions that cause pain in association with torsion** ([16,36](#)).

Hysterectomy

In many patients, hysterectomy can be performed under laparoscopic direction. **Laparoscopic hysterectomy encompasses a variety of procedures, including the facilitation of vaginal hysterectomy with variable extents of endoscopic dissection, supracervical hysterectomy by dissection, amputation and mechanical removal of the fundus, and the removal of the entire uterus with the assistance of the laparoscope** ([37](#)). The procedure is performed with scissors, sutures, electricity, clips, and, in some instances, linear cutting and stapling devices to dissect or ligate pedicles. Laparoscopic hysterectomy offers no advantage for women in whom vaginal hysterectomy is possible because the endoscopic approach is more expensive and has a higher risk for postoperative morbidity ([38,39](#)).

Infertility Operations

Laparoscopic treatment of infertility includes operations used to reconstruct the normal anatomic relationships altered by an inflammatory process: fimbrioplasty, adhesiolysis, and salpingostomy for distal obstruction ([40](#)). Fimbrioplasty is distinguished from salpingostomy because it is performed in the absence of preexisting complete distal obstruction. Endometriosis associated with adnexal distortion can be treated by laparoscopic adhesiolysis. There is no known additional benefit of laparoscopic (or medical) treatment to coexistent active endometriosis. Laparoscopy has been superseded by ultrasound for the retrieval of oocytes for *in vitro* fertilization but is still used for procedures in which gametes (gamete intrafallopian transfer) or zygotes (zygote intrafallopian transfer) are placed into the fallopian tube.

Adhesiolysis may be accomplished by blunt or sharp dissection with scissors, laser, or an electro-surgical electrode. These instruments are usually passed through an ancillary port; those who use laser energy frequently use the channel of the operating laparoscope. Although there has been controversy regarding the most appropriate modality, both methods are probably equally effective in appropriately trained hands.

Laparoscopic operations for the treatment of mechanical infertility are probably equally effective to similar procedures performed by laparotomy. In patients with extensive adhesions, however, the effectiveness of all procedures is limited. Assisted reproductive technologies such as *in vitro* fertilization and embryo transfer are necessary in these situations ([16,41](#)).

Endometriosis

The laparoscopic management of endometriomas parallels that of adnexal masses, although the ultrasonographic complexity of endometriomas may make it difficult to distinguish them preoperatively from a neoplasm. The relationship of the endometrioma to the ovarian cortex and stroma makes it difficult to find surgical dissection planes. There is a tendency either to compromise the function of the remaining ovary by attempting complete removal or to leave part of the endometrioma in place. Therefore, for women who want to retain their fertility, electro-surgical or laser ablative techniques may be used to treat endometriotic tissue that is adherent to the remaining ovary.

Multifocal endometriosis may be treated by mechanical excision or ablation, the latter using coagulation or vaporization with either electrical or laser energy. With proper use, each energy source creates about the same amount of thermal injury ([42,43](#)). Endometriosis is frequently deeper than appreciated, making excisional techniques valuable in many instances ([16,41](#)).

Pelvic Floor Disorders

Laparoscopy can be used to guide procedures to treat pelvic floor prolapse, including enterocele repair, vaginal vault suspension, paravaginal repair, and retropubic cystourethropey for urinary stress incontinence. Although these conditions can be treated vaginally, the abdominal approach may offer benefits, particularly with retropubic urethropey. There is some evidence that this procedure is effective when compared with the traditional approaches (44,45). The laparoscopic treatment of enterocele and vault prolapse may be useful in patients who require abdominal approaches after failure of a previous vaginal procedure.

Gynecologic Malignancies

The role of laparoscopy in the management of gynecologic malignancy has not been clearly established (24,46,47). However, a number of ongoing research protocols relating to cervical, endometrial, and ovarian cancer should help document this role. Lymph node biopsies performed by laparoscopy can be coupled with vaginal hysterectomy for the management of early-stage endometrial cancer. The potential for laparoscopic lymphadenectomy has fostered a resurgence of interest in vaginal radical hysterectomy for stage I carcinoma of the cervix. Laparoscopy is also being investigated for the staging of early ovarian malignancy and for second-look surgery.

Patient Preparation and Communication

The prospective patient must understand the rationale, alternatives, risks, and potential benefits of the selected approach. She should know what would probably happen if the procedure were not done and expectant management were used.

The expectations and risks of diagnostic laparoscopy, as well as those of any other procedures that may be needed, must be explained. The risks of laparoscopy include those associated with anesthesia, infection, bleeding, and injury to the abdominal and pelvic viscera. Infection is uncommon with laparoscopic surgery. For procedures involving extensive dissection, there is a higher risk for visceral injury. The potential for these risks should be clearly presented. The patient should be given realistic expectations regarding postoperative disability.

Because pain and visceral dysfunction normally continue to improve after uncomplicated laparoscopy, the patient should be instructed to communicate immediately any regression in her recovery. After diagnostic or brief operative procedures, patients can be discharged on the day of surgery and usually require 24 to 72 hours away from work or school. If extensive dissection is performed or the surgery lasts longer than 2 hours, hospital admission may be necessary, and the period of disability may be longer.

If the colon may be involved, mechanical bowel preparation should be performed to help improve visualization and minimize the need for a colostomy if the colon is entered. The patient should arrange for a friend or family member to discuss the results of the procedure and to drive her home if she is discharged the same day. Mild analgesia is often necessary.

Technique

Laser and electrical sources of energy manifest their effect by conversion to thermal energy. Highly focused energy produces vaporization or cutting, whereas less focused energy causes desiccation and tissue coagulation. Animal studies fail to demonstrate differences in injury characteristics (41,42 and 43). Randomized controlled studies have shown no differences in fertility outcomes in women undergoing CO₂ laser surgery and electrosurgery (48). Therefore, differences in results are more likely to be caused by other factors, such as patient selection, extent of disease, and degree of surgical expertise. With proper education, modern equipment, and adherence to safety protocols, these techniques can be used safely. To facilitate the discussion of laparoscopic equipment, supplies, and techniques, it is useful to divide procedures into “core competencies,” which are as follows:

1. Patient positioning
2. Operating room organization
3. Peritoneal access
4. Visualization
5. Manipulation of tissue and fluid
6. Cutting, hemostasis, and tissue fastening
7. Tissue extraction
8. Incision management

Patient Positioning

Proper positioning of the patient is essential for safety, comfort of the operator, and optimal visualization of the pelvic organs. Laparoscopy is performed on an operating table that can be rotated around the patient's long axis and tipped to create a steep, head-down (Trendelenburg) position. The footrest can be dropped to allow access to the perineum. The patient is placed in the low lithotomy position, with the legs supported in stirrups and the buttocks protruding slightly from the lower edge of the table (Fig. 21.1). The thighs are usually kept in the neutral position to preserve the sacroiliac angle, reducing the tendency of bowel to slide into the peritoneal cavity. **The feet should rest flat, and the lateral aspect of the knee should be protected with padding or a special stirrup to avoid peroneal nerve injury.** The knees should be kept in at least slight flexion to minimize stretching of the sciatic nerve and to provide more stability in the Trendelenburg position. **The arms are positioned at the patient's side by adduction and pronation to allow freedom of movement for the surgeon and to lower the risk for brachial plexus injury** (Fig. 21.2). Care must be exercised to protect the patient's fingers and hands from injury when the foot of the table is raised or lowered. After the patient is properly positioned, the bladder should be emptied with a catheter and a uterine manipulator attached to the cervix.

Figure 21.1 Patient positioning: the low lithotomy position. The patient's buttocks are positioned so that the perineum is at the edge of the table. The legs are well supported with stirrups, with the thighs in slight flexion. Too much flexion may impede the manipulation of laparoscopic instruments while in the Trendelenburg (head-down) position.

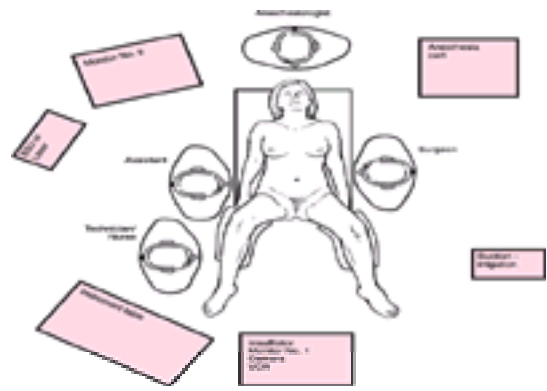

Figure 21.2 Operating room organization. The patient's arms are at the sides. The right-handed surgeon stands on the patient's left. Instruments and equipment are distributed around the patient within view of the surgeon. For pelvic surgery, the monitor should be located between the patient's legs. For upper abdominal surgery, or when operating from below, a monitor should be placed near the patient's head.

Operating Room Organization

The arrangement of instruments and equipment is important for safety and efficiency. The orientation depends on the operation, the instruments used, and whether the surgeon is right- or left-handed. An orientation for a right-handed operator is shown in [Fig. 21.2](#).

For pelvic surgery, the monitor should be placed at the foot of the table within the angle formed by the patient's legs. If a second monitor is used, one should be positioned at each foot of the patient. If upper abdominal surgery is also to be performed, the additional monitor should be moved to the head of the operating table.

The surgeon stands by the patient's left side, at an angle facing the patient's contralateral foot. The nurse or technician and instrument table are positioned near the foot of the operating table to avoid obscuring the video monitor. The insufflator is placed on the patient's right side, in front of the surgeon, to allow continuous monitoring of the inflation rate and intraabdominal pressure. The electrosurgical generator is also positioned on the patient's right side to permit visualization of the power output. When a laser is used through a second puncture site, it is also placed to the patient's right. When the laser is passed through the channel of an operating laparoscope, however, it is situated on the patient's left side, beside the surgeon.

Peritoneal Access

Before inserting the laparoscope, a cannula or port must be positioned in the abdominal wall to establish access to the peritoneal cavity. The *closed technique* is a blind approach in which the cannula is introduced with a sharp trocar used to penetrate the abdominal layers. In *open laparoscopy*, entry into the peritoneal cavity is achieved by a minilaparotomy, with the cannula fixed into position with sutures or other suitable techniques. Gynecologists have generally favored a closed technique, preinflating the peritoneal cavity with CO₂ through a hollow needle. In either case, additional cannulas are inserted by sharp trocars under direct vision to allow the use of laparoscopic hand instruments such as scissors, probes, and other manipulating devices.

Cannula insertion is aided by an understanding of the normal anatomy, especially the location of vessels ([Fig. 21.3](#)). A "safety zone" exists inferior to the sacral promontory in the area bounded cephalad by the bifurcation of the aorta, posteriorly by the sacrum, and laterally by the iliac vessels ([49](#)). In women placed in the Trendelenburg position, the great vessels are situated more cephalad and anterior, making them more vulnerable to injury unless appropriate adjustments are made in the angle of insertion ([Fig. 21.4](#)). Therefore, positioning of the insufflation needle, the initial trocar, and the cannula is best accomplished with the patient in a horizontal position. This approach also facilitates the evaluation of the upper abdomen, which is limited if the intraperitoneal contents are shifted cephalad by the head-down position.

Figure 21.3 Vascular anatomy of the anterior abdominal wall. Location of the vessels that can be traumatized when inserting trocars into the anterior abdominal wall.

Figure 21.4 Vascular anatomy. Location of the great vessels and their changing relationship to the umbilicus with increasing patient weight (*from left to right*).

Insufflation Needles

Virtually all insufflation needles are modifications of the hollow needle designed by Verres ([Fig. 21.5](#)). In cases uncomplicated by previous pelvic surgery, the preferred site for insertion is as close as possible to (or within) the umbilicus, where the abdominal wall is the thinnest.

Figure 21.5 Insufflation needle (Ethicon Endosurgery, Inc., Cincinnati, OH). When pressed against tissue such as fascia or peritoneum, the spring-loaded blunt obturator is pushed back into the hollow needle, revealing its sharpened end. When the needle enters the peritoneal cavity, the obturator springs back into position, protecting the intraabdominal contents from injury. The handle of the hollow needle allows the attachment of a syringe or tubing for insufflation of the distention gas.

1. **A 3-mm incision adequate for the needle is made with a small scalpel, and the abdominal wall is elevated by gripping it in the midline below the umbilicus.** Safe insertion of the insufflation needle mandates that the instrument be maintained in a midline, sagittal plane while the operator directs the tip between the iliac vessels, anterior to the sacrum but inferior to the bifurcation of the aorta and the proximal aspect of the vena cava. Therefore, in women of average weight, the insufflation needle is directed at a 45-degree angle to the patient's spine. In heavy to obese individuals, this angle may be increased incrementally to nearly 90 degrees, accounting for the increasing thickness of the abdominal wall and the tendency of the umbilicus to gravitate caudad with increasing abdominal girth (49). The needle's shaft is held by the tips of the fingers and steadily but purposefully guided into position only far enough to allow the tip's entry into the peritoneal cavity. The tactile and visual feedback created when the needle passes through the facial and peritoneal layers of the abdominal wall may provide guidance and help prevent overaggressive insertion attempts. This proprioceptive feedback is less apparent with disposable needles than with the classic Verres needle. With the former, the surgeon must listen to the "clicks" as the needle obturator retracts when it passes through the rectus fascia and the peritoneum. The needle should never be forced.
2. **In instances in which known or suspected intraabdominal adhesions surround the umbilicus, alternative sites for insufflation needle insertion should be used.** These include the pouch of Douglas, the fundus of the uterus, and the left upper quadrant, most often at the left costal margin (Fig. 21.6). The left upper quadrant is preferred if there has been no previous surgery in this area. In such patients, the stomach must be decompressed with a nasogastric or orogastric tube before the puncture.

Figure 21.6 Insufflation needle and cannula insertion sites. In most instances, both the insufflation needle, if used, and the primary cannula are inserted through the umbilicus. When subumbilical adhesions are known or suspected, the insufflation needle may be placed through the pouch of Douglas or in the left upper quadrant after evacuation of the gastric contents with an orogastric tube.

3. **Before insufflation, the operator should try to detect whether the insufflation needle has been malpositioned in the omentum, mesentery, blood vessels, or hollow organs such as the stomach or bowel.** Using a syringe attached to the insufflation needle, blood or gastrointestinal contents may be aspirated. This examination may be facilitated by injecting a small amount of saline into the syringe. If the needle is appropriately positioned, negative intraabdominal pressure is created by lifting the abdominal wall. This negative pressure may be demonstrated by aspiration of a drop of saline placed over the open, proximal end of the needle or, preferably, by using the digital pressure gauge on the insufflator.
4. **Additional signs of proper placement may be sought after starting insufflation.** The intraabdominal pressure reading should be low, reflecting only systemic resistance to the flow of CO₂. Consequently, there should be little deviation from a baseline measurement, generally less than 10 mm Hg. The pressure varies with respiration and is slightly higher in obese patients. The earliest reassuring sign is the loss of liver "dullness" over the lateral aspect of the right costal margin. However, this sign may be absent if there are dense adhesions in the area, usually the result of previous surgery. Symmetric distention is unlikely to occur when the needle is positioned extraperitoneally. Proper positioning can also be shown by lightly compressing the xiphoid process, which increases the pressure measured by the insufflator.
5. **The amount of gas transmitted into the peritoneal cavity should depend on the measured intraperitoneal pressure, not the volume of gas inflated.** Intraperitoneal volume capacity varies significantly between individuals. Many surgeons prefer to insufflate to 20 mm Hg for positioning of the cannulas. This level usually provides enough counterpressure against the peritoneum, facilitating trocar introduction and potentially reducing the chance of bowel or posterior abdominal wall and vessel trauma. After placement of the cannulas, the pressure should be dropped to 10 to 12 mm Hg, which essentially eliminates hypercarbia or decreased venous return of blood to the heart.

Laparoscopic Cannulas

Laparoscopic cannulas are necessary to allow the insertion of laparoscopic instruments into the peritoneal cavity while maintaining the pressure created by the distending gas (Fig. 21.7 and Fig. 21.8). Cannulas are hollow tubes with a valve or sealing mechanism at or near the proximal end. The cannula may be fitted with a Luer-type port that allows attachment to tubing connected with the CO₂ insufflator. Larger-diameter cannulas (8 to 12 mm) may be fitted with adapters or specialized valves that allow the insertion of smaller-diameter instruments without loss of intraperitoneal pressure.

Figure 21.7 Primary laparoscopic cannulas. Left to right: a nondisposable 10-mm cannula with the obturator removed (Olympus America, Inc., Woodbury, NY), a disposable 5- to 12-mm cannula with a "safety" sheath (Autosuture, Inc, Norwalk, CT), and a Hasson cannula used in open laparoscopy (Ethicon Endosurgery, Inc., Cincinnati, OH).

Figure 21.8 Ancillary laparoscopic cannulas: 5-mm laparoscopic cannulas for ancillary instruments. *Top:* Apple Medical, Boston, MA (disposable). *Middle:* Wolf, Laguna Niguel, CA (nondisposable). These cannulas neither have nor require ports or safety sheaths and are therefore less expensive than other cannulas. *Bottom:* Core Surgical Inc. (Jacksonville, FL).

The trocar is a longer instrument of slightly smaller diameter that is passed through the cannula, exposing its tip. Most trocars have sharp tips, allowing penetration of the abdominal wall after a small skin incision. Many disposable trocar-cannula systems are designed with a safety mechanism—usually a pressure-sensitive spring that either retracts the trocar or deploys a protective sheath around its tip after passage through the abdominal wall. None of these protective devices has been shown to make the procedure safer; however, they all increase the cost.

Cannulas can be inserted following minilaparotomy (open laparoscopy), after the successful creation of a pneumoperitoneum (secondary puncture), or without previously instilling intraperitoneal gas (primary puncture). With open laparoscopy, there is less risk for injury to blood vessels and abdominal viscera. However, open laparoscopy cannot prevent all insertion accidents because intestine can be entered inadvertently no matter how small the laparotomy. There is little evidence that secondary puncture is necessary, at least when there are no preexisting abdominal wall adhesions. Therefore, in women with no previous surgery, the primary puncture can be performed with a sharp-tipped trocar-cannula system, which lowers the cost by eliminating the need for the insufflation needle and by reducing operating time. The first, or primary, cannula must be of sufficient caliber to permit passage of the laparoscope and is usually inserted in or at the lower border of the umbilicus. The incision should be extended only enough to allow insertion of the cannula; otherwise, leakage of gas may occur around the sheath. For the primary puncture, an assistant should elevate the abdominal wall. For the secondary puncture, it is unnecessary to lift the abdominal wall during insertion. Both hands can be positioned on the device, using one to provide counterpressure and control to prevent “overshoot” and resultant injury to bowel or vessels. The angle of insertion is the same as for the insufflation needle; adjustments are made according to the patient’s weight and body habitus. The laparoscope should be inserted to confirm proper intraperitoneal placement before the insufflation gas is allowed to flow. Laparoscope cannulas can become dislodged and slip out of the incision during a procedure. There are a variety of cannula attachments designed to prevent slippage.

Previous abdominal surgery increases the incidence of adhesions of the bowel to the anterior abdominal wall, frequently near the umbilicus and in the path of the primary trocar. In such patients, another primary insertion site should be selected, even if it is used solely for conveying a narrow “scout” laparoscope, some types of which can be inserted through an insufflation needle (Fig. 21.9). Using such a laparoscope, the presence of adhesions under the incision can be confirmed or excluded, and the umbilical cannula can be inserted under direct vision. Alternate insertion sites for primary cannulas are shown in Fig. 21.6. Of these locations, the left upper quadrant is the most useful because adhesions are rarely present. Nasogastric or orogastric suction must be applied preceding insertion to improve vision and reduce the risk for gastric injury.

Figure 21.9 Scout laparoscopes. *Top:* the 2.7-mm-diameter Olympus/Ethicon Endosurgery system. The Imagn outer sheath is introduced with a standard diameter 15-cm insufflation needle, and the Olympus/Ethicon system is inserted with a 3-mm needle. *Bottom:* the 2-mm-diameter Imagn laparoscope (Imagn, Inc., Laguna Niguel, CA).

Ancillary Cannulas

Ancillary cannulas are necessary to perform most diagnostic and operative laparoscopic procedures. Most of the currently available disposable ancillary cannulas are identical to those designed for insertion of the primary cannula. However, many of the integrated design features of the primary cannula are unnecessary for ancillary cannulas. Consequently, simple cannulas without safety sheaths and insufflation ports are sufficient (Fig. 21.8).

Proper positioning of these cannulas depends on a sound knowledge of the abdominal wall vascular anatomy. They should always be inserted under direct vision because injury to bowel or major vessels can occur. Before insertion, the bladder should be drained with a urethral catheter. The insertion sites depend on the procedure, the disease, the patient’s body habitus, and the surgeon’s preference. The most useful and cosmetically acceptable site for an ancillary cannula is usually in the midline of the lower abdomen, about 2 to 4 cm above the symphysis. The ancillary cannula should not be inserted too close to the symphysis because it limits the mobility of the ancillary instruments and access to the cul-de-sac.

Lower-quadrant cannulas are useful for operative laparoscopy, but the inferior epigastric vessels must be located in order to avoid injury (Fig. 21.3). Transillumination of the abdominal wall from within permits the identification of the superficial inferior epigastric vessels in most thin women. However, the deep inferior epigastric vessels cannot be identified by this mechanism because of their location deep to the rectus sheath. **The most consistent landmarks are the medial umbilical ligaments (obliterated umbilical arteries) and the exit point of the round ligament into the inguinal canal.** At the pubic crest, the deep inferior epigastric vessels begin their cephalad course between the medially located umbilical ligament and the laterally positioned exit point of the round ligament. The trocar should be inserted medial or lateral to the vessels if they are visualized. **If the vessels cannot be seen and it is necessary to position the cannula laterally, the cannula should be placed 3 to 4 cm lateral to the medial umbilical ligament or lateral to the lateral margin of the rectus abdominis muscle.** If the insertion is placed too far laterally, it will endanger the deep circumflex epigastric artery. The risk for injury can be minimized by placing a 22-gauge spinal needle through the skin at the desired location, directly observing the entry through the laparoscope. This provides reassurance that a safe location has been identified and allows visualization of the peritoneal needle hole, which provides a precise target for inserting the trocar.

Even after a proper incision, the abdominal wall vessels can be injured if the trocar is directed medially. Large-diameter trocars are more likely to cause injury; therefore, the smallest cannulas necessary to perform the procedure should be used. Ancillary cannulas should not be placed too close together because this results in “knitting” of the hand instruments, which compromises access and maneuverability.

Visualization

During endoscopy, the image must be transferred through an optical system. Although direct optical viewing is feasible and often used for diagnostic purposes, virtually all operative laparoscopy is performed using video guidance.

Operative versus Diagnostic Equipment

Laparoscopes used for operative purposes have a straight channel, parallel to the optical axis, for the introduction of operating instruments. An advantage of such an endoscope is that it provides an additional port for the insertion of instruments and the tangential application of laser energy. However, operative endoscopes are of relatively larger caliber than diagnostic laparoscopes and have smaller fields of view and increased electro-surgical risks. Diagnostic laparoscopes permit better visualization at a given diameter and are associated with fewer electro-surgical risks.

Dimeter

Narrow-diameter laparoscopes allow limited transfer of light both into and out of the peritoneal cavity; therefore, they require a more sensitive camera or a more powerful light source for adequate illumination. Ideal illumination is provided by 10-mm diagnostic laparoscopes, but improvements in optics are making more procedures feasible with smaller-caliber devices ([Fig. 21.10](#)).

Figure 21.10 Laparoscopes. Top to bottom: 5-mm diameter (Olympus, Inc., Woodbury, NY), 10-mm diameter (Karl Storz, Agoura Hills, CA), and 2-mm diameter (Imagyn, Inc., Laguna Niguel, CA) laparoscopes. The 2-mm laparoscope can be inserted by a very narrow cannula passed through an insufflation needle.

Lenses

Most laparoscope lenses are made of optical-quality glass. The use of fibers is necessary for very-small-caliber laparoscopes (<3 mm in diameter) because lens integrity is not well protected by the flexible sheath. Relatively large-caliber fibers tend to “pixellate” the image, although the use of densely packed, fine-caliber fibers reduces this tendency, and with an adequate number and quality of fibers, it is eliminated altogether.

Viewing Angle

The viewing angle depicts the relationship of the visual field to the axis of the endoscope and is usually either zero or 30 degrees to the horizontal. The zero-degree scope is the standard for gynecologic surgery. However, the 30-degree angle provides some advantage in difficult situations such as the performance of retro-pubic urethropexy.

Imaging Systems

Video Cameras

The video camera captures the image transmitted by the endoscope with one or three light-sensitive, charged-coupled device (CCD) chips located in the camera head and coupled with the endoscope. Generally, the camera is attached to the eyepiece of the laparoscope, but with newer instruments, the chip will be affixed to the end of the device (“chip-on-a-stick”), obviating the need for an optical channel. In either case, the image is transmitted to the body of the camera located outside the operative field, where it is processed and sent to a recording device or monitor.

The key functional features of a camera are its light sensitivity and its horizontal resolution. Light sensitivity is measured in lux (1 lux = 1 lumen/m²); lower minimum lux ratings reflect increased sensitivity of the chips in the camera. The most sensitive cameras are rated at 1 lux, but for adequate imaging, the rating should be no higher than 5 lux when used with a 10-mm laparoscope and a 250- to 300-watt light source. Horizontal resolution is measured in lines; the best single-chip and triple-chip resolutions are about 500 and 700 lines, respectively. The images with the highest resolution are provided by cameras that separate chrominance from luminance (sometimes referred to as Y/C or S-Video) or by those that separate the three components of color (RGB—red, green, blue). These cameras are to be distinguished from the lower-resolution composite signals that are provided with standard coaxial cable television. However, the additional cost of triple-chip technology at this time is justified only for the creation of teaching videos or still images for publication.

Monitors

The resolution capability of the monitor should be at least equal to that provided by the camera. The best available monitors have the potential to display about 800 horizontal lines of resolution. This degree of resolution is not produced by S-Video or RGB systems; therefore, expensive Y/C- or RGB-capable cameras are unnecessary.

Light Sources

The more light transmitted through the endoscope, the better the visualization. The best currently available output is achieved from 250 to 300 watts, usually using xenon or metal halide bulbs. Most camera systems are integrated with the light source to vary light output automatically, depending on the amount of exposure required.

Light Cables

Light guides or cables transmit light from the source to the endoscope. They may be constructed of densely packed fibers (fiberoptic) or can be fluid filled. Fiberoptic cables lose function over time, particularly if they are bent at sharp angles, which breaks the fibers. Fluid-filled guides may initially supply more light but are less convenient than fiberoptic cables because they are heavier and less flexible.

Camera–Endoscope Couplers

These instruments connect the video camera to the laparoscope. Couplers with a beam splitter allow direct visualization by the surgeon with simultaneous video monitoring for the assistants. By sending the image through two optical channels, however, the brightness of each is reduced. Couplers also vary in focal length, which affects both the amount of screen occupied by the circular image and the depth of field in focus. For example, a coupler with a wide-angled 28-degree lens will fill all of the screen but will have less depth of field in focus than the smaller image of a 32-degree lens.

Some laparoscopes attach directly to the camera, making a coupler unnecessary. This feature further enhances light transmission and reduces problems with fogging of the lens.

Intraperitoneal Distention

Insufflation Machines

The insufflator delivers CO₂ from a gas cylinder to the patient through tubing connected to one of the ports on the laparoscope. Most insufflators can be set to maintain a predetermined intraabdominal pressure. High flow rates (9 to 20 L/min) are especially useful for maintaining exposure when suction of smoke or fluid depletes the volume of intraperitoneal gas.

Laparoscopic Lifting Systems

Intraperitoneal retractors attached to a pneumatic or mechanical lifting system can be used to create an intraperitoneal space much like a tent. This “gasless” or “apneumatic” technique may have some advantages over pneumoperitoneum, particularly in patients with cardiopulmonary disease. Also, airtight cannulas are not necessary, and instruments do not need to have a uniform, narrow, cylindrical shape. Consequently, some conventional instruments may be used directly through the incisions.

Manipulation of Fluid and Tissue

Fluid Management

Fluid may be instilled into the peritoneal cavity through wide-caliber arthroscopy or cystoscopy tubing using pressure provided by gravity, an infusion cuff, or a high-pressure mechanical pump. The pumps deliver fluid faster than the other techniques, and the highly pressurized stream of fluid may facilitate blunt dissection (hydro- or aqua-dissection). Removal of small volumes of fluid can be performed with a syringe attached to a cannula, but for large volumes, it is necessary to use suction generated by a machine or a wall source.

The cannulas used for suction and irrigation depend on the irrigation fluid used and the fluid being removed. For ruptured ectopic gestations or other procedures in which there is a large amount of blood and clots, large-diameter cannulas (7 to 10 mm) are preferred. Cannulas with narrow tips are more effective in generating the high pressure needed for hydrodissection.

If large volumes of fluid are required, isotonic fluids should be used to avoid fluid overload and electrolyte imbalance. If electrosurgery is to be performed, however, small volumes of a nonelectrolyte-containing solution such as glycine or sorbitol can be used for hemostasis and irrigation. *Heparin* (1,000 to 5,000 U/L) can be added to irrigating solution to prevent blood from clotting, thus allowing it to be removed more easily.

Tissue Manipulation

Uterine Manipulators

A properly designed uterine manipulator should have an intrauterine component, or obturator, and a method for fixation of the device to the uterus. A hollow obturator attached to a port allows intraoperative instillation of liquid dye to demonstrate tubal patency. Articulation of the probe permits acute anteversion or retroversion, both of which are extremely useful maneuvers. If the uterus is large, longer and wider obturators are used so that the manipulations can be performed more effectively. An articulated uterine manipulator is shown in [Fig. 21.11](#).

Figure 21.11 Uterine manipulators. The disposable Clearview (Ethicon Endosurgery, Cincinnati, OH) manipulator is demonstrated. *Inset* is a demonstration of the ability of the obturator to articulate, allowing the uterus to be anteverted or retroverted more easily and completely.

Grasping Forceps

The forceps used during laparoscopy should replicate those used in open surgery. Disposable instruments generally do not have the quality, strength, and precision of nondisposable forceps. Instruments with teeth (toothed forceps) are necessary to grasp the peritoneum or the edge of ovary securely in order to remove an ovarian cyst. Minimally traumatic instruments designed like Babcock clamps are needed to retract the fallopian tube safely. Tenaculum-like instruments are desirable to retract leiomyomas or the uterus. A ratchet is useful to hold tissue in the absence of hand pressure. The instrument should be insulated and capable of transmitting unipolar or bipolar electrical energy for hemostasis.

Cutting, Hemostasis, and Tissue Fixation

Cutting can be achieved by mechanical means, electricity, laser energy, and ultrasonic energy ([Fig. 21.12](#)). The methods for maintaining or securing hemostasis include sutures, clips, linear staplers, energy sources, and topical or injectable substances ([Fig. 21.13](#)). Secure apposition or tissue fixation may be accomplished with sutures, clips, or staples. Because of the visual, tactile, and mechanical limitations of laparoscopy, prevention of bleeding is important.

Figure 21.12 Laparoscopic cutting devices. *Top to bottom:* pointed microscissors (Ethicon Endosurgery, Cincinnati, OH), curved dissecting scissors (Microsurge, Needham, MA), a narrow-angled electrode (Ethicon, Cincinnati, OH), a GIA-30 linear cutter stapler (Autosuture, U.S. Surgical, Norwalk, CT).

Figure 21.13 Hemostatic devices. *Left to right:* preloaded microfibrillar collagen (MedChem Products Inc., Woburn, MA), 1-cm clip applier (U.S. Surgical, Norwalk, CT), monopolar grasping forceps (Ethicon Endosurgery, Cincinnati, OH), GIA-30 linear with stapler (Autosuture, U.S. Surgical, Norwalk, CT), Clarke knot manipulator (Marlow, Inc., Willoughby, OH), Endoloop pretied ligature (Autosuture, U.S. Surgical, Norwalk, CT).

Cutting

The most useful cutting instruments are scissors. Because it is difficult to sharpen laparoscopic scissors, most surgeons prefer disposable instruments that may be used until dull and then discarded. Another mechanical cutting tool is the linear stapler-cutter that can simultaneously cut and hemostatically staple the edges of the incision. The cost and large dimensions of the instruments limit their practical use to only a few highly selected situations, such as separation of the uterus from the ovary and fallopian tube during laparoscopic hysterectomy.

Electrosurgical electrodes that are narrow or pointed are capable of generating the high-power densities necessary to vaporize or cut tissue. Continuous or modulated, usually unipolar, sine-wave outputs are used. For optimal results, they should be used in a noncontact fashion, following (not leading) the energy. Specially designed bipolar cutting probes are available that have one integrated electrode shaped as a needle and the other band-shaped electrode designed to be dispersive. Laparoscopic scissors with unipolar or bipolar electrosurgical attachments are designed to cut mechanically with energy used simultaneously for desiccation and hemostasis when cutting tissue that has small blood vessels.

Laser energy can be focused to vaporize and cut tissue. The most efficient cutting instrument is the CO₂ laser, which has the drawback of requiring linear transmission because light cannot be effectively conducted along bendable fibers. The potassium-titanyl-phosphate (KTP) and neodymium:yttrium, aluminum, garnet (Nd:YAG) lasers are also effective cutting tools. They are capable of propagating energy along bendable quartz fibers but result in slightly greater thermal injury than electrical or CO₂ laser energy. Because of such limitations and the additional expense, these lasers are of limited value.

A laparoscopic instrument has been developed that uses ultrasonic energy for cutting. The device consists of a vibrating pizo electrode located in a handle that causes linear oscillation of a probe tipped with a blade, hook, or clamp. The rapid oscillation (55 kHz) of the probe allows the tip to cut mechanically or create hemostasis by tissue coagulation. In low-density tissue, cutting is augmented by the process of cavitation, in which reduction of local atmospheric pressure allows vaporization of intracellular water at body temperature.

Hemostasis and Tissue Fixation

Electricity is the least expensive and most versatile method for achieving hemostasis during laparoscopy. The process of electrical desiccation (coagulation) is achieved by contacting the tissue, activating the electrode using continuous "cutting" current of adequate power to heat and coagulate the tissue. For large-caliber vessels, the tissue should be compressed before the electrode is activated, allowing the edges of the vessel to seal or coapt. Either unipolar or bipolar grasping devices may be used. Fulguration is near-contact spraying of tissue with unipolar, high-voltage energy from the "coagulation" side of the electrosurgical generator. This technique is useful for control of superficial bleeding.

Clips may be placed with specially designed laparoscopic instruments. Nonabsorbable clips made of titanium are useful for relatively narrow vessels, and longer, self-retaining clips are generally preferred for larger vessels. Clips may be of particular value when securing relatively large vessels near an important structure such as the ureter.

Laparoscopic suturing has only recently become accepted as a method of maintaining hemostasis (50). The cost of materials is far less than that of clips or linear staplers, although operating time may be longer. The two basic methods for securing a ligature around a blood vessel are with intracorporeal and extracorporeal knots, depending on where the suture is tied. Intracorporeal knots are derived from the standard instrument knot and are formed within the peritoneal cavity. Extracorporeal knots are created outside the abdomen under direct vision and then transferred into the peritoneal cavity by knot manipulators (Fig. 21.13) (51).

Topical agents such as microfibrillar collagen are available in 5- and 10-mm diameter laparoscopic applicators (Fig. 21.13). Local injection of diluted vasopressin may be used to maintain hemostasis for myomectomy or removal of ectopic pregnancy.

Removal of Tissue

After excising tissue, it is usually necessary to remove it from the peritoneal cavity. Small samples can be pulled through an appropriate-sized cannula with grasping forceps; however, larger specimens may not fit. If the specimen is cystic, it may be drained by a needle or incised, shrinking it to a size suitable for removal through the cannula or one of the small laparoscopic incisions. Because of the concern for malignancy, an alternative is to place the specimen in an endoscopic retrieval bag before drainage to prevent spillage. More solid tissue may be morcellated with scissors, ultrasonic equipment, or electrosurgery. Electrosurgical morcellation requires special bipolar needles or, if the monopolar technique is used, that the specimen remain attached to the patient to preserve the integrity of the electrical circuit.

Larger specimens may be removed by inserting a larger cannula through an incision in the cul-de-sac (posterior culdotomy) or by extending one of the laparoscopy incisions. With the exception of colpotomy, extension of the umbilical incision may be the most cosmetic approach because removal of the tissue can be directed from an endoscope positioned in one of the ancillary ports.

Incision Management

Dehiscence and hernia risk increase when the fascial incision is made by a trocar that is larger than 10 mm in diameter (52). Closure of the fascia should take place under direct laparoscopic vision to prevent the accidental incorporation of bowel into the incisions. A small-caliber laparoscope passed through one of the narrow cannulas can be used to direct the fascial closure using curved needles or a ligature carrier especially designed for this purpose.

Complications

Laparoscopic procedures can be complicated by infections, trauma, or hemorrhage, as well as by problems associated with anesthetic use. The incidence of infection

is lower than with procedures performed by laparotomy. Conversely, problems associated with visualization in conjunction with the change in anatomic perspective may increase the risk for damage to blood vessels or vital structures such as the bowel, ureter, or bladder.

Some complications are more common with laparoscopy than with procedures performed by laparotomy or the vagina. The instillation of large amounts of fluid into the peritoneal cavity may contribute to electrolyte disturbances or fluid overload. The prolonged use of intraperitoneal gas under pressure may cause metabolic abnormalities or may adversely affect cardiorespiratory function. The intraperitoneal use of electrical or laser energy creates the potential for a variety of complications that can be minimized by knowledge of the energy source, meticulous technique, and maintenance of the instruments.

Anesthetic and Cardiopulmonary Complications

One third of the deaths associated with minor laparoscopic procedures such as sterilization are secondary to complications of anesthesia (52). The potential complications of general anesthesia include hypoventilation, esophageal intubation, gastroesophageal reflux, bronchospasm, hypotension, narcotic overdose, cardiac arrhythmias, and cardiac arrest. These risks can be enhanced by some of the inherent features of gynecologic laparoscopy. For example, the Trendelenburg position, in combination with the increased intraperitoneal pressure provided by pneumoperitoneum, places greater pressure on the diaphragm, increasing the risk for hypoventilation, hypercarbia, and metabolic acidosis. This position, combined with anesthetic agents that relax the esophageal sphincter, promotes regurgitation of gastric content, which in turn can lead to aspiration, bronchospasm, pneumonitis, and pneumonia.

Parameters of cardiopulmonary function associated with both CO₂ and N₂O insufflation include reduced PO₂, O₂ saturation, tidal volume, and minute ventilation and increased respiratory rate. The use of intraperitoneal CO₂ as a distention medium is associated with an increase in P_{CO₂} and a decrease in pH. Elevation of the diaphragm may be associated with basilar atelectasis, resulting in right-to-left shunt and a ventilation–perfusion mismatch (53).

Carbon Dioxide Embolus

Carbon dioxide is the most widely used peritoneal distention medium, largely because of the rapid absorption of CO₂ in blood. However, if large amounts of CO₂ gain access to the central venous circulation, if there is peripheral vasoconstriction, or if the splanchnic blood flow is decreased by excessively high intraperitoneal pressure, severe cardiorespiratory compromise may result.

The signs of CO₂ embolus include sudden and otherwise unexplained hypotension, cardiac arrhythmia, cyanosis, and heart murmurs. The end-tidal CO₂ may increase, and findings consistent with pulmonary edema may occur. Accelerating pulmonary hypertension may occur, resulting in right-sided heart failure.

Because gas embolism may result from direct intravascular injection through an insufflation needle, the proper placement of the needle must be ensured. The intraperitoneal pressure should be maintained at less than 20 mm Hg and, except for the initial placement of trocars, at 8 to 12 mm Hg. The risk for CO₂ embolus is also reduced by careful hemostasis because open venous channels are the portal of entry for gas into the systemic circulation. The anesthesiologist should continuously monitor the patient's color, blood pressure, heart sounds, heartbeat, and end-tidal CO₂ to allow early recognition of the signs of CO₂ embolus.

If CO₂ embolus is suspected or diagnosed, the surgeon must evacuate the CO₂ from the peritoneal cavity and place the patient in the left lateral decubitus position, with the head below the level of the right atrium. A large-bore central venous line should be inserted immediately to allow aspiration of gas from the heart. Because the findings are nonspecific, other causes of cardiovascular collapse should be excluded.

Cardiovascular Complications

Cardiac arrhythmias occur relatively frequently during laparoscopic surgery and are related to a number of factors, the most significant of which are hypercarbia and acidemia. Early reports of laparoscopy-associated arrhythmia were associated with spontaneous respiration; therefore, most anesthesiologists have adopted the practice of mechanical ventilation during laparoscopic surgery. The incidence of hypercarbia is reduced by operating with intraperitoneal pressures less than 12 mm Hg (54).

The risk for cardiac arrhythmia also may be reduced by using NO₂ as a distending medium. However, although NO₂ is associated with a decreased incidence of arrhythmia, it is insoluble in blood. External lifting systems avoid the complication of hypercarbia and can also provide protection against cardiac arrhythmia.

Hypotension can occur because of decreased venous return secondary to very high intraperitoneal pressure, and this condition may be potentiated by volume depletion. Vagal discharge may occur in response to increased intraperitoneal pressure, which can cause hypotension secondary to cardiac arrhythmias (55). All of these side effects are more dangerous for patients with preexisting cardiovascular disease.

Gastric Reflux

Gastric regurgitation and aspiration can occur during laparoscopic surgery, especially in patients with obesity, gastroparesis, hiatal hernia, or gastric outlet obstruction. In these patients, the airway must be maintained with a cuffed endotracheal tube, and the stomach must be decompressed (e.g., with a nasogastric tube). The lowest necessary intraperitoneal pressure should be used to minimize the risk for aspiration. Patients should be moved out of the Trendelenburg position before being extubated. Routine preoperative administration of metoclopramide, H₂-blocking agents, and nonparticulate antacids also reduces the risk.

Extraperitoneal Insufflation

The most common causes of extraperitoneal insufflation are preperitoneal placement of the insufflating needle and leakage of CO₂ around the cannula sites. Although this condition is usually mild and limited to the abdominal wall, subcutaneous emphysema can become extensive, involving the extremities, the neck, and the mediastinum. Another relatively common site for emphysema is the omentum or mesentery, a circumstance that may be mistaken for preperitoneal insufflation.

Subcutaneous emphysema may be identified by the palpation of crepitus, usually in the abdominal wall. Emphysema can extend along contiguous fascial plains to the neck, where it can be visualized directly. Such a finding may reflect mediastinal emphysema, which may indicate impending cardiovascular collapse (56,57 and 58).

The risk for subcutaneous emphysema is reduced by the proper positioning of the insufflation needle and by maintaining a low intraperitoneal pressure after placement of the desired cannulas. Other approaches that reduce the chance of subcutaneous emphysema include open laparoscopy and the use of abdominal wall lifting systems that make gas unnecessary.

If the insufflation has occurred extraperitoneally, the laparoscope can be removed, and the procedure can be repeated. However, difficulty may ensue because of the altered anterior peritoneum. Open laparoscopy or the use of an alternate site, such as the left upper quadrant, should be considered. One approach is to leave the laparoscope in the expanded preperitoneal space while the insufflation needle is reinserted under direct vision through the peritoneal membrane caudad to the tip of the laparoscope (59).

In mild cases of subcutaneous emphysema, the findings quickly resolve after evacuation of the pneumoperitoneum, and no specific intraoperative or postoperative therapy is required. When the extravasation extends to the neck, it is usually preferable to terminate the procedure because pneumomediastinum, pneumothorax, hypercarbia, and cardiovascular collapse may result.

At the end of the procedure, it is prudent to obtain a chest x-ray. The patient's condition should be managed expectantly unless a tension pneumothorax results, in which case immediate evacuation must be performed using a chest tube or a wide-bore needle (14 to 16 gauge) inserted in the second intercostal space in the midclavicular line.

Electrosurgical Complications

Complications of electrosurgery occur secondary to thermal injury from unintended or inappropriate use of the active electrode, current diversion to an undesirable path, and injury at the site of the dispersive electrode. Active electrode injury can occur with either unipolar or bipolar instruments, whereas trauma secondary to current diversion or dispersive electrode accidents occurs only with unipolar technique. Complications of electrosurgery are reduced by adherence to safety protocols coupled with a sound understanding of the principles of electrosurgery and the circumstances that can lead to injury (16).

Active Electrode Trauma

If the foot pedal is accidentally depressed, tissue adjacent to the electrode will be traumatized. Commonly, the bowel or ureter is involved, or, if the electrode lies on the abdomen, the skin is burned. Direct extension injuries occur when the zone of vaporization or coagulation extends to large blood vessels or vital structures such as the bladder, ureter, or bowel. Bipolar technique may reduce but does not eliminate the risk for thermal injury to adjacent tissue (60). Therefore, blood vessels should be isolated before desiccation, especially when they are near vital structures, and appropriate amounts of energy must be applied to allow an adequate margin of noninjured tissue.

The diagnosis of direct thermal visceral injury may be difficult. If unintended activation of the electrode occurs, nearby intraperitoneal structures should be evaluated carefully. The appearance can be affected by several factors, including the output of the generator, the type of electrode, its proximity to tissue, and the duration of its activation. The diagnosis of visceral thermal injury is often delayed until signs and symptoms of fistula or peritonitis appear. Because these complications may not manifest until 2 to 10 days after surgery, patients should be advised to report any postoperative fever or increasing abdominal pain.

Unintended activation injuries can be prevented if the surgeon is always in direct control of electrode activation and if all electrosurgical hand instruments are removed from the peritoneal cavity when not in use. When removed from the peritoneal cavity, the instruments should be detached from the electrosurgical generator, or they should be stored in an insulated pouch near the operative field. These measures prevent damage to the patient's skin if the electrode is accidentally activated.

Thermal injury to the bowel, bladder, or ureter that is recognized at the time of laparoscopy should be managed immediately with laparotomy, taking into consideration the potential extent of the zone of coagulative necrosis (61). Incisions made with the focused energy from a pointed electrode are associated with a minimal amount of surrounding thermal injury. Prolonged or even transient contact with a relatively large-caliber electrode may produce thermal necrosis that extends several centimeters. In such cases, wide excision or resection will be necessary.

Current Diversion

Current diversion can occur when electrons find a direct path out of the patient's body through grounded sites other than the dispersive electrode. Alternatively, the current can be diverted directly to other tissues before it reaches the tip of the active electrode. In either case, if the power density becomes high enough, unintended and severe thermal injury can result.

Alternate Ground Site Burns

These injuries can occur only with ground-referenced electrosurgical generators (ESUs) because they lack an isolated circuit. In such generators, when the dispersive electrode becomes detached, unplugged, or otherwise ineffective, the current seeks any grounded conductor. If the conductor has a small surface area, the current or power density may become high enough to cause thermal injury (Fig. 21.14). Examples include electrocardiograph patch electrodes or the conductive metal components of the operating table.

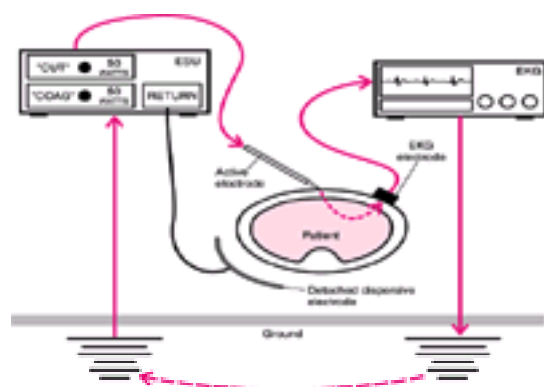

Figure 21.14 Risk of ground-referenced generators. Current diversion along alternate pathways is a risk associated with ground referenced electrosurgical generators, particularly if the dispersive electrode is detached. In the example depicted, the relatively high current density at the electrocardiograph electrode site may result in a skin burn.

Modern ESUs are designed with isolated circuits and impedance monitoring systems that shut down the machine if dispersive electrode detachment occurs. Because ground-referenced machines without such safeguards are still in use, it is important to know the type of ESU used in the operating room.

Insulation Defects

If the insulation coating the shaft of an electrosurgical electrode becomes defective, it can allow current diversion to adjacent tissue, often bowel, potentially resulting in significant injury (Fig 21.15A). Therefore, the instruments should be examined before each procedure to detect worn or obviously defective insulation. When applying unipolar electrical energy, the shaft of the instrument should be kept away from vital structures and, if possible, totally visible in the operative field.

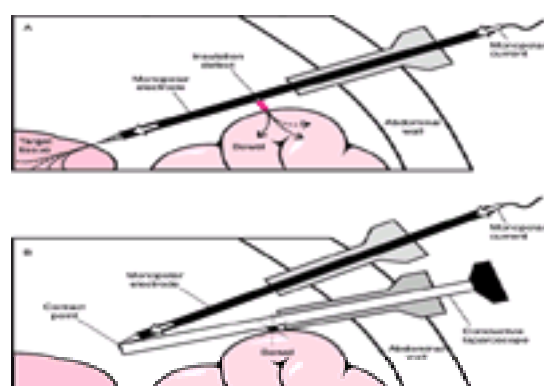

Figure 21.15 series Direct coupling. Direct coupling is a potential complication of monopolar electrosurgery and may occur secondary to defects in the insulation (**A**) or, classically, to contract with a conductive instrument that in turn touches other intraperitoneal structures. In the example depicted (**B**), the active electrode is touching the laparoscope, and current is transferred to bowel through a small enough contact point that thermal injury results. Another common target of such coupling is to noninsulated hand instruments.

Direct Coupling

Direct coupling occurs when an activated electrode touches and energizes another metal conductor such as a laparoscope, cannula, or other instrument, especially one that is not insulated. If the conductor is near or in contact with other tissue, a thermal injury can result (Fig 21.15B). Direct coupling can be prevented by removing the electrode when it is not in use and by visually confirming that there is no contact with other conductive instruments before activation.

Capacitive Coupling

Capacitance is the ability of a conductor to establish an electrical current in an unconnected but nearby circuit. An electrical field is established around the shaft of any activated laparoscopic unipolar electrode, a circumstance that makes the electrode a capacitor. This field is harmless if the circuit is completed through a dispersive, low-power density pathway (Fig. 21.16). For example, if capacitive coupling occurs between the laparoscopic electrode and a metal cannula positioned in the abdominal wall, the current harmlessly "returns" to the abdominal wall, where it traverses to the dispersive electrode (Fig. 21.16A). However, if the metal cannula is anchored to the skin by a nonconductive plastic retaining sleeve or anchor (a hybrid system), the current will not return to the abdominal wall because the sleeve acts as an insulator (Fig. 21.16B). Instead, the capacitor will have to "look" elsewhere to complete the circuit. Therefore, bowel or any other nearby conductor can become the target of a relatively high-power density discharge (Fig. 21.16C). This mechanism can also occur when a unipolar electrode is inserted through an operating laparoscope that, in turn, is passed through a nonconductive plastic laparoscopic cannula. In this configuration, the plastic port acts as the insulator. If the electrode capacitively couples with the metal laparoscope, nearby bowel will be at risk for significant thermal injury (61,62).

Figure 21.16 Capacitive coupling. **A:** All activated monopolar electrodes emit a surrounding charge, proportional to the voltage of the current. This makes the electrode a potential capacitor. **B:** Generally, as long as the charge is allowed to disperse through the abdominal wall, no sequelae result. However, if the "return" to the dispersive electrode is blocked by insulation, such as a plastic anchor (**C**), the current can couple to a conductive cannula or directly to bowel.

Capacitive coupling can be prevented by avoiding the use of hybrid laparoscope-cannula systems that contain a mixture of conductive and nonconductive elements. Instead, it is preferred that all-plastic or all-metal cannula systems be used. When operating laparoscopes are used, all-metal cannula systems should be the rule unless there is no intent to perform unipolar electro-surgical procedures through the operating channel.

Dispersive Electrode Burns

The use of isolated-circuit electro-surgical generators with return electrode monitors has virtually eliminated dispersive electrode-related thermal injury. Return electrode monitoring is actually accomplished by measuring the impedance in the dispersive electrode (patient pad), which should always be low because of the large surface area. Without such devices, partial detachment of the "patient pad" could result in a thermal injury because reducing the surface area of the electrode raises the current density (Fig. 21.17).

Figure 21.17 Dispersive electrode burns. If the dispersive electrode becomes partially detached, the current density may increase to the point that a skin burn results.

Hemorrhagic Complications

Great Vessel Injury

The most dangerous hemorrhagic complications are injuries to the great vessels, including the aorta and the vena cava, the common iliac vessels and their branches, and the internal and external iliac arteries and veins. The injuries most often occur secondary to insertion of an insufflation needle but may be created by the tip of the primary or ancillary trocars. The vessels most frequently damaged are the aorta and the right common iliac artery as it branches from the aorta in the midline. The anatomically more posterior location of the vena cava and the iliac veins provides relative protection, but not immunity, from injury (63). Although most of these injuries are small and amenable to repair with suture, some are larger and require ligation with or without the insertion of a vascular graft. Deaths have been reported.

After vascular injury, patients usually develop profound hypotension with or without hemoperitoneum. In some instances, blood is aspirated through the insufflation needle before the introduction of the distending gas. Frequently, the bleeding may be contained in the retroperitoneal space, which usually delays the diagnosis; consequently, hypovolemic shock may develop. To avoid late recognition, the course of each great vessel must be identified before completing the procedure.

If blood is withdrawn from the insufflation needle, it should be left in place while immediate preparations are made to obtain blood products and perform laparotomy. If hemoperitoneum is diagnosed upon initial visualization of the peritoneal cavity, a grasping instrument may be used, if possible, to occlude the vessel temporarily. Upon entry into the peritoneal cavity, the aorta and vena cava should immediately be compressed just below the level of the renal vessels to gain at least temporary control of blood loss. The most appropriate course of action depends on the site and extent of injury.

Abdominal Wall Vessel Injury

The abdominal wall vessels most commonly injured during laparoscopy are the superficial inferior epigastric vessels as they branch from the femoral artery and vein and course cephalad in each lower quadrant. They are invariably damaged by the initial passage of an ancillary trocar or by the introduction of a wider device later in

the procedure. The problem may be recognized immediately by the observation of blood dripping along the cannula or out through the incision. However, the bleeding may be obstructed by the cannula until it is withdrawn at the end of the operation.

The more serious injuries are those to the deep inferior epigastric vessels, which are branches of the external iliac artery and vein that course cephalad but are deep to the rectus fascia and often deep to the muscles ([Fig. 21.3](#)). More laterally located are the deep circumflex iliac vessels, which are not often encountered in laparoscopic surgery. Laceration of these vessels may cause profound blood loss, particularly when the trauma is unrecognized and causes extraperitoneal bleeding.

Signs of injury, in addition to blood dripping down the cannula, include the postoperative appearance of shock and abdominal wall discolorization or hematoma located near the incision. In some instances, the blood may track to a more distant site, presenting as a pararectal or vulvar mass. Delayed diagnosis may be prevented by laparoscopic evaluation of each peritoneal incision after removal of the cannula.

Superficial inferior epigastric vessel trauma usually stops spontaneously; therefore, expectant management is appropriate. A straight ligature carrier can be used to repair lacerated deep inferior epigastric vessels. If a postoperative hematoma develops, local compression should be used initially. Open removal or aspiration of the hematoma should not be undertaken because it may inhibit the tamponade effect and increase the risk for abscess. However, if the mass continues to enlarge or if signs of hypovolemia develop, the wound must be explored.

Intraperitoneal Vessel Injury

Hemorrhage may result from inadvertent entry into a vessel or failure of a specific occlusive technique. In addition to delayed hemorrhage, there may be a further delay in diagnosis at laparoscopy as a result of the restricted visual field and the temporary occlusive pressure exerted by CO₂ in the peritoneal cavity.

Inadvertent division of an artery or vein is usually evident immediately. Transected arteries may go into spasm and bleed minutes to hours later, going unnoticed temporarily because of the limited visual field of the laparoscope. Therefore, at the end of the procedure, all areas of dissection must be carefully examined. CO₂ should be vented, which decreases the intraperitoneal pressure so that blood vessels temporarily occluded by higher pressure can be recognized.

Gastrointestinal Complications

The stomach, the small bowel, and the colon can be injured during laparoscopy. Mechanical entry into the large or small bowel can occur 10 times more often when laparoscopy is performed in patients who have had prior intraperitoneal inflammation or abdominal surgery. Loops of intestine can adhere to the abdominal wall under the insertion site and be injured ([64,65](#) and [66](#)).

Insufflation Needle Injuries

Needle entry into the gastrointestinal tract may be more common than reported because it often occurs unnoticed and without further complication. Gastric entry may be identified by the increased filling pressure, asymmetric distention of the peritoneal cavity, or aspiration of gastric particulate matter through the lumen of the needle. Initially, the hollow, capacious stomach may allow the insufflation pressure to remain normal. Signs of bowel entry are the same as those for gastric injury, with the addition of feculent odor.

If particulate debris is identified, the needle should be left in place, and an alternate insertion site should be identified, such as the left upper quadrant. Immediately after successful entry into the peritoneal cavity, the site of injury is identified. Defects must be repaired immediately.

Trocar Injuries

Damage caused by a sharp trocar is usually more serious than needle injury. Inadvertent gastric entry usually results from stomach distention because of aerophagia, difficult or improper intubation, or mask induction with inhalation anesthetic. Most often, the injury is created by the primary trocar, although ancillary cannulas may also result in visceral injury.

The risk for gastric perforation can be minimized with the selective use of preoperative nasogastric or oral gastric suction when left upper-quadrant entries are used or when the intubation was difficult. Open laparoscopy can reduce but not eliminate the risk for gastrointestinal complications. For high-risk patients, left upper quadrant needle insertion with a properly decompressed stomach may be preferable ([67,68](#) and [69](#)).

If the trocar of a primary cannula penetrates the bowel, the condition is usually diagnosed when the mucosal lining of the gastrointestinal tract is visualized. If the large bowel is entered, a feculent odor may be noted. However, the injury may not be immediately recognized because the cannula may not stay within the bowel or may pass through the lumen. Such injuries usually occur when a single loop of bowel is adherent to the anterior abdominal wall. The injury may not be recognized until peritonitis, abscess, enterocutaneous fistula, or death occurs ([70,71](#)). Therefore, at the end of the procedure, the removal of the primary cannula must be viewed either through the cannula or an ancillary port, a process facilitated by routine direct visualization of closure of the incision of the primary port.

Trocar injuries to the stomach and bowel require repair as soon as they are recognized. If the injury is small, a trained operator can repair the defect by laparoscopy using a double layer of running 2-0 or 3-0 absorbable suture. Extensive lesions may require resection and reanastomosis, which in most instances requires laparotomy. The preoperative use of mechanical bowel preparation in selected high-risk cases minimizes the need for laparotomy or colostomy.

Dissection and Thermal Injury

It is often easier to recognize intestinal injury that occurs during dissection than thermal injury to the bowel, particularly if the latter was created with electrical or laser energy. Even if thermal injury is recognized, it is difficult to estimate by visual inspection the extent of the damage because the zone of desiccation may exceed the area of visual damage. In some patients, the diagnosis is delayed until the development of peritonitis and fever, usually a few days later but occasionally not for several weeks ([72](#)). When mechanical bowel trauma is recognized during the dissection, treatment is the same as that described for trocar injury. If the diagnosis is delayed until the postoperative recognition of peritonitis, laparotomy must be performed immediately.

Thermal injury may be handled expectantly if the lesion seems superficial and confined. In a study of 33 women with such injuries who were managed expectantly in the hospital, only 2 required laparotomy for perforation ([72](#)).

Urologic Injury

Laparoscopy-associated damage to the bladder or ureter may occur secondary to mechanical or thermal trauma. Ideally, such injury should be prevented; otherwise, it is essential that the lesion be identified intraoperatively.

Bladder Injury

Bladder injury can occur from a trocar perforation of the undrained bladder but may also occur while dissecting the bladder from adherent structures or from the anterior uterus ([73,74](#)). The injury may be readily apparent by direct visualization. If an indwelling catheter is in place, hematuria or pneumaturia (CO₂ in the catheter drainage system) may be noticed. A bladder laceration can be confirmed by injecting sterile milk or a diluted methylene blue solution through a transurethral catheter. Thermal injury to the bladder, however, may not be initially apparent and, if missed, can present as peritonitis or a fistula.

Routine preoperative bladder drainage usually prevents trocar-related cystotomies. Separation of the bladder from the uterus or other adherent structures requires good visualization, appropriate retraction, and excellent surgical technique. Sharp mechanical dissection is preferred, particularly when relatively dense adhesions are present.

Very-small-caliber injuries to the bladder (1 to 2 cm) may be treated with bladder catheterization for 5 to 7 days. If repair is undertaken immediately, catheterization is

unnecessary. When a larger injury is identified, it can be repaired laparoscopically ([73,74](#) and [75](#)). However, if the laceration is near the trigone or involves the trigone, an open procedure should be used. The mechanism of injury should be taken into consideration in making this evaluation because electrical injuries often extend beyond the visible limits of the apparent defect.

For small lesions, closure may be performed with layers of absorbable 2-0 to 3-0 sutures. If there is thermal injury, the coagulated portion should be excised. Postoperative catheterization with either a transurethral or suprapubic catheter should be maintained for 2 to 5 days for small fundal lacerations and for 10 to 14 days for injuries to the trigone. **Cystography should be performed before removal of the urinary catheter.**

Ureteral Injury

The most common cause of ureteral injury during laparoscopy is electrosurgical trauma ([76,77](#)). However, ureteral injury can occur after mechanical dissection and the use of linear cutting and stapling devices ([78,79](#) and [80](#)). Although intraoperative recognition of ureteral injury is possible, the diagnosis is usually delayed ([76](#)). Ureteral lacerations may be confirmed intraoperatively visually or with the intravenous injection of indigo carmine. Thermal injury presents up to 14 days after surgery with fever, abdominal or flank pain, and peritonitis. Leukocytosis may be present, and intravenous pyelography shows extravasation of urine or a urinoma. Mechanical obstruction from staples or a suture can be recognized intraoperatively only by direct visualization. Ureteral obstruction presents a few days to 1 week after surgery with flank pain and often fever ([80](#)).

Abdominal ultrasound may be helpful, but intravenous pyelography can more precisely identify the site and degree of the obstruction.

Discharge or continuous incontinence is a delayed sign of ureterovaginal or vesicovaginal fistulas. A bladder fistula can be confirmed by detecting dye on a tampon previously placed in the vagina after filling the bladder with methylene blue. With a ureterovaginal fistula, the methylene blue will not pass into the vagina, but it can be detected with the intravenous injection of indigo carmine.

Knowledge of the course of the ureter through the pelvis is a prerequisite to reducing the risk for injury. The ureter can usually be seen through the peritoneum of the pelvic sidewall between the pelvic brim and the attachment of the broad ligament. However, because of variation from one patient to another or the presence of disease, the location of the ureter can become obscured, making it necessary to enter the retroperitoneal space. The techniques used for retroperitoneal dissection are also important factors in reducing the risk for ureteric injury. Blunt and sharp dissection with scissors is preferred, although hydrodissection can be used ([81](#)). The selective placement of ureteral stents may also be helpful.

Ureteral injury can be treated immediately if it is diagnosed intraoperatively. Although very limited damage may heal over a ureteral stent left in place for 10 to 21 days, repair is indicated in most patients. Although laparoscopic repair of ureteric lacerations and transections has been performed, most injuries require laparotomy ([76,82](#)).

When the diagnosis of ureteral injury is delayed, the bladder should be drained with a catheter. Incomplete or small obstructions or lacerations may be treated successfully with either a retrograde or antegrade ureteral stent. Urinomas may be drained percutaneously. If a stent cannot be placed successfully, a percutaneous nephrostomy should be performed before operative repair is undertaken.

Neurologic Injury

Peripheral nerve injury is usually related either to poor positioning of the patient or to excessive pressure exerted by the surgeons. Nerve injury may also occur as a result of the surgical dissection.

In the extremities, the trauma may be direct, such as when the common peroneal nerve is compressed against the stirrups. The femoral nerve or the sciatic nerve or its branches may be overstretched and damaged by inappropriate positioning of the hip or the knee joint ([83,84](#)). Brachial plexus injuries may occur secondary to the surgeon or assistants leaning against the abducted arm during the procedure. If the patient is placed in a steep Trendelenburg position, the brachial plexus may be damaged because of the pressure exerted on the shoulder joint ([85](#)). In most cases, sensory or motor deficits are found as the patient emerges from anesthesia. The likelihood of brachial plexus injury can be reduced with adequate padding and support of the arms and shoulders or by placing the patient's arms in an adducted position.

Most injuries to peripheral nerves resolve spontaneously. The time to recovery depends on the site and severity of the lesion. For most peripheral injuries, full sensory nerve recovery occurs in 3 to 6 months. Recovery may be facilitated by physical therapy, appropriate braces, and electrical stimulation of the affected muscles. Open microsurgery should be performed for transection of major intrapelvic nerves.

Incisional Hernia and Wound Dehiscence

Incisional hernia after laparoscopy has been reported in more than 900 cases ([51](#)). Although no incision is immune to the risk, defects that are larger than 10 mm in diameter are particularly vulnerable ([86,87](#)). In most cases, these defects can be prevented by proper technique and closure of large defects. All ancillary cannulas should be removed under direct vision to ensure that bowel is not drawn into the incision. For incisions larger than 10 mm in diameter, the fascia should be closed while viewing the defect with the laparoscope to minimize the risk for intestinal injury. A small-diameter laparoscope should be used through a narrow cannula to facilitate incisional closure.

The most common defect is when intestinal hernia develops in the immediate postoperative period. The hernia may be asymptomatic or, within the first postoperative week, may cause pain, fever, periumbilical mass, obvious evisceration, and the symptoms and signs of mechanical bowel obstruction.

Because Richter's hernias contain only a portion of the intestine in the defect, the diagnosis is often delayed. Hernias most often occur in incisions lateral to the midline. The initial symptom is usually pain because the incomplete obstruction still allows the passage of intestinal contents. Fever can be present if incarceration occurs, and peritonitis may result from subsequent perforation. The condition is difficult to diagnose, requires a high index of suspicion, and may be confirmed with an ultrasound or a CT scan ([88](#)).

The management of laparoscopic incisional defects depends on the time of presentation and the presence and condition of entrapped bowel. Evisceration always requires surgical intervention. If the condition is diagnosed immediately, the intestine is replaced into the peritoneal cavity (if there is no evidence of necrosis or intestinal defect), and the incision is repaired, usually with laparoscopic guidance. If the diagnosis is delayed or the bowel is incarcerated or at risk for perforation, laparotomy is necessary to repair or resect the intestine.

Infection

Wound infections after laparoscopy are uncommon; most are minor skin infections that can be treated successfully with expectant management, drainage, or antibiotics ([89](#)). Severe necrotizing fasciitis can occur rarely ([90](#)). Bladder infection, pelvic cellulitis, and pelvic abscess have been reported ([91](#)).

The risk for infection associated with laparoscopy is much lower than that for infection associated with open abdominal or vaginal surgery. Prophylactic antibiotics should be offered to selected patients (e.g., those with enhanced risk for bacterial endocarditis and those for whom hysterectomy is planned). Patients should be instructed to monitor their body temperature after discharge and to report immediately a temperature higher than 38°C.

Hysteroscopy

The hysteroscopic lysis of intrauterine adhesions was first described in 1973 ([92](#)). The technique of endoscopically guided electrosurgical resection was adapted from urology to gynecology for the removal of uterine leiomyomas ([93](#)). Hysteroscopic division of uterine septa was developed using a technique in which scissors are passed along the outside of the endoscope ([94](#)). Hysteroscopic destruction of the endometrium has been reported using Nd:YAG laser vaporization, electrosurgical

resection, and electrosurgical coagulation ([95,96](#) and [97](#)).

The use of diagnostic and operative hysteroscopy has been limited by the difficulties in obtaining a consistently acceptable image (as a result of inadequate distention, bleeding) and the perception that its therapeutic potential is low. Although hysteroscopic technology and techniques are still being developed, the current quality of the images is excellent because smaller-diameter endoscopes have been made possible by improvements in fiber technology. The concomitant use of ultrasound imaging can provide a view of the myometrial wall during resectoscopic procedures.

Because diagnostic hysteroscopy can be performed in an office or clinic setting without anesthetic, its widespread use has been advocated to investigate abnormal uterine bleeding. Hysteroscopic surgical procedures include removal of polyps, excision of leiomyomas, endometrial ablation, and division of adhesions and uterine septa. Some of these procedures are well established; others, although promising, require more clinical investigation. Hysteroscopy has been suggested as a method to replace blind sampling of the uterine cavity because it may provide better results at a lower cost ([98,99](#)).

Diagnostic Hysteroscopy

Diagnostic hysteroscopy can provide information that cannot be obtained by blind endometrial sampling ([98,99,100,101,102,103](#) and [104](#)). In most cases, the additional findings visible with hysteroscopy are endometrial polyps or submucous leiomyomas ([101,102,104,105](#)). Malignant or hyperplastic processes can be identified with hysteroscopy and directed biopsy ([103](#)). Hysteroscopic examination is probably superior to hystero-graphy in the evaluation of the endometrial cavity ([106,107](#)). However, in some situations (e.g., endometritis, hyperplasia), curettage provides information not otherwise available by hysteroscopic evaluation, even when it is combined with directed biopsy ([101,102,104,108](#)). The principal advantage of diagnostic hysteroscopy is that structural anomalies (congenital or acquired) are more easily detected and defined. Potential indications for diagnostic hysteroscopy are as follows.

1. Unexplained abnormal uterine bleeding
 - Premenopausal
 - Postmenopausal
2. Selected infertility cases
 - Abnormal hystero-graphy
 - Unexplained infertility
3. Recurrent spontaneous abortion

In most patients, diagnostic hysteroscopy can be performed in an office or clinic with minimal discomfort and at a much lower cost than in an operating room. For some patients, concerns about patient comfort or a preexisting medical condition may preclude office hysteroscopy.

Although hysteroscopy can, in many patients, provide more information than blind curettage, it should still be used prudently. For most patients, other investigative or therapeutic measures can be undertaken before, or instead of, diagnostic hysteroscopy. For women with perimenopausal and postmenopausal bleeding, office endometrial biopsy or curettage should be performed before diagnostic hysteroscopy. If a satisfactory diagnosis cannot be established, or if bleeding continues without explanation, office hysteroscopy and directed biopsy or repeat curettage is appropriate. For women in their reproductive years, medical or expectant management may be used initially, depending on the severity and inconvenience of the bleeding. For those who do not respond to medical regimens such as oral contraceptives, office hysteroscopy with biopsy or curettage can be performed for diagnosis ([109](#)).

For women with infertility, hysterosalpingography is the best initial imaging step because it provides information about the patency of the oviducts. In the presence of a suspicious or identified abnormality in the endometrial cavity, hysteroscopy can be performed to confirm the diagnoses, to define the abnormality, and perhaps to direct the removal of the lesion. Some consider hysteroscopy mandatory for these patients because of the high occurrence of false-negative radiologic images in those with intrauterine anomalies. However, there has been no evidence that identification and treatment of these “missed” anomalies improves pregnancy rates. Confirmation of patency of the oviduct is unnecessary in women who have recurrent abortions; therefore, these patients can be evaluated primarily with hysteroscopy.

Operative Hysteroscopy

Adhesiolysis, division of a uterine septum, resection of myomas, and endometrial destruction through resection, electrosurgical desiccation, or vaporization with the Nd:YAG laser can be performed hysteroscopically. Hysteroscopy may also be used to remove foreign bodies or to position instruments in the fallopian tube.

Foreign Body

If the string of an intrauterine device is absent, the device usually can be removed with a specially designed hook or a toothed curette (e.g., Novak). When removal is difficult or impossible, the location of the device may be confirmed by hysteroscopy, allowing removal with a grasping forceps.

Septum

When a single uterus with a divided cavity is present, hysteroscopic division of uterine septa improves reproductive outcome at a rate comparable to abdominal metroplasty, with reduced morbidity and cost ([110,111,112](#) and [113](#)). The procedure may be performed mechanically with scissors or with energy-based techniques such as the Nd:YAG laser or an electrosurgical knife or loop. Because most septa have few vessels, scissors can be used easily, and the minimal risk for thermal damage is avoided.

Endometrial Polyps

Although endometrial polyps can be removed with blind curettage, many are missed ([101,102,104,105](#)). Therefore, known or suspected endometrial polyps are more successfully treated with hysteroscopic guidance, which can often be performed in a clinic or office using local anesthesia. Hysteroscopy may be used either to evaluate the result of blind curettage, or preferably, to guide a grasping forceps. Alternatively, for larger polyps, a uterine resectoscope may be used to sever the stalk or morcellate the lesion.

Leiomyomas

Hysteroscopy may be used to remove intracavitary leiomyomas in women with menorrhagia or infertility ([114,115,116,117,118,119,120](#) and [121](#)). However, this approach is limited by the location and size of the leiomyomas. In some patients, excision is relatively easy, whereas in others, laparotomy is necessary.

Pedunculated leiomyomas may be removed by transecting the stalk with scissors or a resectoscope. For larger lesions, electrosurgical morcellation with a resectoscope may be necessary before removal. In some patients, hysteroscopy can be used to direct the attachment of a tenaculum so that the lesion can be twisted off. Although preferable, it is not absolutely necessary to remove the leiomyoma because it will be expelled spontaneously.

Selected submucous leiomyomas that extend into the uterine wall may be resected using a loop electrode. The extent of intramural involvement may be evaluated by performing abdominal ultrasound with saline instilled into the endometrial cavity (i.e., sonohystero-graphy) ([121](#)). If the leiomyoma is too deeply imbedded in the myometrium, it may not be resectable, or the uterus might be perforated if overzealous attempts are made to remove the tumor. Selected intramural leiomyomas may be removed completely during a second procedure performed after a suitable interval ([119](#)). Instead of a second procedure, the Nd:YAG laser or bipolar electrosurgery can be used to desiccate the remaining portion of the leiomyomas, although the efficacy of this approach is unclear ([115](#)). Preoperative gonadotropin-releasing hormone (GnRH) agonists may help shrink submucous myomas, facilitating their complete removal ([122,123](#) and [124](#)).

Menorrhagia

Menorrhagia that does not respond to medications may be managed by endometrial ablation or resection ([95,96](#) and [97](#), [117](#), [124,125,126,127,128,129,130,131](#) and

[132](#)). Ablation may be performed with the laser ([95,125,126](#)), by electro-surgical desiccation using a uterine resectoscope equipped with a blunt ball- or barrel-shaped electrode ([97,132](#)), or by thermal balloon ablation. Resection is performed with an electro-surgical loop electrode that can shave the endometrium ([96,127,128](#)). Complications of the procedure include fluid overload, electrolyte imbalances, bleeding, perforation, and intestinal injury ([130](#)). The risk for uterine perforation can be reduced by using a combination of resection and electro-surgical ablation; the latter is most suitable for the thinner areas of the myometrium in the cornu and on the lateral walls of the endometrial cavity ([117](#)). The preoperative use of GnRH analogues or *danazol* may reduce operating time, bleeding, and the amount of fluid required ([134,135](#)).

For many women, these procedures are successful in reducing or eliminating menses without hysterectomy or long-term medical therapy ([136](#)). Success rates vary and depend on the duration of follow-up and the definition of success. For many patients, amenorrhea is the goal, whereas for others, it is normalization of menses. About 75% to 95% of patients are satisfied with the surgical procedure after 1 year, and 30% to 90% of patients have amenorrhea. In comparative studies, there is no advantage of laser over electro-surgical techniques ([125,130](#)).

The long-term efficacy and impact of ablation or resection on women with adenomyosis is unknown. Because some endometrium inevitably cannot be ablated, there is the potential for endometrial cancer; therefore, postmenopausal women who have undergone ablation or resection should take progestin as a part of hormonal replacement therapy ([136](#)).

Sterilization

Hysteroscopic sterilization can be performed without entering the peritoneal cavity. Because the tubal ostia are usually visible during hysteroscopy, there are several potential options for sterilization: insertion of a plug, injection of a sclerosing agent, or destruction of the intramural portion of the oviduct. These procedures are being developed and should be performed only as part of an approved clinical trial ([36](#)).

Synechiae

Asherman's syndrome is the presence of adhesions in the endometrial cavity resulting in infertility or recurrent spontaneous abortion with or without amenorrhea. These synechiae may be detected on a hystero-gram but are best shown with diagnostic hysteroscopy. Relatively thin, fragile synechiae may be divided with the tip of a rigid diagnostic hysteroscope ([137](#)). Thicker lesions may require division by semirigid or rigid scissors or energy-based instruments such as a resectoscope or an operative hysteroscope with an Nd:YAG laser. Reproductive outcome depends on the extent of the preoperative endometrial damage ([138,139](#) and [140](#)).

Patient Preparation

Most diagnostic hysteroscopy procedures are performed in the office or clinic, whereas operative hysteroscopy is performed in an operating room or hospital surgicenter. The patient should understand the rationale for either procedure as well as the anticipated discomfort, the potential risks, and the expectant medical and surgical alternatives. The patient must understand the nature of the procedure and the chance of therapeutic success. A realistic estimate of success based on the operator's experience must be presented to the patient.

Diagnostic Hysteroscopy

Diagnostic hysteroscopy is designed to identify or exclude the presence of anatomic or structural abnormalities in the endometrial cavity that may contribute to bleeding, infertility, or recurrent pregnancy loss. The risks of diagnostic hysteroscopy are few, and they rarely have severe consequences. However, those related to anesthesia, perforation, bleeding, and the distention media should be discussed. After diagnostic hysteroscopy, most patients have slight vaginal bleeding and lower abdominal cramps. Severe cramps, dyspnea, and upper abdominal and right shoulder pain can develop if CO₂ passes into the peritoneal cavity. Consequently, the patient should be accompanied by a friend or relative who will escort her home.

Operative Hysteroscopy

Counseling before operative hysteroscopy varies depending on the planned procedure and the type of anesthesia used. The risks of operative hysteroscopy are higher and are potentially more dangerous than those of diagnostic hysteroscopy. **Failure to purge air sufficiently from inflow lines or cervical dilation and insertion of operative instruments into the uterine cavity may be sufficient to cause a clinically significant air embolus. The risk for emboli as room air or gas from electro-surgical combustibles increases with higher intrauterine pressures, longer procedures, and invasion into the deeper myometrial vasculature.** The use of large volumes of hypotonic distention media may not be tolerated in some patients if there is significant intravascular absorption, especially in patients with underlying cardiovascular disease. The patient must be aware of the risk for damage to the intestines or to the urinary tract. If damage occurs during the procedure, it may not be possible to complete the surgery, and laparotomy may be necessary to repair the problem.

Equipment and Technique

The equipment required depends on the reason for the procedure. The surgeon must be knowledgeable about the equipment, its mechanisms, and the technical specifications to facilitate efficiency, optimal clinical outcome, and a decreased probability of complications ([Fig. 21.18](#)). A typical hysteroscopy setup for diagnostic and minor operative procedures is shown in [Fig. 21.19](#). Core competencies required for hysteroscopy are as follows:

Figure 21.18 Office hysteroscopy equipment. A typical diagnostic hysteroscopy setup. On the table are a hysteroscope, a video camera mount, and diagnostic instruments. On the cart is (*from top*) a super VHS 1/2-inch videotape recorder, a Sony high-resolution monitor, an Olympus hysteroscopic insufflator, and the Olympus video camera base and light source.

Figure 21.19 Diagnostic and minor operative hysteroscopic instruments. *Top to bottom:* a 4-mm-diameter hysteroscope in a 5-mm diagnostic sheath with attached CCD video camera, light cable and insufflation tubing; two semirigid hysteroscopic instruments—scissors and a biopsy forceps; the obturator for the operative sheath; the 7-mm operative sheath with two ports on the right side, allowing the introduction of the semirigid instruments.

1. Patient positioning and cervical exposure
2. Anesthesia
3. Cervical dilation
4. Uterine distention
5. Imaging
6. Intrauterine manipulation

Patient Positioning and Exposure

Hysteroscopy is performed in a modified dorsal lithotomy position; the patient is supine, and the legs are held in stirrups. For hysteroscopic procedures performed while the patient is conscious, comfort must be considered in conjunction with the need to gain good exposure of the perineum. Stirrups that hold and support the knees, calves, and ankles permit prolonged procedures. “Candy cane” stirrups should be avoided for hysteroscopic surgery on conscious patients.

The smallest speculum possible should be used to expose the cervix. A bivalve speculum hinged on only one side allows its removal without disturbing the other instruments needed. The use of weighted specula should be avoided in conscious patients.

Anesthesia

The anesthetic requirements for hysteroscopy vary greatly, depending on the patient's level of anxiety, the status of her cervical canal, the procedure, and the outside diameter of the hysteroscope or sheath. In some patients, diagnostic hysteroscopy is possible without anesthesia, especially if the patient is parous or if narrow-caliber (<3 mm in outside diameter) hysteroscopes are used. The pain of cervical dilation also is avoided or minimized by inserting a laminaria tent in the cervix 3 to 8 hours before the procedure. However, if left in place too long (e.g., longer than 24 hours), the cervix may overdilate, which is counterproductive for CO₂ insufflation.

For most diagnostic procedures, effective cervical anesthesia is obtained with an intracervical block. A spinal needle can be used to instill about 3 mL of 0.5% to 1% lidocaine into the anterior lip of the cervix. A tenaculum is used to grasp the cervix. An intracervical block is administered evenly around the circumference of the internal os. A paracervical block may also be injected into the uterosacral ligaments at the 4- and 8-o'clock positions, if necessary (141). Care must be taken to avoid intravascular injection. Additional topical anesthesia may be given by injecting 5 mL of 2% *mepivacaine* into the endometrial cavity with a syringe. Many operative procedures can be performed with this technique combined with intravenous anxiolytics or analgesics, as necessary. Alternatively, regional or general anesthesia may be used.

Cervical Dilation

Dilation of the cervix, although apparently simple, can be incorrectly performed in a way that compromises the whole procedure. If the objective lens of the hysteroscope cannot be placed in the endometrial cavity, the hysteroscopy cannot be done. The cervix should be dilated as atraumatically as possible. A uterine sound should not be used because it can traumatize the canal or the endometrium, causing unnecessary bleeding and uterine perforation.

Uterine Distention

Distention of the endometrial cavity is necessary to create a viewing space. The choices include CO₂ gas, high-viscosity 32% *dextran 70*, and a number of low-viscosity fluids, including glycine, sorbitol, saline, and dextrose in water. **A pressure of 45 mm Hg or higher is required for adequate distention of the uterine cavity. To minimize extravasation, this pressure should not exceed the mean arterial pressure.** For each of the fluids, there are several methods used to create this pressure by infusion into the endometrial cavity.

Sheaths

A rigid hysteroscope is passed into the endometrial cavity through an external sheath. The design and diameter of the sheath reflect both the dimensions of the endoscope and the purpose of the instrument. Diagnostic hysteroscopes have a sheath slightly wider than the telescope, allowing infusion of the distention media. Sheaths for operative hysteroscopes have one or two additional channels that permit the passage or efflux of distention media or the insertion of semirigid instruments or laser fibers. These sheaths are usually 7 to 8 mm in diameter, and some allow continuous flow of distention media in and out of the endometrial cavity (Fig. 21.16).

Media

CO₂ provides an excellent view for diagnostic purposes, but it is unsuitable for operative hysteroscopy and for diagnostic procedures when the patient is bleeding because there is no effective way to remove blood and other debris from the endometrial cavity. To prevent CO₂ embolus, the gas must be instilled by an insufflator that is specially designed for the procedure—the intrauterine pressure is kept below 100 mm Hg, and the flow rate is maintained at less than 100 mL/min.

Normal saline is a useful and safe medium for procedures that do not require electricity. Even if there is absorption of a significant volume of solution, saline does not cause electrolyte imbalance. Therefore, saline is a good fluid for minor procedures performed in the office.

Dextran 70 is useful for patients who are bleeding, because it does not mix with blood. However, it is expensive and tends to “caramelize” on instruments, which must be disassembled and thoroughly cleaned in warm water immediately after each use. Anaphylactic reactions, fluid overload, and electrolyte disturbances can occur.

For operative hysteroscopy, low-viscosity, nonconductive fluids such as 1.5% glycine and 3% sorbitol are used most often. These solutions can be used with electricity because there are no electrolytes to disperse the current and impede the electrosurgical effect. Both 1.5% glycine and 3% sorbitol are inexpensive and are readily available in 3-L bags suitable for continuous-flow hysteroscopy. Because each fluid is hypotonic, extravasation into the systemic circulation can be associated with fluid and electrolyte disturbances. Therefore, uterine “absorption” must be monitored continuously by collecting outflow from the sheath and subtracting it from the total infused volume. Absorbed volumes greater than 1 L mandate the measurement of electrolyte levels. If there is more than 2 L of extravasated fluid, the procedure should be stopped. Excessive circulating sorbitol may cause hyperglycemia, and large volumes of glycine may elevate levels of ammonia in the blood (142).

Delivery Systems

Syringes can be used for office diagnostic procedures and are especially good for infusing dextran solution. The syringe can be operated by the surgeon and is either connected directly to the sheath or attached by connecting tubing. Because this technique is so tedious, it is suited only for simple operations.

Continuous hydrostatic pressure is effectively achieved by elevating the vehicle containing the distention media above the level of the patient's uterus. The achieved pressure is the product of the width of the connecting tubing and the elevation—for operative hysteroscopy with 10-mm tubing, intrauterine pressure ranges from 70 to 100 mm Hg when the bag is between 1 and 1.5 m above the uterine cavity.

A pressure cuff may be placed around the infusion bag to elevate the pressure in the system. Caution must be exercised, however, because this technique causes

extravasation if intrauterine pressure rises above the mean arterial pressure.

A variety of infusion pumps are available, ranging from simple devices to instruments that maintain a preset intrauterine pressure. Simple pump devices continue to press fluid into the uterine cavity regardless of resistance, whereas the pressure-sensitive pumps reduce the flow rate when the preset level is reached, thereby impeding the efflux of blood and debris and compromising the view.

Imaging

Endoscopes

Hysteroscopes are available in two basic types—flexible and rigid. Flexible hysteroscopes have lower resolution than rigid instruments of a similar diameter and are most useful for cannulation of the fallopian tube. For other uses, rigid hysteroscopes are more durable and provide a superior image. The most commonly used hysteroscopes are 4 mm in diameter, although those smaller than 3 mm in diameter are available. Small-diameter endoscopes have a somewhat lower resolution but are easier to pass through the cervix.

Oblique endoscopes are more useful for hysteroscopy than laparoscopy and are available in zero-degree, 12- to 15-degree, and 25- to 30-degree models ([Fig. 21.20](#)). The zero-degree telescope provides a panoramic view and is best for diagnostic procedures. Hysteroscopes with 25- to 30-degree angles are most often used for both diagnosis and therapy, although the 12- to 15-degree types are a suitable compromise useful for diagnosis, ablation, and resection.

Figure 21.20 Hysteroscope optics. Panoramic (08) and oblique (158 and 308) viewing angles.

Light Sources and Cables

Adequate illumination of the endometrial cavity is essential. Because it runs from a standard 110- or 220-volt wall outlet, the light source requires no special electrical connections. For most cameras and endoscopes, the element must have at least 150 watts of power for direct viewing and preferably 250 watts or more for video and operative procedures ([143](#)).

Video Imaging

Although diagnostic hysteroscopy may be performed with direct visualization, it is best to use video guidance for prolonged operations. Video imaging is important for teaching and recording pathology and procedures. The cameras used for operative hysteroscopy often have greater technical requirements than those used for laparoscopy. The camera must be more sensitive because of the narrow diameter of the endoscope and the frequently dark background of the endometrial cavity, particularly when it is enlarged ([Fig. 21.18](#)).

Intrauterine Manipulation

The instruments available for use through operative hysteroscopes include grasping, cutting, and punch-biopsy devices. These tools are narrow and flexible enough to navigate the 1- to 2-mm diameter operating channel ([Fig. 21.21](#)). Their value is limited by their small size and flimsy construction. However, the scissors can be used to divide adhesions, the biopsy forceps can be used to sample targeted lesions, and the grasping forceps can be used to remove small polyps or intrauterine devices. Some operative hysteroscopes are designed to allow passage of fibers for the conduction of Nd:YAG laser.

Figure 21.21 Hysteroscopy hand instruments. *From top:* biopsy forceps, grasping forceps, and scissors, each of which passes through the instrument channel of an operating hysteroscope. *Bottom:* a rigid sheath with integrated scissors.

The uterine resectoscope is similar to the one used in urology and is designed to apply electrical energy in the endometrial cavity ([Fig. 21.22](#)). An understanding of the principles of electrosurgery is mandatory for safe and effective use of this instrument. By sliding the “working element,” one of a variety of electrode tips can be manipulated back and forth within the cavity. Tissue can be divided with a pointed electrode, excised with a loop, or desiccated with a rolling ball or bar. A clear operative field is maintained by the continuous flow of nonconductive distending media in and out of the cavity. Although basic design modifications have made the resectoscope more useful in gynecology, extraction of resected fragments is time consuming. The most effective approach is the periodic use of a uterine curette or polyp forceps inserted after removal of the hysteroscope.

Figure 21.22 Uterine resectoscope (Olympus America, Inc., Woodbury, NY). **A** (from top): light guide (left) and monopolar electro-surgical cord (right); a 4-mm 128 endoscope; the Iglesias working element; an inner sheath; an outer sheath; the obturator. **B**, Fully assembled resectoscope.

Other Instruments

For any hysteroscopic procedure, it is necessary to have a cervical tenaculum, dilators, uterine curette, and appropriate-sized vaginal specula. When using the resectoscope, it is helpful to have a modern, solid-state, isolated circuit electro-surgical generator capable of delivering both modulated and nonmodulated radiofrequency current. Laparoscopy or laparotomy may be necessary for emergencies secondary to uterine perforation.

Complications

The potential risks of diagnostic hysteroscopy include uterine perforation, infection, excessive bleeding, and complications related to the distention media ([144](#)). The latter include CO₂ embolus and pulmonary edema secondary to overinfusion of 32% dextran 70 (*Hyskon*) or low-viscosity fluids. Diagnostic hysteroscopy performed in the office has a low rate of complications (0% to 1%) ([98,99](#) and [100](#)). The risks of operative hysteroscopy are related to one of five aspects of the procedure performed: (a) anesthesia, (b) perforation, (c) bleeding, (d) the use of energy, and (e) the distention media.

Anesthesia

Local anesthesia is provided by the intracervical or paracervical injection of 0.5% to 2% lidocaine or mepivacaine solution, with or without a local vasoconstrictor such as adrenaline. Overdosage is prevented by ensuring that intravascular injection is avoided and by not exceeding the maximum recommended doses (*lidocaine*, 4 mg/kg; *mepivacaine*, 3 mg/kg). The use of a vasoconstrictor reduces the amount of systemic absorption of the agent, doubling the maximum dose that can be used.

Complications of intravascular injection or anesthetic overdose include allergy, neurologic effects, and impaired myocardial conduction. Allergy is characterized by the typical symptoms of agitation, palpitations, pruritus, coughing, shortness of breath, urticaria, bronchospasm, shock, and convulsions. Treatment measures include administration of oxygen, isotonic intravenous fluids, intramuscular or subcutaneous adrenaline, and intravenous prednisolone and aminophylline. Cardiac effects related to impaired myocardial conduction include bradycardia, cardiac arrest, shock, and convulsions. Emergency treatment measures include the administration of oxygen, intravenous *atropine* (0.5 mg), and intravenous *adrenaline* and the initiation of appropriate cardiac resuscitation. The most common central nervous system manifestations are paresthesia of the tongue, drowsiness, tremor, and convulsions. Options for therapy include intravenous diazepam and respiratory support.

Perforation

Perforation may occur during dilation of the cervix or during the hysteroscopic procedure. With perforation, the endometrial cavity does not distend, and the visual field is lost. When perforation occurs during dilation of the cervix, the procedure must be terminated, but usually there are no other injuries. If the uterus is perforated by a hysteroscopic instrument, the tip of a laser, or an activated electrode, there is a risk for bleeding or injury to the adjacent viscera. Therefore, the operation must be stopped and the instruments withdrawn under hysteroscopic guidance.

If there is evidence of bleeding or presumed visceral injury, laparoscopy or laparotomy should be performed. Injury to the uterus is relatively easy to detect with a laparoscope. However, mechanical or thermal injury to the bowel, ureter, or bladder is more difficult and may require laparotomy. If the patient's condition is managed expectantly, she should be advised of the situation and asked to report any symptoms of bleeding or visceral trauma.

Bleeding

Bleeding that occurs during or after hysteroscopy results from trauma to the vessels in the myometrium or injury to other vessels in the pelvis. Myometrial vessels can be lacerated during the resectoscopic procedures.

In planning operations that involve deep resection, autologous blood can be obtained before surgery. The risk for bleeding may be reduced by the preoperative injection of diluted vasopressin into the cervical stroma ([145](#)). The risk for injury to branches of the uterine artery can be lowered by minimizing the depth of resection in the lateral endometrial cavity near the uterine isthmus, where ablative techniques should be used. When bleeding is encountered during resectoscopic procedures, the ball electrode can be used to desiccate the vessel electro-surgically. Intractable bleeding may respond to the injection of diluted vasopressin or to the inflation of a 30-mL Foley catheter balloon in the endometrial cavity ([117](#)).

Thermal Trauma

The temperature of the uterine serosa does not rise significantly during electro-surgical coagulation of the endometrium, even at the cornu, which is the thinnest area of the myometrium ([146](#)). However, if an activated electrode or laser fiber penetrates the uterus, surrounding structures such as bowel, urinary tract, and blood vessels are at risk. An activated electrode or fiber should never be advanced, but if an activated electrode has penetrated the uterine wall, direct examination of the pelvic viscera is mandatory. Laparoscopy is the appropriate first step. The site of the perforation should be examined to exclude the presence of significant bleeding. Most perforations do not need to be repaired. However, the pelvic sidewalls, the bladder, and the small and large bowel should be carefully inspected. If the intestines are damaged, laparotomy is indicated to repair the damage ([147](#)).

Thermal injury to the intestine or ureter may be difficult to diagnose, and symptoms may not occur for several days to 2 weeks. Therefore, the patient should be advised of the symptoms that could indicate peritonitis.

Distention Media

Carbon Dioxide

CO₂ can cause emboli and result in serious intraoperative morbidity and death ([148,149](#) and [150](#)). These risks can be eliminated by not using CO₂ with operative procedures and by ensuring that the insufflation pressure is always lower than 100 mm Hg and that the flow rate is lower than 100 mL/min. The insufflator used must be especially designed for hysteroscopy; it is difficult to set laparoscopic insufflator flow rates below 1,000 mL/min.

Dextran 70

Dextran 70 is a hyperosmolar medium that can induce an allergic response, coagulopathy, and, if sufficient volumes are infused, vascular overload and heart failure

(151,152). Because dextran is hydrophilic, it can draw 6 times its own volume into the systemic circulation. Consequently, the volume of this agent should be limited to less than 300 mL, particularly for office use.

Low-Viscosity Fluids

The low-viscosity fluids 1.5% glycine and 3% sorbitol are most often used, largely because of their low cost, compatibility with electrosurgery, and availability in large-volume bags. However, the use of a continuous-flow system with hypotonic media can create fluid and electrolyte disturbances.

1. Before undertaking a procedure using the resectoscope, baseline serum electrolyte levels should be measured. Women with cardiopulmonary disease should be evaluated carefully. The selective preoperative use of agents such as GnRH agonists may reduce operating time and media absorption.
2. In the operating room, media infusion and collection should take place in a closed system to allow accurate measurement of the "absorbed" volume. The volume should be calculated every 5 minutes or at least every 15 minutes.
3. The lowest intrauterine pressure necessary for adequate distention should be used to complete the operation, usually at a level that is below the mean arterial pressure. A good range is 70 to 80 mm Hg, which can be achieved with a specially designed pump or by maintaining the meniscus of the infusion bag 1 m above the level of the patient's uterus.
4. Deficits of more than 1 L require measurement of electrolyte levels. The procedure should be completed expeditiously. If the deficit is more than 2 L, the procedure should be terminated, and a diuretic such as mannitol or furosemide should be used as needed. In patients with cardiovascular compromise, deficits must be avoided (36).

Image Documentation

A small video camera can be used to teach and to coordinate the procedure better with the operating room team. It also allows the operation to be recorded for future reference. A video recorder may be attached to a video camera system. For optimal recording, the camera should be attached directly to the recorder so that the image is transmitted to the monitor for viewing during the operation. A number of video recording formats are available, each with inherent advantages and disadvantages. The best quality still images are obtained with a 35-mm single-lens reflex still camera and coupler. The use of a camera is often cumbersome, but the images taken from a standard still camera are of higher resolution than those obtained from videotape. Some video printers provide images suitable for a medical record. Newer digital cameras provide video still images, slides, or prints that are suitable for publication or teaching.

Hysterectomy is one of the most common surgical procedures performed. After cesarean delivery, it is the second most frequently performed major surgical procedure in the United States (1). In 1965, there were 426,000 hysterectomies performed in the United States, with an average length of hospital stay of 12.2 days. This number reached its peak in 1985, when 724,000 procedures were reported, with the length of stay decreasing to 9.4 days. The number of hysterectomies performed in the United States declined to 544,000 in 1991, with an average length of stay of 4.5 days. Of these 544,000 hysterectomies, 408,000 (75%) were performed abdominally, and 136,000 (25%) were performed vaginally (2,3). However, by 1998, the number of hysterectomies performed had increased to more than 600,000 (4). Using 1987 age-specific hysterectomy rates and the population projections supplied by the U.S. Census Bureau, it has been projected that there will be 824,000 hysterectomies in the year 2005 (5).

The rate of hysterectomy has varied between 6.1 and 8.6 per 1,000 women of all ages. A woman's chance of having a hysterectomy is dependent on a variety of factors, including her age, race, and where she lives, and the sex of her physician. Women between the ages of 20 and 49 years constituted the largest segment of women undergoing the procedure. The average age of a woman undergoing hysterectomy is 42.7 years and the median age is 40.9 years, which has remained constant since the 1980s. About 75% of all hysterectomies are performed in women between the ages of 20 and 49 years. The rates of hysterectomy vary by region of the country. The highest overall rate is in the southern states, where the rate tends to be higher for women aged 15 to 44 years. The lowest rates have consistently been in the northeastern portion of the United States. Hysterectomy is more often performed in African American than in white women and is performed more frequently by male gynecologists than by female gynecologists (6,7,8 and 9).

Indications

The indications for hysterectomy are listed in Table 22.1. In virtually all studies, uterine leiomyomas are consistently the leading indication for hysterectomy. As expected, the indications differ with the patient's age (10). For instance, whereas pelvic relaxation accounts for 16% of hysterectomies, this diagnosis is responsible for more than 33% of hysterectomies in women older than 55 years of age. More complete discussions of these indications are presented in the specific chapters indicated.

Table 22.1. Hysterectomy Indication Profile^a

Leiomyomas

Uterine leiomyomas are the most common pelvic tumors in women; therefore, this condition is responsible for a large number of hysterectomies (10). Hysterectomy for uterine leiomyomas should be considered only in patients who do not desire future fertility. Otherwise, fertility-preserving surgical management (myomectomy) is possible in most patients with leiomyomas. The decision to perform a hysterectomy for leiomyomas is usually based on the need to treat symptoms—abnormal uterine bleeding, pelvic pain, or pelvic pressure. Other indications for intervention have included “rapid” uterine enlargement (although this finding is poorly defined), ureteral compression, or uterine growth after menopause. The concept of rapid growth has been challenged (11) because such patients have not been shown clearly to have

malignant conditions. Furthermore, there is no clearly reproducible definition of rapid growth.

The removal of the uterus because it reaches a certain size is widely debated. In the past, surgeons removed the uterus if its size reached that approximating 12 weeks' gestation or greater, even if it was asymptomatic. The reasons given for such an intervention include the inability to palpate the ovaries on bimanual examination and the assumption that, as the uterus enlarges, the morbidity for hysterectomy increases. Malignancy is uncommon in premenopausal patients, however, and adnexal palpation is not possible in many patients whose ovaries are of normal size. No difference in surgical morbidity exists between patients with a 12-week-sized uterus and those with a 20-week-sized uterus if the procedures are performed abdominally (12). **Therefore, hysterectomy for leiomyomas should be considered only in symptomatic patients who do not desire future fertility (12).**

To reduce uterine size before hysterectomy, patients with large leiomyomas may be pretreated with a gonadotropin-releasing hormone (GnRH) agonist (13,14 and 15). In many cases, the reduction of uterine size is sufficient to permit vaginal hysterectomy when otherwise an abdominal hysterectomy would have been necessary. In one prospective trial, premenopausal patients with leiomyomas the size of 14 to 18 weeks of gestation were randomized to receive either 2 months of preoperative depot GnRH agonist or no GnRH agonist (15). Treatment with a short course (8 weeks) of leuprolide acetate before surgery enabled patients' procedures to be converted safely from an abdominal hysterectomy to a vaginal hysterectomy. This preoperative regimen was associated with a rise in hematocrit before surgery and, because patients were more likely to have vaginal than abdominal hysterectomy, shortening the patient's hospital stay and convalescent period.

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding is the indication for about 20% of hysterectomies. Because dysfunctional uterine bleeding usually is the result of anovulation, the bleeding can be controlled by medical interventions with progestin, estrogen, a combination of progestin and estrogen, oral contraceptives, or nonsteroidal antiinflammatory agents (see Chapter 13). In most patients, the bleeding requires no therapy unless anemia is present or bleeding is excessive and interferes with the patient's quality of life. In patients older than 35 years of age, endometrial sampling should be performed before hysterectomy. Dilation and curettage is not an effective means of controlling bleeding and is not necessary before hysterectomy (16). Therefore, hysterectomy should be reserved for patients who do not respond to or who cannot tolerate medical therapy. Alternatives to hysterectomy (e.g., endometrial ablation or resection) should be considered in selected patients because these operations may be cost-effective and have a lower morbidity rate (see Chapter 21).

Intractable Dysmenorrhea

About 10% of adult women are incapacitated for up to 3 days per month as a result of dysmenorrhea (see Chapter 14) (17). Dysmenorrhea can be treated with nonsteroidal antiinflammatory agents used alone or in combination with oral contraceptives or other hormone agents to reduce or ablate menstrual flow (18,19). Hysterectomy is rarely required for the treatment of primary dysmenorrhea. In patients with secondary dysmenorrhea, the underlying condition (e.g., leiomyomas, endometriosis) should be treated primarily. Nonsteroidal antiinflammatory agents may be effective. **Hysterectomy should be considered only if medical therapy fails or if the patient does not want to preserve fertility (20,21 and 22).**

Pelvic Pain

In a review of 418 women in whom hysterectomy was performed for a variety of nonmalignant conditions, 18% had chronic pelvic pain. Preoperative laparoscopy was performed in only 66% of these patients. After hysterectomy, there was a significant reduction in symptoms associated with an improvement in the patient's quality of life (23). Stovall and colleagues reviewed 104 patients who underwent hysterectomy for chronic pelvic pain that was believed to be of uterine origin. Patients were followed for a mean of 21.6 months after hysterectomy, and 78% experienced improvement in their pain (24). However, 22% of patients had no improvement or exacerbation of their pain. **Hysterectomy should be performed only in those patients whose pain is of uterine origin and does not respond to nonsurgical treatments (18)** (see Chapter 14).

Cervical Intraepithelial Neoplasia

In the past, hysterectomy was performed as primary treatment of cervical intraepithelial neoplasia. However, the maximum depth of dysplasia at the squamocolumnar junction is 5.2 mm; 99.7% of dysplasias (including carcinoma *in situ*) are located within 3.8 mm of the epithelial surface (25). Therefore, more conservative treatments such as cryotherapy, laser, or a loop electrosurgical excision procedure can be effective in treating the disease, making hysterectomy unnecessary in most women with these conditions (see Chapter 16). For patients with recurrent high-grade dysplasia who do not desire to preserve fertility, hysterectomy is an appropriate treatment option. Even after hysterectomy, however, patients are at increased risk for vaginal intraepithelial neoplasia.

Genital Prolapse

Hysterectomy for symptomatic genital prolapse accounts for about 15% of hysterectomies performed in the United States (7). **Unless there is an associated condition requiring an abdominal incision, vaginal hysterectomy is the preferred approach for genital prolapse.** Uterine prolapse typically is not an isolated event and is most often associated with a variety of pelvic support defects (see Chapter 20). Each defect must be corrected to optimize the surgical outcome and decrease the chance for future development of pelvic support defects.

Obstetric Emergency

Most emergency hysterectomies are performed because of postpartum hemorrhage resulting from uterine atony. Other indications include uterine rupture that cannot be repaired or a pelvic abscess that does not respond to medical therapy. Hysterectomy may be required for patients with placenta accreta or placenta increta.

Pelvic Inflammatory Disease

Pelvic inflammatory disease can generally be successfully treated with antibiotics. The uterus, tubes, and ovaries should not be removed in a patient with pelvic inflammatory disease unless the patient has not responded to intravenous antibiotic therapy (see Chapter 15). Whether one proceeds with conservative surgical management, abscess drainage, or organ removal is a subjective decision that must be based on the individual. If accessible, some pelvic abscesses may be drained successfully by percutaneous catheter drainage guided by ultrasonography or computed tomography (CT) scanning. Surgical intervention also is necessary if the patient has acute abdominal findings associated with peritonitis and signs of sepsis in the presence of a ruptured tuboovarian abscess. **For the patient who desires future fertility, consideration should be given to unilateral adnexectomy or partial bilateral adnexectomy without hysterectomy.** For the patient in whom bilateral adnexectomy is required, the uterus can be left in place for possible ovum donation and *in vitro* fertilization (see Chapter 27).

Endometriosis

Medical and conservative surgical procedures generally are successful for treatment of endometriosis (see Chapter 26). Therefore, adnexectomy with or without hysterectomy should be performed only in patients who do not respond to conservative surgical (resection or ablation of endometriotic implants) or medical therapy. Most patients with endometriosis who require hysterectomy have unrelenting pelvic pain or dysmenorrhea. Other less common situations include patients who do not desire future fertility and who have endometriosis involving other pelvic organs, such as the ureter or colon.

Cancer

Metastases from nongynecologic sites may cause symptoms requiring hysterectomy. As a primary procedure, hysterectomy with bilateral salpingo-oophorectomy should be considered for patients with colorectal carcinoma because these patients are at risk for either synchronous pelvic cancers or occult metastases (26,27).

Benign Ovarian Tumor

Benign ovarian tumors that are persistent or symptomatic require surgical treatment. Obviously, if the patient desires fertility, the uterus should be conserved. If fertility is not an issue, however, or if the patient is perimenopausal or postmenopausal, a decision must be made regarding whether the uterus should be removed. Gambone and colleagues reviewed 100 patients who underwent adnexectomy plus hysterectomy for benign adnexal disease and compared these patients with a group of risk-matched women who underwent adnexectomy without hysterectomy for the same indication (28). There was a significant increase in operative morbidity, estimated blood loss, and the length of hospital stay for patients in whom hysterectomy was performed.

Vaginal Versus Abdominal Hysterectomy

The proportion of abdominal versus vaginal hysterectomies has not changed significantly since the 1980s—about 75% of hysterectomies are abdominal (2,3,7,29,30,31 and 32). There are no specific criteria that can be used to determine the route of hysterectomy. The route chosen should be individualized. Absolute and relative contraindications have been proposed (27,28 and 29). In a large, multicenter retrospective study conducted by the U.S. Centers for Disease Control between 1978 and 1981, the risks and outcome of abdominal and vaginal hysterectomy were compared (32). The study included 1,851 patients aged 15 to 44 years in whom hysterectomy was performed for benign gynecologic disorders (568 vaginal, 1,283 abdominal). Surgical complications were classified into six categories. The overall complication rate was 24.5 per 100 for vaginal hysterectomy compared with 42.8 per 100 women for abdominal hysterectomy. **The risk for one or more complications after abdominal hysterectomy was 1.7 times the risk after vaginal hysterectomy.** The two major categories of complications were febrile morbidity and hemorrhage requiring transfusion. **The risk for febrile morbidity was 2.1 times higher for abdominal hysterectomy than for vaginal hysterectomy, and the risk for transfusion was 1.9 times higher for abdominal surgery.** Since the collection of these data, transfusion practices within the United States have changed as a result of increased awareness of the human immunodeficiency virus. Although only one fourth of hysterectomies are performed vaginally, this proportion could probably be increased substantially. In a recent study of 617 hysterectomies, 548 were performed vaginally; laparoscopic assistance was used in 63 patients, and an abdominal approach was required in only 6 patients (33). If feasible, vaginal hysterectomy is the preferred approach.

Supracervical Hysterectomy

The indications for supracervical hysterectomy are somewhat vague. Among potential indications are endometriosis with obliteration of the anterior and posterior cul-de-sac, cesarean hysterectomy when the cervix is fully dilated and difficult to identify, and concern for sexual function. During a technically difficult surgical procedure (e.g., obliteration of the cul-de-sac), there may be concern about the potential morbidity associated with the removal of the cervix. However, **the cervix can almost always be removed.** Some women desire to conserve the cervix because they believe that it is important for sexual satisfaction, although there are no sound scientific data to prove this perception. Some authors (currently representing the minority view) believe that the cervix should not be removed unless there is a specific reason. They suggest that removal of the cervix leads to a decrease in sexual pleasure, increased operative and postoperative morbidity, vaginal shortening, vault prolapse, abnormal cuff granulations, and the potential for oviductal prolapse (34,35).

There is a debate about the effects of leaving the cervix *in situ*. Kilku and associates reported on a group of 210 patients who underwent hysterectomy, of whom half had total abdominal hysterectomies and half had supracervical hysterectomies (36). Studies of the same population disclosed an increase in psychiatric symptoms in both groups (34,35 and 36). Sexual desire and functioning was unchanged, although there was a decrease in dyspareunia in both groups. Patients undergoing supracervical hysterectomy were reported to have increased orgasmic frequency when compared with patients in whom the cervix was left intact (36,37,38 and 39). Regardless of the reason for leaving the cervix at the time of hysterectomy, preoperative Papanicolaou (Pap) test results must be normal, and appropriate consent must be obtained from the patient.

Laparoscopically Assisted Hysterectomy

Laparoscopy has been used diagnostically before hysterectomy (see Chapter 21). Kovac (33) performed laparoscopy in 46 patients who had been advised to have abdominal hysterectomies, and the findings suggested that uterine size had been overestimated and that uterine mobility had been underestimated by the referring physicians. All 14 patients who were referred for assessment of adnexal pathology had none. In 91% (42 of 46) of the patients, a vaginal hysterectomy was completed. In another study of seven patients who were candidates for vaginal hysterectomy, except that they had a history suggestive of adhesions, six of the patients underwent laparoscopy, which did not reveal any adhesive disease (40), and were able to undergo vaginal hysterectomy. These findings are consistent with the other data demonstrating that the **presence of pelvic adhesions cannot be predicted based on either history or physical examination** (41). However, if laparoscopy is performed on patients with risk factors for adhesions or endometriosis, many patients will undergo the procedure needlessly, and about half of those with adhesions or endometriosis will be overlooked. Thus, the role of diagnostic laparoscopy immediately before hysterectomy seems limited.

The use of operative laparoscopy to complete some or all of the hysterectomy has been widely reported (42,43,44,45,46,47,48,49,50,51 and 52) (see Chapter 21). However, in most of these studies, the patient population was neither randomized nor defined. Furthermore, the reasons the patient would require an abdominal approach are unclear. **The criteria for patient selection for laparoscopy-assisted vaginal hysterectomy (LAVH) versus abdominal hysterectomy have not been clearly established.**

Summitt and co-workers (46) published a randomized, prospective, controlled trial in which patients who were candidates for vaginal hysterectomy were randomized to either LAVH or a standard vaginal approach. All procedures were performed on an outpatient basis; included were patients who had uterine leiomyomas up to the size of 16 weeks of gestation. There was no difference between the groups in terms of uterine weight, febrile morbidity, or the need for transfusion. Patients undergoing LAVH had a lower hematocrit value on the first and second postoperative days and required more pain medication on the second postoperative day. Although these findings are not clinically significant, they suggest that, when compared with a vaginal approach, LAVH does not reduce perioperative morbidity. The cost of LAVH is significantly higher than that of vaginal hysterectomy (\$7,905 versus \$4,891); the largest component of this difference in cost resulted from the use of disposable equipment. **This study demonstrates that there is no advantage of LAVH over traditional vaginal hysterectomy.**

It has been suggested that LAVH may be helpful in treating patients with documented endometriosis, known pelvic adhesive disease, an adnexal mass that requires hysterectomy, and lack of uterine mobility (see Chapter 21). Depending on the circumstances, LAVH may be appropriate in some patients with stage I endometrial cancer or previous episodes of multiple major pelvic surgery. For example, if the patient has had endometriosis that has been treated previously or adhesions that have been lysed previously and now require hysterectomy, a vaginal approach can most likely be taken. Davis and associates reported on a group of patients with stage III or IV endometriosis, in whom the procedure was successful in 40 of 46 patients (53). Even in the hands of expert laparoscopic surgeons, however, the rate of complications was high.

Mild pelvic adhesions do not preclude vaginal hysterectomy. If the patient has intensive adhesions that involve the adnexa, bowel, and uterus, however, an abdominal approach is usually needed (54). In such patients, laparoscopy may be a better alternative than hysterectomy.

It is uncertain whether LAVH is preferable in patients with limited uterine mobility, and there is no standard method to assess the best approach. The major supporting structures of the uterus are the uterosacral ligaments and lower cardinal complex (55), which are not generally transected with a laparoscopic approach. Transection of the uteroovarian ligament, round ligament, and broad ligament does not improve mobility.

Both LAVH and pelvic lymphadenectomy may be useful in selected patients with endometrial carcinoma (56). The data suggest that a lymphadenectomy can be performed successfully and that hospital stay and morbidity are decreased when compared with the standard transabdominal approach. Long-term prospective studies are needed to address these questions.

Concurrent Surgical Procedures

Oophorectomy at the Time of Hysterectomy

A laparoscopic approach should not be used in conjunction with hysterectomy solely for the purpose of accomplishing ovarian removal. Although not every ovary can be removed through the vagina, it has been shown clearly that most can be removed in this manner (57).

Prophylactic oophorectomy is the most common surgical procedure performed concurrently with hysterectomy. Oophorectomy is performed prophylactically to prevent ovarian cancer and to eliminate the potential need for further surgery for either benign or malignant disease. **Arguments against prophylactic oophorectomy center around the need for earlier and more prolonged hormone replacement.** Although hormone replacement therapy is generally well tolerated and provides good symptomatic relief, it may not be as effective as normal ovarian function, and the implications of long-term replacement therapy are not fully known. Therefore, the decision to proceed with oophorectomy should be considered carefully after the patient has been informed of the risks and benefits.

The risk for developing ovarian cancer after hysterectomy for benign disease is lower than would be expected based on its prevalence. Of those women who have no history of ovarian tumors and normal-appearing ovaries at the time of abdominal hysterectomy, 0.14% subsequently develop ovarian cancer in their conserved ovaries (58). Considering that as many as 1.4% of women are expected to get ovarian cancer, this is about one tenth the expected rate. Presumably, this lower rate occurs because the cohort of women with normal-appearing ovaries in whom hysterectomy is performed for benign disease is a “selected” population. In women who do not have ovarian disease at the time of hysterectomy, the risk for developing benign ovarian tumors is less than 5% (59). The risk for ovarian cancer in women with a strong family history is 3% to 50%, depending on the pedigree (60,61) (see Chapter 32).

Long-term compliance with posthysterectomy estrogen replacement therapy is low (62). Only 20% to 40% of women who initiate treatment after hysterectomy and bilateral oophorectomy continue to take estrogen for more than 5 years. Therefore, it should not be assumed that patients will receive adequate replacement estrogen after oophorectomy. Women who subsequently develop breast cancer may be advised not to take estrogen.

Appendectomy

Appendectomy may be performed concurrently with hysterectomy to prevent appendicitis and to remove disease that may be present. The former use is of limited value, however, because the peak incidence of appendicitis is between 20 and 40 years of age, whereas the peak age for hysterectomy is 10 to 20 years later (63). Appendectomy is effective in removing previously undetected disease, but the likelihood that these abnormalities would cause any clinical problems is uncertain. In one study, histologic abnormalities were found in 71% (32 of 45) of appendices removed at the time of hysterectomy, and two had asymptomatic carcinoid tumors (64). In another study, 22% of appendices removed at the time of hysterectomy showed evidence of pathologic alterations, and five carcinoid tumors were identified (65).

There is no increase in morbidity associated with appendectomy performed at the time of hysterectomy (65,66 and 67), although it does require an average of 10 minutes of additional operating time (59). Appendectomy has also been performed with vaginal hysterectomy without additional intraoperative or postoperative morbidity (68,69,70 and 71).

Cholecystectomy

Gallbladder disease is about four times more common in women than men, and its highest incidence occurs between 50 and 70 years of age, when hysterectomy is most often performed. Thus, women may require both procedures. A combined procedure does not appear to result in increased febrile morbidity or length of hospital stay (72,73).

Abdominoplasty

Abdominoplasty performed at the time of hysterectomy is associated with a shorter hospital stay, a shorter operating time, and a lower intraoperative blood loss than when the two operations are performed separately (74,75). Liposuction also can be performed safely at the time of vaginal hysterectomy (76).

Technique

Negative results of a Pap test performed within the year should be obtained before performing a hysterectomy for benign disease. If the patient is 40 years of age or older and has not recently had a mammography, this examination should be performed. Endometrial sampling is recommended if the patient has reported abnormal uterine bleeding. In patients older than 40 years of age, a stool guaiac test should be performed.

Other preoperative testing should be dictated by the patient's specific medical conditions.

Abdominal Hysterectomy

Preoperative Preparation

Although not mandatory, a cleansing tap water or soap enema given on the evening before or the morning of the scheduled hysterectomy is preferred by some surgeons. To reduce the colony count of skin bacteria, the patient is asked to shower. Hair surrounding the incision area may be removed at the time of surgery or before surgery using a depilatory agent. Hair clipping is preferable to shaving because it decreases the incidence of incisional infection (77).

Patient Positioning The patient is placed in the dorsal supine position for the procedure. After the patient is anesthetized adequately, her legs are placed in the stirrups and a pelvic examination is performed to validate the in-office pelvic examination findings. A Foley catheter is placed in the bladder, and the vagina is cleansed with an iodine solution. The patient's legs are then straightened.

Skin Preparation Several methods for skin cleaning can be recommended, including a 5-minute iodine solution scrub followed by application of iodine solution, iodine solution scrub followed by alcohol with application of an iodine-impregnated occlusive drape, or an iodine-alcohol combination with or without application of an iodine-impregnated occlusive drape.

Surgical Technique

Incision The choice of incision should be determined by the following considerations:

1. Simplicity of the incision
2. The need for exposure
3. The potential need for enlarging the incision
4. The strength of the healed wound
5. Cosmesis of the healed incision
6. The location of previous surgical scars

The skin is opened with a scalpel, and the incision is carried down through the subcutaneous tissue and fascia. With traction applied to the lateral edges of the incision, the fascia is divided. The peritoneum is opened similarly. This technique minimizes the possibility of inadvertent enterotomy, entering the abdominal cavity.

Abdominal Exploration After entering the peritoneal cavity, the upper abdomen and the pelvis are explored systematically. The liver, gallbladder, stomach, kidneys, paraaortic lymph nodes, and large and small bowel should be examined and palpated. Cytologic sampling of the peritoneal cavity, if needed, should be performed before abdominal exploration.

Retractor Choice and Placement A variety of retractors have been designed for pelvic surgery. The Balfour and the O'Connor-O'Sullivan retractors are used most often. The Bookwalter retractor has a variety of adjustable blades that can be helpful, particularly in obese patients.

Elevation of the Uterus The uterus is elevated by placing broad ligament clamps at each cornu so that it crosses the round ligament. The clamp tip may be placed

close to the internal os. This placement provides uterine traction and prevents backbleeding ([Fig. 22.1](#)).

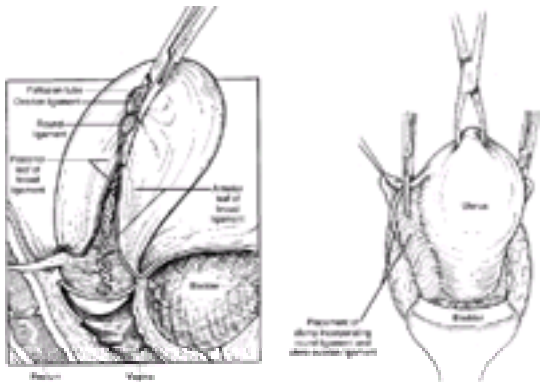

Figure 22.1 The uterus is elevated by placement of clamps across the broad ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Round Ligament Ligation The uterus is deviated to the patient's left side, stretching the right round ligament. With the proximal portion held by the broad ligament clamp, the distal portion of the round ligament is ligated with a suture ligature or simply transected with Bovie cautery ([Fig. 22.2](#)). The distal portion can be grasped with forceps, and the round ligament is cut to separate the anterior and posterior leaves of the broad ligament. The anterior leaf of the broad ligament is incised with Metzenbaum scissors or electrocautery along the vesicouterine fold, separating the peritoneal reflection of the bladder from the lower uterine segment ([Fig. 22.3](#)).

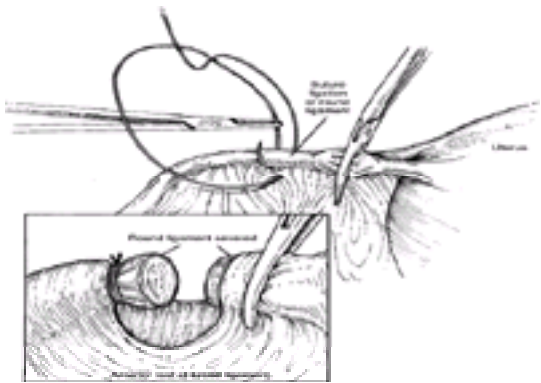

Figure 22.2 The round ligament is transected and the broad ligament is incised and opened. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996.)

Figure 22.3 The incision in the anterior broad ligament is extended along the vesicouterine fold. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Ureter Identification The retroperitoneum is entered by extending the incision cephalad on the posterior leaf of the broad ligament. Care must be taken to remain lateral to both the infundibulopelvic ligament and iliac vessels. The external iliac artery courses along the medial aspect of the psoas muscle and is identified by bluntly dissecting the loose alveolar tissue overlying it. **By following the artery cephalad to the bifurcation of the common iliac artery, the ureter is identified crossing the common iliac artery. The ureter should be left attached to the medial leaf of the broad ligament to protect its blood supply ([Fig. 22.4](#)).**

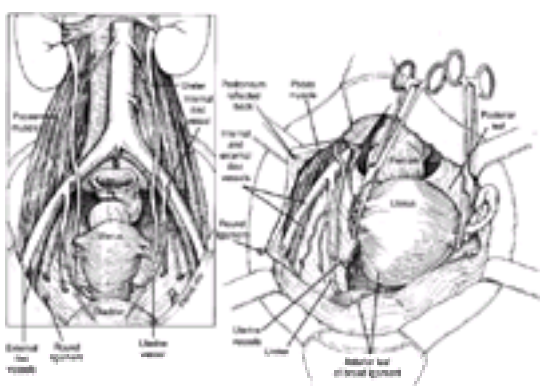

Figure 22.4 Identification of the ureter in the retroperitoneal space on the medial leaf of the broad ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Uteroovarian or Infundibulopelvic Ligament Ligation If the ovaries are to be preserved, the uterus is retracted toward the pubic symphysis and deviated to one side, placing tension on the contralateral infundibulopelvic ligament, the tube, and the ovary. **With the ureter under direct visualization, a window is created in the peritoneum of the posterior leaf of the broad ligament under the uteroovarian ligament and fallopian tube.** The tube and uteroovarian ligament are clamped on each side with a curved Heaney or Ballentine clamp, cut, and ligated with both a free-tie and a suture ligature. The medial clamp at the uterine cornu should control backbleeding; if it does not, the clamp should be repositioned to do so ([Fig. 22.5](#)).

Figure 22.5 Ligation of the uteroovarian ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

If the ovaries are to be removed, the peritoneal opening is enlarged and extended cephalad to the infundibulopelvic ligament and caudad to the uterine artery. This opening allows proper exposure of the uterine artery, the infundibulopelvic ligament, and the ureter. In this manner, the ureter is released from its proximity to the uterine vessels and the infundibulopelvic ligament.

A curved Heaney or Ballentine clamp is placed lateral to the ovary (Fig. 22.6); care is taken to ensure that the entire ovary is included in the surgical specimen. The infundibulopelvic ligament on each side is cut and doubly ligated (Fig. 22.7). Alternatively, free ties can be passed around the infundibulopelvic ligament, two cephalad and one caudad, before the ligament is cut.

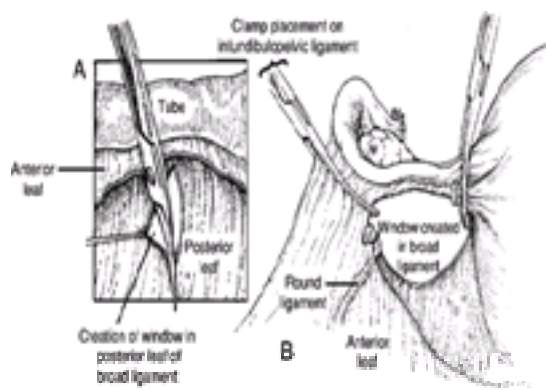

Figure 22.6 Ligation of the infundibulopelvic ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Figure 22.7 Transection of the infundibulopelvic ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Bladder Mobilization Using Metzenbaum scissors, with the tips pointed toward the uterus, the bladder is sharply dissected from the lower uterine segment and cervix. Alternatively, Bovie electrocautery can be used. An avascular plane, which exists between the lower uterine segment and the bladder, allows for this mobilization. Tonsil clamps may be placed on the bladder edge to provide countertraction and easier dissection (Fig. 22.8).

Figure 22.8 Dissection of the vesicouterine plane to mobilize the bladder. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Uterine Vessel Ligation The uterus is retracted cephalad and deviated to one side of the pelvis, stretching the lower ligaments. The uterine vasculature is dissected or "skeletonized" from any remaining areolar tissue, and a curved Heaney clamp is placed perpendicular to the uterine artery at the junction of the cervix and body of the uterus. Care is taken to place the tip of the clamp adjacent to the uterus at this anatomic narrowing. The vessels are cut, and the suture is ligated. The same procedure is repeated on the opposite side (Fig. 22.9).

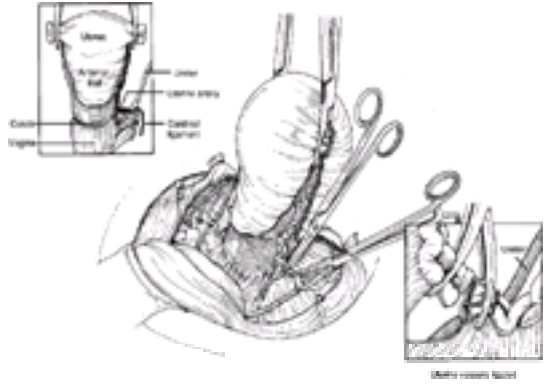

Figure 22.9 Ligation of the uterine blood vessels. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Incision of Posterior Peritoneum If the rectum is to be mobilized from the posterior cervix, the posterior peritoneum between the uterosacral ligaments just beneath the cervix and rectum may be incised (Fig. 22.10). A relatively avascular tissue plane exists in this area, allowing mobilization of the rectum inferiorly out of the operative field. A sponge may be placed to control the venous oozing that often occurs.

Figure 22.10 Incision of the rectouterine peritoneum and mobilization of the rectum from the posterior cervix. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Cardinal Ligament Ligation The cardinal ligament is divided by placing a straight Heaney clamp medial to the uterine vessel pedicle for a distance of 2 to 3 cm parallel to the uterus. The ligament is then cut, and the pedicle suture is ligated. This step is repeated on each side until the junction of the cervix and vagina is reached (Fig. 22.11).

Figure 22.11 Ligation of the cardinal ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Removal of the Uterus The uterus is placed on traction cephalad and the tip of the cervix is palpated. Curved Heaney clamps are placed bilaterally, incorporating the uterosacral ligament and upper vagina just below the cervix. **Care should be taken to avoid foreshortening the vagina.** The uterus is then removed with heavy curved scissors (Fig. 22.12).

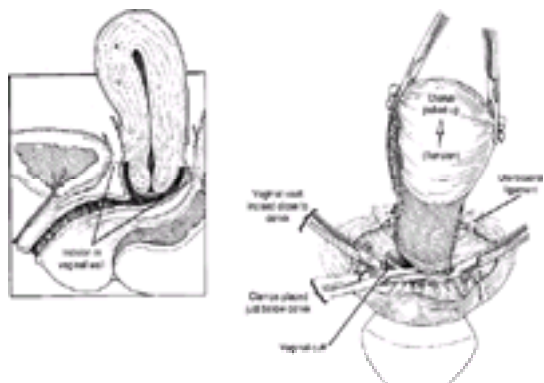

Figure 22.12 Removal of the uterus by transection of the vagina. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996.)

Vaginal Cuff Closure Several techniques of vaginal cuff closure have been described. A figure-of-eight suture of 0-0 braided absorbable material is placed between the tips of the two clamps. The suture is used for both traction and hemostasis. Sutures are also placed at the tip of each clamp, and the pedicles are sutured with a Heaney stitch, thereby incorporating the uterosacral and cardinal ligament at the angle of the vagina (Fig. 22.13). Alternatively, the vaginal cuff can be left open to heal secondarily. If this method is used, a running-locked suture is used for hemostasis along the cuff edge (Fig. 22.14).

Figure 22.13 Vaginal cuff closure incorporating the uterosacral and cardinal ligaments. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

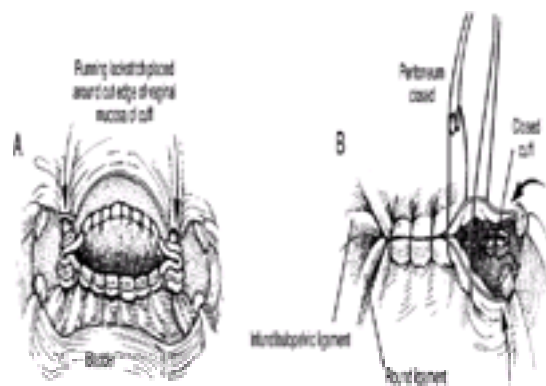

Figure 22.14 Vaginal cuff left open with a running suture along the cuff. B: Peritoneum closed. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Irrigation and Hemostasis The pelvis is thoroughly irrigated with saline or lactated Ringer's solution. Meticulous care is taken to ensure hemostasis throughout the pelvis, particularly of the vascular pedicles. Ureteral position and integrity are checked again to ensure that they are intact and do not appear dilated.

Peritoneal Closure The pelvic peritoneum is not reapproximated. Research using animal models suggests that reapproximation may increase tissue trauma and promote adhesion formation (77).

If the ovaries have been retained, they may be suspended to the pelvic sidewall to minimize the risk of becoming retroperitoneal or adherent to the vaginal cuff.

Incision Closure The parietal peritoneum is not reapproximated as a separate layer. Fascia can be closed with an interrupted or a continuous 0-0 or 1-0 monofilament absorbable suture. A continuous suture may reduce the risk for necrosis, which may occur when interrupted sutures are tied too tightly (77). As with interrupted sutures, bites should be taken about 1 cm from the cut edge of the fascia and about 1 cm apart to prevent wound dehiscence.

Skin Closure The subcutaneous tissue should be irrigated, with careful attention given to maintaining hemostasis. Subcutaneous sutures are not used because they may increase the incidence of wound infection (77). Skin staples or subcuticular sutures are used to reapproximate the skin edges. A bandage is applied and left in place for about 24 hours.

Intraoperative Complications

Most intraoperative injuries during abdominal hysterectomy can be traced to poor lighting, unsatisfactory assistance, undue haste, anatomic variants, or involvement of the injured organ in the disease process (78). Some of these factors can be eliminated with careful attention to detail and use of proper surgical technique. However, some operative injuries cannot be avoided by even the most skilled surgeons. The surgeon, therefore, must be prepared to recognize and repair these injuries. Even with a high level of attention to detail, injuries and complications, recognized and unrecognized, can still occur.

Ureteral Injuries

Injury to the pelvic ureter is one of the most formidable complications of hysterectomy (79,80 and 81). Because of the risk for subsequent renal impairment, injury to the ureter is far more serious than injury to the bladder or bowel (82,83).

It is essential to be aware of the proximity of the ureter to the other pelvic structures at all times. **Most ureteral injuries can be avoided by opening the retroperitoneum and directly identifying the ureter.** The use of ureteral catheters as a substitute for direct visualization is often of little help in patients with extensive fibrosis or scarring resulting from endometriosis, pelvic inflammatory disease, or ovarian cancer. In these instances, a false sense of security may actually increase an already high risk for ureteral injury (84). The use of ureteral catheters can also be associated with hematuria and acute urinary retention. Their complications are usually transitory in nature.

Direct visualization is accomplished by opening the retroperitoneum lateral to the external iliac artery. Blunt dissection of the loose areolar tissue is performed to visualize the artery directly. The artery may then be traced cephalad to the bifurcation of the internal and external iliac arteries. The ureter crosses the common iliac artery at its bifurcation and may be followed throughout its course in the pelvis.

Despite these precautions, ureteral injuries may occur. Prompt consultation is necessary if the surgeon has not been trained in ureteral repair. If a ureteral obstruction is suspected, confirmation may be obtained by intravenous injection of 1 ampule of indigo carmine dye, opening the dome of the bladder, and observing the presence or absence of bilateral spill of tinted urine. Alternatively, ureteral patency may be established by opening the dome of the bladder and positioning retrograde ureteral stents. Cystoscopic evaluation may replace opening the bladder to evaluate the spill of tinted urine (79,80,81,82,83 and 84).

Bladder Injury

Because of the close anatomic relationship of the bladder, uterus, and upper vagina, the bladder is the segment of the lower urinary tract that is most vulnerable to injury (82,84). Bladder injury may occur on opening the peritoneum or, more frequently, during the dissection of the bladder off the cervix and upper vagina (85). Unless there is involvement of the bladder trigone, a bladder laceration is easily repaired. In the nonirradiated bladder, a one- or two-layer closure with a small-caliber braided absorbable suture such as a 3-0 polyglycolic acid is adequate. The bladder should be drained postoperatively. The length of time that drainage is required is controversial. If the bladder is not compromised, drainage should be continued at least until gross hematuria clears, which may occur as soon as 48 hours postoperatively. A more conservative practice is to continue drainage until the patient is ready for discharge, usually a total of 3 to 4 days. Elective incision into the dome of the bladder is performed similarly (85). If the trigone is involved, a surgeon trained in complicated urologic repair should be consulted.

Bowel Injury

Small bowel injuries are the most common intestinal injuries in gynecologic surgery (86). Small defects of the serosa or muscularis may be repaired using a single

layer of continuous or interrupted 3-0 braided absorbable suture. Although single-layer closure of the small bowel has proved adequate, it is safer to close defects involving the lumen in two layers using a 3-0 braided absorbable suture. **The defect should be closed in a direction perpendicular to the intestinal lumen.** If a large area has been injured, resection with reanastomosis may be necessary ([85,87](#)).

Because the bacterial flora of the ascending colon is similar to that of the small bowel, injuries can be repaired in a similar manner. The transverse colon rarely is injured in normal gynecologic procedures because it is well outside the operative field. However, the descending colon and the rectosigmoid colon are intimately involved with the pelvic structures and are at significant risk for injury during gynecologic surgery. Injuries not involving the mucosa may be repaired with a single running layer of 2-0 or 3-0 braided absorbable suture. If the laceration involves the mucosa, it may be closed as with small bowel injuries if the colon has been prepared adequately. Otherwise, diverting colostomy may be necessary in some patients to protect the repair site from fecal contamination, especially if the defect is larger than 5 cm or if there is spillage of the bowel contents ([85,87](#)).

Hemorrhage

Significant arterial bleeding usually arises from the uterine arteries or the ovarian vessels near the insertion of the infundibulopelvic ligaments ([88](#)). Blind clamping of these vessels presents a risk for ureteral injury; therefore, the ureters should be identified in the retroperitoneal space and traced to the area of bleeding to avoid inadvertent ligation. It is best to apply a pressure pack to tamponade the bleeding and then slowly remove the pack in an effort to visualize, isolate, and individually clamp the bleeding vessels. Mass ligatures should be avoided. The use of surgical clips may be helpful. Venous bleeding, while less dramatic, is often more difficult to manage, particularly in the presence of extensive adhesions and fibroids. This type of bleeding can be controlled with pressure alone or with suture ligation. Bleeding from peritoneal edges or denuded surfaces may be controlled with pressure, application of topical agents such as thrombin or collagen, or cautery with the Bovie. A variety of laser techniques have been used to control bleeding.

Postoperative Management

Bladder Drainage Overdistention of the female bladder resulting from bladder trauma or the patient's reluctance to initiate the voluntary phase of voiding is one of the most common complications after abdominal hysterectomy ([89](#)). For this reason, an indwelling bladder catheter should be used for the first few postoperative hours until the patient is able to ambulate and urinate.

If retropubic urethropexy has been performed, consideration should be given to using a suprapubic catheter, which allows postvoid residual levels to be checked without repetitive catheterizations. This catheter may be removed when satisfactory postvoid residual levels of less than 100 mL have been obtained.

Diet In anticipation of the rare case in which the patient must be returned to the operating room, the patient is allowed only ice chips and liquids on the day of surgery. On the first postoperative day, assuming bowel sounds are present, diet is resumed, beginning with a soft diet and advancing to solid foods as tolerated. This dietary regimen assumes minimal intraoperative bowel manipulation and dissection. Early postoperative feeding has been shown not only to be safe but also to speed return of bowel function and recovery. In patients who have undergone pelvic and paraaortic lymph node dissection, bowel surgery, or other extensive dissections, clear liquids should not be given until flatus has been passed. The diet should be advanced only as tolerated.

Activity Early ambulation decreases the incidence of thrombophlebitis and pneumonia. Patients are encouraged to begin ambulation on their first postoperative day if possible and to increase progressively their time out of bed as their strength improves. On discharge, the patient is instructed to avoid lifting more than 20 pounds for 6 weeks, thereby minimizing stress on fascia to allow full healing. Sexual intercourse is not recommended until 6 weeks after surgery, when the vaginal cuff is fully healed. Patients are instructed to avoid driving until full mobility returns because postoperative pain and tenderness may hinder sudden braking or steering maneuvers in emergency situations. With these exceptions, the patient is encouraged to return to normal activities as soon as she feels comfortable doing so.

Wound Care The abdominal incision normally requires little attention, except for ordinary hygienic measures. The wound is kept covered with a sterile bandage for the first 24 hours after surgery, by which time the incision has sealed itself. After the bandage has been removed, the incision should be cleaned daily with mild soap and water and kept dry.

Vaginal Hysterectomy

Preoperative Evaluation

Evaluation of Pelvic Support The most important observation in determining the feasibility of a vaginal hysterectomy is the demonstration of uterine mobility ([89,90](#)). A vaginal approach should not be chosen if the uterus is not freely mobile. Pelvic support structures are elevated at the initial pelvic examination. In patients with no apparent prolapse, poor pelvic support can often be demonstrated by observing descent of the uterus with a series of Valsalva maneuvers. Although vaginal hysterectomy is easier to perform when the uterine supporting ligaments are lax, it is not an absolute requirement. Some gynecologists advocate the application of a tenaculum to the anterior cervical lip, with subsequent traction applied as the patient bears down. Although this exercise may give some indication of uterine mobility, it is uncomfortable and not necessarily predictive of the success of vaginal hysterectomy. Therefore, **the practice of applying traction to the cervix with a tenaculum to demonstrate descent of an apparently well-supported uterus is not recommended.**

Evaluation of the Pelvis After assessment of pelvic support, the bony pelvis should be evaluated. Ideally, the angle of the pubic arch should be 90 degrees or greater, the vaginal canal should be ample, and the posterior vaginal fornix should be wide and deep. The surgeon may use a closed fist to approximate the bituberous diameter, which should exceed 10 cm. The size and shape of the female pelvis contributes to increased exposure.

Surgical Considerations

Patient Positioning Once the patient is in the dorsal lithotomy position, the buttocks should be positioned just over the table's edge. Several stirrup types are available, including those that support the entire leg and those that suspend the legs in straps. To avoid nerve injury, adequate padding should be used; marked flexion of the thigh and pressure points should be avoided. Trendelenburg (10- to 15-degree) positioning aids in the intravaginal visualization needed during surgery.

Vaginal Preparation A povidone-iodine solution is applied to the vagina, the bladder is drained, and the catheter is removed. Several methods for draping have been proposed, including individual or single-piece drapes; the method chosen is at the surgeon's discretion. There is usually no need to shave or clip the pubic hair. Individual drapes with an adhesive barrier should be used to hold the drapes in place and prevent the pubic hair from compromising the field.

Instruments Instruments specific to and useful in performing a vaginal hysterectomy include right-angled retractors, narrow Deaver retractors, weighted specula, Heaney needle holders, and an assortment of Briesky-Navratil vaginal retractors. Heaney and Heaney-Ballentine hysterectomy clamps are preferable. Several other clamps also are commonly used, including the Masterson clamp.

Lighting Overhead high-intensity lamps should be used and positioned to direct light over the operator's shoulder. In addition, the surgeon may prefer a headlight, which can be worn to provide direct horizontal lighting. Although not routinely used, a fiberoptic-lighted irrigating suction system can provide additional light and transilluminate tissue planes.

Suture Material Various suture materials have been advocated for gynecologic surgery. The type of suture material chosen should be based on the surgeon's preference. A synthetic delayed absorbable polyglactin or polyglycolic acid suture and atraumatic needles are generally preferable.

Procedure

The patient is examined while anesthetized to confirm prior findings and to assess uterine mobility and descent. The decision is then made whether to proceed vaginally or abdominally.

Grasping and Circumscribing the Cervix The anterior and posterior lips of the cervix are grasped with a single- or double-toothed tenaculum. With downward

traction applied on the cervix, a circumferential incision is made in the vaginal epithelium at the junction of the cervix ([Fig. 22.15](#)).

Figure 22.15 Circumferential incision in the vagina to infiltrate a vaginal hysterectomy. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Dissection of Vaginal Mucosa After the initial incision is made, the vaginal epithelium may be dissected sharply from the underlying tissue or pushed bluntly with an open sponge ([Fig. 22.16](#)). If the initial incision is made too close to the external cervical os, there is a greater amount of dissection required and associated bleeding. Therefore, this circumscribing incision should be made just below the bladder reflection. It is important to continue the dissection in the correct cleavage plane because dissection in the wrong plane will increase blood loss.

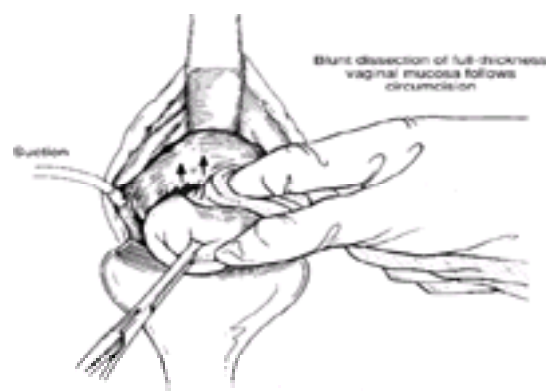

Figure 22.16 Dissection of the vaginal mucosa. (From eries Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Posterior Cul-de-Sac Entry The peritoneal reflection of the posterior cul-de-sac (cul-de-sac of Douglas) can be identified by stretching the vaginal mucosa and underlying connective tissue with forceps ([Fig. 22.17](#)). If difficulty is encountered (e.g., if the cervix is elongated and the peritoneum is not evident), the vaginal mucosa may be incised vertically to the point at which the cul-de-sac becomes more apparent.

Figure 22.17 Entry into the posterior cul-de-sac. (From eries Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

If the vaginal mucosa has been dissected in the wrong plane, the hysterectomy may be begun extraperitoneally by clamping and cutting the uterosacral and cardinal ligaments close to the cervix. The posterior cul-de-sac will then become readily identifiable.

If the peritoneal reflection of the posterior cul-de-sac still cannot be identified, entry into the anterior peritoneum is attempted, and a finger is hooked into the posterior cul-de-sac to place tension on the peritoneum. The peritoneum is opened with Mayo scissors. An interrupted suture is placed to approximate the peritoneum and vaginal cuff and thus provide hemostasis ([Fig. 22.18](#)).

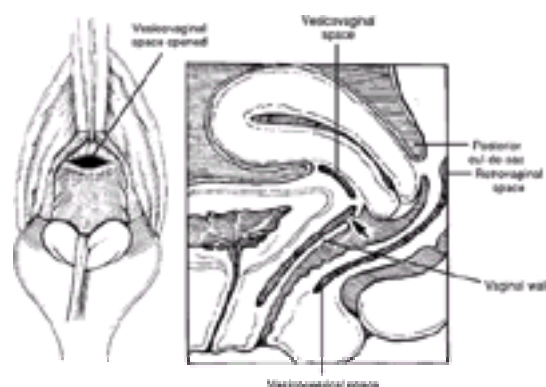

Figure 22.18 Interrupted suture is placed on posterior vaginal cuff and peritoneum for hemostasis. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

The posterior pelvic cavity is examined for pathologic alterations of the uterus or adhesive disease of the cul-de-sac. The weighted speculum is placed into the

posterior cul-de-sac.

Uterosacral Ligament Ligation With retraction of the lateral vaginal wall and countertraction on the cervix, the uterosacral ligaments are clamped, with the tip of the clamp incorporating the lower portion of the cardinal ligaments ([Fig. 22.19](#)). The clamp is placed perpendicular to the uterine axis, and the pedicle is cut close to the clamp and sutured. A small pedicle (0.5 cm) distal to the clamp is optimal because a larger pedicle becomes necrotic and the tissue sloughs, which may present culture medium for microorganisms. The pedicle should be incised no more than one half to three fourths of the way around the tip of the clamp. Limiting the incision prevents the next pedicle, which may be vascular, from being cut.

Figure 22.19 Ligation of the uterosacral ligaments. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

When suturing any pedicle, the needle point is placed at the tip of the clamp, and the needle is passed through the tissue by a rolling motion of the operator's wrist. Once ligated, the uterosacral ligaments may be transfixed to the posterolateral vaginal mucosa ([Fig. 22.20](#)).

Figure 22.20 Transfixion of the uterosacral ligament to the posterolateral vaginal mucosa. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

This suture may lend additional support to the vagina and provides hemostasis at this point on the vaginal mucosa. This suture is held with a hemostat to facilitate location of any bleeding at the completion of the procedure and to aid in the closure of vaginal mucosa.

Entry versus Nonentry into the Vesicovaginal Space (Cul-de-Sac) Downward traction is placed on the cervix. Using either Mayo scissors, with the points directed toward the uterus, or an open moistened 4 × 4 gauze sponge, the bladder is advanced. If the vesicovaginal peritoneal reflection is easily identified at this point, the vesicovaginal space may be entered. Otherwise, it may be preferable to delay entry. There is no danger in delaying entry so long as the operator has ascertained that the bladder has been advanced.

After the bladder has been advanced, a curved Deaver or Heaney retractor is placed in the midline, holding the bladder out of the operative field. This process precedes each step of the vaginal hysterectomy until the vesicovaginal space is entered.

Cardinal Ligament Ligation With traction on the cervix continued, the cardinal ligaments are identified, clamped, and cut. The suture is ligated ([Fig. 22.21](#)).

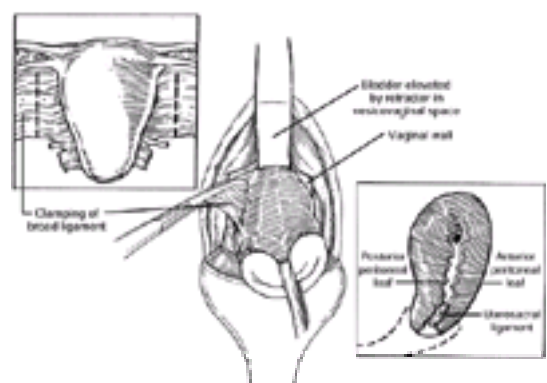

Figure 22.21 Ligation of the cardinal ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Advancement of Bladder The bladder again is advanced out of the operative field. A blunt dissection technique may be used; however, sharp dissection may be helpful if the patient has had previous surgery such as cesarean delivery, which may have scarred the bladder reflection.

Uterine Artery Ligation Contralateral and downward traction is placed on the cervix. With an effort to incorporate the anterior and posterior leaves of the visceral peritoneum, the uterine vessels are identified, clamped, and cut, and the suture is ligated ([Fig. 22.22](#)). A single suture and single clamp technique is adequate and decreases the potential risk for ureteral injury. When the uterus is large or when a fibroid distorts the anatomic relationships, a second suture may be required to ligate any remaining branches of the uterine artery.

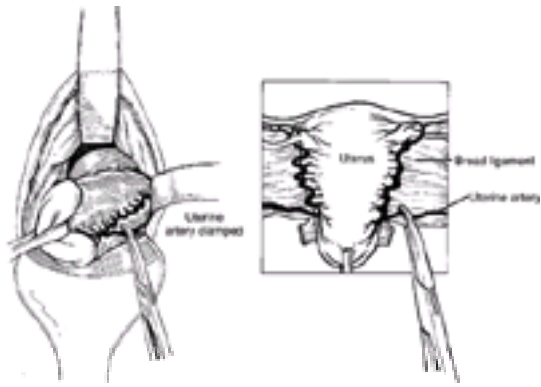

Figure 22.22 Ligament of the uterine artery. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996.)

Entry into the Vesicovaginal Space The anterior peritoneal fold usually can be identified readily just before or after clamping and suture ligation of the uterine arteries. The anterior peritoneal cavity should not be opened blindly because of the increased risk for bladder injury ([Fig. 22.23](#)). The peritoneum is grasped with forceps, tented, and opened with scissors with the tips pointed toward the uterus. A Heaney or Deaver retractor is then placed, and the peritoneal contents are identified. This retractor serves to keep the bladder out of the operative field.

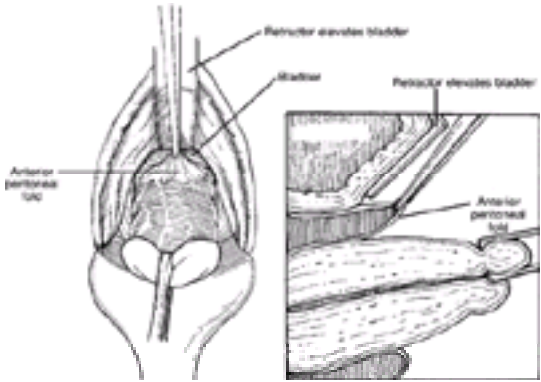

Figure 22.23 Entry into the vesicovaginal space. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Delivery of the Uterus A tenaculum is placed onto the uterine fundus in a successive fashion to deliver the fundus posteriorly ([Fig. 22.24](#)). The operator's index finger is used to identify the uteroovarian ligament and aid in clamp placement.

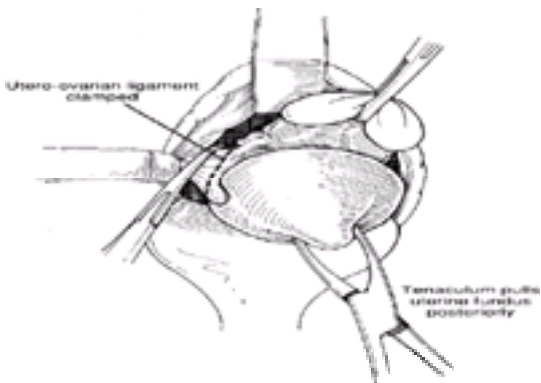

Figure 22.24 Delivery of the uterine fundus posteriorly. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Uteroovarian and Round Ligament Ligation With the posterior and anterior peritoneum opened, the remainder of the broad ligament and uteroovarian ligaments are clamped, cut, and ligated ([Fig. 22.25](#)). The uteroovarian and round ligament complexes are double ligated with a suture tie followed by a ligature medial to the first suture. A hemostat is placed on the second suture to aid in the identification of any bleeding and to assist with peritoneal closure. A hemostat should not be placed on the first suture or any other vascular pedicle in order to avoid the risk for loosening the tie.

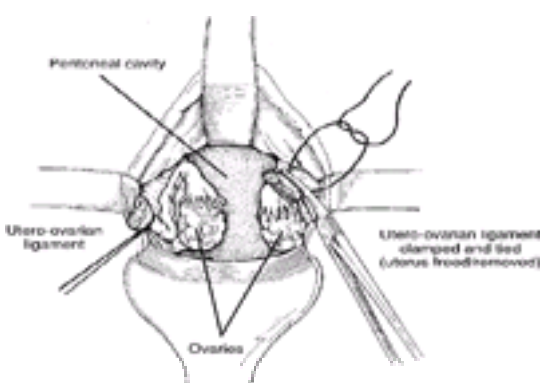

Figure 22.25 Ligation of the uteroovarian and round ligaments. (From Mann WA, Stovall TG. *Gynecologic Surgery*. New York: Churchill Livingstone, 1996, with permission.)

Removal of the Ovaries When the adnexa are removed, the round ligaments should be removed separately from the adnexal pedicles. Traction is placed on the uteroovarian pedicle. The ovary is drawn into the operative field by grasping it with a Babcock clamp. A Heaney clamp is placed across the infundibulopelvic ligament, and the ovary and tube are excised ([Fig. 22.26](#)). A transfixion tie and suture ligature are placed on the infundibulopelvic ligament. The surgeon should not be reluctant to remove the fallopian tube separately from the ovary if taking them together risks loss of the tissue pedicle or injury to the ureter or nearby blood vessels.

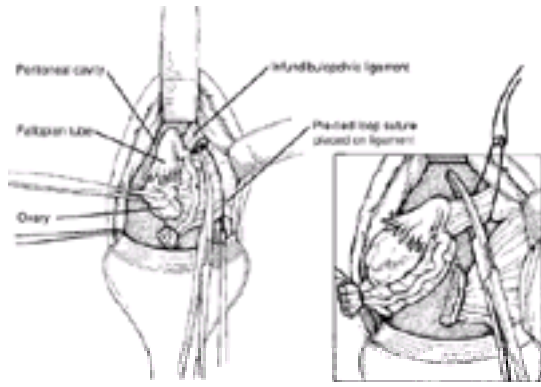

Figure 22.26 Removal of the ovaries and fallopian tubes by clamping across the infundibulopelvic ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

Hemostasis A retractor or tagged sponge is placed into the peritoneal cavity, and each of the pedicles is visualized and inspected for hemostasis. If additional sutures are required, they should be placed precisely with care to avoid the ureter or bladder.

Peritoneal Closure Because the pelvic peritoneum does not provide support and reforms in 24 hours after surgery, the peritoneum need not be reapproximated routinely. If it is believed to be important, the anterior peritoneal edge is identified and grasped with forceps. A continuous absorbable 0-0 suture is begun at the 12-o'clock position. The suture is continued in a pursestring fashion and incorporates the distal portion of the left upper pedicle and the left uterosacral ligament ([Fig. 22.27](#)). Tension is applied to the suture placed at the beginning of the procedure that incorporates the posterior peritoneum and vaginal mucosa. This allows for high posterior reperitonealization, which shortens the cul-de-sac and thus helps to prevent future enterocele formation. The right uterosacral ligament and the distal portion of the right upper pedicle are incorporated, and this continuous suture ends at the point on the anterior peritoneum where it was begun.

Figure 22.27 Closure of the peritoneum. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

The intraabdominal tagged sponge is removed and inspected for the presence of blood at its distal end. The slack of the pursestring peritoneal suture is taken up by pulling the suture tight. Before tying the peritoneal suture, the surgeon should make certain that no prolapse of viscera has occurred.

Vaginal Mucosa Closure The vaginal mucosa can be reapproximated in a vertical or horizontal manner, using either interrupted or continuous sutures ([Fig. 22.28](#)). The vaginal mucosa is, in this case, reapproximated horizontally with interrupted absorbable sutures.

Figure 22.28 Closure of the vaginal mucosa. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York: Churchill Livingstone, 1996, with permission.)

The sutures are placed through the entire thickness of the vaginal epithelium, with care taken to avoid entering the bladder anteriorly. These sutures will obliterate the underlying dead space and produce an anatomic approximation of the vaginal epithelium, thereby decreasing the postoperative formation of granulation tissue.

Bladder Drainage After completion of the procedure, the bladder is drained. Unless an anterior or posterior colporrhaphy or other reconstructive procedure is performed, a bladder catheter or vaginal packing is not mandatory.

Surgical Techniques for Selected Patients

Injection of Vaginal Mucosa The use of paracervical and submucosal injection of 20 to 30 mL of 0.5% *lidocaine* with 1:200,000 epinephrine before incision of the vaginal mucosa is believed by some to decrease postoperative pain and facilitate identification of surgical planes. There is no need to inject the cervix. Areas to be injected include the bladder pillars, lower portion of the cardinal ligament, uterosacral ligaments, and paracervical tissue. However, it has been shown that the incidence of cuff cellulitis and cuff abscess formation is increased when *epinephrine* is injected into the cervicovaginal mucosa.

Morcellation of the Large Uterus

Uterine morcellation is a well-known but often underutilized surgical procedure whereby the uterus is removed piecemeal. Several methods of uterine morcellation have been described ([91](#)), including hemisection or bivalving, wedge or "V" incisions, and intramyometrial coring. Before beginning any morcellation procedure, the uterine vessels must be ligated, and the peritoneal cavity must be entered.

When uterine hemisection or bivalving is performed, the cervix is split at the midline, and the uterus is cut into halves, which are removed separately ([92,93](#)). This method seems best suited for fundal, midline leiomyomas.

Wedge morcellation is best suited for anterior or posterior fibroids or for fibroids in the other broad ligaments (i.e., when the fibroids are away from the midline)

(93,94,95,96 and 97). The cervix is amputated, and the myometrium is grasped with clamps. Wedge-shaped portions of myometrium are removed from the anterior or posterior uterine wall. The apex of the wedge is kept in the midline, thereby reducing the bulk of the myometrium. This process is repeated until the uterus can be removed or until a pseudocapsule of a fibroid can be grasped with a Leahy clamp or towel clip. Traction is then applied, and a "myomectomy" is performed.

When the intramyometrial coring technique is used, the myometrium above the site of the ligated vessels is incised parallel to the axis of the uterine cavity and serosa of the uterus. This incision is continued around the full circumference of the myometrium in a symmetric fashion beneath the uterine serosa. Traction is maintained on the cervix, and the avascular myometrium is cut to allow the undisturbed endometrial cavity, with a thick layer of myometrium, to be delivered with the cervix. As a result, the inside of the uterus with its unopened endometrial cavity is brought closer to the operator. Incision of the lateral portions of the myometrium medial to the remaining attachment of the broad ligament results in considerable additional descent of the uterus and greatly increases the mobility of the uterine fundus. The uterus is converted from a globular to an elongated tissue mass. The cored uterus is removed by clamping the uteroovarian pedicle and fallopian tubes.

McCall Culdoplasty

A McCall culdoplasty has been thought by some surgeons to help decrease future enterocele formation (96). Whether this is accurate remains open to debate. An absorbable suture is placed through the full thickness of the posterior vaginal wall at the point of the highest portion of the vaginal vault. The patient's left uterosacral ligament pedicle is grasped and sutured. The suture then incorporates the posterior peritoneum, between the uterosacral ligaments and the right uterosacral ligament. The suture is completed by passing the needle from the inside to the outside at the same point at which it was begun. The suture is tied, thereby approximating the uterosacral ligaments and the posterior peritoneum.

Schuchardt Incision

When vaginal exposure is difficult, the Schuchardt incision may be used (96). If the surgeon is right-handed, the incision is made on the patient's left side. To decrease blood loss, the area can be infiltrated with lidocaine-containing epinephrine. The incision follows a curved line from the 4-o'clock position at the hymenal margin to a point halfway between the anus and the ischial tuberosity. The incision may be continued as high as necessary in the vaginal vault to gain exposure. The depth of the incision is the medial portion of the pubococcygeus muscle, which may be divided in extreme cases. The incision must be closed in layers at the completion of the procedure.

Intraoperative Complications

Bladder Injury

Injury to the urinary bladder is one of the most common intraoperative complications associated with hysterectomy. **If the bladder is inadvertently entered, repair generally should be performed when the injury is discovered and not delayed until completion of surgery (84).** When bladder injury is recognized, the edges of the wound should be mobilized to assess the full extent of the injury and to allow repair without tension. This assessment should include visualization of the trigone to exclude injury to that area. The bladder may then be repaired with a single- or double-layered closure with a small-caliber absorbable suture. Methylene blue or a dye of sterile milk formula can be instilled into the bladder to ensure that the repair is adequate.

Bowel Injury

Because patients with suspected pelvic adhesions or obvious pelvic disease are excluded as candidates for vaginal hysterectomy, bowel injuries do not often occur. Bowel injuries more often are associated with the performance of a posterior colporrhaphy and are usually confined to the rectum (84,96).

If the rectum is entered, the injury is repaired with a single- or double-layer closure using a small-caliber absorbable suture, followed by copious irrigation. Postoperatively, the patient should be given a stool softener and a low-residue diet.

Hemorrhage

Intraoperative hemorrhage invariably is the result of failure to ligate securely a significant blood vessel, bleeding from the vaginal cuff, slippage of a previously placed ligature, or avulsion of tissue before clamping (96). Most intraoperative bleeding can be avoided with adequate exposure and good surgical technique. Using square knots with attention to proper knot-tying mechanisms will prevent bleeding in most cases. Likewise, the use of Heaney-type sutures minimizes ligature slippage and subsequent bleeding. When bleeding does occur, blind clamping, which may endanger the ureter, should be avoided. The bleeding vessel should be identified and precisely ligated with visualization of the ureter if necessary. If the location of the ureter is in question, it should be visualized before suturing a bleeding vessel. Although excessive blood loss occasionally occurs despite these precautions, it should be infrequent.

Perioperative Care

Bladder Drainage Postoperative bladder drainage should be employed after any procedure in which spontaneous, complete voiding is not anticipated. Reasons to consider closed bladder drainage include significant local pain, additional vaginal reparative procedures, surgery for stress incontinence, the use of a vaginal pack, and patient anxiety.

After vaginal hysterectomy without additional repair, most patients can void spontaneously, and therefore, catheter drainage is not required. The relative amount of pain after a vaginal hysterectomy is less than with abdominal hysterectomy and, in the absence of additional repairs or a pack, no obstructive effect should be present.

If the patient does not tolerate pain well postoperatively or is extremely anxious, the transurethral insertion of a 16-Fr. catheter after completing surgery is warranted. This catheter may also be inserted postoperatively if the patient is unable to void spontaneously on two attempts. Closed-catheter drainage after vaginal hysterectomy usually is not necessary for longer than 24 hours. The catheter is removed without clamping, and there is no need to obtain a urine specimen for culture and sensitivity.

Diet Although little manipulation of the bowel occurs during vaginal hysterectomy, there is some slowing of gastrointestinal motility. This slowing rarely occurs to a degree that limits some form of oral intake soon after surgery. Most patients experience some degree of nausea after surgery, which, combined with drowsiness from analgesics, usually makes them disinterested in food on the evening after surgery. A clear liquid diet is suitable during the first 24 hours after surgery. On the first full postoperative day, a regular diet can usually be consumed. The patient is often the best judge of what she can tolerate.

Perioperative Complications of Hysterectomy

A comprehensive discussion of postoperative complications after gynecologic surgery is presented in [Chapter 19](#).

Wound Infections

Wound infections occur after 4% to 6% of abdominal hysterectomies (29). Measures believed to reduce the incidence of wound infections include a preoperative shower, no removal of hair, or if hair removal is necessary, removal of hair with clippers in the operating room, use of adhesive drapes and prophylactic antibiotics, and delayed primary closure (see [Chapter 19](#)).

Hemorrhage

Immediately after hysterectomy, hemorrhage may become apparent in one of two ways (88). First, bleeding from the vagina may be noted by the nursing staff or physician within the first few hours after surgery. Second, and less commonly, the patient may be noted to have little bleeding from the vagina but deteriorating vital

signs manifested by low blood pressure and rapid pulse, falling hematocrit level, and flank or abdominal pain. The first presentation usually is in the form of bleeding from the vaginal cuff or one of the pedicles. The second presentation may be a retroperitoneal hemorrhage. Each situation is approached differently in its evaluation and treatment, but both involve the same general principles of rapid diagnosis, stabilization of vital signs, appropriate fluid and blood replacement, and constant surveillance of the patient's overall condition ([98](#)).

After vital signs are assessed, attention should be directed to the amount of bleeding. A small amount of bleeding is expected after any vaginal hysterectomy. However, steady bleeding 2 to 3 hours after surgery suggests lack of hemostasis. The patient should be taken promptly to the examining room, where the operative site is viewed using a large speculum and good lighting. If bleeding is not excessive, the vaginal cuff can be inspected, and in many instances, bleeding from the cuff edge will be found. Hemostasis can easily be achieved with one or two sutures placed through the mucosa.

If bleeding is excessive or appears to be coming from above the cuff, or if the patient is too uncomfortable to tolerate adequate examination, she should be taken to the operating room. General anesthesia should be administered and the vaginal operative site should be thoroughly explored. Any bleeding point may be sutured or ligated. However, bleeding that is coming from above the cuff or is extremely brisk usually cannot be controlled through the vaginal route. An exploratory laparotomy is necessary to examine the pelvic floor, identify and isolate the bleeding vessel, and achieve hemostasis. The ovarian vessels and uterine arteries should be thoroughly inspected because they often are the source of excessive vaginal bleeding. If it is difficult to localize bleeding to a specific pelvic vessel, ligation of the hypogastric artery may be necessary.

In the patient with little vaginal bleeding in whom vital signs have deteriorated, retroperitoneal hemorrhage should be suspected. Input and output should be monitored. Hematocrit assessment, along with cross-matching, should be performed immediately. Examination may reveal tenderness and dullness in the flank. In cases of intraperitoneal bleeding, abdominal distention may occur. Diagnostic radiologic studies can be used to confirm the presence of retroperitoneal or intraabdominal bleeding. Ultrasonography is one option for viewing low pelvic hematomas. CT provides better visualization of retroperitoneal spaces, however, and can delineate a hematoma.

If the patient's condition stabilizes rapidly with intravenous fluids, one of two approaches may be used for continued care. The first is to give the patient a transfusion and follow serial hematocrit assessments and vital signs. In many instances, retroperitoneal bleeding will tamponade and stop, forming a hematoma that may eventually be resorbed. The risk with this approach is that the hematoma will later become infected, necessitating surgical drainage. In some instances when the patient's condition is stable, radiologic embolization may be considered.

Another option is to perform abdominal exploratory surgery while the patient's condition is stable. This approach adds the morbidity of a second procedure but avoids the possibility of the patient's condition deteriorating with continued delay or the formation of a pelvic abscess. Once adequate exposure is obtained, the peritoneum over the hematoma should be opened, and the blood should be evacuated. All bleeding vessels should be identified and ligated. Again, if control of bleeding is difficult, consideration should be given to unilateral or bilateral ligation of the anterior division of the internal iliac artery. Once hemostasis is achieved, the pelvis should be drained using a closed system.

Urinary Tract Complications

Urinary Retention

Urinary retention after hysterectomy is an uncommon occurrence ([32](#)). If the urethra is unobstructed and retention occurs, it is usually the result of either pain or bladder atony resulting from anesthesia. Both are temporary effects.

If a catheter was not placed after surgery, retention can be relieved initially with the insertion of a Foley catheter for 12 to 24 hours. Most patients are able to void after the catheter is removed 1 day later. If the patient still has trouble voiding and urethral spasm is suspected, success often can be achieved with a skeletal muscle relaxant such as *diazepam* (2 mg twice a day). In most cases, waiting is the best course, and voiding usually occurs spontaneously.

Ureteral Injury

In patients who develop flank pain soon after vaginal hysterectomy, ureteral obstruction should be suspected. The incidence of ureteral injury is lower with vaginal hysterectomy than with abdominal hysterectomy ([83](#)). One risk factor for its occurrence is total uterine prolapse, in which the ureters are drawn outside the bony pelvis.

In a patient with flank pain in whom ureteral obstruction is suspected, intravenous pyelography and urinalysis should be performed ([80](#)). If obstruction is noted on intravenous pyelography, it is usually present near the ureterovesical junction. The first immediate step should be attempted passage of a catheter through the ureter under cystoscopic guidance. If a catheter can be passed through the ureter, it should be left in place for at least 4 to 6 weeks, allowing sutures to absorb and the obstruction or kinking to release. If the catheter cannot be passed through the ureter, the best course is to perform abdominal exploratory surgery and repair the ureter at the site of obstruction ([79,80,81,82,83](#) and [84](#)).

Vesicovaginal Fistula

Vesicovaginal fistulas occur most often after total abdominal hysterectomy for benign gynecologic disease ([83](#)). Intraoperative steps to avoid the formation of a vesicovaginal fistula include correct identification of the proper plane between the bladder and cervix, sharp rather than blunt dissection of the bladder, and care in clamping and suturing the vaginal cuff. The development of a postoperative vesicovaginal fistula after hysterectomy is rare; the incidence is as low as 0.2% ([82,83](#)).

Patients who have a postoperative vesicovaginal fistula develop a watery vaginal discharge 10 to 14 days after surgery. Some fistulas resulting from surgery are noted as early as the first 48 to 72 hours after surgery ([84](#)). After vaginal examination with a speculum, the diagnosis can usually be confirmed with the insertion of a cotton tampon into the vagina followed by the instillation of *methylene blue* or *indigo carmine* dye through a transurethral catheter. If the tampon stains blue, a vesicovaginal fistula is present. If no staining occurs, however, the presence of a ureterovaginal fistula must be ruled out by the intravenous injection of 5 mL of *indigo carmine* dye. Within 20 minutes, the tampon should stain blue if a ureterovaginal fistula is present. Intravenous pyelography should also be performed to rule out ureteral obstruction.

If a vesicovaginal fistula is diagnosed, a Foley catheter should be inserted for prolonged drainage. As many as 15% of fistulas spontaneously close with 4 to 6 weeks of continuous bladder drainage. If closure has not occurred by 6 weeks, operative correction is necessary. Waiting 3 to 4 months from the time of diagnosis before operative repair is recommended to allow reduction of inflammation and to improve vascular supply. After vaginal hysterectomy, the fistula site is above the bladder trigone and away from the ureters. Vaginal repair can be anticipated in most patients. The surgical correction is generally undertaken in a four-layered closure: the bladder mucosa, the seromuscular layer, the endopelvic fascia, and the vaginal epithelium.

Incidental cystotomy at the time of hysterectomy is more common than vesicovaginal fistula. When repaired correctly, cystotomy rarely results in the development of a fistula ([82](#)).

Prolapse of the Fallopian Tube

Posthysterectomy prolapse of the fallopian tube is a rare event and is often confused with granulation tissue at the vaginal apex ([32](#)). Predisposing factors for the development of fallopian tube prolapse include development of a hematoma and an abscess at the vaginal apex. As many as half of patients undergoing vaginal hysterectomy form some granulation tissue at the vaginal vault. In patients in whom granulation tissue persists after attempts to cauterize it or pain is experienced with attempts to remove it, fallopian tube prolapse should be suspected. A biopsy of the area is warranted and usually reveals tubal epithelium if a fallopian tube is present.

If fallopian tube prolapse is diagnosed, it should be repaired with surgery. In general, the surrounding vaginal mucosa should be opened and undermined widely. The tube is then ligated high and removed, followed by closure of the vaginal mucosa.

Discharge Instructions

Before discharging the patient, instructions should be reviewed. Printed postoperative instructions are helpful to the patient and should include the following information:

1. Avoid strenuous activity for the first 2 weeks and increase activity level gradually.
2. Avoid heavy lifting, douching, or sexual intercourse until instructed by the physician.
3. Bathe as needed using shower or tub baths.
4. Follow a regular diet.
5. Avoid straining for a bowel movement or urination. For constipation, use *Milk of Magnesia* or *Metamucil* (1 tsp in juice).
6. Call the physician if excessive vaginal bleeding or fever occurs.
7. Schedule a return appointment at the time specified by the physician.

The physician should provide telephone numbers for emergencies both during and after office hours. Typically, the first postoperative visit is scheduled about 4 weeks after discharge from the hospital. At the time of that visit, the patient should be ambulating well, and vaginal discharge or bleeding should be minimal. Speculum examination of the cuff should be gentle and cursory, but the patient should be assured that the healing process is proceeding normally. Finally, the patient's questions should be answered, and advice should be given on increasing her activity level, including sexual activity, work, and normal household activity.

Psychosomatic Aspects

The decision to proceed with hysterectomy should be made jointly by the patient and her physician. Factors leading a patient or her physician to choose hysterectomy and reasons that patients with similar conditions choose different treatments are uncertain. For many patients, the decision to undergo hysterectomy may be sudden. They face the potential risks of anesthesia and surgery, and, if premenopausal, they must also cope with the loss of menstruation and the ability to procreate. Many women are concerned that the procedure will result in a loss of femininity, a decrease in sexual satisfaction, or an increase in interpersonal problems with their spouses. The concern over the loss of the reproductive tract is greater than that related to the loss of other intraabdominal organs (99). To minimize the possibility that the patient has a poor outcome, preoperative counseling and preparation are essential.

Drellich and Bieber studied 23 women after hysterectomy. Most of these women regretted the loss of menstruation, which was true even for women who had experienced dysmenorrhea (100). Several of these women viewed the menstrual cycle as a way for the body to "rid itself of waste," and they felt better after the menstrual phase of their cycle.

Depression

There is wide variation in women's responses to hysterectomy. Most studies suggest that there is little evidence that hysterectomy increases the risk for depression. Some investigators have reported depression and an increased incidence of psychiatric symptoms after hysterectomy (101,102). Hollender reported that almost twice as many women were admitted to a psychiatric hospital after pelvic operations compared with other types of surgery (103). However, other authors have not found such an association (104), and some report a decrease in symptoms after hysterectomy (105,106,107,108 and 109). The impact of hysterectomy on the development of depression is unknown because most studies are retrospective and not well controlled for preoperative depression (see Chapter 12).

Patients who had a moderate amount of preoperative anxiety do much better postoperatively than patients with little or no anxiety or patients who had an exaggerated response (110). Both long delays before surgery and a very short time before surgery increase patients' anxiety. Thus, women should be scheduled for surgery several weeks in advance to avoid this problem (110). Women who planned to have children in the future had more problems during the immediate postoperative period. The patient's response to previous loss (e.g., death of family members) predicted her response after hysterectomy (111).

Sexuality

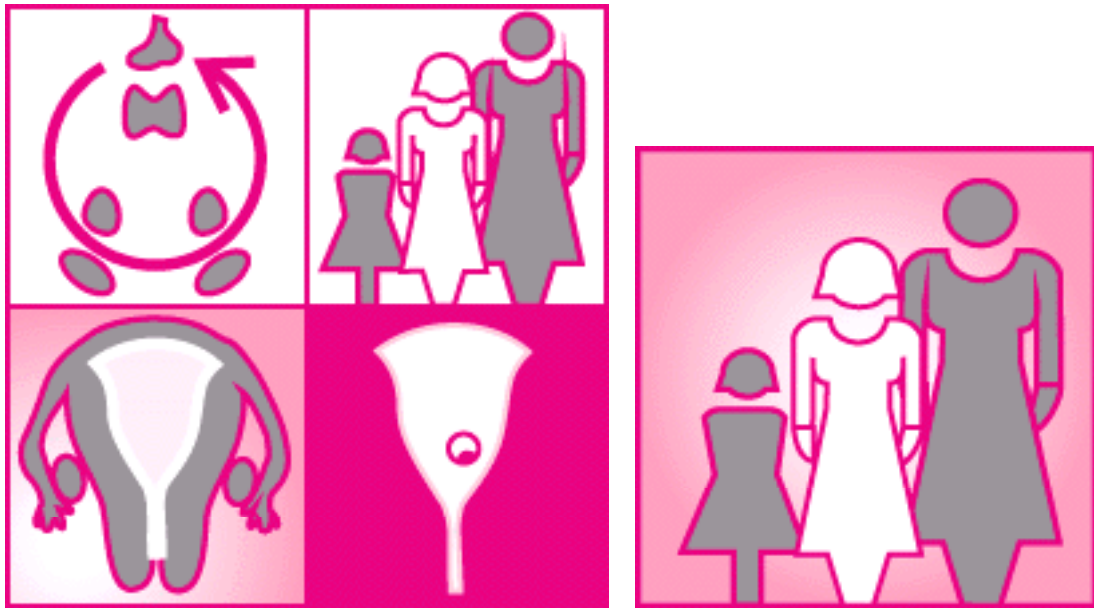

The incidence of sexual dysfunction after hysterectomy ranges from 10% to 40%. Estimates vary based on study variations, cultural variations, and the definitions used to determine the diagnosis. Some report a decrease in libido after hysterectomy, whereas others suggest that libido is increased because of the reduced fear of unwanted pregnancy (102,112). Humphries found that most patients do not have a change in their sexual practices after hysterectomy (113), whereas others report a deterioration of sexual relations (114). Preoperative anxiety about sexual functioning is often associated with an overall deterioration of sexual relations (115).

The literature supports that hysterectomy does not cause psychiatric sequelae or diminished sexual functioning in most patients. The best predictor of satisfaction after hysterectomy is the patient's preoperative understanding of the procedure. **The best predictor of postoperative sexual functioning is the patient's preoperative sexual satisfaction.** Preoperatively, these issues should be discussed with the patient, and her questions and concerns should be addressed to decrease the fear and anxiety associated with surgery.

Puberty is defined as the period during which secondary sexual characteristics begin to develop and the capability of sexual reproduction is attained. The physical changes accompanying pubertal development result directly or indirectly from maturation of the hypothalamus, stimulation of the sex organs, and secretion of sex steroids. Hormonally, puberty in humans is characterized by the resetting of the classic negative gonadal steroid feedback loop, alterations in circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the woman of a positive estrogen feedback loop, which controls the monthly rhythm as an interdependent expression of gonadotropins and ovarian steroids.

The ability to evaluate and treat aberrations of pubertal development requires an understanding of the normal hormonal and physical changes that occur at puberty. An understanding of these changes is also important in evaluating young women with amenorrhea.

Normal Pubertal Development

Factors Affecting Time of Onset

The major determinant of the timing of the onset of puberty is no doubt genetic, but a number of other factors appear to influence both the age at onset and the progression of pubertal development. Among these influences are nutritional state, general health, geographic location, exposure to light, and psychological state ([1](#)). The concordance of the age of menarche in mother–daughter pairs and between sisters and in ethnic populations illustrates the importance of genetic factors ([1](#)). Typically, the age of menarche is earlier than average in children with moderate obesity (up to 30% above normal weight for age), whereas delayed menarche is common in those with severe malnutrition. Children who live in urban settings, closer to the equator, and at lower altitudes typically begin puberty earlier than those who live in rural areas, farther from the equator, and at higher elevations. Blind girls apparently undergo menarche earlier than sighted girls, suggesting some influence of light ([2](#)).

In western Europe, the age of menarche declined 4 months each decade between 1850 and 1960 ([1](#)). Recent data suggest that the trend toward earlier pubertal development is continuing among girls (but not boys) who live in the United States ([3](#)). It has been presumed that these changes represent improved nutritional status and healthier living conditions.

One of the more controversial hypotheses has centered on the role of total body weight and body composition on the age of menarche. Frisch has argued that a girl must reach a critical body weight (47.8 kg) before menarche ([4](#)). More importantly, body fat must increase to 23.5% from the typical 16% of the prepubertal state, which presumably is influenced by nutritional status ([5](#)). This hypothesis is supported by observations that menarche occurs earliest in obese girls, followed by normal-weight girls, then underweight girls, and lastly anorectic girls ([Fig. 23.1](#)). The importance of other factors is indicated by observations that menarche is often delayed in morbidly obese girls, those with diabetes, and those who exercise intensely but are of normal body weight and body fat percentage. Moreover, girls with precocious puberty may undergo menarche even if they have a low body fat percentage, and other girls show no pubertal development with a body fat percentage of 27% ([6](#)). The hypothesis linking menarche to body weight and composition does not always seem valid because menarche is a late event in pubertal development.

Figure 23.1 Normal twins at 12 years of age. The heavier twin (weighing 143 lb) is clearly more advanced in puberty than the lighter twin (weighing 87 lb). Anecdotal photographs and data such as these served to provide the basis for the theory that body fat, body mass, and menarche are linked. (From **Wilkins L.** *The diagnosis and treatment of endocrine disorders in childhood and adolescence*. 3rd ed. Springfield, IL:Charles C. Thomas, 1965:218, with permission.)

Physical Changes during Puberty

The changes associated with puberty occur in an orderly sequence over a definite time frame. Any deviation from this sequence or time frame should be regarded as abnormal. Moreover, the pubertal changes, their relationships to each other, and the ages at which they occur are distinctly different in girls and in boys. Although this chapter focuses on girls, changes in boys are considered briefly as well.

Tanner Stage

In girls, pubertal development typically requires 4.5 years (Fig. 23.2). Although generally the first sign of puberty is accelerated growth, breast budding is usually the first recognized pubertal change, followed by the appearance of pubic hair, peak growth velocity, and menarche. The stages initially described by Marshall and Tanner are often used to describe breast and pubic hair development (7).

Figure 23.2 Schematic sequence of events at puberty. An idealized average girl and an idealized average boy are represented. (From Rebar RW. Practical evaluation of hormonal status. In: Yen SSC, Jaffe RB, eds. *Reproductive endocrinology: physiology, pathophysiology and clinical management*. 3rd ed. Philadelphia: WB Saunders, 1991:830, with permission; based on data from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303, and Marshall WA, Tanner JM. Variation in the pattern of pubertal changes in boys. *Arch Dis Child* 1970;45:13–23, with permission.)

With regard to breast development (Fig. 23.3), Tanner stage 1 refers to the prepubertal state and includes no palpable breast tissue, with the areolae generally less than 2 cm in diameter. The nipples may be inverted, flat, or raised. In stage 2, breast budding occurs, with a visible and palpable mound of breast tissue. The areolae begin to enlarge, the skin of the areolae thins, and the nipple develops to varying degrees. Stage 3 is reflected by further growth and elevation of the entire breast. When the individual is seated and viewed from the side, the nipple is generally at or above the midplane of breast tissue. In most girls, stage 4 is defined by projection of the areola and papilla above the general breast contour in a secondary mound. Breast development is incomplete until Tanner stage 5, in which the breast is mature in contour and proportion. In most women, the nipple is more pigmented at this stage than earlier in development, and Montgomery's glands are visible around the circumference of the areola. The nipple is generally below the midplane of breast tissue when the woman is seated and viewed from the side. Full breast development usually occurs over 3 to 3.5 years but may occur in as little as 2 years or not progress beyond stage 4 until the first pregnancy. Breast size is no indication of breast maturity.

Figure 23.3 Diagrammatic depiction of Tanner breast stages in adolescent women. (From Ross GT, VandeWiele RL, Frantz AG. The ovaries and the breasts. In: Williams RH, ed. *Textbook of endocrinology*. 6th ed. Philadelphia, WB Saunders, 1981:355, with permission; as adapted from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303.)

Pubic hair staging is related both to quantity and distribution (Fig. 23.4). In *Tanner stage 1*, there is no sexually stimulated pubic hair present, but some nonsexual hair may be present in the genital area. *Tanner stage 2* is characterized by the first appearance of coarse, long, crinkly pubic hair along the labia majora. In *Tanner stage 3*, coarse, curly hair extends onto the mons pubis. *Tanner stage 4* is characterized by adult hair in thickness and texture, but the hair is not distributed as widely as in adults and typically does not extend onto the inner aspects of the thighs. Except in certain ethnic groups, including Asians and American Indians, pubic hair extends onto the thighs in *Tanner stage 5*.

Figure 23.4 Diagrammatic depiction of Tanner pubic hair staging in adolescent women. (From Ross GT, VandeWiele RL, Frantz AG. The ovaries and the breasts. In: Williams RH, ed. *Textbook of endocrinology*. 6th ed. Philadelphia: WB Saunders, 1981:355, with permission; as adapted from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303.)

The staging of male pubertal sexual maturation is based on genital size and pubic hair development. *Tanner stage 1* is prepubertal. *Tanner stage 2* of genital growth begins when testicular enlargement is first evident. Testis length along the longitudinal axis ranges from 2.5 to 3.2 cm. The size of the penis increases as well. Pigmented, curly pubic hair is first visible around the base of the penis. In *Tanner stage 3*, there is further growth of the penis in both length and diameter, the scrotum

develops further, and testis length increases to 3.3 to 4 cm. Thicker, curly hair extends above the penis. *Tanner stage 4* involves further growth of the genitalia, with testis length ranging from 4 to 4.5 cm. Extension of pubic hair over the genital area continues, but the volume is less than in the adult. At this stage, the prostate gland is palpable by rectal examination. In *Tanner stage 5*, the genitalia are within the adult range in size. Stretched penile length measured along the dorsum averages 15.7 cm in adult men. Pubic hair spreads laterally onto the medial thighs. Hair may or may not extend from the pubic area toward the umbilicus and anus.

Pigmented pubic hair is often the first recognized sign of male puberty even though it typically occurs 6 months after genital growth begins. Tanner stage 3 puberty is often accompanied by symmetric or asymmetric gynecomastia, and mature sperm first can be identified with microscopic urinalysis.

Height and Growth Weight

Plotting height increments (i.e., growth velocity) against the phases of puberty allows one to see relationships during puberty (Fig. 23.2). Girls reach peak height velocity early in puberty before menarche. As a consequence, they have limited growth potential after menarche. In contrast, boys reach peak height velocity about 2 years later than girls. Boys grow an average of 28 cm during the growth spurt, in comparison to a mean of 25 cm for girls. Adult men eventually are an average of 10 cm taller than adult women largely because they are taller at the onset of the growth spurt. Hormonal control of the pubertal growth spurt is complex. Growth hormone, insulin-like growth factor 1 (IGF-1), and gonadal steroids play major roles. Adrenal androgens appear to be less important.

During the growth spurt associated with puberty, the long bones in the body lengthen, and the epiphyses ultimately close. The bone or skeletal age of any individual can be estimated closely by comparing x-rays documenting the development of bones in the nondominant hand (most commonly), knee, or elbow to standards of maturation for the normal population. The Greulich and Pyle atlas (8) is used most often for this purpose. Skeletal age is more closely correlated with pubertal stage than with chronologic age during puberty. With height and chronologic age, an individual's bone age can be used to predict final adult height using the Bayley-Pinneau tables (9).

Another practical clinical approach to predicting adult height uses midparental height. **The adjusted midparental height is calculated by adding 13 cm to the mother's height (for boys) or subtracting 13 cm from the father's height (for girls) and then determining the mean of the heights of the parents, including the adjusted height of the opposite-sex parent. Adding and subtracting 8.5 cm to the calculated predicted height approximates the target range of the third to the ninety-seventh percentile for the anticipated adult height of the child.** This quick calculation can be of assistance in evaluating individuals with delayed or precocious pubertal development and those with short stature.

Several changes in body composition also occur during pubertal development. Although lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, by maturity, men have 1.5 times the lean body mass and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat as men (1). The changes in body contour in girls, with accumulation of fat at the thighs, hips, and buttocks, occur during the pubertal growth spurt. Voice and other changes also are associated with the changes in body composition.

Hormonal Changes

By 10 weeks of gestation, gonadotropin-releasing hormone (GnRH) is present in the hypothalamus, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are present in the pituitary gland (10). Gonadotropin levels are elevated in both female and male fetuses before birth; the levels of FSH are higher in females. At birth, gonadotropin and sex steroid concentrations are still high, but the levels decline during the first several weeks of life and remain low during the prepubertal years. The hypothalamic-pituitary unit appears to be suppressed by the extremely low levels of gonadal steroids present in childhood. Gonadal suppression of gonadotropin secretion is demonstrated by higher gonadotropin levels in children with gonadal dysgenesis and those who undergo gonadectomy before puberty (11).

Several of the hormonal changes associated with pubertal development begin before any of the physical changes are obvious. Early in puberty, there is increased sensitivity of LH to GnRH. Sleep-entrained increases in both LH and FSH can be documented early in puberty (12). In boys, the nocturnal increases in gonadotropin levels are accompanied by simultaneous increases in circulating testosterone levels (13). In contrast, in girls, the nighttime increases in circulating gonadotropin levels are followed by increased secretion of estradiol the next day (14) (Fig. 23.5). This delay in estradiol secretion is believed due to the additional synthetic steps required in the aromatization of estrogens from androgens. Basal levels of both FSH and LH increase through puberty. The patterns differ in boys and girls, with LH levels (measured in mIU/mL) eventually becoming greater than FSH levels (15) (Fig. 23.6). Although it now appears that gonadotropins are always secreted in an episodic or pulsatile fashion, even before puberty, the pulsatile secretion of gonadotropins is more easily documented as puberty progresses and basal levels increase (16).

Figure 23.5 Patterns of circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol in a stage 3 pubertal girl over a 24-hour period with the encephalographic stage of sleep indicated. (From Boyar RM, Wu RHK, Roffwarg H, et al. Human puberty: 24-hour estradiol patterns in pubertal girls. *J Clin Endocrinol Metab*. 1976;43:1418–1421, with permission.)

Figure 23.6 Increases (\pm standard error) in circulating levels of gonadotropins and adrenal and gonadal steroids through puberty in girls. DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate. (From Emans SJH, Goldstein DP. The physiology of puberty. In: Emans SJH, Goldstein DP, eds. *Pediatric and adolescent gynecology*. 3rd ed. Boston: Little, Brown, 1990:95, with permission.)

Increased adrenal androgen secretion is important in stimulating adrenarche, the appearance of pubic and axillary hair, in both boys and girls. Pubarche specifically refers to the appearance of pubic hair. Progressive increases in circulating levels of the major adrenal androgens, dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), begin as early as 2 years of age, accelerate at 7 to 8 years of age, and continue until 13 to 15 years of age (17,18 and 19). The accelerated

increases in adrenal androgens begin about 2 years before the increases in gonadotropin and gonadal sex steroid secretion when the hypothalamic–pituitary–gonadal unit is still functioning at a low prepubertal level.

In girls, estradiol, secreted predominantly by the ovaries, increases steadily during puberty (15). Although, as noted, increases in estradiol first appear during the daytime hours, basal levels increase during both the day and night. Estrone, which is secreted in part by the ovaries and arises in part from extraglandular conversion of estradiol and androstenedione, also increases early in puberty but plateaus by midpuberty. Thus, **the ratio of estrone to estradiol decreases throughout puberty, indicating that ovarian production of estradiol becomes increasingly important and peripheral conversion of androgens to estrone becomes less important during maturation.**

In boys, most of the testosterone in the circulation arises from direct secretion by the Leydig cells of the testis. Testosterone induces development of a male body habitus and voice change, whereas dihydrotestosterone (DHT), produced following 5 α reduction within target cells, induces enlargement of the penis and prostate gland, beard growth, and temporal hair recession during puberty. Mean plasma testosterone levels rise progressively during puberty, with the greatest increase occurring during Tanner stage 2 (20).

Mechanisms Underlying Puberty

The mechanisms responsible for the numerous hormonal changes that occur during puberty are poorly understood, although it is recognized that a “central nervous system program” must be responsible for initiating puberty. It appears that the hypothalamic–pituitary–gonadal axis in girls develops in two distinct stages during puberty. First, sensitivity to the negative or inhibitory effects of the low levels of circulating sex steroids present in childhood decreases early in puberty. Second, late in puberty, there is maturation of the positive or stimulatory feedback response to estrogen, which is responsible for the ovulatory midcycle surge of LH.

Current evidence suggests that the central nervous system inhibits the onset of puberty until the appropriate time (21). Based on this theory, the neuroendocrine control of puberty is mediated by GnRH-secreting neurons in the medial basal hypothalamus, which act together as an endogenous pulse generator. At puberty, the GnRH pulse generator is reactivated (i.e., disinhibited), leading to increased amplitude and frequency of GnRH pulses. In turn, the increased GnRH secretion results in increased gonadotropin and then gonadal steroid secretion. What causes this “disinhibition” of GnRH release is unknown.

Aberrations of Pubertal Development

Classification

Several aberrations of pubertal development, as detailed in [Table 23.1](#), can occur in girls. Pubertal aberrations can be classified in four broad categories:

Table 23.1. Aberrations of Pubertal Development

1. **Delayed or interrupted puberty** exists in girls who fail to develop any secondary sex characteristics by age 13, have not had menarche by age 16, or have not attained menarche 5 or more years since the onset of pubertal development.
2. **Asynchronous pubertal development** is characterized by pubertal development that deviates from the normal pattern of puberty.
3. **Precocious puberty** has been defined as pubertal development beginning before the age of 7 years in white girls and before the age of 6 years in African American girls (3). This new definition is controversial and has been challenged because some feel that evaluation for breast or pubic hair development before 8 or 9 years of age, respectively, may be warranted (22). It is clear that in most cases, development nearer to the mean age of puberty is less likely to have a pathologic basis. Precocious pubertal development is characterized in several ways. In isosexual precocious puberty, the early changes are common to the phenotypic sex of the individual. In heterosexual precocious puberty, the development is characteristic of the opposite sex. Precocious puberty is sometimes termed “true” when it is of central origin with activation of the hypothalamic–pituitary unit. In precocious pseudopuberty, also known as *precocious puberty of peripheral origin*, secretion of hormones in the periphery (commonly by neoplasms) stimulates pubertal development.
4. **Heterosexual puberty** is characterized by a pattern of development that is typical of the opposite sex occurring at the expected age of normal puberty.

Delayed or Interrupted Puberty

Disorders of sexual development and amenorrhea may be considered in relation to this classification of the aberrations of puberty. It is very helpful to document the growth of the individual and to plot the individual's height and weight on one of several commonly available growth charts ([Fig. 23.7](#)).

Figure 23.7 Growth chart showing stature by age percentiles for girls aged 2 to 18 years. Weight can be plotted in a similar fashion. Several excellent growth charts are available to clinicians, including those from Ross Laboratories (Columbus, OH), Serono Laboratories (Randolph, MA), and Genentech, Inc. (South San Francisco, CA). (From **Hamill PVV, Drizd TA, Johnson CL, et al.** Physical growth: National Center for Health Statistics percentiles. *Am J Clin Nutr* 1979;32:607–629, with permission; based on data from the National Center for Health Statistics.)

The history and physical examination, with particular attention to growth, are most important in the evaluation of individuals with delayed puberty. One possible

approach to evaluation is depicted in [Fig. 23.8](#).

Figure 23.8 Flow diagram for the evaluation of delayed or interrupted pubertal development, including primary amenorrhea, in phenotypic girls. Girls with asynchronous development often present because of failure to menstruate. (From **Rebar RW**. Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al**, eds. *Gynecology and obstetrics: a longitudinal approach*. New York: Churchill Livingstone, 1993: 97–133.)

Anatomic Abnormalities of the Genital Outflow Tract

Those girls who have mature secondary sex characteristics and any of a number of disorders of the outflow tract and uterus, often termed müllerian agenesis and dysgenesis, are most often identified on examination ([Fig. 23.9](#)). One of the most logical classification schemes that has been proposed is shown in [Table 23.2](#) ([23](#)). The incidence of these anomalies was estimated to be 0.02% of the female population several years ago ([24](#)), but the incidence may have increased as a result of the maternal ingestion of diethylstilbestrol (DES) and the resultant increase in anomalies of the lumen of the uterus (class VI) ([25](#)). Of the disorders unrelated to drugs, the septate uterus (class V) is most common.

Figure 23.9 Hysterosalpingograms of normal and abnormal female genital tracts. The radiographic photographs have been reversed to accentuate the uterine cavities. **A:** Normal study with bilateral spill. **B:** Bicornuate uterus. **C:** Uterus didelphis. **D:** Uterus didelphis with double vagina. (Courtesy of Dr. A. Gerbie; from **Spitzer IB, Rebar RW**. Counselling for women with medical problems: ovary and reproductive organs. In: **Hollingsworth D, Resnik R**, eds. *Medical counselling before pregnancy*. New York: Churchill Livingstone, 1988:213–248, with permission.)

Class I. Segmental müllerian agenesis or hypoplasia
A. Vaginal
B. Cervical
C. Fundal
D. Subal
E. Cervicovaginal
Class II. Bicornuate uterus
A. With a multicavity horn
1. With a communicating endometrial cavity
2. With a noncommunicating cavity
3. With no cavity
B. Without any multicavity horn
Class III. Uterus didelphis
Class IV. Bicornuate uterus
A. Complete to the internal os
B. Partial
C. Accuate
Class V. Septate uterus
A. With a complete septum
B. With an incomplete septum
Class VI. Uterus with internal luminal changes

Adapted from **Batterson VC Jr, Cibbons WE**. Müllerian anomalies: a proposed classification (an analysis of 144 cases). *Fertil Steril* 1970;32:86, with permission.

Table 23.2. Classification of Müllerian Anomalies

Disorders of the outflow tract and uterus often occur as a part of a syndrome of malformations that include abnormalities of the skeletal and renal systems (Rokitansky-Küster-Hauser syndrome). Familial aggregates of the most common disorders of müllerian differentiation in females—müllerian aplasia and incomplete müllerian fusion—are best explained on the basis of polygenic and multifactorial inheritance ([26](#)). It is clear that the *HOX* genes, a family of regulatory genes that encode for transcription factors, are essential for proper development of the müllerian tract in the embryonic period ([27](#)), and *HOXA 13* has been found to be altered in hand-foot-genital syndrome.

The most common single anatomic disorder of puberty is the imperforate hymen, which prevents the passage of endometrial tissue and blood. These products can accumulate in the vagina (*hydrocolpos*) or uterus (*hydrometrocolpos*) and result in a bulging hymen that is often bluish in color. The affected individual often has a history of vague abdominal pain with approximately monthly exacerbations. It is sometimes difficult to distinguish an imperforate hymen from a transverse vaginal septum, and in most situations, examination under anesthesia is required.

Regardless of the cause, uterine anomalies not involving segmental müllerian agenesis or hypoplasia (class I) are compatible with normal pregnancy. However, increased fetal wastage has been reported ([28](#)). Uterine malformations have been associated with spontaneous abortion, premature labor, abnormal presentations, and complications of labor (i.e., retained placenta). Many of these uterine anomalies can be identified with hysterosalpingography ([Fig. 23.9](#)). Hysterosalpingography, laparoscopy, and hysteroscopy have been used to differentiate a septate uterus (class V) from a bicornuate uterus (class IV). It is now clear that magnetic resonance imaging (MRI) and endovaginal ultrasonography (sometimes with sonohysterography) are as accurate as these invasive techniques in identifying the abnormality ([29](#)).

Obstruction or malformation of the distal genital tract must be distinguished from androgen insensitivity. Individuals with androgen insensitivity have breast development in the absence of significant pubic and axillary hair development; the vagina may be absent or foreshortened in these women.

Hypergonadotropic and Hypogonadotropic Hypogonadism

Basal levels of FSH and prolactin should be determined in individuals in whom secondary sex characteristics have not developed to maturity ([Fig. 23.8](#)). Bone age should be estimated from x-rays of the nondominant hand. If prolactin levels are elevated, thyroid function should be assessed to determine whether the individual has primary hypothyroidism. Paradoxically, primary hypothyroidism can result in precocious puberty as well. If thyroid function is normal, a hypothalamic or pituitary

neoplasm is possible, and careful evaluation of the hypothalamic and pituitary area by MRI or computed tomography (CT) is indicated.

The karyotype should be determined in any individual with delayed puberty and increased basal FSH concentrations. Regardless of the karyotype, the individual with hypergonadotropic hypogonadism has some form of ovarian “failure.”

Forms of Gonadal Failure

Turner's Syndrome Most affected individuals have a 45X karyotype and Turner's syndrome; still others have mosaic karyotypes (i.e., 45X/46XX; 45X/46XY) and may present with the Turner's phenotype as well. Intrauterine growth restriction is common in infants with a 45X karyotype. After birth, these patients generally grow slowly, beginning in the second or third year of life. They typically have many of the associated stigmata, including lymphedema at birth; a webbed neck; multiple pigmented nevi; disorders of the heart, kidneys (most commonly horseshoe), and great vessels (most commonly coarctation of the aorta); and small hyperconvex fingernails (30) (Fig. 23.10). Diabetes mellitus, thyroid disorders, essential hypertension, and other autoimmune disorders are often present in individuals with 45X karyotypes. Most 45X patients have normal intelligence, but many affected individuals have an unusual cognitive defect characterized by an inability to appreciate the shapes and relations of objects with respect to one another (i.e., space-form blindness). As they grow older, affected children typically are shorter than normal. Although they do not develop breasts at puberty, some pubic or axillary hair may develop because appropriate adrenarche can occur with failure of thelarche (i.e., breast development). **Although less severe short stature and some adolescent development may occur with chromosomal mosaicism, it is reasonable to assume that any short, slowly growing, sexually infantile girl has Turner's syndrome until proved otherwise because this disorder is so prevalent (about 1 in 2,500 newborn phenotypic females). In fact, the 45X karyotype is the single most frequent chromosomal disorder in humans, but most affected fetuses are aborted spontaneously early in pregnancy. However, trisomy is the most common chromosomal type or category of abnormality in first-trimester losses.**

Figure 23.10 Typical appearance of two individuals with 45X gonadal dysgenesis. A: This 16-year-old individual has obvious short stature, a webbed neck, shortened fourth metatarsals, and a thoracotomy scar from the repair of the coarctation of the aorta that was performed at 13 years of age. **B:** This 13-year-old individual had evidence of adrenarche with some pubic and axillary hair development. She is quite short, but the stigmata of Turner's syndrome are less obvious than in the patient in **A**.

Even in the presence of typical Turner stigmata, a karyotype is indicated to eliminate the possibility of any portion of a Y chromosome. If a Y chromosome is identified, surgical extirpation of the gonads is warranted to eliminate any possibility of a germ cell neoplasm (estimated 20% to 30% prevalence) (31,32). In individuals in whom there is no evidence of neoplastic dissemination, the uterus may be left *in situ* for donor *in vitro* fertilization and embryo transfer. The evaluation of other commonly involved organ systems should include a careful physical examination, with special attention to the cardiovascular system, and thyroid function tests (including antibody assessment), fasting blood glucose, renal function tests, and intravenous pyelography or a renal ultrasonography.

Treatment of Turner's Syndrome To increase final adult height, treatment strategies using exogenous growth hormone (GH) are commonly accepted (33). It is not yet known what dose of GH is optimal or if an anabolic steroid such as oxandrolone will provide additional growth. However, GH in doses 25% greater than those recommended for GH deficiency are proving safe and effective, with a net increase in height of 8.1 cm over the average height of about 146 cm in untreated individuals.

The treatment of patients with Turner's syndrome is as follows:

1. **To promote sexual maturation, therapy with exogenous estrogen should be initiated when the patient is psychologically ready, at about 12 to 13 years of age, and after GH therapy is completed.**
2. Because the intent is to mimic normal pubertal development, therapy with low-dose estrogen alone (such as 0.3 to 0.625 mg conjugated estrogens orally each day) should be initiated.
3. Progestins (5 to 10 mg medroxyprogesterone acetate or 200 mg micronized progesterone orally for 12 to 14 days every 1 to 2 months) can be added to prevent endometrial hyperplasia after the patient first experiences vaginal bleeding or after 6 months of unopposed estrogen use if the patient has not yet had any bleeding.
4. The dose of estrogen is increased slowly over 1 to 2 years until the patient is taking about twice as much estrogen as is administered to postmenopausal women.
5. Girls with gonadal dysgenesis must be monitored carefully for the development of hypertension with estrogen therapy.
6. The patients and their parents should be counseled regarding the emotional and physical changes that will occur with therapy.

Mosaic Forms of Gonadal Dysgenesis Individuals with rare mosaic forms of gonadal dysgenesis may develop normally at puberty. The decision to initiate therapy with exogenous estrogen should be based mainly on circulating FSH levels because FSH levels in the normal range for the patient's age imply the presence of functional gonads.

Pregnancies can be achieved in these individuals, with success rates of more than 50%, by using donor oocytes (34).

Pure Gonadal Dysgenesis The term, *pure gonadal dysgenesis* refers to 46XX or 46XY phenotypic females who have streak gonads. This condition may occur sporadically or may be inherited as an autosomal recessive trait or as an X-linked trait in XY gonadal dysgenesis (Fig. 23.11). Affected girls are typically of average height and have none of the stigmata of Turner's syndrome, but they have elevated levels of FSH because the streak gonads produce neither steroid hormones nor inhibin. When gonadal dysgenesis occurs in 46XY individuals, it is sometimes termed *Swyer's syndrome*. Surgical extirpation is warranted in individuals with a 46XY karyotype to prevent development of germ cell neoplasms. Both 46XX and 46XY forms of gonadal dysgenesis benefit from exogenous estrogen and are potential candidates for donor oocytes.

Figure 23.11 A: A 16-year-old individual with 46XX gonadal dysgenesis and primary amenorrhea. Circulating follicle-stimulating hormone (FSH) levels were markedly elevated. The small amount of breast development (Tanner stage 2) is unusual, but some pubertal development may occur in such patients. **B: A 16-year-old individual with 46XY gonadal dysgenesis who presented with primary amenorrhea and markedly elevated FSH levels.** Most affected individuals do not present with as much pubic and axillary hair development. The right gonad contained a dysgerminoma, but there was no evidence of metastases. (From **Rebar RW**. Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al**, eds. *Gynecology and obstetrics: a longitudinal approach*. New York: Churchill Livingstone, 1993:97–133, with permission.)

In early gonadal failure, the ovaries apparently develop normally but contain no oocytes by the expected age of puberty. These disorders are considered further in the discussion delineating the evaluation of amenorrhea (see [Chapter 24](#)).

Hypogonadotropic Hypogonadism

Hypothalamic–pituitary disturbances are usually associated with low levels of circulating gonadotropins (with both LH and FSH ≤ 10 mIU/mL) ([35](#)). There are both sporadic and familial causes of hypogonadotropic hypogonadism, and the differential diagnosis is extensive. Mutations in several genes have been shown to cause hypogonadotropic hypogonadism in humans ([36](#)). This condition can arise from abnormalities in hypothalamic GnRH secretion, impaired release of gonadotropins from the pituitary gland, or both. At least four genes have been identified as causes of hypogonadotropic hypogonadism: (a) *KAL*, (b) *DAX 1* (the gene for X-linked congenital adrenal hypoplasia), (c) *GNRHR* (the gene for the GnRH receptor), and (d) *PC1* (the gene for prohormone convertase 1) ([37](#)). Because defects in these four genes account for less than 20% of all cases of isolated hypogonadotropic hypogonadism, additional mutations probably exist but have yet to be identified. It is important to remember, however, that low levels of LH and FSH are normally present in the prepubertal years; thus, girls with constitutionally delayed puberty may mistakenly be presumed to have hypogonadotropic hypogonadism. **In fact, constitutional delay is the most common cause of delayed puberty.** Constitutional delayed growth and adolescence can be diagnosed only after careful evaluation excludes other causes of delayed puberty and longitudinal follow-up documents normal sexual development. The farther below the third percentile for height that the young girl is, the less likely it is that the cause is constitutional.

Kallmann's Syndrome As originally described in 1944 ([38](#)), Kallmann's syndrome consisted of the triad of anosmia, hypogonadism, and color blindness in men. Women may be affected as well, and other associated defects may include cleft lip and palate, cerebellar ataxia, nerve deafness, and abnormalities of thirst and vasopressin release. Because autopsy studies have shown partial or complete agenesis of the olfactory bulb, the term *olfactogenital dysplasia* has also been used to describe the disorder. These anatomic findings coincide with embryologic studies documenting that GnRH neurons originally develop in the epithelium of the olfactory placode and normally migrate into the hypothalamus ([39](#)). In some affected individuals, gene defects have been found in one protein, anosmin, that facilitates this neuronal migration, thus leading to an absence of GnRH neurons in the hypothalamus and olfactory bulbs and consequent hypogonadotropic hypogonadism and anosmia (Kallmann's syndrome) ([40](#)). The gene defect resulting in loss of this facilitatory adhesion protein has been localized to the X chromosome in an X-linked form of the syndrome, and this locus has been designated *KAL 1*. Because confirmed mutations in the coding sequence of the *KAL* gene occur only in a minority of individuals with Kallmann's syndrome ([41](#)), other mutations no doubt will be identified in the future. Moreover, the disorder is so heterogeneous that it appears likely that this disorder forms a structural continuum with other midline defects. Septooptic dysplasia represents the most severe disorder.

Clinically, affected individuals typically present with sexual infantilism and an eunuchoid habitus, but some degree of breast development may occur ([Fig. 23.12](#)). Primary amenorrhea is the rule. The ovaries are usually small, with follicles seldom developing beyond the primordial stage. Circulating gonadotropin levels are usually very low but almost invariably measurable. Affected individuals respond readily to pulsatile administration of exogenous GnRH, and clearly this is the most physiologic approach to ovulation induction ([34](#)). For women not seeking pregnancy, replacement therapy with exogenous estrogen and progestin is indicated.

Figure 23.12 A 21½-year-old woman with Kallmann's syndrome. Note that the patient has some pubic and axillary hair. Bone age was 16 years. It is rare to see affected individuals today who were not given oral contraceptive agents to induce menses (with some consequent breast development). (From **Wilkins L**. *The diagnosis and treatment of endocrine disorders in childhood and adolescence*. 3rd ed. Springfield, IL:Charles C. Thomas, 1965, with permission.)

Isolated gonadotropin deficiency can also occur in association with the Prader-Labhardt-Willi syndrome, which is characterized by obesity, short stature, hypogonadism, small hands and feet (acromicria), mental retardation, and infantile hypotonia; and in association with the Laurence-Moon-Bardet-Biedl syndrome, which is characterized by retinitis pigmentosa, postaxial polydactyly, obesity, and hypogonadism. Prader-Labhardt-Willi syndrome apparently results from rearrangements of chromosome 15q11 to q13, an imprinted region of the human genome ([42](#)). Laurence-Moon-Bardet-Biedl syndrome, inherited in an autosomal recessive manner, is apparently heterogeneous, with at least four involved gene loci having been mapped to date ([43](#)).

Multiple pituitary hormone deficiencies, which are usually hypothalamic in origin, may be congenital and either part of an inherited constellation of findings or sporadic. If growth hormone (GH) or thyroid-stimulating hormone (TSH) concentrations are subnormal, growth and pubertal development will be affected. Thus, the condition should be diagnosed before the age of puberty. Because individuals with hypopituitarism have a high mortality rate, predominantly caused by vascular and respiratory disease ([44](#)), it is important to identify affected individuals. Later age at diagnosis, female sex, and above all craniopharyngioma have been identified as significant independent risk factors. Untreated gonadotropin deficiency also is an important risk factor for early mortality.

Tumors of the Hypothalamus and Pituitary Several different tumors of the hypothalamic and pituitary regions may also lead to hypogonadotropic hypogonadism ([45](#)) ([Fig. 23.13A](#)). Except for craniopharyngiomas, these tumors are relatively uncommon in children. Craniopharyngiomas are usually suprasellar in location and may be asymptomatic well into the second decade of life. Such tumors may present as headache, visual disturbances, short stature or growth failure, delayed puberty, or diabetes insipidus. Visual field defects (including bilateral temporal hemianopsia), optic atrophy, or papilledema may be seen on physical examination. Laboratory evaluation should document hypogonadotropinism and may also reveal hyperprolactinemia as a result of interruption of hypothalamic dopamine inhibition of prolactin release. Radiographically, the tumor may be either cystic or solid and may show areas of calcification. Appropriate therapy for hypothalamic–pituitary tumors may involve surgical excision or radiotherapy (with adequate pituitary hormone replacement therapy) and is best decided by a team of physicians that includes an endocrinologist, a neurosurgeon, and a radiotherapist.

Figure 23.13 A: A 16-year-old girl with delayed puberty. Breast budding began at 11 years of age, but there was no further development. During the year before presentation, her scholastic performance in school deteriorated, she gained 25 lb, she became increasingly lethargic, and nocturia and polydipsia were noted. Initial evaluation documented low follicle-stimulating hormone, elevated prolactin, and a bone age of 10.5 years. Computed tomography scanning documented a large hypothalamic neoplasm that proved to be an ectopic germinoma. The patient was also documented to be hypothyroid and hypoadrenal and to have diabetes insipidus. Despite the elevated prolactin, she had no galactorrhea because of the minimal breast development. (From **Rebar RW**. Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al**, eds. *Gynecology and obstetrics: a longitudinal approach*. New York: Churchill Livingstone, 1993:97–133, with permission.) **B: A 16-year-old girl with primary amenorrhea who progressed in puberty until about 12 years of age.** Breast budding occurred at about 10 years of age. The patient's short stature is obvious. She proved to have hypopituitarism. Classic radiographic findings established the diagnosis of Langerhans cell-type histiocytosis (Hand-Schüller-Christian disease).

Other Central Nervous System Disorders Other central nervous system disorders that may lead to delayed puberty include infiltrative diseases, such as Langerhans-type histiocytosis, particularly the form known previously as Hand-Schüller-Christian disease ([Fig. 23.13B](#)). Diabetes insipidus is the most common endocrinopathy (because of infiltration of the supraoptic nucleus in the hypothalamus), but short stature resulting from GH deficiency, and delayed puberty caused by gonadotropin deficiency are not uncommon in this disorder ([46](#)).

Irradiation of the central nervous system for treatment of any neoplasm or leukemia may result in hypothalamic dysfunction. Although GH deficiency occurs most often, partial or complete gonadotropin deficiency may develop in some patients.

Severe chronic illnesses, often accompanied by malnutrition, may also lead to slowed growth in childhood and delayed adolescence. Regardless of the cause, weight loss to less than 80% to 85% of ideal body weight often results in hypothalamic GnRH deficiency. If adequate body weight and nutrition are maintained in chronic illnesses such as Crohn's disease or chronic pulmonary or renal disease, sufficient gonadotropin secretion usually is present to initiate and maintain pubertal development.

Anorexia Nervosa and Bulimia Significant weight loss and psychological dysfunction occur simultaneously with anorexia nervosa ([47,48](#)). Although many anorectic girls experience amenorrhea after pubertal development has begun, if the disorder begins sufficiently early, pubertal development may be delayed or interrupted ([Fig. 23.14](#)). The following constellation of associated findings confirms anorexia nervosa in most individuals:

Figure 23.14 An 18-year-old girl with anorexia nervosa. As is true of most such patients, pubertal development had been completed and menses initiated before anorexia led to marked weight loss.

1. Relentless pursuit of thinness
2. Amenorrhea, sometimes preceding the weight loss
3. Extreme inanition
4. Obsessive-compulsive personality often characterized by overachievement
5. Distorted and bizarre attitude toward eating, food, or weight
6. Distorted body image

Because normal body weight is commonly maintained in bulimia, it is unusual for bulimic patients to experience either delayed development or amenorrhea. Girls with anorexia nervosa may have, in addition to hypogonadotropic hypogonadism, partial diabetes insipidus, abnormal temperature regulation, chemical hypothyroidism with low serum triiodothyronine (T_3) and high reverse T_3 levels, and elevated circulating cortisol levels in the absence of evidence of hypercortisolism ([49](#)).

Fear of obesity, a syndrome of self-induced malnutrition common among teenage gymnasts and ballet dancers, also may slow growth and delay pubertal development ([50](#)). These children voluntarily reduce their caloric intake as much as 40%, leading to nutritional growth retardation. Any additive role for endurance training in the delayed development is possible, but the mechanisms are unclear at this point. These conditions are essentially severe forms of hypothalamic amenorrhea. It is clear, however, that delayed puberty will occur inevitably unless adequate caloric intake is provided.

Hyperprolactinemia Low levels of LH and FSH may be associated with hyperprolactinemia. As noted, galactorrhea cannot occur in the absence of complete breast development. Pituitary prolactinomas are rare during adolescence but must be considered when certain signs and symptoms are present. Many individuals with prolactinomas have a history of delayed menarche. The association between the ingestion of certain drugs (most often psychotropic agents and opiates in this age group) is well established. Primary hypothyroidism also is associated with hyperprolactinemia because increased levels of thyrotropin-releasing hormone (TRH) stimulate secretion of prolactin. The empty sella syndrome, in which the sella turcica is enlarged but has been replaced by cerebrospinal fluid, may also be associated with hyperprolactinemia.

Asynchronous Puberty

Figure 23.15 A: This 17-year-old individual presented with primary amenorrhea and was found to have a blind-ending vagina and bilateral inguinal masses. Circulating levels of testosterone were at the upper limits of the normal range for men and the karyotype was 46XY, confirming androgen insensitivity. **B:** Two inguinal testes were found at surgery. (From Simpson JL, Rebar RW. Normal and abnormal sexual differentiation and development. In: Becker KL, ed. *Principles and practice of endocrinology and metabolism*. 2nd ed. Philadelphia: JB Lippincott, 1995:788–822, with permission.)

Asynchronous pubertal development is characteristic of androgen insensitivity (i.e., testicular feminization). Affected individuals typically present with breast development (usually only to Tanner stage 3) out of proportion with the amount of pubic and axillary hair (Fig. 23.15). In this disorder, 46XY individuals have bilateral testes, female external genitalia, a blindly ending vagina (often foreshortened and sometimes absent), and no müllerian derivatives (i.e., uterus and fallopian tubes) (51). Infrequently, patients may have clitoral enlargement and labioscrotal fusion at puberty, which is referred to as *incomplete androgen insensitivity*.

Asynchronous puberty is heterogeneous but is always related to some abnormality of the androgen receptor or of androgen action (52). In perhaps 60% to 70% of cases, androgen receptors cannot be detected (i.e., the patient is receptor negative). In the remaining cases, androgen receptors are present (i.e., receptor positive), but mutations in the androgen receptor have been detected or there is a defect at a more distal step in androgen action (i.e., a postreceptor defect). Receptor-positive individuals are indistinguishable clinically from receptor-negative individuals. Several different mutations in the androgen receptor gene, most of which occur within the androgen-binding domain of the receptor, have been identified in affected individuals who are receptor positive. Severe X-linked androgen receptor gene mutations cause complete androgen insensitivity, mild mutations impair virilization with or without infertility, and moderate mutations result in a wide phenotypic spectrum of expression among siblings (53).

Because the Sertoli cells of the testis make antimüllerian hormone (AMH), müllerian derivatives are absent in this disorder; thus, müllerian regression occurs normally. The testes are often normal in size and may be located anywhere along the path of embryonic testicular descent—in the abdomen, inguinal canal, or labia. Half of all individuals with androgen insensitivity develop inguinal hernias. Recognizing that most such girls will be 46XX, it is important to determine the karyotype in prepubertal girls with inguinal hernias, especially if a uterus cannot be detected with certainty by ultrasound

The frequency of gonadal neoplasia is increased with this condition, but the extent is uncertain (31). Most clinicians believe the risk for neoplasia is low before 25 years of age; thus, the testes should be left in place until after pubertal feminization, especially because the risk for neoplasia appears to increase with age. Exogenous estrogen should be provided after gonadectomy.

The diagnosis is often suspected by the typical physical findings and strongly suggested by normal (or even somewhat elevated) male levels of testosterone, normal or somewhat elevated levels of LH, and normal levels of FSH. The diagnosis is confirmed by a 46XY karyotype.

Interacting with the patient and family requires sensitivity and care. It may be inadvisable to begin by informing the patient of the karyotype; the psychological implications may be devastating because the patient has been reared as a female. Family members should be informed initially that müllerian aplasia occurred and that the risk for neoplasia mandates gonadectomy after puberty. Because the disorder can be inherited in an X-linked recessive fashion, families should undergo appropriate genetic counseling and screening to identify the possible existence of other affected family members.

Precocious Puberty

Although precocious pubertal development may be classified in several ways, it is perhaps simplest to think of the development as gonadotropin dependent (in which case it is almost invariably of central origin) or gonadotropin independent (of peripheral origin). The evaluation of precocious puberty is as follows:

1. Measurement of basal gonadotropin levels is the first step in the evaluation of a child with sexual precocity (Fig. 23.16).

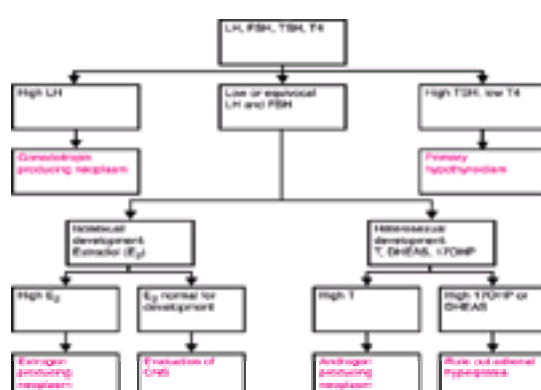

Figure 23.16 Flow diagram for the evaluation of precocious puberty in phenotypic females. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al, eds. *Gynecology and obstetrics: a longitudinal approach*. New York: Churchill Livingstone, 1993:97–133, with permission.)

2. Thyroid function should also be evaluated to rule out primary hypothyroidism as the cause of precocious development.
3. High levels of LH (which really may be human chorionic gonadotropin detected because of cross-reactivity with LH in immunoassays) suggest a gonadotropin-producing neoplasm, most often a pinealoma (ectopic germinoma) or choriocarcinoma or, less often, a hepatoblastoma. (Gonadotropin-producing neoplasms are the only causes of precocious puberty in which the gonadotropin dependence does not equate with central precocious puberty.)
4. Low or pubertal levels of gonadotropins indicate the need to determine circulating estradiol concentrations in girls with isosexual development and to assess androgen levels, specifically testosterone, dehydroepiandrosterone sulfate, and 17a-hydroxyprogesterone in girls with heterosexual development.
5. Increased estradiol levels suggest an estrogen-secreting neoplasm, probably of ovarian origin.
6. Increased testosterone levels suggest an androgen-producing neoplasm of the ovary or the adrenal gland. Such neoplasms may be palpable on abdominal or rectal examination. Increased 17a-hydroxyprogesterone levels are diagnostic of 21-hydroxylase deficiency (i.e., congenital adrenal hyperplasia [CAH]). Dehydroepiandrosterone sulfate levels are elevated in various forms of CAH as well.
7. If the estradiol levels are compatible with the degree of pubertal development observed, evaluation of the central nervous system by MRI or CT scanning is warranted.
8. Bone age should always be assessed in evaluating an individual with sexual precocity.

Perhaps the most difficult decision for the gynecologist is determining how much evaluation is warranted for the young girl brought in by her mother for precocious breast budding only (*precocious thelarche*) or the appearance of pubic or axillary hair alone (*precocious pubarche* or *adrenarche*). In such cases, it is acceptable to many clinicians to follow the patient at frequent intervals and to proceed with evaluation if there is evidence of pubertal progression. The feasibility of this approach may depend on the concerns of the parents. Premature thelarche may be caused by increased sensitivity of the breasts to low levels of estrogen or to increased

estradiol secretion by follicular cysts. Premature adrenarche or pubarche may be due to increased sensitivity to low levels of androgens and must be distinguished from late-onset (nonclassic) CAH. If there is no evidence of breast development and the appearance of sexually stimulated hair (i.e., precocious puberty) or of progression, these conditions are virtually always benign.

Constitutional sexual precocity is the most common cause of precocious puberty. It is often familial and represents the so-called “tail” of the gaussian curve (i.e., the early 2.5% for the age distribution for the onset of puberty).

Central (True) Precocious Puberty

In central precocious puberty, GnRH prematurely stimulates increased gonadotropin secretion. Central precocious puberty may occur in children in whom there is no structural abnormality, in which case it is termed *constitutional* or *idiopathic*. Alternatively, central precocious puberty may result from a tumor, infection, congenital abnormality, or traumatic injury affecting the hypothalamus. Tumors of the hypothalamus include hamartomas and, less frequently, neurogliomas and pinealomas. It appears that hamartomas produce GnRH in a pulsatile manner and thus stimulate gonadotropin secretion (54) (Fig. 23.17). A number of congenital malformations, including hydrocephalus, craniostenosis, arachnoid cysts, and septooptic dysplasia, also can be associated with precocious puberty (as well as with sexual infantilism).

Figure 23.17 A 7½-year-old girl with Tanner stage 4 pubertal development who began menstruating 1 month earlier. She was 57 inches tall (above the ninety-fifth percentile). Luteinizing hormone and follicle-stimulating hormone levels were consistent with her development. A large neoplasm that proved to be a hypothalamic hamartoma was present on computed tomography scan. Pubertal development began at about 5 years of age.

Precocious Puberty of Peripheral Origin

In gonadotropin-independent precocious puberty, production of estrogens or androgens from the ovaries, adrenals, or rare steroid-secreting neoplasms leads to early pubertal development. Small functional ovarian cysts, typically asymptomatic, are common in children and may cause transient sexual precocity (55). Simple cysts (with a benign ultrasonographic appearance) can be observed and usually resolve over time. Of the various ovarian neoplasms that can secrete estrogens, granulosa-theca cell tumors occur most frequently but are still rare (56). Although such tumors may grow rapidly, more than two thirds are benign.

The McCune-Albright syndrome is characterized by polyostotic fibrous dysplasia of bone, irregular café-au-lait spots on the skin, and hyperfunctioning endocrinopathies. Girls develop sexual precocity as a result of functioning ovarian cysts. Other endocrinopathies may include hyperthyroidism, hypercortisolism, hyperprolactinemia, and acromegaly. It is now known that mutations of the GS_{α} subunit of the G protein, which couples extracellular hormonal signals to the activation of adenylate cyclase, are responsible for the autonomous hyperfunction of the endocrine glands and, presumably, for the other defects present in this disorder (57). Exposure to exogenous estrogens can mimic gonadotropin-independent precocious puberty. Ingestion of oral contraceptives, other estrogen-containing pharmaceutical agents, and estrogen-contaminated foods and the topical use of estrogens have been implicated in cases of precocious development in infants and children. Severe primary hypothyroidism has also been associated with sexual precocity; associated hyperprolactinemia may result in galactorrhea in affected individuals.

Congenital Adrenal Hyperplasia

Heterosexual precocious puberty is always of peripheral origin and is most often caused by CAH. Three adrenal enzyme defects—21-hydroxylase deficiency, 11 β -hydroxylase deficiency, and 3 β -hydroxysteroid dehydrogenase deficiency—can lead not only to heterosexual precocity but also to virilization of the external genitalia because of increased androgen production beginning *in utero* (58). The clinical presentation of the various forms of CAH depend on (a) the affected enzyme, (b) the extent of residual enzymatic activity, and (c) the physiologic consequences of deficiencies in the end products and excesses of precursor steroids.

21-Hydroxylase Deficiency Most patients with classic CAH have 21-hydroxylase deficiency (Fig. 23.18). Neonatal screening suggests an incidence of about 1 in 15,000 births. This disorder is inherited as an autosomal recessive trait closely linked to the human leukocyte antigen (HLA) major histocompatibility complex on the short arm of chromosome 6. Thus, siblings with 21-hydroxylase deficiency usually have identical HLA types. There are various forms of 21-hydroxylase deficiency, including simple virilizing or classic (typically identified at birth because of genital ambiguity), salt-wasting (in which there is impairment of mineralocorticoid as well as glucocorticoid secretion), and late-onset or nonclassic (in which heterosexual development occurs at the expected age of puberty). All types involve alleles at the same locus. The nonclassic form is discussed in the following section on heterosexual pubertal development.

Figure 23.18 Left: A 10½-year-old girl with 21-hydroxylase deficiency before treatment. 17-Ketosteroid (KS) excretion was 34 mg/day. **Right: The same patient after 9 months of therapy with cortisone** (17-KS excretion: 4.6 mg/day). (From Wilkins L. *The diagnosis and treatment of endocrine disorders in childhood and adolescence*. 3rd ed. Springfield, IL: Charles C. Thomas, 1965:439, with permission.)

Deficiency of 21-hydroxylase results in the impairment of the conversion of 17 α -hydroxyprogesterone to 11-deoxycortisol and of progesterone to deoxycorticosterone (Fig. 23.19). As a consequence, precursors accumulate, and there is increased conversion to adrenal androgens. Because the development of the external genitalia is controlled by androgens, in the classic form of this disorder, girls are born with ambiguous genitalia, including an enlarged clitoris, fusion of the labioscrotal folds, and the urogenital sinus. The internal female organs (including the uterus, fallopian tubes, and ovaries) develop normally because they are not affected by the increased androgen levels. Almost two thirds of affected newborns rapidly develop salt-wasting 21-hydroxylase deficiency, hyponatremia, hyperkalemia, and hypotension. During childhood, untreated girls with either the classic or salt-wasting form grow rapidly but have advanced bone ages, enter puberty early, experience early closure of their epiphyses, and ultimately are short in stature as adults. CAH, with appropriate therapy, is the only inherited disorder of sexual

differentiation in which normal pregnancy and childbearing are possible. The classic and salt-wasting forms of 21-hydroxylase deficiency are easily diagnosed based on the presence of genital ambiguity and markedly elevated levels of 17 α -hydroxyprogesterone. Some states have initiated neonatal screening programs to detect 21-hydroxylase deficiency at birth.

Figure 23.19 Gonadal and adrenal steroid pathways and the enzymes required for steroid conversion. (From Rebar RW, Kenigsberg D, Hodgen GD. The normal menstrual cycle and the control of ovulation. In: Becker KL, ed. *Principles and practice of endocrinology and metabolism*. 2nd ed. Philadelphia: JB Lippincott, 1995:868–880, with permission.)

3 β -Hydroxysteroid Dehydrogenase Deficiency of 3 β -hydroxysteroid dehydrogenase (3 β -HSD) affects the synthesis of glucocorticoids, mineralocorticoids, and sex steroids. Typically, levels of 17-hydroxypregnenolone and DHEA are elevated (Fig. 23.19). The classic form of the disorder, detectable at birth, is quite rare, and affected girls may be masculinized only slightly. In severe cases, salt-wasting may also be present.

A nonclassic form of this disorder may be associated with heterosexual precocious pubertal development (as is the classic form if untreated), but postpubertal hyperandrogenism occurs more often. The androgen excess in individuals with nonclassic 3 β -HSD deficiency appears to result from androgens derived from the peripheral conversion of increased serum concentrations of DHEA. This disorder is inherited in autosomal recessive fashion, with allelism at the 3 β -HSD gene on chromosome 1 believed to be responsible for the varying degrees of enzyme deficiency.

11-Hydroxylase Deficiency The classic form of 11-hydroxylase deficiency is believed to constitute 5% to 8% of all cases of CAH. Deficiency in 11-hydroxylase results in the inability to convert 11-deoxycortisol to cortisol, resulting in the accumulation of androgen precursors (Fig. 23.19). Markedly elevated levels of 11-deoxycortisol and deoxycorticosterone are present in the disorder. Because deoxycorticosterone acts as a mineralocorticoid, many individuals with this disorder become hypertensive. A mild nonclassic form of 11-hydroxylase deficiency has been reported but apparently is very uncommon.

Treatment of Congenital Adrenal Hyperplasia The treatment of CAH involves providing replacement doses of the deficient steroid hormones.

Hydrocortisone (10 to 20 mg/m² body surface area) or its equivalent is given daily in divided doses to suppress the elevated levels of pituitary corticotropin present and thus suppress the elevated androgen levels. With such treatment, signs of androgen excess should regress. In children, growth velocity and bone age should be monitored carefully because both overreplacement and underreplacement can result in premature closure of the epiphyses and short stature. Data now indicate that early diagnosis and compliance with therapy lead to adult height within 1 standard deviation of the anticipated target height in girls with 21-hydroxylase deficiency (59).

Mineralocorticoid replacement is generally required in individuals with 21-hydroxylase deficiency whether or not they are salt-losing. The intent of glucocorticoid therapy should be to suppress morning 17 α -hydroxyprogesterone levels to between 300 and 900 ng/dL. Sufficient *fludrocortisone* should be given daily to suppress plasma renin activity to less than 5 mg/mL per hour. Girls with ambiguous genitalia may require reconstructive surgery, including clitoral recession and vaginoplasty. Timing of such surgery is debated, but the girl must be of appropriate size to permit the surgery to be as simple as possible.

Heterosexual Pubertal Development

The most common cause of heterosexual development at the expected age of puberty is **polycystic ovarian syndrome (PCO)** (Fig. 23.20). Because the syndrome is heterogeneous and poorly defined, clinical difficulties result in diagnosis and management (60). For the sake of simplicity, **PCO may be defined as LH-dependent hyperandrogenism** (61). Most clinical manifestations arise as a consequence of the hyperandrogenism and often include hirsutism beginning at or near puberty and irregular menses from the age of menarche because of oligoovulation or anovulation. Clinical manifestations are as follows:

Figure 23.20 Typical appearance of a young 21-year-old woman with polycystic ovarian syndrome. The patient is well feminized but has apparent hirsutism on her face (A) and on her torso (B).

1. Affected girls may be but are not necessarily somewhat overweight.
2. In rare instances, menarche may be delayed, and primary amenorrhea also may occur.
3. Basal levels of LH tend to be elevated in most affected individuals, and androgen production is invariably increased, even though circulating levels of androgens may be near the upper limits of the normal range in many affected women.
4. In anovulatory women, estrone levels are typically greater than estradiol levels.
5. Because circulating levels of estrogens are not diminished in PCO and androgen levels are only mildly elevated, affected girls become both feminized and masculinized at puberty. This is an important feature because girls with classic forms of CAH who do not experience precocious puberty (and even those who do) only become masculinized at puberty (i.e., they do not develop breasts).
6. Some degree of insulin resistance may be present, even in the absence of overt glucose intolerance (62).

Differential Diagnosis and Evaluation

Distinguishing PCO from the nonclassic forms of CAH is problematic and controversial (63,64). The evaluation is as follows:

1. Some clinicians advocate measurement of 17 α -hydroxyprogesterone in all women who develop hirsutism. Although values of 17 α -hydroxyprogesterone are commonly elevated more than 100-fold in individuals with classic 21-hydroxylase deficiency, they may or may not be elevated in nonclassic late-onset forms of

the disorder.

2. Measurement of 17a-hydroxyprogesterone also can identify women with various forms of 11-hydroxylase deficiency.
3. Basal levels of DHEAS as well as 17a-hydroxyprogesterone may be moderately elevated in patients with PCO, making the diagnosis even more difficult.
4. To screen for CAH, 17a-hydroxyprogesterone should be measured in early morning.
5. In women with regular cyclic menses, it is important to measure 17a-hydroxyprogesterone only in the follicular phase because basal levels increase at midcycle and in the luteal phase.

Measurements of 17a-hydroxyprogesterone appear to be of value in populations at high risk for nonclassic late-onset 21-hydroxylase deficiency. In the white population, the gene occurs in only about 1 in 1,000 individuals, but it occurs in 1 in 27 Ashkenazi Jews, 1 in 40 Hispanics, 1 in 50 Yugoslavs, and 1 in 300 Italians (58). The incidence is also increased among Eskimos and French Canadians. Alternatively, screening might be restricted to hirsute teenagers presenting with the more "typical" features of nonclassic 21-hydroxylase deficiency, including severe hirsutism beginning at puberty, "flattening" of the breasts (i.e., defeminization), shorter stature than other family members, and increased DHEAS levels (between 5,000 and 7,000 ng/mL). Women with a strong family history of hirsutism or hypertension might be screened as well (35) (Fig. 23.21).

Figure 23.21 A 19-year-old girl with secondary amenorrhea and severe acne and hirsutism beginning at the normal age of puberty. Stimulatory testing with corticotropin documented nonclassic 21-hydroxylase deficiency. Flattening of the breasts is apparent. She was shorter than her one sister and her mother.

Basal Levels of 17-Hydroxyprogesterone Basal levels of 17a-hydroxyprogesterone higher than 800 ng/dL are virtually diagnostic of CAH. Levels between 300 and 800 ng/dL require stimulatory testing with corticotropin to distinguish between PCO and CAH. To complicate the situation even further, nonclassic 21-hydroxylase deficiency may occur even when basal levels of 17a-hydroxyprogesterone are below 300 ng/dL, thus requiring stimulatory testing in those cases as well.

Cosyntropin Stimulation Test The most commonly used stimulatory test involves measurement of 17a-hydroxyprogesterone 30 minutes after administration of a bolus of 250 mg of synthetic cosyntropin (Cortrosyn) (65). In normal women, this value seldom exceeds 400 ng/dL. Patients with classic 21-hydroxylase deficiency achieve peak levels of 3,000 ng/dL or higher. Patients with nonclassic 21-hydroxylase deficiency commonly achieve levels of 1,500 ng/dL or more. Heterozygous carriers achieve peak levels up to about 1,000 ng/dL. In hirsute women with hypertension, 11-deoxycortisol levels can be determined during the test. If both 11-deoxycortisol and 17a-hydroxyprogesterone levels are increased, the rare 11-hydroxylase deficiency is present. Only measurements of several steroid precursors after corticotropin stimulation can identify individuals with nonclassic forms of 3b-HSD deficiency.

The elevated levels of 17a-hydroxyprogesterone present in all forms of 21-hydroxylase deficiency are rapidly suppressed by administration of exogenous corticoids. Even a single dose of a glucocorticoid such as dexamethasone will suppress 17a-hydroxyprogesterone in CAH but not in virilizing ovarian and adrenal neoplasms.

Hirsutism It has been suggested that androgen-receptor blockade may be preferable to glucocorticoids as primary treatment of nonclassic 21-hydroxylase deficiency (66). Although menses usually (but not always) become regular shortly after beginning therapy with glucocorticoids, the hirsutism in this disorder has proved to be remarkably refractory to glucocorticoids.

Distinguishing nonclassic forms of CAH from idiopathic hirsutism also may be problematic. Individuals with idiopathic hirsutism have regular ovulatory menses, thus effectively eliminating PCO from consideration. Confusion can be created by the fact that some women with nonclassic CAH may continue to ovulate. Basal levels of 17a-hydroxyprogesterone are normal in idiopathic hirsutism, as is the response to ACTH stimulation. Idiopathic hirsutism represents enhanced androgen action at the hair follicle (67).

Mixed Gonadal Dysgenesis

The term *mixed gonadal dysgenesis* is used to designate those individuals with asymmetric gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other side. Most individuals with this rare disorder have a mosaic karyotype of 45X/46XY and are raised as females who then virilize at puberty. Gonadectomy is indicated to remove the source of androgens and eliminate any risk for neoplasia.

Reifenstein's Syndrome

Individuals who have rare forms of male pseudohermaphroditism, especially 5a-reductase deficiency (the so-called "penis at 12" syndrome) and the Reifenstein's syndrome, generally have ambiguous female genitalia with variable virilization at puberty. Cushing syndrome, too, may occur rarely during the pubertal years, as may adrenal or ovarian androgen-secreting neoplasms.

Genital Ambiguity at Birth

Because of the concerns of the parents and the need to prevent life-threatening complications, the infant with genital ambiguity should be evaluated promptly. Evaluation and treatment is best conducted by a team of physicians. The initial evaluation is as follows:

1. Cytogenetic and endocrine studies should be initiated promptly. Use of specific probes for the Y chromosome and fluorescent *in situ* hybridization can assist in obtaining a karyotype within 48 hours. Probes for many specific inherited disorders are now available.
2. To exclude CAH, the most common cause of genital ambiguity, serum levels of sodium, potassium, and 17a-hydroxyprogesterone and urinary excretion of 17-ketosteroids, pregnanetriol, and tetrahydrodeoxycortisol should be measured. Infants should be monitored closely to prevent development of dehydration, hyponatremia, and hyperkalemia.
3. It has been suggested that antimüllerian hormone be measured in infants with genital ambiguity because it is elevated in males and undetectable in females in the first several years of life (68).

Physical Signs

During the 3 to 4 days required for evaluation, it is important to be supportive of the parents. Many clinicians believe that it is important not to attach any unusual significance to the genital ambiguity and to treat the abnormality as just another "birth defect." Physicians should emphasize that the child should undergo normal psychosexual development regardless of the sex-of-rearing selected. Either a name compatible with either sex should be chosen or the naming of the infant should be delayed until the studies have been completed.

Although the diagnosis is not usually obvious on examination, there are some helpful distinguishing features (Fig. 23.22). In normal males, there is only a single

midline frenulum on the ventral side of the phallus; in normal females, there are two frenula lateral to the midline. A female with clitoral enlargement still has two frenula, and a male with hypospadias has a single midline frenulum or several irregular fibrous bands (chordee).

Figure 23.22 Two newborn girls with 46XX karyotypes and genital ambiguity. Both had clitoral hypertrophy, paired frenula, so-called scrotalization of the labia, and a common urogenital sinus (shown by the probe in **B**). Both were shown to have 21-hydroxylase deficiency. (From **Rebar RW**. Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al**, eds. *Gynecology and obstetrics: a longitudinal approach*. New York: Churchill Livingstone, 1993:97–133, with permission.)

It is important to determine whether any müllerian derivatives are present. Recent studies suggest that MRI may be the most effective way of evaluating the infant for the presence of müllerian tissue (69).

The location or consistency of the gonad may be helpful in deducing its composition. A gonad located in the labial or inguinal regions almost always contains testicular tissue. A testis is generally softer than an ovary or a streak gonad and is more apt to be surrounded by blood vessels imparting a reddish cast. An ovary is more often white, fibrous, and convoluted. A gonad that varies in consistency may be an ovotestis or a testis or a streak gonad that has undergone neoplastic transformation. If a well-differentiated fallopian tube is absent on only one side, the side without the tube probably contains a testis or ovotestis.

Diagnosis and Management

Although genital ambiguity is usually identified at birth, it may not be recognized for several years. Questions about changing the sex-of-rearing may arise. It has been believed that sex-of-rearing may be changed before 2 years of age without psychologically damaging the child, but experience with individuals with 5 α -reductase deficiency suggests that gender changes may be made after 2 years of age in certain instances (70). In any case, surgery for genital ambiguity to make the external genitalia (and development) as compatible with the sex-of-rearing of the child is warranted but has not always been proved successful. Clitoral recession and clitorrectomy are the most frequently performed surgical procedures.

It is possible to diagnose prenatally 21-hydroxylase deficiency in patients known to be at risk (58). The diagnosis is established by documenting elevated levels of 17 α -hydroxyprogesterone or 21-deoxycortisol in amniotic fluid. Genetic diagnosis using specific probes and cells obtained by chorionic villus sampling or amniocentesis is also possible. Unfortunately, prenatal treatment of the fetus by administering dexamethasone to the mother is usually but not always successful in preventing genital ambiguity (71). Moreover, maternal complications, including hypertension, massive weight gain, and overt Cushing's syndrome, have been noted in about 1% of pregnancies in which the mothers are given low doses of dexamethasone. Despite the risks and the nonuniformity of beneficial outcome to affected female fetuses, many parents may choose prenatal medical treatment because of the psychological impact of ambiguous genitalia.

Teratogens

It is important to recognize that ambiguous genitalia can result from the maternal ingestion of various teratogens, most of which are synthetic steroids (Table 23.3). Exposure to the teratogen must occur early in pregnancy, during genital organogenesis. Moreover, not all exposed fetuses manifest the same anomalies or even the presence of any anomalies. In principle, most synthetic steroids with androgenic properties, including weakly androgenic progestins, can affect female genital differentiation. However, the doses required to produce genital ambiguity are generally so great that the concern is only theoretical. The one agent that clearly can lead to genital ambiguity when ingested in clinically used quantities is danazol. There is no evidence that inadvertent ingestion of oral contraceptives, which contain relatively low doses of either mestranol or ethinyl estradiol and a 19-nor-steroid, results in virilization (72,73).

Proved	No Effect	Insufficient Data
Testosterone enanthate	Progesterone	Ethinodiol diacetate
Testosterone propionate	17 β -Hydroxyprogesterone	Dexamethasone
Methylandrosterone	Medroxyprogesterone	Norgestrel
6 α -Methyltestosterone	Norethynodiol	Desogestrel
Ethisterone		Cestodone
Norethandrone		Norgestimate
Danazol		

^aThese agents proved to cause genital ambiguity do so only when administered in relatively high doses. Insufficient data exist regarding effects of dexamethasone and norgestrel. In low doses (e.g., as in oral contraceptives), progestins, even including norethandrone, seem unlikely to virilize a female fetus.

A complex hormonal interaction must take place in order for normal menstruation to occur. The hypothalamus must secrete gonadotropin-releasing hormone (GnRH) in a pulsatile fashion, which is modulated by neurotransmitters and hormones. The GnRH stimulates secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary, which promotes ovarian follicular development and ovulation. A normally functioning ovarian follicle secretes estrogen; after ovulation, the follicle is converted to a corpus luteum and progesterone is secreted in addition to estrogen. These hormones stimulate endometrial development. If pregnancy does not occur, estrogen and progesterone secretion decrease, and withdrawal bleeding begins. If any of the components (hypothalamus, pituitary, ovary, outflow tract, and feedback mechanism) are nonfunctional, bleeding cannot occur.

Primary amenorrhea is defined as the absence of menses by 16 years of age in the presence of normal secondary sexual characteristics, or by 14 years of age when there is no visible secondary sexual characteristic development. The definition represents approximately two standard deviations from the mean age when secondary sexual characteristic development and menstruation should occur. **A woman who has previously menstruated can develop secondary amenorrhea, which is defined as absence of menstruation for three normal menstrual cycles or 6 months.**

Patients may develop slight alterations in the hypothalamic–pituitary–ovarian axis that are not severe enough to cause amenorrhea but instead cause anovulation. Anovulatory patients usually have irregular menses and may bleed excessively during menstruation because estrogen is unopposed. This often occurs at the beginning and end of the reproductive years. Luteal phase defect is caused by minimal alterations in the hypothalamic–pituitary–ovarian axis, and patients have regular menses along with infertility or recurrent pregnancy loss. Except for amenorrhea from anatomic and chromosomal etiologies, luteal phase defects and anovulation have causes similar to those of amenorrhea, but the hypothalamic, pituitary, or ovarian hormonal dysfunction is less severe or of shorter duration than with amenorrhea.

In order to detect the cause of amenorrhea, it is useful to determine whether secondary sexual characteristics are present ([Fig. 24.1](#)). The absence of secondary sexual characteristics indicates that a woman has never been exposed to estrogen stimulation.

Figure 24.1 Decision tree for evaluation of amenorrhea.

Amenorrhea without Secondary Sexual Characteristics

Although the diagnosis and treatment of disorders associated with hypogonadism have been discussed in [Chapter 23](#), they will also be mentioned here because these conditions may cause primary amenorrhea. Abnormal findings on physical examination may suggest certain enzyme deficiencies ([Fig. 24.1](#)). Because these conditions are very rare, however, it is more clinically relevant to discuss the causes of amenorrhea on the basis of gonadotropin status.

Causes of Primary Amenorrhea

Hypergonadotropic Hypogonadism

Primary gonadal failure and the resulting impaired secretion of gonadal steroids is manifested by elevated levels of LH and FSH that result from decreased negative feedback. Gonadal failure as well as primary amenorrhea are most often associated with genetic abnormalities ([Table 24.1](#)). **Approximately 30% of patients with primary amenorrhea have an associated genetic abnormality (1).** The syndrome of gonadal dysgenesis, or Turner's syndrome, and its variants represent the most common form of hypogonadism in women (see [Chapter 23](#)). Other disorders associated with primary amenorrhea include structurally abnormal X chromosomes, mosaicism, pure gonadal dysgenesis (46,XX and 46,XY with gonadal streaks), and 17 α -hydroxylase deficiency. Individuals with these conditions have gonadal failure and cannot synthesize ovarian steroids. Therefore, gonadotropin levels are elevated because of the lack of negative estrogen feedback on the hypothalamic–pituitary axis. Patients with 17 α -hydroxylase deficiency have primordial follicles, but gonadotropin levels are elevated because the enzyme deficiency

prevents synthesis of sex steroids. Most patients with these conditions have primary amenorrhea and lack secondary sexual characteristics. Occasionally patients with a partial deletion of the X chromosome, mosaicism, or pure gonadal dysgenesis (46,XX) may synthesize enough estrogen in early puberty to induce breast development and a few episodes of uterine bleeding. Ovulation and, occasionally, pregnancy are possible.

Table 24.1 Amenorrhea Associated with a Lack of Secondary Sexual Characteristics

Genetic Disorders

Gonadal Dysgenesis Turner's syndrome (45,X) is the most common chromosomal abnormality causing gonadal failure and primary amenorrhea (1,2). Turner's syndrome is discussed in [Chapter 23](#).

Partial Deletions of the X Chromosome Individuals with partial deletions of the X chromosome have the karyotype 46,XX with part of one of the X chromosomes missing. The phenotype is variable, depending on the amount and location of the missing genetic material. Patients with a deletion of part of the long arm of the X chromosome (Xq-) often exhibit sexual infantilism, normal stature, no somatic abnormalities, and streak gonads (3,4). Some patients may be eunuchoid in appearance and have delayed epiphyseal closure. Patients with a deletion of the short arm of the X chromosome (Xp) and patients with isochromosome of the long arm of the X chromosome, with or without mosaicism, usually are phenotypically similar to individuals with Turner's syndrome (5).

Mosaicism Primary amenorrhea is associated with various mosaic states, the most common of which is 45,X/46,XX (6). As discussed in [Chapter 23](#), the clinical findings in patients with 45,X/47,XXX and 45,X/46,XX/47,XXX are similar to those in 45,X/46,XX and vary in estrogen and gonadotropin production, depending on the number of follicles in the gonads. When compared with the pure 45,X cell line, individuals with 45,X/46,XX are taller and have fewer abnormalities, although 80% of those with 45,X/46,XX mosaics are shorter than their peers and 66% have some somatic abnormalities. **Spontaneous menstruation occurs in approximately 20% of these patients (6).**

Pure Gonadal Dysgenesis Pure gonadal dysgenesis refers to phenotypically female individuals who have sexual infantilism, primary amenorrhea with normal stature, and no chromosomal abnormalities (46,XX or 46,XY). The gonads are usually streaks, but there may be some development of secondary sexual characteristics as well as a few episodes of uterine bleeding. Mutations in the SRY (sex-determining region gene on the Y chromosome) have been identified in some XY females with gonadal dysgenesis (7).

Enzyme Deficiencies

Congenital Lipoid Adrenal Hyperplasia Patients with this autosomal recessive disorder have an inability to convert cholesterol to pregnenolone, which is the first step in steroid hormone biosynthesis. A defect has not been found in the *P450scc* gene, which is the conversion enzyme responsible for this step in the pathway. Instead, 15 different mutations have been identified in the steroidogenic acute regulatory protein that facilitates the transport of cholesterol from the outer to the inner mitochondrial membrane. This protein appears to be the rate-limiting step for steroid hormone biosynthesis stimulated by tropic hormones. These patients in infancy suffer from hyponatremia, hyperkalemia, and acidosis. Both XX and XY individuals are phenotypically female. With appropriate mineralocorticoid and glucocorticoid replacement, these patients can survive into adulthood. Patients who are XY do not have a uterus and remain sexually infantile without hormone replacement, whereas XX patients may acquire some secondary sexual characteristics at puberty but develop early ovarian failure as a result of accumulation of cholesterol in the ovaries (8).

17 α -Hydroxylase Deficiency 17 α -Hydroxylase deficiency may be associated with either 46,XX or 46,XY karyotypes. The uterus is absent in individuals with 46,XY karyotype, a feature distinguishing them from individuals with 46,XX karyotype. Individuals with 17 α -hydroxylase deficiency have primary amenorrhea, no secondary sexual characteristics, hypertension, and hypokalemia (9). The diminished levels of 17 α -hydroxylase that characterize this disorder lead to a reduction in cortisol production, which in turn causes an increase in adrenocorticotropic hormone (ACTH). 17 α -Hydroxylase is not required for production of mineralocorticoids; thus, excessive amounts of mineralocorticoid are produced, resulting in sodium retention, loss of potassium, and hypertension. Over 20 mutations, which alter the reading frame of the gene, have been identified even though fewer than 200 people in the world have the disorder (10).

17,20-Desmolase Deficiency Complete block in the d-4 pathway of 17,20-desmolase leads to a female phenotype in individuals with an XY karyotype. The uterus is absent, and sexual development does not occur at puberty. Although cortisol levels respond normally to ACTH stimulation, testosterone levels are low and do not respond to human chorionic gonadotropin (hCG) stimulation (11).

Aromatase Deficiency This rare autosomal recessive abnormality, which has been reported in only six cases, prevents the affected individual from aromatizing androgens to estrogen. This syndrome may be suspected even before birth because most mothers of affected children develop virilization during pregnancy. The placenta cannot convert the fetal androgens to estrogen, leading to androgen diffusion into the maternal circulation. The female child is born with clitoromegaly and posterior labioscrotal fusion. At puberty breasts do not develop, primary amenorrhea occurs, virilization worsens, growth spurt is absent, bone growth is delayed, and multicystic ovaries are present. The diagnostic hormonal pattern consists of an elevation of FSH, LH, testosterone, and dehydroepiandrosterone sulfate (DHEAS) levels and undetectable levels of estradiol.

Estrogen therapy has been shown to improve the ovarian and skeletal abnormalities, but it must be titrated to mimic normal estrogen levels. Therefore, only minimal amounts need to be given during childhood and then should be increased at puberty (12,13).

Gonadotropin Receptor Mutations

Luteinizing Hormone Receptor Mutation LH receptor inactivation caused by a homozygous premature stop codon was identified in a Brazilian family with 3,XY pseudohermaphroditism with primary amenorrhea in the absence of development of secondary sexual characteristics. The Leydig cells are unable to respond to LH; as a result, Leydig cell hypoplasia occurs, leading to early testicular failure and preventing masculinization. An XX sibling with the same mutation developed normal secondary sexual characteristics but was amenorrheic with elevated LH levels, normal FSH levels, and cystic ovaries (14).

Follicle-stimulating Receptor Mutation In six Finnish families, an autosomal recessive single amino acid substitution in the extracellular domain of the FSH receptor has been identified that prevents FSH binding. This leads to primary or early secondary amenorrhea, variable development of secondary sexual characteristics, and high levels of FSH and LH (15).

Other Causes of Primary Ovarian Failure

Amenorrhea and premature ovarian failure can occur in association with irradiation of the ovaries (16), chemotherapy with alkylating agents (e.g., *cyclophosphamide*) (17), or combinations of radiation and other chemotherapeutic agents. In girls, galactosemia often is associated with premature ovarian failure, but usually it is

detected by newborn screening programs. Gonadotropin resistance, autoimmune ovarian failure, and ovarian failure resulting from infectious and infiltrative processes also have been described.

Hypogonadotropic Hypogonadism

Primary amenorrhea resulting from hypogonadotropic hypogonadism occurs when the hypothalamus fails to secrete adequate amounts of GnRH or when a pituitary disorder associated with inadequate production or release of pituitary gonadotropins is present.

Physiologic Delay Physiologic or constitutional delay of puberty is the most common manifestation of hypogonadotropic hypogonadism. Amenorrhea may result from the delay of physical development caused by delayed reactivation of the GnRH pulse generator. Levels of GnRH are functionally deficient in relation to chronologic age but normal in terms of physiologic development.

Kallmann's Syndrome The second most common hypothalamic cause of primary amenorrhea associated with hypogonadotropic hypogonadism is insufficient pulsatile secretion of GnRH (Kallmann's syndrome), which has varied modes of genetic transmission, as discussed in [Chapter 23](#). Insufficient pulsatile secretion of GnRH leads to deficiencies in FSH and LH. Deficiencies in GnRH may also be caused by developmental or genetic defects, inflammatory processes, tumors, vascular lesions, or trauma. Patients with isolated deficiencies of LH and FSH usually are a normal height for their age, whereas patients with physiologic delay of puberty are usually short for their chronologic age but normal for their bone age ([18](#)).

Central Nervous System Tumors Central nervous system tumors that lead to primary amenorrhea, the most common of which is craniopharyngioma, are usually extracellular masses that interfere with synthesis and secretion of GnRH or stimulation of pituitary gonadotropins. Virtually all patients with these tumors have disorders in the production of other pituitary hormones as well as LH and FSH ([19,20](#)). Prolactin-secreting pituitary adenomas are rare in childhood and more commonly occur after development of secondary sexual characteristics.

Genetic Disorders

5 α -Reductase Deficiency 5 α -Reductase deficiency should also be considered as a cause of amenorrhea ([21](#)). Patients with this disorder are genotypically XY, frequently experience virilization at puberty, have testes (because of functioning Y chromosomes), and have no müllerian structures due to functioning müllerian-inhibiting factor (MIF). 5 α -Reductase converts testosterone to its more potent form, dihydrotestosterone. **Patients with 5 α -reductase deficiency differ from patients with androgen insensitivity, because they do not develop breasts at puberty and have low gonadotropin levels as a result of testosterone levels sufficient to suppress breast development and to allow normal feedback mechanisms to remain intact.** Normal male differentiation of the urogenital sinus and external genitalia do not occur, because dihydrotestosterone is required for this development. However, normal internal male genitalia derived from the Wolffian ducts are present because this development requires only testosterone.

Gonadotropin-releasing Hormone Receptor Mutations In two families with hypogonadotropic hypogonadism, compound heterozygous mutations (autosomal recessive inheritance) have been identified in the GnRH receptor gene. The GnRH receptor is a G-protein-coupled receptor. Functional studies show that the mutations either cause marked decrease in binding of GnRH to its receptor or prevent second-messenger signal transduction. Without a functional signal transduction, FSH and LH are not stimulated and are unable to promote follicular growth ([22,23](#)).

Follicle-stimulating Hormone Deficiency These patients usually seek treatment for delayed puberty and primary amenorrhea due to hypoestrogenism. They are distinguished from other hypoestrogenic patients by having decreased FSH levels and increased LH levels. These patients have low serum androgen levels despite the abnormal LH-to-FSH ratio, indicating that FSH-stimulated follicular development is a prerequisite for thecal cell androgen production. In some of these patients autosomal recessive mutations in the FSH β subunit, which impair dimerization of α and β subunits and prevent binding to the FSH receptor, have been identified ([24](#)). Pregnancy was achieved in one patient after induction of ovulation with injectable gonadotropins ([25](#)).

Other Hypothalamic and Pituitary Dysfunctions

Functional gonadotropin deficiency results from malnutrition, malabsorption, weight loss or anorexia nervosa, stress, excessive exercise, chronic disease, neoplasias, and marijuana use ([26,27,28,29](#) and [30](#)). Hypothyroidism, Cushing's syndrome, hyperprolactinemia, and infiltrative disorders of the central nervous system are rare causes of primary amenorrhea ([31,32](#)).

Diagnosis

A careful history and physical examination are necessary to appropriately diagnose and manage primary amenorrhea associated with hypogonadism. The physical examination may be particularly helpful in patients with Turner's syndrome. A history of short stature but consistent growth rate, a family history of delayed puberty, and normal physical findings (including assessment of smell, optical discs, and visual fields) may suggest physiologic delay. Headaches, visual disturbances, short stature, symptoms of diabetes insipidus, and weakness of one or more limbs suggest central nervous system lesions ([20](#)). Galactorrhea may be seen with prolactinomas, and the history of galactorrhea is also helpful when diagnosing postinfectious, inflammatory, or vascular lesions of the central nervous system; trauma; anorexia nervosa; stress-related amenorrhea; or other systemic disease processes.

The diagnostic workup is summarized as follows:

1. Assessment of the serum FSH level should be performed as the initial laboratory test unless the history and physical examination suggest otherwise. The FSH level differentiates hypergonadotropic and hypogonadotropic forms of hypogonadism. If the FSH level is elevated, a karyotype is obtained. An elevated FSH level in combination with a 45,X karyotype confirms the diagnosis of Turner's syndrome. Partial deletion of the X chromosome, mosaicism, pure gonadal dysgenesis, and mixed gonadal dysgenesis are diagnosed by obtaining a karyotype.
2. Because of the association of coarctation of the aorta and thyroid dysfunction, patients with Turner's syndrome should undergo echocardiography and thyroid function studies.
3. If the karyotype is normal and the FSH is elevated, it is important to consider the diagnosis of 17 α -hydroxylase deficiency because it may be a life-threatening disease if untreated. This diagnosis should be considered when testing indicates elevated serum progesterone levels (>3 ng/ml), a low 17 α -hydroxyprogesterone level (<0.2 ng/ml), and an elevated serum deoxycorticosterone (DOS) level ([33](#)). The diagnosis is confirmed with an ACTH stimulation test. After ACTH bolus administration, affected individuals have markedly increased levels of serum progesterone compared with baseline levels and no change in serum 17 α -hydroxyprogesterone levels.
4. If the screening FSH level is low, the diagnosis of hypogonadotropic hypogonadism is established.
5. If the history suggests the presence of a central nervous system lesion or galactorrhea, imaging of the head using computed tomography (CT) or magnetic resonance imaging (MRI) is helpful in the diagnosis. Suprasellar or intrasellar calcification in an abnormal sella is found in approximately 70% of patients with craniopharyngioma ([20](#)).

Physiologic delay is a diagnosis of exclusion that is difficult to distinguish from insufficient GnRH secretion. The diagnosis can be supported by a history suggesting physiologic delay, a radiograph showing delayed bone age, and the absence of a central nervous system lesion on CT or MRI scanning. Gonadotropin-deficient patients can usually be distinguished from patients with physiologic delay by their response to GnRH stimulation. Patients with physiologic delay have a normal LH response to GnRH stimulation for their bone age, in contrast with gonadotropin-deficient patients, in whom the LH and FSH responses are low ([34](#)).

Treatment of Amenorrhea

Individuals with primary amenorrhea associated with all forms of gonadal failure and hypergonadotropic hypogonadism need cyclic estrogen and progestin therapy to initiate, mature, and maintain secondary sexual characteristics. Prevention of osteoporosis is an additional benefit of estrogen therapy:

1. Therapy is usually initiated with 0.625 mg/day of conjugated estrogens or 1 mg/day of estradiol.
2. If the patient is short in stature, higher doses should not be used in an attempt to prevent premature closure of the epiphyses. Most of these patients are of

normal height, however, and higher estrogen doses may be used initially and then reduced to the maintenance doses after several months.

- Estrogens can be given daily in combination with progestin (medroxyprogesterone acetate) or progesterone to prevent unopposed estrogen stimulation of the endometrium in patients with a uterus. Medroxyprogesterone acetate may be administered daily at a dose of 2.5 mg or for 12 to 14 days every 1 to 2 months at a dose of 5 to 10 mg. Oral micronized progesterone may be administered at a dose of 100 mg daily or 200 mg for 12 to 14 days every 1 to 2 months. Likewise, progesterone suppositories may be administered at a dose of 50 mg daily or 100 mg for 12 to 14 days every 1 to 2 months.
- Occasionally, individuals with mosaicism and gonadal streaks may ovulate and be able to conceive either spontaneously or after the institution of estrogen replacement therapy (5).
- If 17 α -hydroxylase deficiency is confirmed, treatment is instituted with corticosteroid replacement as well as estrogen. Progestin is added if a uterus is present.

If possible, therapeutic measures are aimed at correcting the primary cause of amenorrhea:

- Craniopharyngiomas may be resected with a transphenoidal approach or during craniotomy, depending on the size of the tumor. Some studies have shown improved prognosis with radiation therapy used in combination with limited tumor removal (20,35).
- Germinomas are highly radiosensitive, and surgery is rarely indicated (36).
- Prolactinomas and hyperprolactinemia often may respond to dopamine agonists (37).
- Specific therapies are directed toward malnutrition, malabsorption, weight loss, anorexia nervosa, exercise amenorrhea, neoplasia, and chronic diseases.
- Logically, it would appear that patients with hypogonadotropic hypogonadism of hypothalamic origin should be treated with long-term administration of pulsatile GnRH. This form of therapy is impractical, however, because of the necessity for the use of an indwelling catheter and a portable pump for prolonged periods. Therefore, these patients should be treated with cyclic estrogen and progestin therapy.
- Patients with Kallmann's syndrome, as well as patients with exercise or stress amenorrhea and anorexia and weight loss, are treated with hormone replacement.
- If the patient has physiologic delay of puberty, the only management required is reassurance that the anticipated development will occur eventually (38).

Individuals whose karyotypes contain a Y cell line (45,X/46,XY mosaicism, or pure gonadal dysgenesis 46,XY) are predisposed to gonadal ridge tumors such as gonadoblastomas, dysgerminomas, and yolk sac tumors. The gonads of these individuals should be removed when the condition is diagnosed to prevent malignant transformation (18,33). There is some evidence that hirsute individuals without Y chromosomes should also undergo gonad removal. One patient with hirsutism and the karyotype 45,X was noted to have a streak gonad; the contralateral gonad was dysgenic and contained developing follicles, well-differentiated seminiferous tubules, and Leydig cells. This patient was found to be H-Y antigen-positive (39).

Clomiphene citrate is ineffective in inducing ovulation in patients with hypogonadism who desire pregnancy, because such patients are hypoestrogenic. In patients with hypogonadism, ovulation induction with injectable gonadotropins is generally successful, and pulsatile treatment with GnRH may be used in patients who have normal pituitary function. In patients without ovarian function, oocyte donation may be appropriate. Because most patients with hypogonadism and lack of sexual development are young, pregnancy is not desired.

Amenorrhea with Secondary Sexual Characteristics and Anatomic Abnormalities

Causes

Anatomic Abnormalities

Amenorrhea occurs if there is blockage of the outflow tract or if the outflow tract is missing (Table 24.2). An intact outflow tract includes a patent vagina as well as a functioning cervix and uterus. Any transverse blockage of the müllerian system (Buttram and Gibbons classification I) will cause amenorrhea (40). Such outflow obstructions include imperforate hymen, transverse vaginal septum, and hypoplasia or absence of the uterus, cervix, and vagina (Mayer-Rokitansky-Küster-Hauser syndrome). Mayer-Rokitansky-Küster-Hauser syndrome has been associated with abnormal galactose metabolism (41). Of the patients with this syndrome 15% have an absent kidney, 40% have a double urinary collecting system (42), and 5% to 12% have skeletal abnormalities (43). Transverse blockage of the outflow tract with an intact endometrium frequently causes cyclic pain without menstrual bleeding in adolescents. The blockage of blood flow can cause hematocolpos, hematometra, or hemoperitoneum. Endometriosis may develop.

Secondary sexual characteristics present
Müllerian anomalies
Imperforate hymen
Transverse vaginal septum
Mayer-Rokitansky-Küster-Hauser syndrome
Androgen insensitivity
True hermaphrodites
Absent endometrium
Asherman's syndrome
Secondary to prior uterine or cervical surgery
Curettage, especially postpartum
Cone biopsy
Loop electroexcision procedure
Secondary to infections
Pelvic inflammatory disease
IUD-related
Tuberculosis
Schistosomiasis

IUD, intrauterine device.

Table 24.2 Anatomic Causes of Amenorrhea

When the findings of the physical examination are normal, anatomic abnormalities may still be considered. A congenitally absent endometrium is a rare finding in patients with primary amenorrhea. Asherman's syndrome, which is more common with secondary amenorrhea or hypomenorrhea, may occur in patients with risk factors for endometrial or cervical scarring, such as a history of uterine or cervical surgery, infections related to use of an intrauterine device, and severe pelvic inflammatory disease. It is found in 39% of patients undergoing hysterosalpingography who have previously undergone postpartum curettage (44). Infections such as tuberculosis and schistosomiasis may cause Asherman's syndrome but are rare in the United States. Cervical stenosis resulting from surgical removal of dysplasia (cone biopsy, loop electroexcision procedure) may also lead to amenorrhea.

Androgen Insensitivity

Phenotypic females with complete congenital androgen insensitivity (previously called testicular feminization) develop secondary sexual characteristics but do not have menses. These patients are male pseudohermaphrodites. Genotypically, they are male (XY) but have a defect that prevents normal androgen receptor function, leading to the development of the female phenotype. Defects in the androgen receptor gene located on the X chromosome include absence of the gene that encodes for the androgen receptor and abnormalities in the androgen-binding domain of the receptor. Postreceptor defects also exist (45). Total serum testosterone concentration is in the range of normal males. Because anti-müllerian hormone is present and functions normally in these patients, internal female (müllerian) structures such as a uterus, vagina, and fallopian tubes are absent. Testes rather than ovaries are present in the abdomen or in inguinal hernias because of the presence of normally functioning genes on the Y chromosome. Patients have a blind vaginal pouch, and scant or absent axillary and pubic hair. These patients experience abundant breast development at puberty; however, the nipples are immature and the areolae are pale. Testosterone is not present during development to suppress the formation of breast tissues; at puberty, the conversion of testosterone to estrogen stimulates breast growth. Patients are unusually tall with eunuchoidal tendency (long arms with big hands and feet) (Fig. 24.2).

Figure 24.2 A: A well-developed patient with complete androgen insensitivity. Note the characteristic paucity of pubic hair and well-developed breasts. (From Yen SSC, Jaffe RB. *Reproductive endocrinology*, 3rd ed. Philadelphia: WB Saunders, 1991:497, with permission.) **B:** Another patient with androgen insensitivity syndrome with a contrasting thin body habitus. This is a 17-year-old twin 46,XY. (From Jones HW Jr, Scott WW. *Hermaphroditism, genital anomalies, and related endocrine disorders*, 2nd ed. Baltimore: Williams & Wilkins, 1971, with permission.)

True Hermaphroditism

True hermaphroditism is a rare condition that should be considered as a possible cause of amenorrhea. Both male and female gonadal tissue is present in these patients, in whom XX, XY, and mosaic genotypes have been found. Two-thirds of the patients menstruate, but menstruation has never been reported in XY genotypes. The external genitalia is usually ambiguous, and breast development frequently occurs in these individuals.

Diagnosis

Most congenital abnormalities can be diagnosed by physical examination:

1. An imperforate hymen is diagnosed by the presence of a bulging membrane that distends during Valsalva maneuver. Ultrasonography or MRI is useful to identify the müllerian anomaly when the abnormality cannot be identified by physical examination. The patient should also be examined for skeletal malformations and assessed with intravenous pyelography to detect concomitant renal abnormalities.
2. It is difficult to differentiate a transverse septum or complete absence of the cervix and uterus in a female from a blind vaginal pouch in a male pseudohermaphrodite. Androgen insensitivity is diagnosed when pubic and axillary hair is absent. To confirm the diagnosis, a karyotype determination should be performed to see whether a Y chromosome is present. In some patients, the defect in the androgen receptor is not complete and virilization occurs.
3. An absent endometrium is an outflow tract abnormality that cannot be diagnosed by physical examination in a patient with primary amenorrhea. This abnormality is so rare that, in a patient with normal physical findings, it may be advisable to proceed with evaluation of endocrine abnormalities. Absence of the endometrium should be suspected in patients with primary amenorrhea and normal secondary sexual characteristics when the results of hormonal studies are normal and the patients do not bleed after withdrawal of combined estrogen and progesterone replacement.
4. *Asherman's syndrome* also cannot be diagnosed by physical examination. It is diagnosed by performing hysterosalpingography, saline infusion, ultrasonography, or hysteroscopy. These tests will show either complete obliteration or multiple filling defects caused by synechiae (Fig. 24.3). If tuberculosis or schistosomiasis is suspected, endometrial cultures should be performed.

Figure 24.3 A: Intrauterine adhesion seen on hysterosalpingogram in a patient with Asherman's syndrome. **B:** Hysteroscopic view of intrauterine adhesion in a patient with Asherman's syndrome. (From Donnez J, Nisolle M. *The encyclopedia of visual medicine series—an atlas of laser operative laparoscopy and hysteroscopy*. New York: Parthenon Publishing Group, 1994:306, with permission.)

Treatment

The treatment of congenital anomalies can be summarized as follows:

1. **Treatment of an imperforate hymen involves making a cruciate incision to open the vaginal orifice.** Most imperforate hymens are not diagnosed until after a hematocolpos forms. It is unwise to place a needle into the hematocolpos without completely removing the obstruction because a pyocolpos may occur.
2. **If a transverse septum is present, surgical removal is required.** Forty-six percent of transverse septa occur in the upper one-third of the vagina, and 40% occur in the middle one-third of the vagina (46). Frank dilators should be used to distend the vagina until it is healed to prevent vaginal adhesions (47). Patients have a fully functional reproductive system after surgery; however, patients with repaired high transverse septa have lower pregnancy rates (48).
3. **Hypoplasia or absence of the cervix in the presence of a functioning uterus is more difficult to treat than other outflow obstructions.** Surgery to repair the cervix has not been successful, and hysterectomy is required (49). Endometriosis is a common finding, and it is questionable whether this condition should be treated with initial surgery or if it will resolve spontaneously after surgical repair of the obstruction. The ovaries should be retained to provide the benefits of estrogen and to allow for the possibility of future childbearing by removing mature oocytes for *in vitro* fertilization and using a surrogate mother for implantation.
4. **If the vagina is absent or short, progressive dilation is usually successful in making it functional (47,50).** If dilation fails or the patient is unable to perform dilation, the *McIndoe split thickness graft* technique may be performed (51,52). The initial use of vaginal dilators is required to maintain a functional vagina.
5. **In patients with complete androgen insensitivity, the testes should be removed after pubertal development is complete to prevent malignant degeneration (53).** In patients with testes, 52% develop a neoplasia, most often a gonadoblastoma. Almost one-half of the testicular neoplasms are malignant (dysgerminomas), but transformation usually does not occur until after puberty (54). In patients who develop virilization and have an XY karyotype, the testes should be removed immediately to preserve the female phenotype and to promote female gender identity. Bilateral laparoscopic gonadectomy is the preferred procedure for removal of intraabdominal testes.
6. **Adhesions in the cervix and uterus (Asherman's syndrome) can be removed using hysteroscopic resection with scissors or electrocautery.** A pediatric Foley catheter should be placed in the uterine cavity for 7 to 10 days postoperatively (along with systemic administration of broad-spectrum antibiotic therapy), and a 2-month course of high-dose estrogen therapy with monthly progesterone withdrawal is used to prevent reformation of adhesions. Eighty percent of patients thus treated achieve pregnancy, but complications including miscarriage, premature labor, placenta previa, and placenta accreta are common (55). Cervical stenosis can be treated by cervical dilation.

Amenorrhea with Secondary Sexual Characteristics and Nonanatomic Causes

Pregnancy must be considered in all women of reproductive age with amenorrhea. Thyroid dysfunction and hyperprolactinemia are also frequent causes of

amenorrhea and are discussed further in [Chapter 25](#). The three major causes of amenorrhea with secondary sexual characteristics are ovarian failure, pituitary and hypothalamic lesions, and abnormal hypothalamic GnRH secretion.

Causes

Ovarian Failure

Ovarian failure is a normal occurrence during menopause. The age of menopause is determined by genetic inheritance. Once a patient is exposed to estrogen, estrogen withdrawal causes hot flashes and vaginal dryness. This occurs in approximately 50% of patients, whether ovarian failure is premature or occurs at the normal age ([56](#)). Physical examination reveals vaginal mucosal atrophy and no cervical mucus. When ovarian failure occurs before 40 years of age, it is pathologic. Earlier failure may be caused by decreased follicular endowment or accelerated follicular atresia. If ovarian failure occurs before puberty, the patient's breasts will not develop (i.e., Turner's syndrome), and gonadal agenesis results ([Table 24.1](#) and [Table 24.3](#)).

Chromosomal etiology
iatrogenic causes
Radiation
Chemotherapy
Surgical alteration of ovarian blood supply
Infections
Autoimmune disorders
Galactosemia (mild form or heterozygote)
Savage syndrome
Cigarette smoking
Idiopathic

Table 24.3 Causes of Ovarian Failure After Development of Secondary Sexual Characteristics

Despite the numerous causes of ovarian failure, in most cases the etiology cannot be determined. In some patients, ovarian failure resolves spontaneously. Pregnancies have been reported to occur after the diagnosis of ovarian failure in <0.09% to 8.2% ([56,57](#)).

Cigarette smoking has been shown to have a clear inverse dose-response relationship with age of menopause ([58](#)). Other studies have confirmed this association, some eliminating potential confounding factors such as body weight that could affect the age of menopause ([59](#)). Cigarette smoking alters both gametogenesis and hormonogenesis, suggesting an effect on the follicle. Smoking has also been shown to increase the risk of diminished ovarian reserve ([60](#)).

Sex Chromosome Disorders Deletion of the X chromosome (**Turner's Syndrome**) is associated with premature ovarian failure despite normal development of the ovaries due to accelerated atresia of the follicles ([61](#)). Mosaicism of an XO or XY cell line may cause ovarian failure in patients younger than 30 years of age. A deletion of a portion of the X chromosome may be present in patients with premature ovarian failure. The Xq26–28 region is critical ([62](#)). Individuals with a 47,XXX karyotype also may develop ovarian failure. Familial ovarian failure is inherited by dominant mendelian inheritance in some cases ([63](#)).

Iatrogenic Causes Radiation, chemotherapy (especially alkylating agents such as cyclophosphamide) ([64](#)), surgical interference with ovarian blood supply, and infections can cause ovarian failure from early loss of follicles. At a radiation dose of 800 cGy, all patients become sterile. Ovarian failure can be caused by as little as 150 cGy in some patients, especially if they are older than 40 years with limited follicle reserves.

Autoimmune Disorders Premature ovarian failure may be part of a polyglandular autoimmune syndrome. Antibodies are present in a variable number of patients with premature ovarian failure, depending on the autoimmune studies performed. One study showed that 92% of patients with premature ovarian failure had autoantibodies ([65](#)). However, only 20% of these patients exhibited signs of immunologic dysfunction, most frequently a thyroid disorder ([57](#)). Rarely, premature ovarian failure is associated with myasthenia gravis, idiopathic thrombocytopenic purpura, rheumatoid arthritis, vitiligo, autoimmune hemolytic anemia, diabetes mellitus, and other autoimmune disorders ([66,67](#) and [68](#)).

Galactosemia Galactosemia is caused by a lack of functional galactose-1-phosphate uridyl transferase. Galactose metabolites appear to have toxic effects on ovarian follicles, causing their premature destruction ([69](#)). There is also evidence that heterozygote carriers of this disorder may have suboptimal ovarian function ([70](#)). Early dietary modification may delay the ovarian failure.

Savage Syndrome In some patients follicles are present, but they do not mature in response to FSH because FSH receptors are absent or a postreceptor defect exists ([67,71](#)). In six Finnish families an autosomal recessive single amino acid substitution has been identified in the FSH receptor, which prevents binding of FSH ([15](#)). These patients experience ovarian resistance (Savage syndrome) as opposed to ovarian failure, in which no follicles are present. Except in the rare cases in which a genetic defect has been identified, ovarian biopsy is the only way to distinguish these disorders. Biopsy is not advised, however, because diagnosing resistant ovarian failure will not affect management. Although the use of GnRH agonists, estrogen therapy, and ovarian stimulation have been attempted in patients desiring pregnancy, studies have shown little success.

Pituitary and Hypothalamic Lesions

Hypothalamic Tumors In order for normal menstruation to occur, the hypothalamus must be able to secrete GnRH, and the pituitary must be able to respond with production and release of FSH and LH. Tumors of the hypothalamus or pituitary such as craniopharyngiomas, germinomas, tubercular or sarcoid granulomas, or dermoid cysts may prevent appropriate hormonal secretion. Patients with these disorders may exhibit neurologic abnormalities and abnormal secretion of other hypothalamic and pituitary hormones. Craniopharyngiomas are the most common tumors. They are located in the suprasellar region and frequently cause headaches and visual changes. The surgical and radiologic treatment of tumors may in itself cause further abnormalities in hormone secretion ([Table 24.4](#)).

Pituitary and hypothalamic
Craniopharyngioma

Primary hyperthyroidism
Infarction
Lymphocytic hypophysitis
Surgical or radiologic ablations
Sheehan's syndrome
Diabetic vasculitis

Table 24.4 Pituitary and Hypothalamic Lesions

Pituitary Lesions Hypopituitarism is rare because a large portion of the gland must be destroyed before decreased hormonal secretion affects the patient clinically. The pituitary gland may be destroyed by tumors (nonfunctioning or hormone secreting), infarction, infiltrating lesions such as lymphocytic hypophysitis, granulomatous

lesions, and surgical or radiologic ablations.

Sheehan's syndrome is associated with postpartum necrosis of the pituitary resulting from a hypotensive episode that, in its severe form (pituitary apoplexy), causes shock. The patient may develop a localized severe retroorbital headache or abnormalities in visual fields and visual acuity. Patients with a mild form of postpartum pituitary necrosis experience failure to lactate, loss of pubic and axillary hair, and failure to resume menses after delivery.

Diabetic vasculitis and sickle cell anemia rarely manifest as pituitary failure. Hypopituitarism is associated with hyposecretion of ACTH and thyroid-stimulating hormone (TSH) as well as gonadotropins; therefore, thyroid and adrenal function also must be evaluated. If hypopituitarism occurs prior to puberty, menses and secondary sexual characteristics will not develop.

Growth hormone (GH), TSH, ACTH, and prolactin also are secreted by the pituitary, and the excess production of each by pituitary tumors causes menstrual abnormalities. The menstrual abnormalities are caused by adverse effects of these hormones on the GnRH pulse generator and not by directly effecting the ovary. **Prolactinomas are the most common hormone-secreting tumors in the pituitary** (see [Chapter 25](#)).

Altered Hypothalamic GnRH Secretion

The pulsatile secretion of GnRH is modulated by interactions with neurotransmitters and peripheral gonadal steroids. Endogenous opioids, corticotropin-releasing hormones (CRH), melatonin, and γ -aminobutyric acid (GABA) inhibit the release of GnRH, whereas catecholamines, acetylcholine, and vasoactive intestinal peptide (VIP) stimulate GnRH pulses. Dopamine and serotonin have variable effects ([72](#)). Chronic disease, malnutrition, stress, psychiatric disorders, and exercise inhibit GnRH pulses, thus altering the menstrual cycle ([Table 24.5](#)). Other hormonal systems that produce excess or insufficient hormones can cause abnormal feedback and adversely affect GnRH secretion. In hyperprolactinemia, Cushing's disease (excess ACTH), and acromegaly (excess GH) excess pituitary hormones are secreted that inhibit GnRH secretion. When the decrease in GnRH pulsatility is severe, amenorrhea results. With less severe alterations in GnRH pulsatility, anovulation can occur. Even slight defects in the pulsatility may result in luteal phase defect.

Luteoma

*Severity of the condition determines estrogen status; the more severe, the more likely to manifest as hypergonadotropism.

Table 24.5 Abnormalities Affecting Release of Gonadotropin-Releasing Hormone

Anorexia Nervosa

Anorexia nervosa is an eating disorder that affects 5% to 10% of adolescent women in the United States. The criteria for anorexia nervosa as stated in the psychiatric diagnostic manual (DSM-IV) are refusal to maintain body weight above 15% below normal, an intense fear of becoming fat, altered perception of one's body image (i.e., patients see themselves as fat despite being underweight), and amenorrhea. Patients attempt to maintain their low body weight by food restriction, induced vomiting, laxative abuse, and intense exercise. **This is a life-threatening disorder with a mortality rate as high as 9%.** Amenorrhea may precede, coincide with, or follow the weight loss. Multiple hormonal patterns are altered. The 24-hour patterns of FSH and LH may show constantly low levels as seen in childhood or increased LH pulsatility during sleep consistent with the pattern seen in early puberty. Hypercortisolism is present despite normal ACTH levels, and the ACTH response to CRH administration is blunted. Circulating triiodothyronine (T_3) is low, yet circulating inactive reverse T_3 concentrations are high ([73](#)). Patients may develop cold and heat intolerance, lanugo hair, hypotension, bradycardia, and diabetes insipidus. They may have yellowish discoloration of the skin resulting from elevated levels of serum carotene caused by altered vitamin A metabolism.

Exercise and Stress-induced Disorders

In patients with exercise-induced amenorrhea, there is a decrease in the frequency of GnRH pulses, which is assessed by measuring a decreased frequency of LH pulses. These patients are usually hypoestrogenic, but less severe alterations may cause minimal menstrual dysfunction (anovulation or luteal phase defect). The decrease in LH pulsatility can be caused by hormonal alterations such as elevations in endogenous opioids, ACTH, prolactin, adrenal androgens, cortisol, and melatonin ([74](#)). Rates of amenorrhea by sport have been attributed to differences in body fat content. Runners and ballet dancers are at higher risk for amenorrhea than swimmers ([75](#)). Frisch and McArthur suggest that a minimum of 17% body fat is required for the initiation of menses and 22% body fat for the maintenance of menses ([76](#)). However, newer studies suggest that inappropriately low caloric intake during strenuous exercise is more important than body fat content ([77](#)). Higher intensity training, poor nutrition, stress of competition, and associated eating disorders increase an athlete's risk for menstrual dysfunction ([78](#)).

Stress-related amenorrhea can be caused by abnormalities in neuromodulation in hypothalamic GnRH secretion, similar to those that occur with exercise and anorexia nervosa. Excess endogenous opioids and elevations in CRH secretion inhibit the secretion of GnRH ([72](#)). These mechanisms are not fully understood but appear to be the common link between amenorrhea and chronic diseases, pseudocyesis, and malnutrition.

Obesity

Most obese patients have normal menstrual cycles, but the percentage of women with menstrual disorders increases from 2.6% in normal-weight patients to more than 8.4% in women 75% above ideal body weight. The menstrual disorder is more often irregular uterine bleeding with anovulation than amenorrhea. **Obese women have an excess number of fat cells in which extraglandular aromatization of androgens to estrogen occurs. They also have lower circulating levels of sex hormone-binding globulin, which allows a larger proportion of free androgens to be converted to estrone. Excess estrogen creates a higher risk for endometrial cancer for these women.** The decrease in sex hormone-binding globulin also allows an increase in free androgen levels, which initially are removed by an increased rate of metabolic clearance. This compensatory mechanism diminishes over time, and hirsutism can develop. Frequently, these patients are classified as having polycystic ovary (PCO) syndrome. Alterations in the secretion of endorphins, cortisol, insulin, growth hormone, and insulin-like growth factor-1 (IGF-1) may interact with the abnormal estrogen and androgen feedback to the GnRH pulse generator to cause menstrual abnormalities.

Other Hormonal Dysfunctions

The secretion of hypothalamic neuromodulators can be altered by feedback from abnormal levels of peripheral hormones. Excesses or deficiencies of thyroid hormone, corticosteroids, androgens, and estrogens can cause menstrual dysfunction. PCO syndrome usually causes irregular bleeding but may cause amenorrhea. It is likely that PCO syndrome is the result of peripheral alteration in IGF-1, androgen, and estrogen levels, which leads to hypothalamic dysfunction. Elevations in androgens (e.g., Sertoli-Leydig, hilus, and lipid cell tumors) and estrogens (e.g., granulosa cell tumors) by ovarian tumors may lead to abnormal menstrual patterns, including amenorrhea. In patients who are hirsute and amenorrheic, androgen-secreting adrenal tumors and congenital adrenal hyperplasia should be considered.

Excess secretion of GH, TSH, ACTH, and prolactin from the pituitary gland can cause abnormal feedback inhibition of GnRH secretion, leading to amenorrhea. GH excess causes acromegaly, which may be associated with anovulation, hirsutism, and polycystic ovaries as a result of stimulation of the ovary by IGF-1. More commonly, GH excess is accompanied by amenorrhea, low gonadotropin levels, and elevated prolactin levels. Acromegaly is characterized by enlargement of facial features, hands, and feet, hyperhidrosis, visceral organ enlargement, and multiple skin tags. Cushing's disease is caused by an ACTH-secreting pituitary tumor

manifested by truncal obesity, moon facies, hirsutism, proximal weakness, depression, and menstrual dysfunction.

Diagnosis

A pregnancy test (urine or serum hCG) should be performed in a reproductive-age woman with normal secondary sexual characteristics and normal pelvic examination findings who has amenorrhea. If the results of the pregnancy test are negative, amenorrhea should be evaluated using the following assessments:

1. Serum TSH level
2. Serum prolactin level
3. FSH levels
4. Estrogen status
5. Pituitary and hypothalamic function.

Thyroid-stimulating Hormone and Prolactin Levels

1. Sensitive TSH assays can be used to evaluate hypothyroidism and hyperthyroidism. Further evaluation of a thyroid disorder is required if abnormalities in TSH levels are found.
2. Hyperprolactinemia is a common cause of anovulation in women. If elevated TSH and prolactin levels are found, the hypothyroidism should be treated before hyperprolactinemia is treated. Often, the prolactin level will normalize with treatment of hypothyroidism because thyroid-releasing hormone, which is elevated in hypothyroidism, stimulates prolactin secretion.

Follicle-stimulating Hormone Levels

Serum FSH levels are required to determine whether the patient has hypergonadotropic, hypogonadotropic, or eugonadotropic amenorrhea. **A circulating FSH level of >40 mIU/ml indicated on at least two blood samples is indicative of hypergonadotropic amenorrhea.** Hypergonadotropism signifies that the cause of amenorrhea is at the level of the ovary. The history should reveal whether chemotherapy or radiation therapy are the cause for ovarian failure. Galactose-1-phosphate uridyl transferase level should be measured to assess whether the patient has galactosemia disease or is a carrier.

In patients less than 30 years of age with hypergonadotropic amenorrhea, a karyotype is required to rule out the presence of a Y cell line. *In situ* hybridization studies may prove the existence of Y chromosomal material with a Y-specific probe when the karyotype is normal (79). It is important to identify Y chromosomal material so it may be removed to prevent malignant degeneration.

There is much debate regarding the extent of an autoimmune workup required for a patient with ovarian failure.

1. It is reasonable to screen patients with nonspecific tests, such as those for antinuclear antibodies (ANA), rheumatoid factor (RF), and erythrocytic sedimentation rate (ESR).
2. A normal partial thromboplastin time (PTT) is sufficient to exclude lupus anticoagulant.
3. Assessments of serum electrolytes, calcium, and phosphorus concentrations can be used to evaluate the possibility that parathyroid autoantibodies are active.
4. Other assessments that should be performed include TSH, antithyroglobulin antibodies, and antimicrosomal antibodies to evaluate thyroid status, and 24-hour urinary free cortisol to evaluate the presence of antiadrenal antibodies.
5. A more extensive workup may include assessment of parietal cell antibodies, islets of Langerhans antibodies, and antiadrenal antibodies; it is unclear, however, if these tests will alter clinical management.

Tests should be repeated yearly because of the transient nature of autoimmune disorders.

In a patient with hypergonadotropic amenorrhea, it is not advisable to perform ovarian biopsy to determine whether follicles are present. Even if oocytes are found, no good method exists to stimulate those oocytes to ovulate. Some patients with negative biopsy results later ovulated spontaneously. This phenomenon can be explained by considering that the biopsy samples only a small portion of the ovary (57).

Assessment of Estrogen Status

Traditionally, estrogen status has been determined by giving medroxyprogesterone acetate, either 5 or 10 mg for 10 days, to determine whether the patient bleeds after withdrawal of the medication (usually 2 to 10 days after the last dose). There is a debate as to how much bleeding constitutes withdrawal bleeding. If vaginal bleeding does not occur after oral administration of progesterone, frequently 100 to 200 mg progesterone in oil is given intramuscularly. Other ways of testing for estrogen status may be quicker and easier. The development of vaginal dryness and hot flashes increase the likelihood of a diagnosis of hypoestrogenism. A sample of vaginal secretions can be obtained during the physical examination, and mucosal estrogen response can be demonstrated by the presence of superficial cells. A serum estradiol level higher than 40 pg/ml is considered adequate, but interassay discrepancies often exist.

The finding of vaginal bleeding after progesterone challenge is important when Asherman's syndrome is suspected. In a patient with primary amenorrhea and an apparently normal estrogen status, a progesterone challenge will diagnose the rare finding of congenitally absent endometrium. If estrogen status is questioned, 2.5 mg conjugated estrogen or 2 mg micronized estradio. can be given for 25 days with 5 to 10 mg of medroxyprogesterone acetate added for the last 10 days of therapy. Congenital absence of the endometrium is confirmed if no bleeding occurs with this regimen in a patient with primary amenorrhea and no physical abnormalities. Transvaginal ultrasonography to assess endometrial thickness may also be helpful. If similar findings occur in patients with secondary amenorrhea, Asherman's syndrome is diagnosed. **Asherman's syndrome must be confirmed by showing filling defects on hysterosalpingography or by visualizing adhesions with hysteroscopy.**

Assessment of the Pituitary and Hypothalamus

If the patient is hypoestrogenic and the FSH level is not high, pituitary and hypothalamic lesions should be excluded.

1. A complete neurologic examination, including electroencephalography (EEG), may help localize a lesion.
2. Either CT or MRI scanning should be performed to confirm the presence of a tumor. MRI can identify smaller lesions than can CT; if a lesion is too small for identification by MRI, it may be clinically insignificant.
3. After anatomic lesions have been excluded, the patient's history of weight changes, exercise, eating habits, body image, and career or school achievements are important factors in identifying anorexia nervosa, malnutrition, obesity, or exercise-induced or stress-induced menstrual disorders.

Amenorrheic patients who have hypothalamic dysfunction and are hypoestrogenic may have disorders similar to those who are well estrogenized. The hypothalamic dysfunction caused by chronic disease, anorexia nervosa, stress, and malnutrition may be more severe or may exist for a more prolonged time in hypoestrogenic patients than in euestrogenic patients.

Patients with appropriate clinical findings should undergo screening for other hormonal alterations as follows:

1. Androgen levels should be assessed in any hirsute patient to ensure that adrenal and ovarian tumors are not present as well as to diagnose PCO syndrome (Chapter 25).
 2. Acromegaly is suggested by coarse facial features, large doughy hands, and hyperhidrosis and may be confirmed by measuring IGF-1 levels.
 3. Cushing's syndrome should be ruled out by assessing 24-hour urinary cortisol levels or a 1-mg overnight dexamethasone suppression test in patients with truncal obesity, hirsutism, hypertension, and erythematous striae.
-

Treatment

The treatment of nonanatomic causes of amenorrhea associated with secondary sexual characteristics varies widely according to the cause. The underlying disorder should be treated whenever possible. Patients who are pregnant may be counseled regarding the options for continued care. When thyroid abnormalities are discovered, thyroid hormone, radioactive iodine, or antithyroid drugs may be administered as appropriate. When hyperprolactinemia is discovered, treatment may include discontinuation of contributing medications, treatment with dopamine agonists such as *bromocriptine* or *cabergoline* and, rarely, surgery for particularly large pituitary tumors. When ovarian failure causes amenorrhea, hormone replacement is prescribed for prevention of osteoporosis and to diminish menopausal symptoms. Gonadectomy is required when a Y cell line is present.

Surgical removal, radiation therapy, or a combination of both is generally advocated for treatment of central nervous system tumors other than prolactinomas. It may be necessary to treat individuals who have panhypopituitarism with various replacement regimens once all the deficits have been elucidated. These regimens include estrogen replacement for lack of gonadotropins, corticosteroid replacement for lack of ACTH, thyroid hormone for lack of TSH, and *desmopressin acetate* (*1-deamino-8-D-AVP [DDAVP]*) to replace vasopressin.

The treatment of amenorrhea associated with hypothalamic dysfunction also depends on the underlying cause:

1. Hormonally active ovarian tumors are surgically removed.
2. Obesity, malnutrition or chronic disease, Cushing's syndrome, and acromegaly should be specifically treated.
3. Pseudocyesis and stress-induced amenorrhea may respond to psychotherapy.
4. Exercise-induced amenorrhea may improve with moderation of activity and weight gain when appropriate.
5. Anorexia nervosa generally demands a multidisciplinary approach, with severe cases requiring hospitalization.
6. Chronic anovulation or PCO syndrome may be treated after identifying the desires of the patient. Patients often are concerned about their lack of menstruation but not about hirsutism or infertility. The endometrium of these individuals should be protected from the environment of unopposed estrogen that accompanies the anovulatory state. An oral contraceptive is a good alternative for those patients who also require contraception. For those patients who are not candidates for oral contraceptives, cyclic administration of progestin is advised. This treatment option presumes an adequate estrogenic environment to induce proliferation of the endometrium and is not sufficient to cause withdrawal bleeding in patients who are hypoestrogenic (i.e., anorexia nervosa). In these individuals, estrogen replacement must be added to the progestin regimen for successful menstrual regulation and prevention of osteoporosis. The most common progestin used to induce withdrawal bleeding and thus protect the endometrium from hyperplastic transformation is *medroxyprogesterone acetate* (10 mg for 10 days per month). Occasionally, ovulation may occur; therefore, patients should be made aware that pregnancy is possible and appropriate contraceptive measures should be used. There is concern that medroxyprogesterone acetate used in early pregnancy may increase the incidence of pseudohermaphroditism (80). Alternatively, *progesterone* suppositories (50 to 100 mg) or *micronized progesterone* (200 mg) could be given for 10 days to induce withdrawal bleeding. No increased incidence of birth defects has been associated with the use of these natural progesterones (81).
7. When chronic anovulation is caused by attenuated congenital adrenal hyperplasia, glucocorticoid administration (i.e., *dexamethasone* 0.5 mg at bedtime) is sometimes successful in restoring the normal feedback mechanisms, thereby permitting regular menstruation and ovulation.

Hirsutism

Patients who have oligomenorrhea or amenorrhea resulting from chronic anovulation may have hirsutism (Chapter 25). After ruling out androgen-secreting tumors and congenital adrenal hyperplasia, treatment may be aimed at decreasing coarse hair growth.

Oral Contraceptives Oral contraceptives may be effective by decreasing ovarian androgen production as well as increasing circulating levels of sex hormone-binding globulin, leading to decreased free androgen circulation.

Antiandrogens *Spiroolactone* has also been used because of its ability to decrease androgen production as well as compete with androgens at the androgen receptor level. Side effects include limited diuresis and dysfunctional uterine bleeding.

Flutamide is approved by the U.S. Food and Drug Administration for adjuvant therapy in prostatic cancer, and in the treatment of hirsutism it has effects similar to *spiroolactone* with fewer side effects (82). Liver function should be monitored because of the rare complication of hepatotoxicity.

Cyproterone acetate, a strong progestin and antiandrogen, is used widely abroad but is not currently available in the United States. It is usually administered in combination with *ethinyl estradiol* in an oral contraceptive. By decreasing circulating androgen and LH levels, and by inducing antagonism of androgen effects at the peripheral level, *cyproterone acetate* is effective in treating hirsutism (83).

GnRH Agonist GnRH agonist administration with add-back therapy is increasingly being used in the United States. Administration of GnRH agonist agents virtually eliminates ovarian steroid production, and estrogen-progestin add-back therapy allows long-term administration and protection against osteoporosis.

5 α -Reductase Inhibitors *Finasteride*, a 5 α -reductase inhibitor, is approved by the U.S. Food and Drug Administration for the treatment of benign prostatic hypertrophy (*Proscar*) and male pattern baldness (*Propecia*). It is effective in treating hirsutism, although perhaps no more effective than other available agents (84,85). *Finasteride* has significant teratogenic potential, which precludes its use in any woman who may become pregnant. Its major advantage is that it is exceptionally well tolerated and may be used when side effects preclude the use of other therapeutic options for hirsutism.

Eflornithine hydrochloride, a topical cream, has been approved by the U.S. Food and Drug Administration for use on the face and chin. Improvements in facial hirsutism may be seen in 4 to 8 weeks of twice-daily applications.

Ovulation Induction

A large subset of patients with amenorrhea or oligomenorrhea and chronic anovulation seek care because they are unable to conceive (Chapter 27). Ovulation induction therapy is generally the treatment of choice for such patients, but pretreatment counseling should be provided in sufficient detail to ensure realistic expectations. The patient should be provided with information regarding the chances of a successful pregnancy (considering age of the patient and treatment modality), potential complications (hyperstimulation and multiple gestation), expense, time, and psychological impact involved in completing the course of therapy (86). **Patients may be advised that there is no increase in congenital anomalies in children born following ovulation induction (87).**

Recent studies have raised the possibility of a relationship between ovulation induction and the risk of ovarian cancer (88,89). Ongoing studies are attempting to address this issue conclusively, but data support an increase of approximately 2.5-fold in ovarian cancer in patients treated for infertility, which appears unrelated to the use of ovulation-inducing drugs (90,91). No change in ovulation induction practices seems warranted at the present time. Pregnancy and treatment with oral contraceptives before or after childbearing may protect against ovarian cancer.

***Clomiphene citrate* is the usual first choice for ovulation induction in most patients because of its relative safety, efficacy, route of administration (oral), and relatively low cost (92).** *Clomiphene citrate* is indicated primarily in patients with adequate levels of estrogen and normal levels of FSH and prolactin. It is generally ineffective in hypogonadotropic patients who already have a poor estrogen supply (93). Patients with inappropriate gonadotropin release (an increased LH-to-FSH ratio), such as that which occurs in PCO syndrome, are also candidates for therapy with *clomiphene citrate*. Up to 80% of certain patients can be expected to ovulate after *clomiphene citrate* therapy, and pregnancy rates approach 40% (86). Contraindications to the use of *clomiphene citrate* include pregnancy, liver disease, and preexisting ovarian cysts. Side effects include hot flashes (>11% of patients) and poorly understood visual symptoms, which generally have been viewed as an indication to discontinue subsequent *clomiphene citrate* use. The incidence of multiple gestation ranges from 6.25% to 12.3% (86). The most commonly recommended treatment regimen is 50 mg daily for 5 days, beginning on the third to fifth day of menstrual or withdrawal bleeding. Cycles are easily monitored by measuring midcycle estradiol levels and midluteal progesterone levels to assess folliculogenesis and ovulation. Ultrasonographic monitoring may also be helpful, especially for ovulation triggering with hCG. With these data, it is possible to adjust immediately the dose for the subsequent cycle if a given regimen is ineffective. Dosage increases of 50 mg/day are usually used, and more than 70% of conceptions occur at doses no higher than 100 mg/day for 5 days (94). Dosages higher than 150 mg/day for 5 days are usually ineffective, and patients who remain anovulatory with this dosage should undergo further evaluation accompanied by changes in the therapeutic plan. Longer courses of *clomiphene citrate* therapy, as well as adjunctive therapy with glucocorticoids and hCG, have been recommended (93). Patients

with PCO syndrome, especially those with insulin resistance, may benefit from the use of insulin-sensitizing agents either as primary or adjunctive therapy (95). These include the biguanide *metformin* and thiazolidinediones (*rosiglitazone* and *pioglitazone*).

Women who do not ovulate or become pregnant with *clomiphene citrate*, as well as women with hypogonadotropic hypogonadism, may be candidates for therapy with injectable gonadotropins. Much higher pregnancy rates (up to 90%) occur in the latter category. Available preparations include recombinant FSH or products purified from the urine of menopausal women (FSH or FSH-LH combinations). Oral gonadotropin therapy is currently in research and development. Administration protocols and dosages vary widely and should be adjusted to individual needs. Safe administration requires careful monitoring of ovarian response with ultrasonography and serial estradiol measurements. In general, gonadotropins are administered at a dose of 75 to 150 IU/day by subcutaneous or intramuscular injection for 3 to 5 days, after which estradiol and follicular monitoring commence. In most cycles, gonadotropin administration lasts from 7 to 12 days. Ovulation is triggered by subcutaneous or intramuscular injection of 5,000 to 10,000 IU hCG once the lead follicle reaches 16 to 20 mm in diameter based on ultrasonographic assessments. Ovulation generally occurs approximately 36 hours after hCG administration. Luteal phase support is sometimes given with additional injections of hCG or with progesterone supplementation.

The two major complications associated with induction of ovulation with gonadotropins are multiple pregnancy (10% to 30%) and ovarian hyperstimulation syndrome. The incidence of both of these complications can be lowered by careful monitoring. Cycles complicated by the recruitment of numerous follicles or by estradiol levels approaching or exceeding 2,000 pg/ml may be canceled by withholding the ovulatory dose of hCG. Selected patients may be converted safely to *in vitro* fertilization. Because severe ovarian hyperstimulation syndrome is life-threatening and may lead to prolonged hospitalization, ovulation induction with gonadotropins generally is performed by experienced practitioners who devote a significant portion of their practice to the treatment of infertility.

Ovulation induction with GnRH may be effective in patients with chronic anovulation associated with low levels of estrogen and gonadotropins. In order for therapy to be successful, a functional ovary and pituitary gland must be present. Therefore, patients with ovarian or pituitary failure do not respond to GnRH therapy. To be effective, GnRH must be administered in a pulsatile fashion either intravenously or subcutaneously by a programmable pump. Ovulation induction with GnRH, as compared with gonadotropins, is associated with a relatively low incidence of ovarian hyperstimulation and multiple births. In addition, the need for appropriate timing of the ovulatory dose of hCG is avoided because patients treated with pulsatile GnRH have an appropriately timed endogenous LH surge. Disadvantages are mainly related to maintaining the programmable pump and injection site. After ovulation, luteal phase support is necessary and may be provided with hCG, progesterone, or continuation of the GnRH therapy.

Patients who lack oocytes (ovarian failure) and desire pregnancy may be candidates for oocyte donation. Oocytes may be harvested after ovulation induction from appropriate donors, fertilized with sperm from the recipient's husband, and transferred into the recipient's uterus after the endometrium has been appropriately prepared with hormonal regimens. Estrogen and progesterone are used to prepare the endometrium for implantation of the transferred embryo(s).

The endocrine disorders encountered most frequently in gynecologic patients are those related to androgen excess, including what is arguably the most common endocrinopathy in women—polycystic ovary syndrome (PCOS). Rare causes of virilization in women include tumors of the ovary and the adrenal gland. These conditions, as well as common disorders of the pituitary and thyroid glands, are reviewed in this chapter.

Hyperandrogenism

Diseases that reflect a state of hyperandrogenism result from either excess production of androgen such as from an adrenal or ovarian tumor, from metabolic derangements such as PCOS, or from increased end-organ sensitivity.

Hirsutism

Hirsutism, which is the most frequent manifestation of androgen excess in women, is defined as excessive growth of terminal hair in a malelike pattern.

This refers particularly to midline hair, side burns, moustache, beard, chest or intermammary hair, and inner thigh and midline lower back hair entering the intergluteal area. The response of the pilosebaceous unit to androgens causes vellus hair to transform into terminal hair in androgen-dependent areas. The resulting terminal hair is coarse, stiff, pigmented, and long.

Androgens affect various types of hair differently. Hair that shows no androgen dependence includes lanugo, eyebrows, and eyelashes. Hair that is more dependent on adrenal androgens includes axillary and pubic hair. Hair that depends significantly on gonadal androgens includes midline, facial, and intermammary hair. Scalp hair is inhibited by gonadal androgens, resulting in the common temporal balding seen in males and in virilized females. Hirsutism results from both increased androgen production and skin sensitivity to androgens. Skin sensitivity depends on the local activity of 5 α -reductase, the enzyme that converts testosterone to dihydrotestosterone (DHT), the active androgen in hair follicles.

Hair demonstrates cyclic activity between growth (anagen), involution (catagen), and resting (telogen) phases. Both the growth and resting phases vary in length for different areas of hair growth. Much of the influence of androgens or pharmaceutical agents depends on the phase of hair growth. Synchronization in the hair growth phase may lead to dramatic consequences, such as the hair loss occasionally encountered during pregnancy.

Social and clinical reactions to hirsutism may vary significantly. Androgen-dependent hair (excluding pubic and axillary hair) occurs in only 5% of premenopausal Caucasian women and is considered abnormal in white women of North America. The presence of sexual hair in other locations is viewed as normal, however, and is socially acceptable in some ethnic groups, such as Eskimos and women of Mediterranean origin.

Two conditions should be distinguished from hirsutism. **Hypertrichosis is the term reserved for androgen-independent growth of hair that is prominent in nonsexual areas, such as the trunk and extremities.** This may be either an autosomal-dominant congenital disorder or may be caused by metabolic disorders (such as anorexia nervosa, hyperthyroidism, porphyria cutanea tarda) or medications (phenytoin, minoxidil, cyclosporine, diazoxide). **Virilization is characterized by male-pattern baldness (crown routinely and temples occasionally), coarsening of the voice, decrease in breast size, increase in muscle mass, loss of female body contour (obesity, particularly of the upper segment, and alteration of the waist-to-hip ratio), and enlargement of the clitoris (the mean transverse diameter of the glans is 3.4 \pm 1 mm and the longitudinal diameter is 5.1 \pm 1.4 mm) (1).**

The history should focus on the age of onset and rate of progression of hirsutism or virilization. A fast rate of progression is associated with a more severe degree of hyperandrogenism and should raise suspicion of ovarian and adrenal neoplasms or Cushing's syndrome. The same is true of rapid progression or onset of symptoms before or after adolescence. Anovulation, manifesting as amenorrhea or oligomenorrhea, increases the probability of hyperandrogenism. Hirsutism in women with regular cycles may be associated with normal androgen levels and is considered *idiopathic hirsutism*.

A sensitive and tactful approach by the physician is mandatory and should include questioning of the patient regarding whether she shaves or removes hair chemically or mechanically and, if so, how frequently. A family history should be obtained to disclose evidence of idiopathic hirsutism, PCOS, congenital adrenal hyperplasia (CAH), diabetes mellitus, and cardiovascular disease. A history of drug use should also be obtained. In addition to drugs that commonly cause hypertrichosis, anabolic steroids and testosterone derivatives may cause virilization. During the physical examination, attention should be directed to obesity, hypertension, galactorrhea, male-pattern baldness, acne (face and back), and hyperpigmentation. The presence of an androgen-producing ovarian neoplasm or Cushing's syndrome should be considered. In many cases of Cushing's syndrome, the patient's initial symptom is hirsutism. The physician should search for the physical signs of the syndrome such as "moon face," plethora, purple striae, dorsocervical and supraclavicular fat pads, and proximal muscle weakness. The type,

pattern, and extent of hair growth are next evaluated.

Typically, clinical evaluation of the degree of hirsutism is subjective. Most physicians arbitrarily classify the degree of hirsutism as mild, moderate, or severe. Objective assessment is helpful, however, especially in establishing a baseline from which therapy can be evaluated. A hirsutism scoring scale of androgen-sensitive hair in nine body areas rated on a scale of 0 to 4 has been used (2). A score higher than 8 is defined as hirsutism.

Role of Androgens

Androgens and their precursors are produced by both the adrenal glands and the ovaries in response to their respective trophic hormones, luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH) (Fig. 25.1). Biosynthesis begins with the rate-limiting conversion of cholesterol to pregnenolone by side-chain cleavage enzyme. Thereafter, pregnenolone undergoes a two-step conversion to the 17-ketosteroid dehydroepiandrosterone (DHEA) along the D-5 steroid pathway. This conversion is accomplished by CYP17, an enzyme with both 17 α -hydroxylase and 17,20-lyase activities. In a parallel fashion, progesterone undergoes transformation to androstenedione in the D-4 steroid pathway. The metabolism of D-5 to D-4 intermediate is accomplished via a D-5-isomerase, 3 β -hydroxysteroid dehydrogenase (3 β -HSD).

Figure 25.1 Major steroid biosynthesis pathway.

Adrenal 17-Ketosteroids

Secretion of adrenal 17-ketosteroids begins prepubertally (adrenarche) with a dramatic change in the response of the adrenal cortex to ACTH and with preferential secretion of D-5 steroids, including 17-hydroxyprogesterone, DHEA, and dehydroepiandrosterone sulfate (DHEAS). The basis for this action is related to the increase in the zona reticularis and in the increased activity of the 17-hydroxylase and the 17,20-lyase enzymes.

Testosterone

Approximately one-half of a woman's serum testosterone is derived from peripheral conversion of secreted androstenedione, and the other one-half is derived from direct glandular secretion. The ovaries and adrenal glands contribute about equally to the direct glandular testosterone production in women.

Approximately 66% to 78% of circulatory testosterone is bound to sex hormone-binding globulin (SHBG) and is considered biologically inactive. Most of the proportion of serum testosterone that is not bound to SHBG is associated with albumin (20% to 32%). Finally, a small percentage (1% to 2%) of testosterone is entirely unbound or free.

The concentration of free testosterone has an inverse relationship with the SHBG concentration. Increased SHBG levels are noted in conditions associated with high estrogen levels. Thus, pregnancy and the luteal phase, use of estrogen (including oral contraceptives), and conditions causing elevated thyroid hormone levels and cirrhosis of the liver are associated with reduced free testosterone levels caused by elevated SHBG levels. Conversely, levels of SHBG decrease and result in elevated free testosterone levels in response to androgens, androgenic medications (progestational agents with androgenic biologic activities, danazol), androgenic disorders (PCOS, CAH, Cushing's syndrome), glucocorticoids, growth hormone, prolactin, insulin, and obesity.

Because nearly all practitioners measure some form of testosterone level, a basic understanding of the methods and accuracy of various techniques is critical. Testosterone nonspecifically bound to albumin (AT) is linearly related to free testosterone (FT) by the equation $AT = K_a [A] \times FT$, where AT is the albumin-bound testosterone, K_a is the association constant of albumin for testosterone, and [A] is the albumin concentration. In most cases of hirsutism, albumin levels are within a tight physiologic range and thus do not significantly affect the free testosterone concentration. **Therefore, in most cases of hirsutism, the free testosterone level can be calculated by measuring the total testosterone as well as the SHBG concentration.** A physiologic albumin level is assumed, and the free testosterone level is calculated with good reliability when compared with equilibrium dialysis. This method provides a rapid, simple, and accurate determination of the total and calculated free testosterone level as well as the concentration of SHBG.

The bioavailable testosterone level is also based on the relationship of albumin and free testosterone but incorporates the actual measurement of albumin levels with the total testosterone and SHBG. The assessment of free testosterone by methods other than the direct immunoassay of total testosterone, SHBG, and albumin in the case of bioavailable testosterone is unreliable (3).

A notable exception to the accuracy of the aforementioned measurements is pregnancy. During pregnancy estradiol occupies a large proportion of SHBG binding sites, resulting in an overestimation of the actual binding capacity of SHBG. Testosterone is unable to bind all the SHBG sites because they are occupied by estradiol; thus, an underestimation of free testosterone level occurs. Therefore, during pregnancy a total testosterone level is the only clinically reliable measurement and can be used to help rule out a testosterone-secreting tumor.

For testosterone to exert its biologic effects on many target tissues, it must be converted into its active metabolite, DHT, by 5 α -reductase (a cytosolic enzyme that reduces testosterone and androstenedione levels). Two isozymes of 5 α -reductase exist: type 1, which predominates in the skin, and type 2, or acidic 5 α -reductase, which is found in the liver, prostate, seminal vesicles, and genital skin. The type 2 isozyme has a 20-fold higher affinity for testosterone than type 1. Both type 1 and 2 deficiencies in males result in ambiguous genitalia, and both isozymes may play a role in androgen effects on hair growth. Dihydrotestosterone is more potent than testosterone, primarily because of its higher affinity and slower dissociation from the androgen receptor. The relative androgenicity of androgens is as follows: DHT = 300, testosterone = 100, androstenedione = 10, and DHEAS = 5.

Until adrenarche, androgen levels remain low. Around 8 years of age, adrenarche is heralded by a marked increase in DHEA and DHEAS. The half-life of free DHEA is extremely short (about 30 minutes) but extends to several hours if DHEA is sulfated. Although no clear role is identified for DHEAS, it is associated with stress and level is inversely related to aging.

With age, the adrenal glands produce less DHEA and DHEAS. Once the ovaries cease production of estrogen during menopause, the production of testosterone and androstenedione increases. The diurnal variation is maintained by the adrenal contribution. These androgens are ultimately converted to estrone (E_1) and estradiol (E_2) via extragonadal aromatization.

Laboratory Evaluation

Critical laboratory testing for the assessment of hirsutism should include total testosterone, SHBG, calculated free or bioavailable testosterone (includes actual albumin concentration measurement), DHEAS, and 17-hydroxyprogesterone (17-OHP) measurements (Table 25.1). If a patient is oligomenorrheic, LH,

follicle-stimulating hormone (FSH), prolactin, and thyroid-stimulating hormone (TSH) values are useful in the initial evaluation. Hyperthyroidism and hyperprolactinemia may result in reduced levels of SHBG and may significantly increase free testosterone levels resulting in hirsutism. Elevated LH-to-FSH ratios are noted in over one-half of women with PCOS and are occasionally helpful in establishing the diagnosis of PCOS. In cases of suspected Cushing's syndrome, patients should undergo screening with a 24-hour urinary cortisol (most sensitive) assessment or an overnight dexamethasone suppression test. For this test, the patient takes 1 mg of dexamethasone at 11:00 PM, and a blood cortisol assessment is performed at 8:00 AM the next day. **Cortisol levels of 2 mg/ml or higher require a further workup for evaluation of Cushing's syndrome.**

Testosterone (total)	20-80 ng/dl
Free testosterone (calculated)	0.5-6.8 pg/ml
Percent free testosterone	0.4-2.4%
Bioavailable testosterone	1.5-19.1 ng/dl
SHBG	18-114 nmol/L
Albumin	3100-4800 mg/dl
Androstenedione	20-250 ng/dl
Dehydroepiandrosterone sulfate	100-350 µg/dl
17-hydroxyprogesterone (follicular phase)	30-200 ng/dl

SHBG, sex hormone-binding globulin.
 *Normal values may vary among different laboratories. Free testosterone is calculated using measurements for total testosterone and sex hormone-binding globulin, while bioavailable testosterone is calculated using measured total testosterone, sex hormone-binding globulin, and albumin. Calculated values for free and bioavailable testosterone compare well with equilibrium dialysis methods of measuring unbound testosterone. Bioavailable testosterone includes free plus weakly bound (non-SHBG, non-albumin) testosterone. Bioavailable testosterone is an assessment of bioactive testosterone in the serum.

Table 25.1 Normal Values for Serum Androgens^a

Some hirsute women manifest testosterone levels above normal (20 to 80 ng/dl [0.723 nmol/L]). However, there is no direct correlation between the level of hirsutism and the total testosterone concentration because hirsutism is caused by the action of the testosterone metabolite DHT, which in turn is related to the concentration of SHBG. Low SHBG levels, which frequently occur in the presence of elevated androgen and insulin levels, increase free testosterone levels. The result is hirsutism in the absence of an increase in total testosterone. Therefore, the total serum testosterone concentration is subject to wide variation in the concentration of binding proteins, and therefore is not a reliable index of bioavailable testosterone. It does, however, serve as a marker for androgen-producing neoplasms. **Total testosterone levels >200 ng/dl should prompt a workup for ovarian or adrenal tumors.**

In the past, testing for androgen conjugates (e.g., 3 α -androstenediol G [3 α -diol G] and androsterone G [AOG] as markers for 5 α -reductase activity in the skin) has been advocated. However, routine determination of androgen conjugates to assess hirsute patients is not recommended, because hirsutism itself is an excellent bioassay of free testosterone action on the hair follicle and because these androgen conjugates arise from adrenal precursors and are likely markers of only adrenal and not ovarian steroid production (4).

In most laboratories, the upper limit of a DHEAS level is 350 µg/dl (9.5 nmol/L). A random sample is sufficient because the level of variation is minimized as a result of the long half-life of the sulfated form. A normal level essentially rules out adrenal disease, and moderate elevations are a common finding in the presence of PCOS. As a rule, a DHEAS level of over 700 µg/dl (20 nmol/L) indicates the need to rule out an adrenal tumor or Cushing's syndrome. Occasionally, ovarian tumors are associated with high DHEAS levels.

Because the 17-OHP level varies significantly in the cycle, standardized testing requires evaluation in the morning during the follicular phase. A baseline follicular phase 17-OHP level should be less than 200 ng/dl (6 nmol/L). When levels are greater than 200 ng/dl but less than 800 ng/dl (24 nmol/L), ACTH testing should be performed. Levels greater than 800 ng/dl (24 nmol/L) also warrant ACTH testing but are virtually diagnostic of 21-hydroxylase deficiency.

Polycystic Ovary Syndrome

The most common cause of hyperandrogenism and hirsutism is PCOS. The association of amenorrhea with bilateral polycystic ovaries was first described in 1935 by Stein and Leventhal (5) and was known for decades as the Stein-Leventhal syndrome. In the past the clinical diagnosis rested on the triad of hirsutism, amenorrhea, and obesity. **Subsequently it has been recognized that PCOS has an extremely heterogeneous clinical picture and is multifactorial in etiology (6).** Following are diagnostic criteria based on the modified consensus of the National Institutes of Health and Child Health and Human Development.

- **Major**

Chronic anovulation

Hyperandrogenemia

Clinical signs of hyperandrogenism

Other etiologies excluded

- **Minor**

Insulin resistance

Perimenarchal onset of hirsutism and obesity

Elevated LH-to-FSH ratio

Intermittent anovulation associated with hyperandrogenemia (free testosterone, DHEAS)

In this schema, there are only two major criteria for PCOS: anovulation and the presence of laboratory or clinical evidence or both of hyperandrogenism in the absence of other pathologies such as ovarian and adrenal neoplasms, pituitary disease, or CAH.

All other frequently encountered manifestations are less consistent findings and therefore qualify only as minor criteria. They include insulin resistance, perimenarchal onset of hirsutism and obesity, elevated LH-to-FSH ratio, ultrasonographic evidence of PCOS, and oligoovulation.

Hirsutism occurs in approximately 70% of patients in the United States with PCOS (7) and in only 10% to 20% of Japanese patients with PCOS (8). A likely explanation for this discrepancy is the genetically determined differences in skin 5 α -reductase activity (9,10).

Menstrual dysfunction typically occurs in PCOS, ranging from oligomenorrhea to amenorrhea. As a rule, patients with PCOS exhibit anovulation. Even in hyperandrogenic women with regular menstrual cycles, the rate of anovulation is 21% (11). Severe acne in the teenage years appears to be an accurate predictor of PCOS (12).

Obesity is found in over 50% of patients with PCOS. The body fat is usually deposited centrally (android obesity), and a higher waist-to-hip ratio indicates an increased risk of diabetes mellitus and cardiovascular disease (13).

Insulin resistance and hyperinsulinemia are commonly exhibited in PCOS. Insulin resistance is now recognized as a major risk factor for the development of type 2 diabetes mellitus (14). About one-third of obese PCOS patients have impaired glucose tolerance (IGT), and 7.5% to 10% have type 2 diabetes mellitus (15,16). These

rates are mildly increased even in nonobese women who have PCOS (10% IGT; 1.5% diabetes, respectively) (16), compared with the general population of the United States (7.8% IGT; 1% diabetes, respectively) (17).

Abnormal lipoproteins are common in PCOS and include elevated total cholesterol, triglycerides, and low-density lipoproteins (LDL), and low levels of high-density lipoproteins (HDL) and apoprotein A-I (13,18). According to one report, the most characteristic lipid alteration is decreased levels of HDL_{2a} (19).

Other observations in women with PCOS include impaired fibrinolysis as shown by elevated circulating levels of plasminogen activator inhibitor (20), an increased incidence of hypertension over the years that reaches a 40% incidence by perimenopause (18), a greater prevalence of atherosclerosis and cardiovascular disease (21,22), and an estimated sevenfold increased risk for myocardial infarction (23).

Pathology

Macroscopically, ovaries in women with PCOS are 2 to 5 times the normal size. A cross-section of the surface of the ovary discloses a white, thickened cortex with multiple cysts that are typically less than a centimeter in diameter (24). Microscopically, the superficial cortex is fibrotic and hypocellular and may contain prominent blood vessels. In addition to smaller atretic follicles, there is an increase in the number of follicles with luteinized theca interna. The stroma may contain luteinized stromal cells (24).

Pathophysiology and Laboratory Findings

The hyperandrogenism and anovulation that accompany PCOS may be caused by abnormalities in four endocrinologically active compartments, (a) the ovaries, (b) the adrenal glands, (c) the periphery (fat), and (d) the hypothalamus-pituitary compartment.

In patients with PCOS, the ovarian compartment is the most consistent contributor of androgens. Dysregulation of CYP17, the androgen-forming enzyme in both the adrenals and the ovaries, may be one of the central pathogenetic mechanisms underlying hyperandrogenism in PCOS (25). The ovarian stroma, theca, and granulosa contribute to ovarian hyperandrogenism and are stimulated by LH (26). This hormone relates to ovarian androgenic activity in PCOS in a number of ways.

1. Total and free testosterone levels correlate directly with LH levels (27).
2. The ovaries are more sensitive to gonadotropic stimulation, possibly as a result of CYP17 dysregulation (25).
3. Treatment with a gonadotropin-releasing hormone (GnRH) agonist effectively suppresses serum testosterone and androstenedione levels (28).
4. Larger doses of a GnRH agonist are required for androgen suppression than for estrogen suppression (29).

The increased testosterone levels in patients with PCOS are considered ovarian in origin. The serum total testosterone levels are usually no more than twice the upper normal range (20 to 80 ng/dl). However, in ovarian hyperthecosis, values may reach 200 ng/dl or more (30). High intraovarian androgen concentrations inhibit follicular maturation. Although ovarian theca cells are hyperactive, the retarded follicular maturation results in inactive granulosa cells with minimal aromatase activity for conversion to estrogens.

The adrenal compartment also plays a role in the development of PCOS. Although the hyperfunctioning CYP17 androgen-forming enzyme coexists in both the ovaries and the adrenal glands (30), DHEAS is increased in only about 50% of patients with PCOS (31,32). The hyperresponsiveness of DHEAS to stimulation with ACTH (30), the onset of symptoms around puberty, and the observation that 17,20-lyase activation (one of the two CYP17 enzymes) is a key event in adrenarche have led to the concept of PCOS as an exaggerated adrenarche.

The peripheral compartment, defined as the skin and the adipose tissue, manifests its contribution to the development of PCOS in several ways.

1. The presence and activity of 5 α -reductase in the skin largely determines the presence or absence of hirsutism (9,10).
2. Aromatase and 17 β -hydroxysteroid dehydrogenase activities are increased in fat cells (33), and peripheral aromatization is increased with body weight (34).
3. The metabolism of estrogens, by way of reduced 2-hydroxylation and 17 α -oxidation, is decreased (35).
4. Whereas E₂ is at a follicular phase level in patients with PCOS, E₁ levels are increased as a result of peripheral aromatization of androstenedione (36).
5. A chronic hyperestrogenic state results with reversal of the E₁-to-E₂ ratio.

The hypothalamic-pituitary compartment also participates in aspects critical to the development of PCOS.

1. An increase in LH pulse frequency is the result of increased GnRH pulse frequency (37).
2. This increase in LH pulse frequency typically results in elevated LH and LH-to-FSH ratio.
3. FSH is not increased with LH, probably because of the synergistic negative feedback of chronically elevated estrogen levels and normal follicular inhibin.
4. About 25% of patients with PCOS exhibit elevated prolactin levels. The hyperprolactinemia may result from abnormal estrogen feedback to the pituitary gland. In some patients with PCOS, *bromocriptine* has reduced LH levels and restored ovulatory function (38).

Genetic association and linkage analysis studies presently under way suggest an oligogenic origin for PCOS.

Insulin Resistance

Patients with PCOS are at risk for hyperinsulinemia and insulin resistance. The most common cause of insulin resistance and compensatory hyperinsulinemia is obesity. The insulin resistance seen in PCOS seems to be independent of the expected insulin resistance that occurs with obesity alone (38). The following observations provide evidence that the insulin resistance associated with PCOS is not the result of hyperandrogenism:

1. Hyperinsulinemia is not a characteristic of hyperandrogenism in general but is uniquely associated with PCOS (39).
2. In obese women with PCOS, 30% to 45% have glucose intolerance or frank diabetes mellitus, whereas ovulatory hyperandrogenic women have normal insulin levels and glucose tolerance (39). It seems that the negative effects of PCOS and obesity on the action of insulin are synergistic.
3. Treatment with long-acting GnRH analogs does not change insulin levels or insulin resistance (40).
4. Oophorectomy in patients with hyperthecosis accompanied by hyperinsulinemia and hyperandrogenemia does not change insulin resistance, despite a decrease in androgen levels (41).

Acanthosis nigricans is considered a marker for insulin resistance in hirsute women. This thickened, pigmented, velvety skin lesion is most often found in the vulva and may be present on the axilla, over the nape of the neck, below the breast, and on the inner thigh (42). Women with severe insulin resistance sometimes develop HAIR-AN syndrome (43), consisting of hyperandrogenism (HA), insulin resistance (IR), and acanthosis nigricans (AN). These patients usually have high testosterone levels (>150 ng/dl), fasting insulin levels of greater than 25 μ U/ml (normal <20 to 24 μ U/ml), and maximal serum insulin responses to glucose load exceeding 300 μ U/ml (normal is <160 μ U/ml at 2 hours post-glucose load).

Insulin alters ovarian steroidogenesis independent of gonadotropin secretion in PCOS. Insulin and insulin-like growth factor I (IGF-I) receptors are present in the ovarian stromal cells. A specific defect in the early steps of insulin receptor-mediated signaling (diminished autophosphorylation) has been identified in 50% of women with PCOS (44).

Clinically, it is important to realize that patients with PCOS are at increased risk for glucose intolerance or frank diabetes mellitus early in life. Therefore, it is appropriate to screen obese women with PCOS for glucose intolerance on a regular basis, once or twice a year. Abnormal glucose metabolism may be significantly improved with weight reduction, which may also reduce hyperandrogenism and restore ovulatory function (45). In obese, insulin-resistant women, caloric restriction that results in weight reduction will reduce the severity of insulin resistance (a 40% decrease in insulin level with a 10-kg weight loss) (46). This decrease in insulin levels should result in a marked decrease in androgen production (a 35% decrease in testosterone levels with a 10-kg weight loss) (46).

Radiologic Studies

Ultrasonographic examination may be a useful method for the early detection and subsequent follow-up of PCOS (47). Generally, ovarian size is increased (48,49). The most important ultrasonographic finding is a bilaterally increased number of microcysts measuring 0.5 to 0.8 cm with generally more than five microcysts in each ovary. As the number of microcysts increases and the ovarian volume enlarges, clinical and endocrine abnormalities become more obvious, and the condition becomes more severe.

Long-term Risks

In chronic anovulatory patients with PCOS, persistently elevated estrogen levels, uninterrupted by progesterone, increase the risk of endometrial carcinoma (50). These neoplasms are usually well differentiated, stage I lesions with a cure rate of more than 90% (see Chapter 30). Likewise, the hyperestrogenic state is associated with an increased risk of breast cancer (51). **The risk is greater in nonobese women and patients who have not been taking oral contraceptives (OCs). The risk of ovarian cancer also is increased two- to threefold in women with PCOS (52).** The risk is greater in nonobese women and patients who have not been taking OCs.

Treatment of Hyperandrogenism and PCOS

Treatment depends on a patient's goals. Some patients require hormonal contraception, whereas others desire ovulation induction. Interruption of the steady state of hyperandrogenism and control of hirsutism usually can be accomplished simultaneously. An exception is those patients desiring pregnancy, in whom effective control of hirsutism may not be possible. Treatment regimens for hirsutism are listed in Table 25.2. The induction of ovulation and treatment of infertility are discussed in Chapter 27.

Treatment Category	Specific Regimens
Weight loss	—
Hormonal suppression	Oral contraceptives Medroxyprogesterone Gonadotropin-releasing hormone analogs Glucocorticoids
Steroidogenic enzyme inhibitors	Ketocozazole
5 α -reductase inhibitors	Finasteride
Antiandrogens	Spiroolactone Cypsterone acetate Flutamide
Mechanical	Temporary Permanent Electrolysis Laser hair removal

Table 25.2 Treatment of Hirsutism

Weight Reduction

Weight reduction in obese patients is the initial recommendation, because it reduces insulin, SHBG, and androgen levels (mainly calculated or bioavailable testosterone), and may restore ovulation either alone or combined with ovulation-induction agents (52). Weight loss of as little as 5% to 7% over a 6-month period can reduce the calculated or bioavailable free testosterone significantly and restore ovulation and fertility in over 75% of women (53).

Oral Contraceptives

Combination OCs decrease adrenal and ovarian steroid production (55,56,57 and 58) and reduce hair growth in nearly two-thirds of hirsute patients.

Treatment with OCs offers the following benefits:

1. The progestin component suppresses LH, resulting in diminished ovarian androgen production.
2. The estrogen increases hepatic production of SHBG, resulting in decreased free testosterone concentration (59,60).
3. Circulating androgen levels are reduced, which to some extent is independent of the effects of both LH and SHBG (13).
4. Estrogens decrease conversion of testosterone to DHT in the skin by inhibition of 5 α -reductase.
5. Adrenal androgen secretion is reduced (61).

When an OC is used to treat hirsutism, a balance must be maintained between the decrease in free testosterone levels and the intrinsic androgenicity of the progestin. Three progestin compounds that are present in OCs (*norgestrel*, *norethindrone*, and *norethindrone acetate*) are believed to be androgen dominant. The androgenic bioactivity of these steroids may be a factor of their shared structural similarity with 19-nortestosterone steroids (62). Oral contraceptives containing the so-called new progestins (*desogestrel*, *gestodene*, *norgestimate*, and *drospirenone*) have minimized androgenic activity.

The use of OCs alone may be relatively ineffective (<10% success rate) in the treatment of hirsutism in women with PCOS (63). Insulin resistance may also be enhanced by OCs in these patients (64).

Medroxyprogesterone Acetate

Oral or intramuscular administration of *medroxyprogesterone acetate* has been used successfully for treatment of hirsutism (65). It directly affects the hypothalamic–pituitary axis by decreasing GnRH production and the release of gonadotropins, thereby reducing testosterone and estrogen levels. Despite a decrease in SHBG, total and free androgen levels are decreased significantly (66). **The recommended oral dosage is 20 to 40 mg daily in divided doses or 150 mg given intramuscularly every 6 weeks to 3 months in the depot form.** Hair growth is reduced in up to 95% of patients (67). Side effects of the treatment include amenorrhea, headaches, fluid retention, weight gain, hepatic dysfunction, and depression.

Gonadotropin-releasing Hormone Agonists

Administration of GnRH agonists may allow the differentiation of androgen produced by adrenal sources from that of ovarian sources (29). It has been shown to suppress ovarian steroids to castration levels in patients with PCOS (68). Treatment with *leuprolide acetate* given intramuscularly every 8 days decreases hirsutism and hair diameter in both idiopathic hirsutism and hirsutism secondary to PCOS (69). Ovarian androgen levels are significantly and selectively suppressed. The addition of OC or estrogen replacement therapy to GnRH agonist treatment (add-back therapy) prevents bone loss and other side effects of menopause, such as hot flashes and genital atrophy. The hirsutism-reducing effect is retained (66,70). Suppression of hirsutism is not potentiated by the addition of estrogen replacement therapy to GnRH agonist treatment (71).

Glucocorticoids

Dexamethasone may be used to treat patients with PCOS who have either adrenal or mixed adrenal and ovarian hyperandrogenism. Doses of *dexamethasone* as low as 0.25 mg nightly or every other night are used initially to suppress DHEAS concentrations to less than 400 μ g/dl. **Because dexamethasone has 40 times the glucocorticoid effect of cortisol, daily doses greater than 0.5 mg every evening should be avoided to prevent the risk of adrenal suppression and severe side effects that resemble Cushing's syndrome.** To avoid oversuppression of the pituitary–adrenal axis, morning serum cortisol levels should be monitored intermittently (maintain at >2 μ g/dl). Reduction in hair growth rate has been reported (72), as well as significant improvement in acne associated with adrenal hyperandrogenism.

Ketoconazole

Ketoconazole inhibits the key steroidogenic cytochromes. Administered at a low dose (200 mg/day), it can significantly reduce the levels of androstenedione, testosterone, and calculated free testosterone (73).

Spironolactone

Spironolactone is a specific antagonist of aldosterone, which competitively binds to the aldosterone receptors in the distal tubular region of the kidney. It is, therefore, an effective potassium-sparing diuretic, which was originally used for treatment of hypertension. The effectiveness of *spironolactone* in the treatment of hirsutism is based on the following mechanisms:

1. Competitive inhibition at the intracellular receptor level for DHT (74).
2. Suppression of testosterone biosynthesis by a decrease in the CYP enzymes (75).
3. Increase in androgen catabolism (with increased peripheral conversion of testosterone to estrone).
4. Inhibition of skin 5 α -reductase activity (74).

Although total and free testosterone levels are significantly reduced in patients with both PCOS and idiopathic hirsutism (hyperandrogenism with regular menses) after treatment with *spironolactone*, total and free testosterone levels in patients with PCOS remain higher than those with idiopathic hirsutism (hyperandrogenism with regular menses) (76). In both groups, SHBG levels are unaltered. The reduction in circulating androgen levels observed within a few days of *spironolactone* treatment partially accounts for the progressive regression of hirsutism.

At least a modest improvement in hirsutism can be anticipated in 70% to 80% of women using at least 100 mg of *spironolactone* per day for 6 months (77). *Spironolactone* reduces the daily linear growth rate of sexual hair, hair shaft diameters, and daily hair volume production (78). **The most common dosages is 25 to 100 mg twice daily. Women treated with 200 mg/day show a greater reduction in hair shaft diameter than women receiving 100 mg/day (79).** Maximal effect on hair growth is noted between 3 and 6 months but continues for 12 months. Electrolysis can be recommended 9 to 12 months after the initiation of *spironolactone* for permanent hair removal.

The most common side effect of *spironolactone* is menstrual irregularity (usually metrorrhagia), which may occur in over 50% of patients with a dosage of 200 g/day (79). Normal menses may resume with reduction of the dosage. Infrequently, other side effects such as urticaria, mastodynia, or scalp hair loss occur (79). Nausea and fatigue can occur with high doses (77). Because *spironolactone* can increase serum potassium levels, its use is not recommended in patients with renal insufficiency or hyperkalemia. Periodic monitoring of potassium and creatinine levels is suggested.

Return of normal menses in amenorrheic patients is reported in up to 60% of cases (76). Patients must be counseled to use contraception while taking *spironolactone* because it theoretically can feminize a male fetus.

Cyproterone Acetate

Cyproterone acetate is a synthetic progestin derived from 17-OHP that has potent antiandrogenic properties. The primary mechanism of *cyproterone acetate* is competitive inhibition of testosterone and DHT at the level of androgen receptors (80). This agent also induces hepatic enzymes and may increase the metabolic clearance rate of plasma androgens (81).

The combination of *ethinyl estradiol* with *cyproterone acetate*, which was commonly used in Europe for many years, significantly reduces plasma testosterone and androstenedione levels, suppresses gonadotropins, and increases SHBG levels (82). *Cyproterone acetate* also shows mild glucocorticoid activity (83) and may reduce DHEAS levels (84). Administered in a reverse sequential regimen (*cyproterone acetate* 100 g/day on days 5 to 15, and *ethinyl estradiol* 30 to 50 mg/day on cycle days 5 to 26), this cyclic schedule allows regular menstrual bleeding, provides excellent contraception, and is effective in the treatment of even severe hirsutism and acne (85). When a desired clinical response is achieved, the dose of *cyproterone acetate* may be tapered gradually at 3- to 6-month intervals.

Side effects of *cyproterone acetate* include fatigue, weight gain, decreased libido, irregular bleeding, nausea, and headaches. These symptoms occur less often when *ethinyl estradiol* is added. *Cyproterone acetate* administration has been associated with liver tumors in beagles and is not approved by the U.S. Food and Drug Administration for use in the United States.

Flutamide

Flutamide, a pure nonsteroidal antiandrogen, is approved for treatment of advanced prostate cancer. Its mechanism of action is inhibition of nuclear binding of androgens in target tissues. Although it has a weaker affinity to the androgen receptor than *spironolactone* or *cyproterone acetate*, larger doses (250 mg given 2 or 3 times daily) may compensate for the reduced potency. *Flutamide* is also a weak inhibitor of testosterone biosynthesis.

In a single, 3-month study of *flutamide* alone, most patients demonstrated significant improvement in hirsutism with no change in androgen levels (86). Significant improvement in hirsutism with a significant drop in androstenedione, DHT, LH, and FSH levels was observed in an 8-month follow-up of *flutamide* and low-dose OCs in women who did not respond to OCs alone (87). The side effects of *flutamide* treatment combined with a low-dose OC included dry skin, hot flashes, increased appetite, headaches, fatigue, nausea, dizziness, decreased libido, liver toxicity, and breast tenderness (88). Many patients taking *flutamide* (50% to 75%) report dry skin or a blue-green discoloration of urine. The risk of liver toxicity precludes *flutamide* as a routine option for the treatment of hirsutism.

Cimetidine

Cimetidine is a histamine H₂ receptor antagonist that has demonstrated a weak antiandrogenic effect as a result of its ability to occupy androgen receptors and inhibit DHT binding at the level of the hair follicles. Although *cimetidine* has been reported to reduce hair growth in women with hirsutism (89), two later studies show no beneficial effect (90,91).

Finasteride

Finasteride is a specific inhibitor of type 2 5 α -reductase enzyme activity that has been approved in the United States at a 5-mg dose for the treatment of benign prostatic hyperplasia and at a 1-mg dose to treat male-pattern baldness. In a study in which *finasteride* (5 mg daily) was compared with *spironolactone* (100 mg daily) (92), both drugs resulted in similar significant improvement in hirsutism despite differing effects on androgen levels. Most of the improvement in hirsutism occurred after 6 months of therapy with 7.5 mg of *finasteride* daily (93). The improvement in hirsutism in the presence of rising testosterone levels serves as convincing evidence that it is the binding of DHT and not testosterone to the androgen receptor that is responsible for hair growth. *Finasteride* does not prevent ovulation or cause menstrual irregularity. The increase in SHBG caused by OCs further decreases free testosterone levels; OCs in combination with *finasteride* are more effective in reducing hirsutism than *finasteride* alone. As with *spironolactone*, *finasteride* could theoretically feminize a male fetus; therefore, both of these agents are used only with additional contraception.

Ovarian Wedge Resection

Bilateral ovarian wedge resection is associated with only transient reduction in androstenedione levels and a prolonged minimal decrease in plasma testosterone (94,95). In patients with hirsutism and PCOS who have had wedge resection, hair growth was reduced by approximately 16% (96,97). Although Stein's original report cited a pregnancy rate of 85% following wedge resection and maintenance of ovulatory cycles, subsequent reports show lower pregnancy rates and a concerning incidence of periovarian adhesions (98).

Laparoscopic Electrocautery

Laparoscopic ovarian electrocautery is used as an alternative to wedge resection in patients with severe PCOS whose condition is resistant to *clomiphene citrate*. In a recent series (99), ovarian drilling was achieved laparoscopically with an insulated electrocautery needle, using 100-W cutting current to aid in entry and 40-W coagulating current to treat each microcyst over 2 seconds (8-mm needle in ovary). In each ovary, 10 to 15 punctures were created. This led to spontaneous ovulation in 73% of patients, with 72% conceiving within 2 years. Of those who had undergone a follow-up laparoscopy, 11 of 15 were adhesion free. To reduce adhesion formation, a technique that cauterized the ovary only in four points led to a similar pregnancy rate (100), with a miscarriage rate of 14% (much lower than the usual miscarriage rate of 30% to 40% for patients with PCOS). Most series report a decrease in both androgen and LH concentrations and an increase in FSH concentrations (101,102). Unilateral diathermy has been shown to result in bilateral ovarian activity (103). Further studies are anticipated to define candidates who may benefit most from such a procedure. The risk of adhesion formation should be discussed with the patient.

Physical Methods of Hair Removal

Depilatory creams remove hair only temporarily. They break down and dissolve hair by hydrolyzing disulfide bonds. Although depilatories can have a dramatic effect, many women cannot tolerate these irritative chemicals. The topical use of corticosteroid cream may prevent contact dermatitis. *Eflornithine hydrochloride* cream also known as *difluoromethylornithine (DMFO)*, irreversibly blocks ornithine decarboxylase (ODC), the enzyme in hair follicles that is important in regulating hair growth. It also has proved effective in the treatment of unwanted facial hair (104).

Shaving is effective. Contrary to common belief, it does not change the quality, quantity, or texture of hair (105). However, plucking, if done unevenly and repeatedly, may cause inflammation and damage to hair follicles and render them less amenable to electrolysis. Waxing is a grouped method of plucking in which hairs are plucked out from under the skin surface. The results of waxing last longer (up to 6 weeks) than shaving or depilatory creams (105).

Bleaching removes the hair pigment through the use of hydrogen peroxide (usually 6% strength), which is sometimes combined with ammonia. Although hair lightens and softens during oxidation, this method is frequently associated with hair discoloration, or skin irritation, and is not always effective (104).

Electrolysis and laser hair removal are the only permanent means recommended for hair removal. Under magnification, a trained technician destroys each hair follicle individually. When a needle is inserted into a hair follicle, galvanic current, electrocautery, or both used in combination (blend) destroy the hair follicle. After the needle is removed, a forceps is used to remove the hair. Hair regrowth ranges from 15% to 50%. Problems with electrolysis include pain, scarring, and pigmentation. Cost can also be an obstacle (106). Laser hair removal destroys the hair follicle through photoablation.

Insulin Sensitizers

Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.

Metformin (Glucophage) is an oral biguanide antihyperglycemic drug used extensively in Europe for non-insulin-dependent diabetes. Given its category B status, there has been limited use of the drug in pregnant women with diabetes. Preliminary studies evaluating *metformin* use in pregnancy suggest no teratogenicity and a reduced miscarriage rate but a potential increased risk of preeclampsia and perinatal mortality (107,108).

Metformin lowers blood glucose mainly by inhibiting hepatic glucose production and by enhancing peripheral glucose uptake. *Metformin* enhances insulin sensitivity at the postreceptor level and stimulates insulin-mediated glucose disposal (109).

The hyperandrogenism of PCOS is substantially relieved with metformin therapy, which leads to a drop in insulin levels and improved reproductive function (110,111 and 112). *Metformin* (500 mg 3 times daily) increases ovulation rates both spontaneously and when used in combination with *clomiphene citrate* in obese patients with PCOS. In this group, a 90% ovulation rate has been achieved (113).

The most common side effects are gastrointestinal, including nausea, vomiting, diarrhea, bloating, and flatulence. Because the drug has caused fatal lactic acidosis in men with diabetes who have renal insufficiency, baseline renal function testing is suggested. The drug should not be given to women with elevated serum creatinine levels (109).

Troglitazone, another insulin sensitizer, has been reported to enhance the number of ovulatory cycles when used alone or with *clomiphene citrate* (114). The drug has been withdrawn from the market because of liver toxicity and other adverse effects.

A step-by-step approach to ovulation induction in women with PCOS has been suggested (109). This algorithm offers a practical way to integrate insulin sensitizers and ovulation induction in the treatment of PCOS. This regimen may need to be modified as knowledge of the disorder and its treatment continues to evolve. The step approach is: If body-mass index is elevated, loss of at least 5% of current body weight,

Ovulation induction with *clomiphene* (with or without glucocorticoid if DHEAS is elevated), Insulin sensitizer as a single agent, Insulin sensitizer in combination with *clomiphene citrate*, Gonadotropin therapy, Insulin sensitizer in combination with gonadotropin therapy, Ovarian surgery, and *In vitro* fertilization (IVF).

Current concepts regarding the role of obesity and insulin resistance/hyperinsulinemia in PCOS suggest that the primary intervention should be to recommend and assist with weight loss (5–10% of body weight). In those with an elevated BMI, *orlistat* has proven to be helpful in initiating and maintaining weight loss. A percentage of PCOS patients will respond to weight loss with spontaneous ovulation. In those who do not respond to weight loss alone or who are unable to lose weight, the sequential addition of *clomiphene citrate* followed by an insulin sensitizer alone, followed by the combination of these agents may promote ovulation without the need to proceed to injectable gonadotropins.

A prevailing concern over the increased incidence of spontaneous abortions in women with PCOS and the potential reduction afforded by insulin sensitizers suggest that insulin sensitizers may be beneficial in combination with gonadotropin therapy for ovulation induction or *in vitro* fertilization (115).

Cushing's Syndrome

The adrenal cortex produces three classes of steroid hormones—glucocorticoids, mineralocorticoids, and sex steroids (androgen and estrogen precursors). Hyperfunction of the adrenal gland can produce clinical signs of increased activity of any or all of these hormones. Increased glucocorticoid action results in nitrogen wasting and a catabolic state. This causes muscle weakness, osteoporosis, atrophy of the skin with striae, nonhealing ulcerations and ecchymoses, reduced immune resistance that increases the risk of bacterial and fungal infections, and glucose intolerance resulting from enhanced gluconeogenesis and antagonism to insulin action.

Although most patients with Cushing's syndrome gain weight, some lose it. Obesity is typically central, with characteristic redistribution of fat over the clavicles around the neck and on the trunk, abdomen, and cheeks. Cortisol excess may lead to insomnia, mood disturbances, depression, and even overt psychosis. With overproduction of sex steroid precursors, women may develop some degree of masculinization (hirsutism, acne, oligomenorrhea or amenorrhea, thinning of scalp hair), and men may manifest some degree of feminization (gynecomastia and impotence). With overproduction of mineralocorticoids, patients may manifest arterial hypertension and hypokalemic alkalosis. The associated fluid retention may cause pedal edema.

The characteristic laboratory findings associated with hypercortisolism are confined mainly to a complete blood count showing evidence of granulocytosis and reduced levels of lymphocytes and eosinophils. Increased urinary calcium secretion may be present.

Causes

The six recognized noniatrogenic causes of Cushing's syndrome can be either ACTH dependent or ACTH independent (Table 25.3). The ACTH-dependent causes can result from ACTH secreted by pituitary adenomas or from an ectopic source. The hallmark of ACTH-dependent forms of Cushing's syndrome is

the presence of normal or high plasma ACTH concentrations with increased cortisol levels. The adrenal glands are hyperplastic bilaterally. Pituitary ACTH-secreting adenoma, or Cushing's disease, is the most common cause of Cushing's syndrome. These pituitary adenomas are usually microadenomas (<10 mm in diameter) that may be as small as 1 mm. They behave as if they are resistant, to a variable degree, to the feedback effect of cortisol. Like the normal gland, these tumors secrete ACTH in a pulsatile fashion; unlike the normal gland, the diurnal pattern of cortisol secretion is lost. Ectopic ACTH syndrome most often is caused by malignant tumors. About one-half of these tumors are small-cell carcinomas of the lung (116). Other tumors include bronchial and thymic carcinomas, carcinoid tumors of the pancreas, and medullary carcinoma of the thyroid.

Category	Case	Relative incidence
ACTH-dependent	Cushing's syndrome	60%*
	Ectopic ACTH-secreting tumors	15%
	Ectopic CRH-secreting tumors	Rare
ACTH-independent	Adrenal cancer	15%
	Adrenal adenoma	10%
	Micronodular adrenal hyperplasia	Rare
	Isogenous/familial	Common

ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.
 *ACTH-dependent Cushing's syndrome may be caused by pituitary adenoma, isogenous hyperplasia, nodular adrenal hyperplasia, or cyclic Cushing's syndrome.

Table 25.3 Causes of Cushing's Syndrome

Ectopic corticotropin-releasing hormone (CRH) tumors are rare and include such tumors as bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic carcinoma (116). The presence of an ectopic CRH-secreting tumor should be suspected in patients who react biochemically similar to those with pituitary ACTH-dependent disease but who have rapid disease progression and very high plasma ACTH levels.

The most common cause of ACTH-independent Cushing's syndrome is exogenous or iatrogenic (i.e., superphysiologic therapy with corticosteroids) or factitious (self-induced). Corticosteroids are used in pharmacologic quantities to treat a variety of diseases with an inflammatory component. Over time, this practice will result in Cushing's syndrome. When corticosteroids are taken by the patient but not prescribed by a physician, the diagnosis may be especially challenging. The diagnostic workup for Cushing's syndrome is summarized in Fig. 25.2 and Table 25.4 and Table 25.5 (117,118 and 119).

Figure 25.2 The workup of Cushing's syndrome.

Category	Case	Relative incidence
ACTH-dependent	Cushing's syndrome	60%*
	Ectopic ACTH-secreting tumors	15%
	Ectopic CRH-secreting tumors	Rare
ACTH-independent	Adrenal cancer	15%
	Adrenal adenoma	10%
	Micronodular adrenal hyperplasia	Rare
	Isogenous/familial	Common

Table 25.4 Diagnostic Workup for Cushing's Syndrome

Diagnosis	24-hour Urinary Cortisol	DEX Low Dose	DEX High Dose	ACTH
ACTH-dependent				
Cushing's syndrome (60%)	Increased	Increased	Decreased	Normal
Pituitary adenoma	Increased	Increased	Decreased	Normal
Isogenous hyperplasia	Increased	Increased	Decreased	Normal
Micronodular adrenal hyperplasia	Increased	Increased	Decreased	Normal
Cyclic Cushing's syndrome	Increased	Increased	Decreased	Normal
ACTH-independent				
Adrenal neoplasia	Increased	Increased	Increased	Decreased
Adenoma (10%)	Increased	Increased	Increased	Decreased
Carcinoma (15%)	Increased	Increased	Increased	Decreased
Primary adrenocortical nodular hyperplasia (<1%)	Increased	Increased	Increased	Decreased
Pseudo Cushing's syndrome (pseudo-Cushing's, <1%)	Increased	Increased	Decreased	Normal
Exogenous glucocorticoids/factitious (self-induced)	Increased or decreased	Decreased	Decreased	Decreased

DEX, dexamethasone; ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

Table 25.5 Laboratory Diagnosis of Cushing's Syndrome

Treatment of ACTH-independent Forms of Cushing's Syndrome

Excluding cases that are of iatrogenic or factitious etiology, ACTH-independent forms of Cushing's syndrome are adrenal in origin. Adrenal cancers are usually very large by the time Cushing's syndrome is manifest. This is because the tumors are relatively inefficient in the synthesis of steroid hormones. In general, tumors are larger than 6 cm in diameter and are easily detectable by computed tomography (CT) scanning or magnetic resonance imaging (MRI). Adrenal cancers often produce steroids other than cortisol. Thus, when Cushing's syndrome is accompanied by hirsutism or virilization in women or feminization in men, adrenal cancer should be suspected.

An adrenal tumor that appears large and irregular on radiologic imaging is suggestive of carcinoma. In these cases, a unilateral adrenalectomy through an abdominal exploratory approach is preferable. In most malignant tumors, complete resection is virtually impossible. However, a partial response to postoperative chemotherapy

or radiation may be achieved. Most patients with malignancy die within 1 year. When administered immediately after surgery, mitotane (O,P-DDD, adrenocorticolytic drug) may be of benefit in preventing or delaying recurrent disease (124). Manifestations of Cushing's syndrome in these patients are controlled by adrenal enzyme inhibitors.

Adrenal adenomas are smaller than carcinomas and average 3 cm in diameter. These tumors are usually unilateral and infrequently are associated with other steroid-mediated syndromes. Micronodular adrenal disease is a disorder of children, adolescents, and young adults. The adrenal glands contain numerous small (>3 mm) nodules, which often are pigmented and secrete sufficient cortisol to suppress pituitary ACTH. This condition can be sporadic or familial.

Surgical removal of a neoplasm is the treatment of choice (127,128). If a unilateral, well-circumscribed adenoma is identified by MRI or CT scanning, the flank approach may be the most convenient. The cure rate following surgical removal of adrenal adenomas approaches 100%. Several months of corticosteroid replacement therapy usually is required.

Treatment of Cushing's Disease

The treatment of choice for Cushing's disease is transsphenoidal resection. The cure rate is approximately 80% in patients with microadenomas who undergo surgery by an experienced surgeon (120) and is less than 50% in patients with macroadenomas (121). Transient diabetes insipidus is common (122).

Radiation Therapy

High-voltage external pituitary radiation (4,200 to 4,500 cGy) is given at a rate not exceeding 200 cGy/day. Although only 15% to 25% of adults show total improvement (122), approximately 80% of children respond (123).

Medical Therapy

Mitotane can be used to induce medical adrenalectomy during or after pituitary radiation (124). The role of medical therapy is to prepare the severely ill patient for surgery and to maintain normal cortisol levels while a patient awaits the full effect of radiation. Occasionally, medical therapy is used for patients who respond to therapy with only partial remission. Adrenal enzyme inhibitors include *aminoglutethimide*, *metyrapone*, *trilostane*, and *etomidate*.

A combination of *aminoglutethimide* and *metyrapone* may cause a total adrenal enzyme block requiring corticosteroid-replacement therapy. *Ketoconazole*, an FDA-approved antifungal agent, also inhibits adrenal steroid biosynthesis at the side arm cleavage and 11 β -hydroxylation steps. The dose of *ketoconazole* for adrenal suppression is 600 to 800 mg/day for 3 months to 1 year (125). *Ketoconazole* is effective for long-term control of hypercortisolism of either pituitary or adrenal origin.

Nelson's syndrome is an ACTH-secreting pituitary adenoma that develops after bilateral adrenalectomy for Cushing's disease (126). This syndrome reportedly complicates 10% to 50% of bilateral adrenalectomy cases. Nelson's syndrome is less common today because bilateral adrenalectomy is less frequently used as initial treatment. Present medical management produces such an effective block to steroid overproduction that it is used primarily as well as after the failure of surgical and radiation therapy. This syndrome is usually caused by a macroadenoma that produces sellar pressure symptoms of headaches, visual field disturbances, and ophthalmoplegia. Extremely high ACTH levels are associated with severe hyperpigmentation (melanocyte-stimulating hormone activity). The treatment is surgical removal or radiation.

Congenital Adrenal Hyperplasia

CAH is transmitted as an autosomal recessive disorder. Several adrenocortical enzymes necessary for cortisol biosynthesis may be affected. Failure to synthesize the fully functional enzyme has the following effects:

1. A relative decrease in cortisol production
2. A compensatory increase in ACTH levels
3. Hyperplasia of the zona reticularis of the adrenal cortex
4. An accumulation of the precursors of the affected enzyme in the bloodstream.

21-Hydroxylase Deficiency

Deficiency of 21-hydroxylase is responsible for over 90% of all cases of CAH. The disorder produces a spectrum of conditions. Salt-wasting CAH, which is the most severe form, affects 75% of patients in whom, during the first 2 weeks of life, a hypovolemic salt-wasting crisis is manifest, accompanied by hyponatremia, hyperkalemia, and acidosis. The salt-wasting crisis results from ineffective aldosterone synthesis. The condition is usually diagnosed earlier in affected women than in men because it causes genital virilization (e.g., clitoromegaly, labioscrotal fusion, and abnormal urethral course).

In simple virilizing CAH, affected patients are diagnosed as virilized newborn females or as rapidly growing masculinized boys at 3 to 7 years of age.

1. Basal follicular phase 17-OHP <200 ng/dl virtually excludes the disorder; no further testing is required.
2. Basal 17-OHP >500 ng/dl establishes the diagnosis; there is no need for further testing (125).
3. Basal 17-OHP >200 ng/dl and <500 ng/dl requires ACTH stimulation testing.
4. In the ACTH stimulation test, plasma levels of 17-OHP are checked 1 hour following intravenous administration of a bolus of 0.25 mg ACTH 1-24 (*cosyntropin* [Cortrosyn]) (Fig. 25.3). 17-OHP levels after ACTH stimulation in adult-onset adrenal hyperplasia are generally >1,000 ng/dl (129) (Fig. 25.3).

Figure 25.3 Basal and stimulated 17-hydroxyprogesterone concentration.

5. Individuals who are heterozygous (carriers) for both adult-onset adrenal hyperplasia and CAH reveal stimulated 17-OHP values <1,000 ng/dl. In many cases, an overlap with the values seen in the normal population is observed (130) (Fig. 25.3).

Nonclassic Congenital Adrenal Hyperplasia

The nonclassic type 21-hydroxylase deficiency represents partial deficiency in 21-hydroxylation, which produces a late-onset, milder hyperandrogenemia. Some women with a mild gene defect demonstrate elevated circulating 17-OHP concentrations but no clinical symptoms or signs.

The hyperandrogenic symptoms of adult-onset CAH are mild and typically present at or after puberty. Following are the three phenotypic varieties ([129](#)):

1. PCOS (39%)
2. Hirsutism alone without oligomenorrhea (39%)
3. Cryptic (22%) (hyperandrogenism but no hyperandrogenic symptoms).

The need for screening patients with hirsutism for adult-onset adrenal hyperplasia depends on the patient population. The disease frequency is estimated to occur in 0.1% of the general population, 1% to 2% of Hispanics and Yugoslavs, and 3% to 4% of Ashkenazi Jews ([131](#)).

Genetics of 21-Hydroxylase Deficiency

1. The 21-hydroxylase gene is located on the short arm of chromosome 6, in the midst of the HLA region.
2. The 21-hydroxylase gene is now termed *CYP21*. Its homologue is the pseudogene *CYP21P* ([132](#)).
3. Because *CYP21P* is a pseudogene, the lack of transcription renders it nonfunctional. The *CYP21* is the active gene.
4. The *CYP21* gene and the *CYP21P* pseudogene alternate with two genes called *C4B* and *C4A*, both of which encode for the fourth component (C4) of serum complement ([132](#)).
5. The close linkage between the 21-hydroxylase genes and HLA alleles has allowed the study of 21-hydroxylase inheritance patterns in families through blood HLA typing (e.g., linkage of HLA-B14 was found in Ashkenazi Jews, Hispanics, and Italians) ([133](#)).

Prenatal Diagnosis and Treatment

In families at risk for CAH, first-trimester prenatal screening is advocated ([132](#)). Currently, the fetal DNA is used for specific amplification of the *CYP21* gene using polymerase chain reaction (PCR) amplification ([134](#)). An aggressive and still controversial approach involves the use of *dexamethasone* treatment for all pregnant women at risk of having a child with CAH. The dosage is 20 mg/kg in three divided doses administered as soon as pregnancy is recognized and no later than 9 weeks of gestation. This is done prior to performing chorionic villus sampling or amniocentesis in the second trimester. *Dexamethasone* crosses the placenta and suppresses ACTH in the fetus. If the fetus is determined to be an unaffected female or a male, treatment is discontinued. If the fetus is an affected female, dexamethasone therapy is continued. When *dexamethasone* is administered before 9 weeks of gestation and is continued to term, it effectively reduces genital ambiguity in genetic females ([132](#)). However, at least two-thirds of treated females still require surgical repair of the genitalia. Although prenatal treatment reduces virilization in females, the efficacy and safety to both mother and baby have not been verified. The unnecessary treatment in seven out of every eight pregnancies poses a serious ethical dilemma ([135](#)).

11b-Hydroxylase Deficiency

In a small percentage of patients with CAH, hypertension rather than mineralocorticoid deficiency develops. The hypertension responds to corticosteroid replacement ([136](#)). Most of these patients have a deficiency in 11b-hydroxylase. In most populations, 11b-hydroxylase deficiency accounts for 5% to 8% of the cases of CAH, or 1 in 100,000 births ([137](#)). A much higher incidence, 1 in 5,000 to 7,000, has been described in Moroccan Jewish immigrants ([138](#)).

Two 11b-hydroxylase isoenzymes are responsible for cortisol and aldosterone synthesis, respectively, CYP11-B1 and CYP11-B2. They are encoded by two genes on the middle of the long arm of chromosome 8 ([139,140](#)). No HLA linkage has been identified.

Inability to synthesize a fully functional 11b-hydroxylase enzyme causes a decrease in cortisol production, a compensatory increase in ACTH secretion, and increased production of 11-deoxycortisol, 11-deoxycorticosterone, DHEA, and androstenedione. The diagnosis of 11b-hydroxylase-deficient late-onset adrenal hyperplasia is determined when 11-deoxycortisol levels are higher than 25 ng/ml 60 minutes after ACTH 1-24 stimulation ([141](#)).

Patients with 11b-hydroxylase deficiency may present with either a classic pattern of the disorder or symptoms of a mild deficiency. The severe, classic form occurs in about two-thirds of the patients with mild-to-moderate hypertension during the first years of life. In about one-third of the patients it is associated with left ventricular hypertrophy, with or without retinopathy, and death is occasionally reported from cerebrovascular accident ([136](#)). Signs of androgen excess are common in the severe form and are similar to those seen in the 21-hydroxylase deficiency.

In the mild, nonclassic form, children are found to have virilization or precocious puberty but not hypertension. Adult women will seek treatment for postpubertal onset of hirsutism, acne, and amenorrhea.

3b-Hydroxysteroid Dehydrogenase Deficiency

Deficiency of 3b-hydroxysteroid dehydrogenase occurs with varying frequency in hirsute patients ([142,143](#)). The enzyme is found in both the adrenal glands and ovaries (unlike 21- and 11-hydroxylase) and is responsible for transforming D-5 steroids into the corresponding D-4 compounds. The diagnosis of this disorder relies on the relationship of D-5 and D-4 steroids. A marked elevation of DHEA and DHEAS in the presence of normal or mildly elevated testosterone or androstenedione may be a signal to initiate a screening protocol for 3b-hydroxysteroid dehydrogenase deficiency using exogenous ACTH stimulation ([142](#)). Following intravenous administration of a 0.25-mg ACTH 1-24 bolus, 17-hydroxypregnenolone levels rise significantly within 60 minutes in women with 3b-hydroxysteroid dehydrogenase deficiency compared with normal women (2,276 ng/dl compared with normal of 1,050 ng/dl). The mean poststimulation ratio between 17-hydroxypregnenolone and 17-OHP was markedly elevated (mean ratio of 11 compared with 3.4 in normal controls and 0.4 in 21-hydroxylase deficiency). Because of the rarity of this disorder, routine screening of hyperandrogenic patients is not justified ([142,143](#)).

Treatment of Adult-onset Congenital Adrenal Hyperplasia

In adults with CAH, *dexamethasone* has been shown to suppress the hypothalamic-pituitary axis better than cortisone acetate or hydrocortisone administered in equivalent doses and to possibly induce less fluid retention than other corticosteroids. Evening administration with a dosage of 0.25 to 0.5 mg is most effective ([144](#)). In some patients, alternate-day therapy using the same dosage is sufficient. Periodic evaluation of serum cortisol is recommended. If morning serum cortisol concentrations are maintained at greater than 2 µg/dl, oversuppression is unlikely ([145](#)).

Androgen-secreting Ovarian and Adrenal Tumors:

Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. In prepubertal girls, virilizing tumors may cause signs of heterosexual precocious puberty in addition to hirsutism, acne, and virilization. A markedly elevated total testosterone level (2.5 times the upper normal range or over 200 ng/dl) is typical of an ovarian androgen-secreting tumor, and a DHEAS level greater than 800 µg/dl is typical of an adrenal tumor. An adrenal tumor is unlikely when serum DHEAS and urinary 17-ketosteroid excretion measurements are in the normal basal range and the serum cortisol concentration is greater than 3.3 µg/dl after dexamethasone administration ([146](#)). The results of other dynamic tests, especially testosterone suppression and stimulation, are unreliable ([147](#)).

A vaginal and abdominal ultrasonographic examination is the first step in the evaluation of an ovarian neoplasm. Duplex Doppler scanning may increase the accuracy of tumor localization ([148](#)).

CT scanning can reveal tumors larger than 10 mm (1 cm) in the adrenal gland but may not help to distinguish among different types of solid tumors ([149](#)). In the ovaries, CT scanning cannot help differentiate hormonally active from functional tumors ([148,149](#)).

MRI is comparable, if not superior, to CT scanning in detecting ovarian neoplasms. When CT and selective venous catheterization fail, nuclear medicine scanning of the abdomen and pelvis after injection with NP-59 ((¹³¹-iodine) 6-beta-iodomethyl-19-norcholesterol), preceded by adrenal and thyroid suppression, may facilitate

tumor localization ([150](#)).

If all four vessels are catheterized transfemorally, selective venous catheterization allows direct localization of the tumor. Samples are obtained for hormonal analysis, with positive localization defined as a 5:1 testosterone gradient compared with lower vena cava values ([151](#)). Under such circumstances specificity approaches 80%, but this rate should be weighed against the 5% rate of significant complications such as adrenal hemorrhage and infarction, venous thrombosis, hematoma, and radiation exposure ([152](#)).

Androgen-producing Ovarian Neoplasms

Ovarian neoplasms are the most frequent androgen-producing tumors. *Granulosa cell tumors* constitute 1% to 2% of all ovarian tumors and occur mostly in adult women (in postmenopausal more frequently than in premenopausal women) (see [Chapter 32](#)). Usually associated with estrogen production, they are the most common functioning tumors in children and lead to isosexual precocious puberty ([153](#)). Total abdominal hysterectomy and bilateral salpingo-oophorectomy are the treatments of choice. If fertility is desired, in the absence of contralateral or pelvic involvement, unilateral salpingo-oophorectomy is justifiable. The 10-year survival rates vary from 60% to 90%, depending on the stage, tumor size, and histologic atypia ([153](#)).

Thecomas are rare and occur in older patients ([153](#)). In one study only 11% were found to be androgenic, even in the presence of steroid-type cells (luteinized thecomas) ([154](#)). The tumor is rarely malignant and rarely bilateral, and a simple oophorectomy is sufficient treatment.

Sclerosing stromal tumors are benign neoplasms that usually occur in patients younger than 30 years ([153](#)). A few cases with estrogenic or androgenic manifestations have been reported.

Sertoli-Leydig cell tumors, previously classified as androblastoma or arrhenoblastoma, account for 11% of solid ovarian tumors. They contain various proportions of Sertoli cells, Leydig cells, and fibroblasts ([153](#)). Sertoli-Leydig cell tumors are the most common virilizing tumors in women of reproductive age; however, masculinization occurs in only one-third of patients. The tumor is bilateral in 1.5%. In 80% of cases, it is diagnosed at stage IA ([153](#)). Treatment with unilateral salpingo-oophorectomy is justified in patients with stage IA disease who desire fertility. Total abdominal hysterectomy, bilateral salpingo-oophorectomy, and adjuvant therapy are recommended for postmenopausal women who have advanced-stage disease.

Pure Sertoli cell tumors are usually unilateral. For a premenopausal woman with stage I disease, a unilateral salpingo-oophorectomy is the treatment of choice. Malignant tumors are rapidly fatal ([155](#)).

Gynandroblastomas are benign tumors with well-differentiated ovarian and testicular elements. A unilateral oophorectomy or salpingo-oophorectomy is sufficient treatment.

Sex cord tumors with annular tubules (SCTAT) are frequently associated with Peutz-Jeghers syndrome (gastrointestinal polyposis and mucocutaneous melanin pigmentation) ([156](#)). Their morphologic features range between those of the granulosa cell and Sertoli cell tumors.

Whereas SCTAT with Peutz-Jeghers syndrome tend to be bilateral and benign, SCTAT without Peutz-Jeghers syndrome are almost always unilateral and are malignant in one-fifth of cases ([153](#)).

Steroid Cell Tumors

According to Young and Scully, steroid cell tumors are composed entirely of steroid-secreting cells subclassified into stromal luteoma, Leydig cell tumors (hilar and nonhilar), and steroid cell tumors that are not otherwise specific ([153](#)). Virilization or hirsutism is encountered with three-fourths of Leydig cell tumors, with one-half of steroid cell tumors that are not otherwise specific, and with 12% of stromal luteomas.

Nonfunctioning Ovarian Tumors

Ovarian neoplasms, which are usually non-steroid-producing, are occasionally associated with androgen excess and include serous and mucinous cystadenomas, Brenner tumors, Krukenberg tumors, benign cystic teratomas, and dysgerminomas ([157](#)). Gonadoblastomas arising in the dysgenetic gonads of patients with a Y chromosome are associated with androgen and estrogen secretion ([158,159](#)).

Stromal Hyperplasia and Stromal Hyperthecosis

Stromal hyperplasia is a nonneoplastic proliferation of ovarian stromal cells. Stromal hyperthecosis is defined as the presence of luteinized stromal cells at a distance from the follicles ([160](#)). Stromal hyperplasia, which is typically seen in patients between 60 and 80 years of age, may be associated with hyperandrogenism, endometrial carcinoma, obesity, hypertension, and glucose intolerance ([160](#)). *Hyperthecosis* also is seen in a mild form in older patients. In patients of reproductive age, hyperthecosis may demonstrate severe clinical manifestations of virilization, obesity, and hypertension. Hyperinsulinemia and glucose intolerance may occur in up to 90% of patients with hyperthecosis and probably play a role in the etiology of stromal luteinization and hyperandrogenism ([161](#)). Hyperthecosis is found in many patients with hyperandrogenemia, insulin resistance, and acanthosis nigricans (HAIR-AN syndrome).

In patients with hyperthecosis, levels of ovarian androgens, including testosterone, DHT, and androstenedione are increased, usually in the male range. The predominant estrogen, as in PCOS, is estrone, which is derived from peripheral aromatization. The E₁-to-E₂ ratio is increased. Unlike in PCOS, gonadotropin levels are normal ([162](#)).

Wedge resection for the treatment of mild hyperthecosis has been successful and has resulted in resumption of ovulation and even in a pregnancy ([163](#)). However, in cases of more severe hyperthecosis and high free testosterone levels (1 to 3 ng/dl), the ovulatory response to wedge resection is only transient ([162](#)). In a study in which bilateral oophorectomy was used to control severe virilization, hypertension and glucose intolerance sometimes disappeared ([164](#)). Moreover, when a GnRH agonist was used to treat patients with severe hyperthecosis, ovarian androgen production was dramatically suppressed ([165](#)).

Virilization During Pregnancy

Luteomas of pregnancy are frequently associated with maternal and fetal masculinization. This is not a true neoplasm but rather a reversible hyperplasia, which usually regresses postpartum. A review of the literature reveals a 30% incidence of maternal virilization and a 65% incidence of virilized females in the presence of a pregnancy luteoma and maternal masculinization ([166](#)).

Other tumors causing virilization in pregnancy include (in descending order of frequency) Krukenberg tumors, mucinous cystic tumors, Brenner tumors, serous cystadenomas, endodermal sinus tumors, and dermoid cysts. Five cases of virilization of a female child have been reported ([153](#)).

Virilizing Adrenal Neoplasms

High testosterone levels (in the tumor range), accompanied by normal or only moderately elevated DHEAS levels, should not divert attention from the adrenal gland to the ovary. In fact, patients with these adenomas manifest increased testosterone production following stimulation with human chorionic gonadotropin (hCG) or LH and decreased testosterone secretion following LH suppression.

Of the fewer than 100 reported cases of pure virilizing adrenal neoplasms, 90% were benign. Although the peak age for the diagnosis of adenomas was 20 to 40 years, most of the pure testosterone-producing tumors occurred in menopausal women. With one exception, all cases of adenomas and carcinomas were unilateral.

Fifty percent were palpable abdominally in children; in adults, none was detected solely by physical examination ([167](#)).

Prolactin Disorders

Prolactin was first identified as a product of the anterior pituitary in 1933 ([168](#)). Since that time, it has been found in nearly every vertebrate species. The specific activities of human prolactin (hPRL) have been further defined by the separation of its activity from growth hormone ([169](#)) and subsequently by the development of radioimmunoassays ([170,171](#) and [172](#)). Although the initiation and maintenance of lactation is the primary function of prolactin, many studies have documented a significant role for prolactin activity both within and beyond the reproductive system.

Prolactin Secretion

There are 199 amino acids within human prolactin, with a molecular weight (MW) of 23,000 daltons ([Fig. 25.4](#)). Although human growth hormone and placental lactogen have significant lactogenic activity, they have only a 16% and 13% amino acid sequence homology with prolactin, respectively.

Figure 25.4 Amino acid sequence of prolactin. Three cysteine disulfide bands are located within the molecule. (From **Bondy PK. Rosenberg leukocyte esterase: metabolic control and disease**, 8th ed. Philadelphia: WB Saunders, 1980, with permission.)

In the basal state three forms are released, a monomer, a dimer, and a multimeric species, called *little, big, and big-big prolactin*, respectively ([173,174](#) and [175](#)). The two larger species can be degraded to the monomeric form by reducing disulfide bonds ([176](#)). The proportions of each of these prolactin species vary with physiologic, pathologic, and hormonal stimulation ([176,177,178](#) and [179](#)). The heterogeneity of secreted forms remains an active area of research. Overall, studies thus far indicate that little prolactin (MW 23,000 daltons) constitutes more than 50% of all combined prolactin production and is most responsive to extrapituitary stimulation or suppression ([175,178,179](#)). The bioactivity and immunoreactivity of little prolactin is influenced by glycosylation ([180,181,182](#) and [183](#)). It appears that the glycosylated form is the predominant species secreted, but the most potent biologic form appears to be the 23,000-dalton nonglycosylated form of prolactin ([182](#)). To some degree, the physical heterogeneity of prolactin may explain the biologic heterogeneity of this hormone, but it further complicates the physiologic evaluation of prolactin's myriad effects.

In contrast to other anterior pituitary hormones, which are controlled by hypothalamic-releasing factors, prolactin secretion is primarily under inhibitory control mediated by dopamine. **Multiple lines of evidence suggest that dopamine, which is secreted by the tuberoinfundibular dopaminergic neurons into the portal hypophyseal vessels, is the primary prolactin-inhibiting factor.** Dopamine receptors have been found on pituitary lactotrophs ([184](#)), and treatment with dopamine or dopamine agonists suppresses prolactin secretion ([185,186,187,188,189](#) and [190](#)). The dopamine antagonist metaclopramide abolishes the pulsatility of prolactin release and increases serum prolactin levels ([186,187,191](#)). Interference with dopamine release from the hypothalamus to the pituitary routinely increases serum prolactin levels. γ -Aminobutyric acid (GABA) and other neuropeptides also may function as prolactin-inhibiting factors ([Table 25.6](#)) ([192,193,194](#) and [195](#)). Several hypothalamic polypeptides that increase prolactin-releasing activity are listed in [Table 25.6](#).

Table 25.6 Chemical Factors Modulating Prolactin Release and Conditions That Result in Hyperprolactinemia

Hyperprolactinemia

Physiologic alterations or conditions may result in transient as well as persistent elevations in prolactin levels. Drug-related and physiologic conditions resulting in hyperprolactinemia do not always require intervention.

Evaluation

Plasma levels of immunoreactive prolactin are 5 to 27 ng/ml throughout the normal menstrual cycle. Samples should not be drawn soon after the patient awakes or after procedures. Prolactin is secreted in a pulsatile fashion with a pulse frequency ranging from about 14 pulses per 24 hours in the late follicular phase to about nine pulses per 24 hours in the late luteal phase. There also is a diurnal variation, with the lowest levels occurring in midmorning. Levels rise 1 hour after the onset of sleep and continue to rise until peak values are reached between 5:00 and 7:00 AM ([196,197](#)). The pulse amplitude of prolactin appears to increase from early to late follicular and luteal phases ([198,199](#) and [200](#)). Because of the variability of secretion and inherent limitations of radioimmunoassay, an elevated level should always be rechecked. This sample preferably is drawn midmorning and not after stress, previous venipuncture, breast stimulation, or physical examination, which increase prolactin levels.

Prolactin and TSH determinations are basic evaluations in infertile women. Infertile men with hypogonadism also should be tested. Likewise, prolactin levels should be measured in the evaluation of amenorrhea, galactorrhea, amenorrhea with galactorrhea, hirsutism with amenorrhea, anovulatory bleeding, and delayed puberty ([Fig. 25.5](#)).

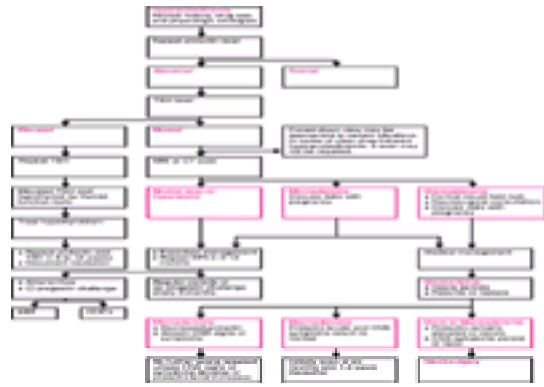

Figure 25.5 Workup for hyperprolactinemia.

Physical Signs

Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women ([201,202](#) and [203](#)). The cessation of normal ovulatory processes attributed to elevated prolactin levels may be related to the following gonadal and hypothalamic-pituitary effects: reduction in granulosa cell number and FSH binding ([204](#)), inhibition of granulosa cell 17 β -estradiol production by interfering with FSH action ([204,205](#) and [206](#)), inadequate luteinization and reduced progesterone ([207,208](#) and [209](#)), and the suppressive effects of prolactin on GnRH pulsatile release, which may mediate most of the anovulatory effects ([210,211,212,213,214,215,216,217,218,219,220,221](#) and [222](#)).

Although isolated galactorrhea commonly is considered indicative of hyperprolactinemia, prolactin levels are within the normal range in nearly 50% of such patients ([223,224](#) and [225](#)) ([Fig. 25.5](#)). In these cases, an earlier transient episode of hyperprolactinemia may have existed, that triggered galactorrhea. This situation is very similar to nursing mothers in whom milk secretion, once established, continues despite normal prolactin levels. Repeat testing is occasionally helpful in detecting hyperprolactinemia. Approximately one-third of women with galactorrhea have normal menses. Conversely, hyperprolactinemia commonly occurs in the absence of galactorrhea (66%), which may result from inadequate estrogenic or progestational priming of the breast.

In patients with both galactorrhea and amenorrhea (including the syndromes described and named by Forbes, Henneman, Griswold, and Albright in 1951, Argonz and del Castilla in 1953, and Chiari and Frommel in 1985), **approximately two-thirds will have hyperprolactinemia; in that group, approximately one-third will have a pituitary adenoma** ([226](#)). In anovulatory women, 3% to 10% of women diagnosed with polycystic ovary disease have hyperprolactinemia ([227,228](#)) ([Fig. 25.6](#)).

Figure 25.6 Prolactin levels in 235 patients with galactorrhea. Among patients with a tumor, open triangles denote associated acromegaly, and solid circles and solid triangles denote previous radiotherapy or surgical resection, respectively. (From **Kleinberg DL, Noel GL, Frantz AG**. Galactorrhea: a study of 235 cases, including 48 with pituitary tumors. *N Engl J Med* 1977;296:589–600.)

In all cases of delayed puberty, pituitary abnormalities, including craniopharyngiomas and adenomas, must be considered. Additionally, the multiple endocrine neoplasia type 1 syndrome should be considered, particularly in patients with a family history of multiple adenomas ([229](#)). Prolactinomas are noted in approximately 20% of patients with multiple endocrine neoplasia type 1 (MEN-1). The *MEN-1* gene is localized to chromosome 11q13 and appears to act as a constitutive tumor suppressor gene. An inactivating mutation results in development of the tumor. It is thought that prolactinomas that occur in patients with MEN-1 may be more aggressive than sporadic prolactinomas ([230](#)). Prolactin and TSH levels should be measured in all patients with delayed puberty.

Once an elevated prolactin level is documented, knowledge of neuroanatomy as well as imaging techniques and their interpretation is essential to further management (see [Chapter 7](#)). Patients can be reassured that hyperprolactinemia usually is associated with a relatively benign condition (pituitary microadenoma or release of pituitary stem cell growth inhibition through activation or loss of function mutations in the pituitary lactotroph) that requires only periodic monitoring. However, it is critical for the physician to exercise vigilance and to consider other potential etiologies, particularly sellar and suprasellar tumors. Levels of TSH should be measured in all cases of hyperprolactinemia ([Fig. 25.5](#))

Imaging Techniques

In patients with larger microadenomas and macroadenomas prolactin levels usually are higher than 100 ng/ml. However, levels lower than 100 ng/ml may be associated with smaller microadenomas and other suprasellar tumors that may be easily missed on a “coned-down” view of the sella turcica. In patients with a clearly identifiable drug-induced or physiologic hyperprolactinemia, scanning may not be necessary. MRI imaging of the sella and pituitary gland with gadolinium enhancement appears to provide the best anatomic detail ([231](#)) ([Fig. 25.7](#)). The cumulative radiation dose from multiple CT scans may cause cataracts, and the “coned-down” views or tomograms of the sella are very insensitive and likewise expose the patient to radiation. Even modest elevations of prolactin can be associated with microadenomas or macroadenomas, nonlactotroph pituitary tumors, and other central nervous system abnormalities; thus, imaging of the pituitary gland must be considered ([Table 25.7](#)). For patients with hyperprolactinemia who desire future fertility, MRI is indicated to differentiate a pituitary microadenoma from a macroadenoma as well as to identify other potential sellar-suprasellar masses. Although rare, when pregnancy-related complications of a pituitary adenoma occur, they occur more frequently in the presence of macroadenomas ([Table 25.7](#)).

Histiocytosis	Sarcoidosis
Hypoplasia	
Hypophysitis	

Table 25.7 Sellar and Suprasellar Tumors and Conditions That May Result in Hyperprolactinemia

In over 90% of untreated women, microprolactinomas do not enlarge over a 4- to 6-year period. For that reason, the argument that medical therapy will prevent a microadenoma from growing is false. Whereas prolactin levels correlate with tumor size, both elevations and reductions in prolactin levels may occur without any change in tumor size. If during follow-up a prolactin level rises significantly or central nervous system symptoms (headache, visual changes) are noted, repeat scanning may be indicated.

Hypothalamic Disorders

Dopamine was the first of many substances demonstrated to be produced in the arcuate nucleus. Dopamine-releasing neurons innervate the external zone of the median eminence. When released into the hypophyseal portal system, dopamine inhibits prolactin release in the anterior pituitary. Lesions that disrupt dopamine release can result in hyperprolactinemia. Such lesions may arise from the suprasellar area, pituitary gland, and infundibular stalk, as well as from adjacent bone, brain, cranial nerves, dura, leptomeninges, nasopharynx, and vessels. Numerous pathologic entities and physiologic conditions in the hypothalamic-pituitary region can disrupt dopamine release and cause hyperprolactinemia ([Table 25.7](#)).

Pituitary Disorders

Microadenoma

In over one-third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma is found. Release of pituitary stem cell growth inhibition via activation or loss-of-function mutations results in cell cycle dysregulation and is critical to the development of pituitary microadenomas and macroadenomas. Microadenomas (<1 cm) are monoclonal in origin. Genetic mutations are thought to release stem cell growth inhibition and result in autonomous anterior pituitary hormone production, secretion, and cell proliferation. Additional anatomic factors that may contribute to adenoma formation include reduced dopamine concentrations in the hypophyseal portal system and vascular isolation of the tumor or both. Recently, the heparin-binding secretory transforming (*HST*) gene has been noted in a variety of cancers as well as in prolactinomas ([232](#)). Patients with microadenomas (<1 cm) can generally be reassured of a benign course ([233,234](#)).

Both microadenomas and macroadenomas (>1 cm) are monoclonal in origin. Pituitary prolactinomas or lactotrope adenomas are sparsely or densely granulated histologically. The sparsely granulated lactotrope adenomas have trabecular, papillary, or solid patterns. Calcification of these tumors may take the form of a psammoma body or a pituitary stone. Densely granulated lactotrope adenomas are strongly acidophilic tumors and appear to be more aggressive than sparsely granulated lactotrope adenomas. Unusual acidophil stem cell adenomas can be associated with hyperprolactinemia with some clinical or biochemical evidence of growth hormone excess.

Microadenomas rarely progress to macroadenomas. Six large series of patients with microadenomas reveal that, with no treatment, the risk of progression for microadenoma to a macroadenoma is only approximately 7% ([235](#)). Treatments include expectant, medical or, rarely, surgical therapy. All affected women should be advised to notify their physicians of chronic headaches, visual disturbances (particularly tunnel vision consistent with bitemporal hemianopsia), and extraocular muscle palsies. Formal visual field testing is rarely necessary.

Expectant Management In women who do not desire fertility, expectant management can be used for both microadenomas and hyperprolactinemia without an adenoma if menstrual function remains intact. Hyperprolactinemia-induced estrogen deficiency, rather than prolactin itself, is the major factor in the development of osteopenia ([236](#)). Therefore, estrogen replacement or OCs are indicated for patients with amenorrhea or irregular menses. Patients with drug-induced hyperprolactinemia can also be managed expectantly with attention to the risks of osteoporosis. In the absence of symptoms, imaging may be repeated in 12 months to assess further growth of the microadenoma.

Medical Treatment Ergot alkaloids are the mainstay of therapy. In 1985, bromocriptine was approved for use in the United States to treat hyperprolactinemia caused by a pituitary adenoma. Ergot alkaloids increase dopamine levels, thus decreasing prolactin levels. *Bromocriptine* decreases prolactin synthesis, DNA synthesis, cell multiplication, and tumor growth. Bromocriptine treatment results in normal prolactinemia or return of ovulatory menses in 80% to 90% of patients.

Because ergot alkaloids, like *bromocriptine*, are excreted via the biliary tree, caution is required using it in the presence of liver disease. The major adverse effects include nausea, headaches, hypotension, dizziness, fatigue and drowsiness, vomiting, headaches, nasal congestion, and constipation. **Many patients tolerate the drug on the following regimen: one-half tablet every evening (1.25 mg) for 1 week, one-half tablet morning and evening (1.25 mg) during the second week, one-half tablet in the morning (1.25 mg) and a full tablet every evening (2.5 mg) during the third week, and one tablet every morning and early evening during the fourth week and thereafter (2.5 mg twice a day).** The lowest dose that maintains the prolactin level in the normal range is continued. Pharmacokinetic studies show peak serum levels occur 3 hours after an oral dose with a nadir at 7 hours. There is little detectable *bromocriptine* in the serum by 11 to 14 hours. Therefore, twice-a-day administration is required. Prolactin levels can be checked soon (6 to 24 hours) after the last dose.

One rare, but notable, adverse effect of *bromocriptine* is a psychotic reaction. Symptoms include auditory hallucinations, delusional ideas, and changes in mood that quickly resolve after discontinuation of the drug ([237](#)).

Many investigators report no difference in fibrosis, calcification, prolactin immunoreactivity, or the surgical success in patients pretreated with *bromocriptine* compared to those not receiving *bromocriptine* ([238](#)).

An alternative to oral administration is the vaginal administration of *bromocriptine* tablets, which is well tolerated ([239](#)). *Cabergoline*, another ergot alkaloid, has a very long half-life and can be given orally once per week. Its long duration of action is attributable to slow elimination by pituitary tumor tissue, high affinity binding to pituitary dopamine receptors, and extensive enterohepatic recirculation.

Cabergoline, which appears to be as effective as *bromocriptine* in lowering prolactin levels and in reducing tumor size, has substantially fewer adverse effects than bromocriptine. Very rarely, patients experience nausea and vomiting with cabergoline; they may be treated with intravaginal *cabergoline* just as with *bromocriptine*. Although *cabergoline* appears to be safe to use during pregnancy, more extensive data regarding the use of *bromocriptine* in pregnancy is available; therefore

bromocriptine is preferred for pregnant patients.

When *bromocriptine* or *cabergoline* cannot be used, other medications such as *pergolide* or *methergoline* may be used. In patients with a microadenoma who are receiving *bromocriptine* therapy, a repeat MRI scan may be performed 6 to 12 months after prolactin levels are normal. Normal prolactin levels and resumption of menses should not be considered absolute proof of tumor response to treatment. Further MRI scans should be performed if new symptoms appear.

Discontinuation of *bromocriptine* therapy after 2 to 3 years may be attempted because some adenomas undergo hemorrhagic necrosis and cease to function.

Macroadenomas

Macroadenomas are pituitary tumors that are larger than 1 cm in size. *Bromocriptine* is the best initial and potentially long-term treatment option, but transsphenoidal surgery may be required. Evaluation for pituitary hormone deficiencies may be indicated. Symptoms of macroadenoma enlargement include severe headaches, visual field changes and, rarely, diabetes insipidus and blindness. After prolactin has reached normal levels following ergot alkaloid treatment, a repeat MRI is indicated within 6 months to document shrinkage or stabilization of the size of the macroadenoma. This examination may be performed earlier if new symptoms develop or if there is no improvement in previously noted symptoms. Normalized prolactin levels or resumption of menses should not be taken as absolute proof of tumor response to treatment.

Medical Treatment Macroadenomas treated with *bromocriptine* routinely show a decrease in prolactin levels and size; nearly one-half show a 50% reduction in size, and another one-fourth show a 33% reduction after 6 months of therapy. Because tumor regrowth occurs in over 60% of cases after discontinuation of *bromocriptine* therapy, long-term therapy is required.

After stabilization of tumor size is documented, the MRI scan is repeated 6 months later and, if stable, yearly for several years. Serum prolactin levels are measured every 6 months. Because tumors may enlarge despite normalized prolactin values, a reevaluation of symptoms at regular intervals (6 months) is required.

Surgical Intervention Tumors that are unresponsive to *bromocriptine* or that cause persistent visual field loss require surgical intervention. Some neurosurgeons have noted that a short (2- to 6-week) preoperative course of bromocriptine increases the efficacy of surgery in patients with larger adenomas ([239](#)). Unfortunately, despite surgical resection, recurrence of hyperprolactinemia and tumor growth is common. Complications of surgery include cerebral carotid artery injury, diabetes insipidus, meningitis, nasal septal perforation, partial or panhypopituitarism, spinal fluid rhinorrhea, and third nerve palsy. Periodic MRI scanning after surgery is indicated, particularly in patients with recurrent hyperprolactinemia.

Metabolic Dysfunction

Occasionally, patients with hypothyroidism exhibit hyperprolactinemia with remarkable pituitary enlargement caused by thyrotroph hyperplasia. These patients respond to thyroid replacement with reduction in pituitary enlargement and normalization of prolactin levels ([240](#)).

Hyperprolactinemia occurs in 20% to 75% of women with chronic renal failure. Prolactin levels are not normalized through hemodialysis but are normalized after transplantation ([241,242,243](#) and [244](#)). Occasionally, women with hyperandrogenemia also have hyperprolactinemia. Elevated prolactin levels may alter adrenal function by enhancing the release of adrenal androgens such as DHEAS ([245](#)).

Drug-induced Hyperprolactinemia

Numerous drugs interfere with dopamine secretion ([Table 25.6](#)). The same principles used in the management of pituitary microadenomas or hyperplasia can be applied in these situations. If medication can be discontinued, resolution of hyperprolactinemia is uniformly prompt.

Use of Estrogen in Hyperprolactinemia

In rodents, rapid pituitary prolactin-secreting adenoma (prolactinoma) occurs with high-dose estrogen administration ([246](#)). However, even conditions associated with high estrogen levels, such as pregnancy, do not cause prolactinomas in humans. Indeed, pregnancy may have a favorable influence on preexisting prolactinomas ([247,248](#)). Studies ([249,250](#) and [251](#)) and autopsy surveys ([228](#)) indicate that estrogen administration is not associated with clinical, biochemical, or radiologic evidence of growth of pituitary microadenomas or the progression of idiopathic hyperprolactinemia to an adenoma status. For these reasons, estrogen replacement or OC use is appropriate for hypoestrogenic patients with hyperprolactinemia secondary to microadenoma or hyperplasia.

Monitoring Pituitary Adenomas During Pregnancy

Prolactin-secreting microadenomas rarely create complications during pregnancy. However, monitoring of patients with serial gross visual field examinations and funduscopic examination is recommended. If persistent headaches, visual field deficits, or visual or funduscopic changes occur, MRI scanning is advisable. Because serum prolactin levels are elevated throughout pregnancy, prolactin measurements are of no value.

Although not recommended, bromocriptine use during pregnancy in women with symptomatic (visual field defects, headaches) microadenoma enlargement has resulted in resolution of deficits and symptoms ([253,254,255](#) and [256](#)).

Pregnant women with previous transsphenoidal surgery for microadenomas or macroadenomas may be monitored additionally with monthly Goldman perimetry visual field testing. Periodic MRI scanning may be necessary in women with symptoms or visual changes. Bromocriptine has been used on a temporary basis to resolve symptoms and visual field deficits in symptomatic patients with macroadenoma to allow completion of pregnancy before initiation of definitive therapy. **Breast feeding is not contraindicated in the presence of microadenomas or macroadenomas** ([253,254,255](#) and [256](#)).

Thyroid Disorders

Thyroid disorders are 10 times more common in women than men ([233](#)). Approximately 1% of the female population of the United States will develop overt hypothyroidism. Even prior to the discovery of the long-acting thyroid stimulator (LATS) in women with Graves' disease in 1956, numerous investigations demonstrated a link between these autoimmune thyroid disorders and reproductive physiology and pathology ([258](#)).

Thyroid Hormones

Iodide is actively transported into the thyroid follicular cell. Sodium-iodide symporter (NIS) is a key molecule in thyroid function. It allows the accumulation of iodide from the circulation into the thyrocyte against an electrochemical gradient. This subtype requires energy that is supplied by Na-K ATPase. Uptake is stimulated by TSH. The enzyme thyroid peroxidase (TPO) then oxidizes iodide near the cell-colloid surface and incorporates it into tyrosyl residues within the thyroglobulin molecule, which results in the formation of monoiodotyrosine (MIT) and diiodotyrosine (DIT). Triiodothyronine (T₃) and thyroxine (T₄), formed by secondary coupling of MIT and DIT, are also catalyzed by TPO. Thyroglobulin, the major protein formed in the thyroid gland, has an iodine content of 0.1% to 1.1% by weight. About 33% of the iodine is present in thyroglobulin in the form of T₃ and T₄, and the remainder is present in the iodotyrosines (MIT and DIT) and unbound iodine. Thyroglobulin provides a storage capacity capable of maintaining a euthyroid state for nearly 2 months without the formation of new thyroid hormones. The membrane-bound, heme-containing oligomer TPO is localized in the rough endoplasmic reticulum, Golgi vesicles, lateral and apical vesicles, and the follicular cell surface. The thyroid antimicrosomal antibodies found in patients with autoimmune thyroid disease are directed against the TPO enzyme ([259,260](#)).

Thyroid-stimulating hormone regulates thyroidal iodine metabolism by activation of adenylate cyclase. This facilitates endocytosis, digestion of thyroglobulin-containing colloid, and the release of thyroid hormones T₄, T₃, and reverse T₃. T₄ is released from the thyroid at 40 to 100 times the concentration of T₃. The reverse T₃ concentration, a histologically inactive metabolite, is 30% to 50% of T₃ secretion and 1% of T₄ concentration. Of thyroid hormones released, 70% are

bound. Although T_4 is present in the circulating storage pool and has a slow turnover rate (about 7 days), T_3 concentration is lower and has a higher turnover rate. Approximately 30% of T_4 is converted to T_3 in the periphery. Reverse T_3 levels may help regulate the conversion of T_4 to T_3 . T_3 is the primary physiologically functional thyroid hormone, which binds the nuclear receptor at 10 times the affinity of T_4 . Thyroid hormone effects on cells include increased oxygen consumption, heat production, and metabolism of fats, proteins, and carbohydrates. Systemically, thyroid hormone activity is responsible for the basal metabolic rate and balances fuel efficiency with performance, much as a carburetor functions in an engine. Hyperthyroid states result in excessive fuel consumption with marginal performance.

Iodide Metabolism

Normal function of the thyroid gland is dependent on iodine. The present recommended daily allowance by the U.S. National Research Council is 150 to 300 mg/day. Present daily consumption in the United States averages 200 to 600 mg/day. Iodine is usually ingested in the form of iodized salt (100 mg of potassium iodine/kg of salt) (261).

Although the thyroid gland depends on iodine, sufficiency of iodine also appears to be associated with the development of autoimmune thyroid disorders (262,263) and reduced remission rates in patients treated for Graves' disease (264). Animal studies suggest that iodine stimulates immunoglobulin production by B lymphocytes, activates macrophages, and increases the immunogenic potential of thyroglobulin because of the higher iodide content (265,266,267 and 268).

Factors Affecting Thyroid Function

Other potential causes of autoimmune thyroid diseases include pollutants (plasticizers, polychlorinated biphenyls, and coal-processing pollutants) (269,270) and antibodies to *Yersinia enterocolitica* (271). The female hormonal milieu and its potential effects on immune surveillance undoubtedly play a role in the increased risk (10-fold) of women to develop autoimmune thyroid disease. The immunoglobulins produced against the thyroid are polyclonal, and the multiple combinations of various antibodies present (stimulating versus blocking, complement fixing, and noncytotoxic) combine to create the clinical spectrum of autoimmune thyroid diseases that affect successful reproductive function.

Evaluation

Thyroid Function

Total serum T_4 is measured by radioimmunoassay. Conditions that elevate the levels of thyroid-binding globulin (TBG) (pregnancy, OC use, estrogen replacement, hepatitis, and genetic abnormalities of TBG) necessitate measuring T_3 resin uptake for clarification.

The T_3 resin uptake determines the concentration of radiolabeled T_3 bound to serum TBG and an artificial resin. The number of binding sites available in TBG is inversely proportional to the amount of labeled T_3 bound to the artificial resin. Therefore, high TBG T_3 receptor site availability results in a low T_3 resin uptake.

The free T_4 index (FTI) is obtained by multiplying the serum T_4 concentration by the T_3 resin uptake percentage, yielding an indirect measurement of free T_4 :

$$\% \text{ free } T_4 \times T_4 \text{ total} = \text{free } T_4.$$

Equilibrium dialysis may be used to determine the percentage of free T_4 . Free T_4 and T_3 may also be determined by radioimmunoassay.

TSH receptor antibodies (TSHR-Ab or TRAb) are pathogenic and capable of activating or blocking TSH receptor functions. TSHR-Ab are detected using two approaches—competitive and functional assays. The competition between antibody and TSH for binding to the TSH receptor is the basis for the measurement of TSH-binding inhibitory immunoglobulin (TSII). The functional assay approach is based on the status of the receptor induced by the antibody-receptor interaction. This functional assay measures the production and accumulation of cyclic (AMP), thyroid hormone or thyroglobulin secretion, or iodide uptake in thyroid epithelial cells or Chinese hamster ovary cells transfected with the human TSH receptor. Whereas the competitive assay does not indicate any functional activity of the antibody, the functional assay identifies whether the antibody is agonistic (thyroid-stimulating antibody [TSAb] or antagonistic TSH stimulation–blocking antibody [TSBAAb or TSHBAAb]). Both types of antibodies may be present in the same patient, and the effect is the algebraic sum of the two levels of activity (agonistic and antagonistic) (Fig. 25.8).

Figure 25.8 Types of autoimmune injury found in Hashimoto's thyroiditis. A: Complement-mediated cytotoxicity, which can be abolished by inactivating the complement system. **B:** Antibody-dependent cell-mediated cytotoxicity (ADCC) function through killer T cells, monocytes, and natural killer cells that have immunoglobulin G fragment receptors. **C:** Stimulation or blockade of hormone receptors leading to hyperfunction or hypofunction or growth, depending on the types of immunoglobulins acting on the target cell. (TBII, TSH-binding inhibitor immunoglobulin; TGI, thyroid growth–promoting immunoglobulin; TSAb, thyroid-stimulating antibodies; TSH, thyroid-stimulating hormone.) (From **Coulam CB, Faulk WP, McIntyre JA. Immunologic obstetrics.** New York: Norton Medical Books, 1992:658, with permission.)

The present TSH sandwich immunoassays are extremely sensitive and are capable of differentiating low-normal from pathologic or iatrogenically subnormal values and elevations. Thus, TSH measurements provide the best single screen for thyroid dysfunction (272) and accurately predict thyroid hormone dysfunction in about 80% of cases.

Immunologic Abnormalities

Many antigen-antibody reactions affecting the thyroid gland can be detected. A number of recognized thyroid autoantigens are listed in [Table 25.8](#). Antibody production to thyroglobulin obviously depends on a breach in normal immune surveillance (273,274). The incidence of thyroid autoantibodies in various autoimmune thyroid disorders is shown in [Table 25.9](#).

Antigen	Location	Function
Thyroglobulin (Tg)	Thyroid	Thyroid hormone storage
Thyroid peroxidase (TPO) (microsomal antigen)	Thyroid	Transduction of signal from TSH
TSH receptor (TSHR)	Thyroid, lymphocytes, fibroblasts, adipocytes (including retroorbital)	Transduction of signal from TSH
Na ⁺ /I ⁻ symporter (NIS)	Thyroid, breast, salivary or lacrimal gland, gastric or colonic mucosa, thymus, pancreas	ATP-driven uptake of I ⁻ along with Na ⁺

TSH, thyroid-stimulating hormone; ATP, adenosine triphosphate.

Table 25.8 Thyroid Autoantigens

Antibody	General Population	Hypothyroid Autoimmune Thyroiditis	Graves' Disease
Anti-thyroglobulin (anti-Tg)	3%	35% to 50%	12% to 30%
Antimicrosomal thyroid peroxidase (anti-TPO)	10% to 15%	80% to 95%	45% to 80%
Anti-TSH receptor (anti-TSHR)	1% to 2%	6% to 50%	70% to 100%
Anti-Na ⁺ /I ⁻ symporter (anti-NIS)	0%	25%	30%

TSH, thyroid-stimulating hormone.

Table 25.9 Prevalence of Thyroid Autoantibodies and Their Role in Immunopathology

Antibodies to thyroglobulin are restricted to one minor and two major epitopes. Antibodies are mainly noncomplement-fixing immunoglobulin G (IgG) polyclonal antibodies (275). Anti-thyroglobulin antibodies are found in patients with Hashimoto's thyroiditis, Graves' disease, acute thyroiditis, nontoxic goiter, and thyroid cancer. They also appear in normal women.

Antimicrosomal antibodies directed against TPO are found in Hashimoto's thyroiditis, Graves' disease, and postpartum thyroiditis. The antibodies produced are characteristically cytotoxic, complement-fixing IgG antibodies. Antimicrosomal antibodies correlate with the histologic appearance of lymphocytic thyroiditis (259,260).

Antibodies to T₃ and T₄ are present in some patients with Hashimoto's thyroiditis and Graves' disease who have anti-thyroglobulin antibodies (276). These antibodies can cause artifacts in the measurement of thyroid hormone levels.

Another group of antibodies important in autoimmune thyroid disease binds the TSH receptor. These antibodies often create the signs and symptoms that lead to an evaluation. TSAb or thyroid-stimulating immunoglobulin (TSI) activates the TSH receptor (Table 25.10). Long-acting thyroid stimulators are monoclonal or limited polyclonal TSAb, which mimic TSH action. They are quantified by their ability to stimulate human thyroid cell cultures to produce cyclic adenosine monophosphate or to release T₃.

Abbreviation	Term	Assay Used	Notes
LATS	Long-acting thyroid stimulator	In vivo assay of stimulation of mouse thyroid	Original description of active molecule able to stimulate mouse thyroid; no longer used
TSAb/Ab, TBAb	TSH receptor antibodies	Any	All antibodies recognizing the TSH receptor
TBI	TSH binding inhibitory immunoglobulins	Competitive binding assays with TSH	Antibodies able to compete with TSH for TSH receptor binding, irrespective of biologic activity
TSAb	Thyroid stimulating antibodies	Biosays of TSH receptor activation	TSH receptor stimulating antibodies
TSI	Thyroid stimulating immunoglobulins	As TSAb	Identical to TSAb
TSBAb, TSI-IBAb	TSH stimulation-blocking antibodies	Competition with TSH in biosays of TSH receptor activation	Antibodies able to block activation of the TSH receptor by TSH

TSH, thyroid-stimulating hormone.

Table 25.10 Nomenclature of Anti-TSH Receptor Antibodies

TBI is detectable in two varieties, those that block TSH binding and those that block both pre- and postreceptor processes. Several investigators have detected such blocking antibodies in patients with primary hypothyroidism who have atrophic thyroid glands (277,278 and 279). The nomenclature and detection assay of TSH receptor antibodies are listed in Table 25.10.

Thyroid growth-promoting immunoglobulins (TGI) stimulate growth but not hormone release (250,251,252,253,254,255,256,257,258 and 259). Their immunologic antagonists are the TGI-blocking antibodies that are capable of inhibiting TSH-mediated growth responses in patients who may have had thyroid damage by immune destruction (277,278,279 and 280).

Antibodies to the NIS are prevalent in a number of thyroid conditions. Increased expression of NIS protein and NIS mRNA is found in patients with autonomous thyroid adenomas and in Graves' disease. They are decreased in Hashimoto's thyroiditis, cold nodules, and thyroid carcinoma.

Autoimmune Thyroid Disease

The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple antibodies produced (281). The various antigen-antibody reactions result in the wide clinical spectrum of these disorders. The transmission of these immunoglobulins transplacentally potentially complicates thyroid function in the fetus. The presence of autoimmune thyroid disorders, particularly Graves' disease, is associated with other autoimmune conditions. Other autoimmune conditions associated with Graves' disease are Hashimoto's thyroiditis, Addison's disease, ovarian failure, rheumatoid arthritis, Sjögren's syndrome, diabetes mellitus (type I), vitiligo, pernicious anemia, myasthenia gravis, and idiopathic thrombocytopenic purpura.

Certain groups of individuals require assessment of thyroid function at least once. Such individuals include women with atrial fibrillation, hyperemesis gravidarum, and hyperlipidemia. Periodic assessment of thyroid function is indicated in patients who receive amiodarone and lithium. Epidemiologists recommend that all women with diabetes be annually screened for thyroid dysfunction. Women with type 1 diabetes are 3 times more likely to experience postpartum thyroid dysfunction, and it is recommended that all women with diabetes be screened in their first trimester with TSH. Any woman with a history of postpartum thyroiditis should also be offered annual surveillance of thyroid function. Because there is a high prevalence of hypothyroidism in women with Turner's and Down's syndrome, an annual check of thyroid function is recommended. Periodic TSH screening in mature women is advisable.

Hashimoto's Thyroiditis

Hashimoto's thyroiditis or chronic lymphocytic thyroiditis, which was first described in 1912, can manifest as hyperthyroidism, hypothyroidism, euthyroid goiter, or diffuse goiter. High levels of antimicrosomal and antithyroglobulin antibody are usually present. Typically, glandular hypertrophy is found, but atrophic forms are also present. The composition of various antibodies (i.e., TBII, causing the atrophic form and congenital hypothyroidism in some neonates, and TGI, causing the goitrous variety) results in varied physical findings.

Three classic types of autoimmune injury are found in Hashimoto's thyroiditis, (a) complement-mediated cytotoxicity, (b) antibody-dependent cell-mediated cytotoxicity, and (c) stimulation or blockade of hormone receptors, which results in hyper- or hypofunction or growth ([Fig. 25.8](#)).

The histologic picture of Hashimoto's thyroiditis includes cellular hyperplasia, disruption of follicular cells, and infiltration of the gland by lymphocytes, monocytes, and plasma cells. Occasionally, adjacent lymphadenopathy may be noted. Some epithelial cells are enlarged and demonstrate oxyphilic changes in the cytoplasm (Askanazy cells or Hürthle cells, which are not specific to this disorder). The interstitial cells show fibrosis and lymphocytic infiltration. Graves' disease and Hashimoto's thyroiditis may cause very similar histologic findings manifested by a similar mechanism of action. Nearly all patients with Hashimoto's thyroiditis and about two-thirds of patients with Graves' disease have sera demonstrating antibody-dependent cell-mediated cytotoxicity.

Clinical Characteristics and Diagnosis of Hashimoto's Thyroiditis

Most patients with Hashimoto's thyroiditis are relatively asymptomatic with painless goiter and hypothyroidism. The goiter can also involve the pyramidal lobe. At later stages of the disease, hypothyroidism can be found without a goiter. Notable manifestations of hypothyroidism include cold intolerance, constipation, carotene deposition in the periorbital region, carpal tunnel syndrome, dry skin, fatigue, hair loss, lethargy, and weight gain. Hashitoxicosis, the hyperthyroid manifestation of autoimmune thyroid disease, may represent a variant of Graves' disease. This form is estimated to occur in 4% to 8% of patients with Hashimoto's thyroiditis. These patients often become hypothyroid during the course of treatment.

In many cases, an elevated serum level of TSH is noted during routine screening. Elevated serum antithyroglobulin and antimicrosomal antibody elevation confirm the diagnosis. The sedimentation rate may be elevated, depending on the course of the disease at the time of recognition. Other causes of hypothyroidism should be considered as listed in [Table 25.11](#).

Primary
Congenital absence of thyroid gland
External thyroid gland radiation
Familial disorders and thyroxine synthesis
Hashimoto's thyroiditis
Iodine-131 ablation for Graves' disease
Ingestion of antithyroid drugs
Iodine deficiency
Idiopathic myxedema (autoimmune)
Surgical removal of thyroid gland
Secondary
Hypothalamic thyrotropin-releasing hormone deficiency
Pituitary or hypothalamic tumors or disease

Table 25.11 Potential Causes of Hypothyroidism

Most clinicians treat women who have elevated serum TSH concentrations and positive thyroid antibody tests, even in the absence of symptoms, in view of the annual risk for hypothyroidism of approximately 5% ([282](#)). If the serum TSH alone is elevated, without positive thyroid antibody titers, the annual risk for hypothyroidism drops to approximately 3% per year.

Treatment

Thyroxine replacement is initiated in patients with symptomatic hypothyroidism, patients who have a goiter that is cosmetically or physically bothersome and are subclinically hypothyroid, and patients who are undergoing fertility therapy and are subclinically hypothyroid. Regression of gland size usually does not occur, but treatment prevents further growth. Pregnant patients with an elevated TSH level should be treated with *levothyroxine*. Treatment does not slow progression of the disease. Replacement therapy is monitored by TSH determinations at least 6 weeks after a change in dose. *Aluminum hydroxide* (antacids), *cholestyramine*, iron, and *sucralfate* may interfere with absorption. The half-life of *levothyroxine* is nearly 7 days; therefore, nearly 6 weeks of treatment are necessary before the effects of a dose change can be evaluated.

Hypothyroidism appears to be associated with decreased fertility resulting from ovulatory difficulties and not with spontaneous abortion ([283,284,285](#) and [286](#)). Studies also suggest that early subclinical hypothyroidism may be associated with menorrhagia ([287](#)).

Severe primary hypothyroidism is associated with amenorrhea or anovulation ([283,288,289](#) and [290](#)). Enhanced sensitivity of the prolactin-secreting cells to thyrotropin-releasing hormone (TRH) and defective dopamine turnover resulting in hyperprolactinemia associated with a deficiency of thyroid hormone are the apparent explanations for the hyperprolactinemia ([291,292,293](#) and [294](#)). Hyperprolactinemia-induced luteal phase defects also are associated with less severe forms of hypothyroidism ([273,274](#) and [275](#)). Replacement therapy appears to reverse the hyperprolactinemia and correct ovulatory defects ([295,296](#) and [297](#)).

Graves' Disease

Graves' disease is characterized by exophthalmos, goiter, and hypothyroidism. A heritable specific defect in immunosurveillance by suppressor T lymphocytes is believed to result in the development of a helper T-cell population that reacts to thyroid antigens and induces a B-cell-mediated response ([301](#)), resulting in the clinical features of Graves' disease. TSAbs are detected in the serum of 90% of patients with Graves' disease. Human leukocyte antigen (HLA) class II antigens DR, DP, DQ, and DS can present antigens to T cells and are expressed on thyroid epithelial cells. Antibodies to the TSH receptor are produced when this immunogen (TSH receptor) is presented to helper T lymphocytes with the D locus antigens ([302](#)).

The class II antigens are upregulated by chronic stimulation of the TSH receptor, reduction in the iodinating capacity of thyroid tissue, viral transformation, and interferon- α ([302,303](#)). The clinical use of *interferon- α* has been associated with autoimmune thyroid disease. Graves' disease is a complex autoimmune disorder in which several genetic susceptibility loci and environmental factors are likely to play a role in the development of the disease. HLA and the CTLA-4 gene region have been established as susceptibility loci; however, the magnitude of their contributions seems to vary among patient populations and study groups. Additional loci are likely to be identified by a combination of genome-wide linkage analyses and allelic association analyses of candidate genes.

Clinical Characteristics and Diagnosis

The classic triad of exophthalmos, goiter, and hyperthyroidism may be associated with frequent bowel movements, heat intolerance, irritability, nervousness, palpitations or tachycardia, tremor, weight loss, and lower extremity swelling. Physical findings include lid lag, nontender thyroid enlargement (2- to 4-times normal), onycholysis, palmar erythema, proptosis, staring gaze, and thick skin. A cervical venous bruit and tachycardia are usually noted. The tachycardia does not respond to increased vagal tone produced with a Valsalva maneuver. Severe cases may demonstrate acropachy, chemosis, clubbing, dermopathy, exophthalmos with ophthalmoplegia, follicular conjunctivitis, pretibial myxedema, and vision loss.

Approximately 40% of patients with new onset of Graves' disease and many of those who have received treatment have elevated T₃ and normal T₄ levels. Therefore, assessment of T₄, T₃, and TSH values is indicated. The TSH value may remain undetectable for some time even after the initiation of treatment. In most patients,

antimicrosomal antibodies are present. Measurement of TSAb is useful in evaluating medical treatment, prognosis, and potential fetal complications such as neonatal thyrotoxicosis. Autonomously functioning, benign thyroid neoplasias that exhibit a similar clinical picture include toxic adenomas and toxic multinodular goiter. Very rare conditions causing thyrotoxicosis include hCG-secreting choriocarcinoma, TSH-secreting pituitary adenomas, and struma ovarii. Factitious ingestion of thyroxine or desiccated thyroid must be considered in patients with eating disorders. Other potential causes of hyperthyroidism are listed in [Table 25.12](#).

Factitious hyperthyroidism
Graves' disease
Metastatic follicular cancer
Pluitary hyperthyroidism
Postpartum thyroiditis
Silent hyperthyroidism (low radioactive uptake)
Struma ovarii
Subacute thyroiditis
Toxic multinodular goiter
Toxic nodule
Tumors secreting human chorionic gonadotropin (molar pregnancy, choriocarcinoma)

Table 25.12 Potential Causes of Hyperthyroidism

Treatment

Iodine-131 Ablation Treatment of women with hyperthyroidism of an autoimmune origin presents unique challenges to the physician who must consider the patient's needs and her reproductive plans. Because the drugs used to treat this disorder have potentially harmful effects on the fetus, special attention must be given to the use of contraception and the potential for pregnancy.

A single dose of radioactive iodine-131 (¹³¹I) is an effective cure in about 80% of cases and is the most commonly used definitive treatment in nonpregnant women. Any woman of childbearing age should be tested for pregnancy before undergoing diagnostic or therapeutic administration of ¹³¹I. Ablation of a second-trimester fetal thyroid gland and congenital hypothyroidism from treatment during the first trimester have been reported (304,305). Nuclear medicine professionals provide expertise in the administration of the radioactive isotope, and the endocrinologist continues to provide suppressive medical treatment for 6 to 12 weeks after administration of ¹³¹I. Therefore, medical therapy is the backbone of therapy even when radioactive ¹³¹I or surgery is eventually planned. Postablative hypothyroidism develops in 50% of patients within the first year after ¹³¹I therapy and in more than 2% of patients per year thereafter.

Thyroid-stimulating Receptor Antibody in Graves' Disease The level of TSHR-Ab (TBII) grossly parallels the degree of hyperthyroidism as assessed by the serum levels of thyroid hormones and total thyroid volume. Recent studies suggest that the combination of a small goiter volume (<40 ml) and a low TBII level (<30 units/L) results in a 45% chance of remission during the 5 years after completion of a 12- to 24-month course of antithyroid drug therapy (306). In contrast, the overall rate of relapse exceeded 70% in patients with a large goiter volume (>70 ml) and a higher TBII level (>30 units/L). Thus, the subgroup of patients with larger goiters and higher TBII levels had less than a 10% chance to remain in remission in the 5 years after treatment. Therefore, although it is not necessary for the diagnosis of Graves' disease, except in some cases of multinodular goiter, a TSHR-Ab measurement may be a useful marker of disease severity and, in combination with other clinical factors, may contribute to the initial decisions regarding treatment. See [Table 25.10](#) to review the nomenclature and assay methods for TSHR-Ab.

TSHR-Ab measurements (TBII) during treatment with antithyroid drugs also are predictive of subsequent outcome. In one series, 73% of TBII-negative patients had remission compared with only 28% of TBII-positive patients who had achieved remission after 12 months of antithyroid drug therapy (307). Furthermore, the duration of a course of antithyroid drug therapy can be modified according to the TSHR-Ab status. In patients whose TSHR-Ab (TSAb) status became negative and antithyroid drug therapy was discontinued, the relapse rate was 41% compared with a rate of 92% for those patients who remained TSAb-positive (308). Regardless of the rapidity of the disappearance of TSAb, it does seem that antithyroid drug therapy should be maintained for 9 to 12 months to minimize the risk of relapse. TSHR-Ab status also appears to determine in an inverse relationship the reduction in thyroid volume after radioactive iodine therapy.

Antithyroid Drugs Antithyroid drugs of the thioamide class include *propylthiouraci (PTU)* and *methimazole*. Low doses of these agents block the secondary coupling reactions that form T₃ and T₄ from MIT and DIT. At higher doses, they also block iodination of tyrosyl residues in thyroglobulin. Approximately one-third of patients treated by this modality alone go into remission and become euthyroid (309).

PTU causes a reduction of hyperthyroid symptoms at a dose of 100 mg taken every 8 hours over 1 month. It blocks the intrathyroid synthesis of T₃ and the peripheral conversion of T₄ to T₃ but does not cross the placenta as easily as *methimazole*, and therefore is the drug of choice during pregnancy. Drug efficacy is monitored weekly by evaluation of appetite, emotional lability, insomnia, and tremor. A general rule is to lower the dosage by 50% when thyroid function returns to normal, which frequently correlates with the return to a normal heart rate and, subsequently, normalization of TSH levels. Thyroxine is usually the first value to become normal.

Pruritus affects 3% to 5% of treated patients. Serious adverse reactions include agranulocytosis (occurring 1 to 2 months after therapy in 0.02%) and a generalized drug eruption accompanied by arthralgia, fever, and sore throat. A complete blood count determination is performed if the patient develops an upper respiratory tract infection. If adverse reactions occur, methimazole may be used.

Methimazole (10 mg) is given every 8–24 hours. Its dosage is reduced, as with *PTU*. It is not the drug of choice in pregnant women because it does not block peripheral conversion and crosses the placenta more readily than *PTU*. It does, however, have fewer adverse reactions, a longer dosing interval, and a lower cost than *PTU*; therefore, it is most often prescribed in nonpregnant women.

Other medical therapies include *iodide* and *lithium*, both of which reduce thyroid hormone release and inhibit the organification of iodine. *Iodide* also leads to the secondary coupling of T₃ and T₄. These medications are rarely used in women of reproductive age because of their risks to the fetal thyroid and to fetal development (*iodine* causes congenital goiter; *lithium* causes Ebstein's anomaly).

Surgery A subtotal thyroidectomy is less commonly used primarily but is used routinely if medical treatment fails or if a patient is hypersensitive to medical therapy. Surgery is the most rapid and consistent method of achieving a euthyroid state in Graves' disease that avoids the possible long-term risks of radioactive iodine. Children, young women, pregnant women, and patients with coexistent thyroid nodules are potential candidates for thyroidectomy. It is felt to be the treatment of choice for a patient with significant Graves' ophthalmology. Patients should be rendered euthyroid before a thyroidectomy. The risks of surgery include postoperative hypoparathyroidism, recurrent laryngeal nerve paralysis, routine anesthetic and surgical risks, hypothyroidism, and failure to relieve thyrotoxicosis.

***β*-Blockers** *Propranolol* is occasionally used prior to surgery in patients who prove to be hypersensitive to other medical therapy and to provide symptomatic relief while awaiting a reduction in T₄ caused by *PTU* or *methimazole*.

Reproductive Effects of Hyperthyroidism

High levels of TSAb in women with Graves' disease have been associated with fetal-neonatal hyperthyroidism (310,311). Despite both the inhibition and elevation of gonadotropins seen in thyrotoxicosis (312), most women remain ovulatory and fertile (313). Severe thyrotoxicosis can result in weight loss, menstrual cycle irregularities, and amenorrhea. An increased risk of spontaneous abortion is noted in women with thyrotoxicosis (313). In those who deliver, an increased incidence of congenital anomalies (6%) is noted in their offspring (287). Effective treatment appears to reduce this risk.

Autoimmune hyperthyroid Graves' disease may improve spontaneously, in which case antithyroid drug therapy may be reduced or stopped. Nevertheless, TSHR-Ab production may persist for several years after radical radioactive iodine therapy or surgical treatment for hyperthyroid Graves' disease. In this circumstance there is a risk of exposing a fetus to TSHR-Ab. Fetal-neonatal hyperthyroidism is observed in 2% to 10% of pregnancies occurring in mothers with a current or previous

Endometriosis is defined as the presence of endometrial tissue (glands and stroma) outside the uterus. The most frequent sites of implantation are the pelvic viscera and the peritoneum. Endometriosis varies in appearance from a few minimal lesions on otherwise intact pelvic organs to massive ovarian endometriotic cysts that distort tuboovarian anatomy and extensive adhesions often involving bowel, bladder, and ureter. It is estimated to occur in 7% of reproductive age women in the United States and often is associated with pelvic pain and infertility. Considerable progress has been made in understanding the pathogenesis, spontaneous evolution, diagnosis, and treatment of endometriosis.

Etiology

Although signs and symptoms of endometriosis have been described since the 1800s, its widespread occurrence was acknowledged only during this century. Endometriosis is an estrogen-dependent disease. Three theories have been proposed to explain the histogenesis of endometriosis:

1. Ectopic transplantation of endometrial tissue
2. Coelomic metaplasia
3. The induction theory

No single theory can account for the location of endometriosis in all cases.

Transplantation Theory The transplantation theory, originally proposed by Sampson in the mid-1920s, is based on the assumption that endometriosis is caused by the seeding or implantation of endometrial cells by transtubal regurgitation during menstruation ([1](#)). Substantial clinical and experimental data support this hypothesis ([2,3](#)). Retrograde menstruation occurs in 70% to 90% of women ([4,5](#)), and it may be more common in women with endometriosis than in those without the disease ([5](#)). The presence of endometrial cells in the peritoneal fluid, indicating retrograde menstruation, has been reported in 59% to 79% of women during menses or in the early follicular phase ([6,7](#)), and these cells can be cultured *in vitro* ([7](#)). Evidence supporting retrograde menstruation is the presence of endometrial cells in the dialysate of women undergoing peritoneal dialysis during menses ([8](#)). Also, endometriosis is most often found in dependent portions of the pelvis—the ovaries, the anterior and posterior cul-de-sac, the uterosacral ligaments, the posterior uterus, and the posterior broad ligaments ([9](#)).

Endometrium obtained during menses can grow when injected beneath abdominal skin or into the pelvic cavity of animals ([10,11](#)). Endometriosis has been found in 50% of Rhesus monkeys after surgical transposition of the cervix to allow intraabdominal menstruation ([12](#)). Increased retrograde menstruation by obstruction of the outflow of menstrual fluid from the uterus is associated with a higher incidence of endometriosis in women ([13,14](#)) and in baboons ([15](#)). Women with shorter intervals between menstruation and longer duration of menses are more likely to have retrograde menstruation and are at higher risk for endometriosis ([16](#)).

Ovarian endometriosis may be caused by either retrograde menstruation or by lymphatic flow from the uterus to the ovary ([17](#)). Extrapelvic endometriosis, although rare (1% to 2%), potentially may result from vascular or lymphatic dissemination of endometrial cells to many gynecologic (vulva, vagina, cervix) and nongynecologic sites. The latter include bowel (appendix, rectum, sigmoid colon, small intestine, hernia sacs), lungs and pleural cavity, skin (episiotomy or other surgical scars, inguinal region, extremities, umbilicus), lymph glands, nerves, and brain ([18](#)).

Coelomic Metaplasia The transformation (metaplasia) of coelomic epithelium into endometrial tissue has been proposed as a mechanism for the origin of endometriosis. This theory has not been supported by either strong clinical or experimental data, however. In contrast, a recent study evaluating structural and cell surface antigen expression in the rete ovarii and epoophoron reported little commonality between endometriosis and ovarian surface epithelium, suggesting that serosal metaplasia is unlikely in the ovary ([19](#)).

Induction Theory The induction theory is, in principle, an extension of the coelomic metaplasia theory. It proposes that an endogenous (undefined) biochemical factor can induce undifferentiated peritoneal cells to develop into endometrial tissue. This theory has been supported by experiments in rabbits ([20,21](#)) but has not been substantiated in women and primates.

Genetic Factors

Population Studies

The risk of endometriosis is 7 times greater if a first-degree relative has been affected by endometriosis (22). Because no specific mendelian inheritance pattern has been identified, multifactorial inheritance has been postulated. A relative risk for endometriosis of 7.2 has been found in mothers and sisters, and a 75% (6 of 8) incidence has been noted in homozygotic twins of patients with endometriosis (23). In another twin study, 51% of the variance of the latent liability to endometriosis may be attributable to additive genetic influences (24). Other investigators reported that 14 monozygotic twin pairs were concordant for endometriosis, and 2 pairs were discordant (25). Of these twin pairs, 9 had moderate to severe endometriosis.

A relationship has been shown between endometriosis and systemic lupus erythematosus (26), dysplastic nevi, and a history of melanoma in women of reproductive age (27). Endometriosis also is linked to the presence of individual human leukocyte antigens (28,29 and 30).

Mutations

In women with endometriosis, no mutations were found in the *TP53* and *RASK* genes (31). No significant differences were observed in *N314D* (galactose-1-phosphate uridyl transferase) mutation frequency between women with endometriosis (18%) and controls (17%) (32).

Steroid Receptor Genetics

An association of estrogen receptor gene polymorphisms (two-allele and multiallele polymorphism) with endometriosis has been reported (33). Furthermore, various exon-deleted progesterone-receptor messenger RNAs (mRNAs) have been documented in human endometrium and ovarian endometriosis (34).

Aneuploidy

Epithelial cells of endometriotic cysts are monoclonal on the basis of phosphoglycerate kinase gene methylation, but normal endometrial glands are monoclonal (35,36). In a comparison of endometriotic tissue with normal tissue from the endometrium flow, cytometric DNA analysis failed to show aneuploidy (37). However, more recent studies using comparative genomic hybridization (38) or multicolor *in situ* hybridization (39) showed aneuploidy for chromosomes 11, 16, and 17 (39), increased heterogeneity of chromosome 17 aneuploidy (40), and losses of 1p and 22q (50%), 5p (33%), 6q (27%), 70 (22%), 9q (22%), and 16 (22%) of 18 selected endometriotic tissues (38).

Loss of Heterozygosity

Microsatellite DNA assays reveal an allelic imbalance (loss of heterozygosity) in *p16 (Ink4)*, *GALT*, *p53*, and *APOA2* loci in patients with endometriosis, even in stage II of endometriosis (41). Another report (36) found in 28% of endometriotic lesions a loss of heterozygosity at one or more sites: chromosomes 9p (18%), 11q (18%), and 22q (15%).

Immunologic Factors and Inflammation

Although retrograde menstruation appears to be a common event in women, not all women who have retrograde menstruation develop endometriosis. The immune system may be altered in women with endometriosis, and it has been hypothesized that the disease may develop as a result of reduced immunologic clearance of viable endometrial cells from the pelvic cavity (42,43). Endometriosis can be caused by decreased clearance of peritoneal fluid endometrial cells due to reduced natural killer (NK) cell activity, or decreased macrophage activity (45). Decreased cell-mediated cytotoxicity toward autologous endometrial cells has been associated with endometriosis (44,45,46,47 and 48). However, these studies used techniques that have considerable variability in target cells and methods (49,50). Whether NK cell activity is lower in patients who have endometriosis than in those without endometriosis is controversial. Some reports demonstrate reduced NK activity (51,52,53 and 54,57), whereas others have found no increase in NK activity, even in women with moderate to severe disease (46,47 and 48,55). There also is great variability in NK cell activity among normal individuals that may be related to variables such as smoking, drug use, and exercise (49).

In contrast, endometriosis can also be considered a condition of immunologic tolerance, as opposed to ectopic endometrium, which essentially is self-tissue (42). It can be questioned why viable endometrial cells in the peritoneal fluid would be a target for NK cells or macrophages. Autotransplantation of blood vessels, muscles, skin grafts, and other tissues is known to be extremely successful in (45,46 and 47). Furthermore, there is no *in vitro* evidence that peritoneal fluid macrophages actually attack and perform phagocytosis of viable peritoneal fluid endometrial cells. High-dose immunosuppression can slightly increase the progression of spontaneous endometriosis in baboons (56). There is no clinical evidence, however, that the prevalence of endometriosis is increased in immunosuppressed patients. The fact that women with kidney transplants, who undergo chronic immunosuppression, are not known to have increased infertility problems can be considered indirect evidence that these patients do not develop extensive endometriosis.

Substantial evidence suggests that endometriosis is associated with a state of subclinical peritoneal inflammation, marked by an increased peritoneal fluid volume, increased peritoneal fluid white blood cell concentration (especially macrophages with increased activation status), and increased inflammatory cytokines, growth factors, and angiogenesis-promoting substances. It has been reported in baboons that subclinical peritoneal inflammation occurs both during menstruation and after intrapelvic injection of endometrium (57). A higher basal activation status of peritoneal macrophages in women with endometriosis may impair fertility by reducing sperm motility, increasing sperm phagocytosis, or interfering with fertilization (58,59), possibly by increased secretion of cytokines such as tumor necrosis factor- α (TNF- α) (60,61 and 62). TNF also may facilitate the pelvic implantation of ectopic endometrium (63,64). The adherence of human endometrial stromal cells to mesothelial cells *in vitro* has been increased by the pretreatment of mesothelial cells with physiologic doses of TNF- α (63). Macrophages or other cells may promote the growth of endometrial cells (65,66) by secretion of growth and angiogenic factors such as epidermal growth factor (EGF) (63), macrophage-derived growth factor (MDGF) (67), fibronectin (68), and adhesion molecules such as integrins (69). After attachment of endometrial cells to the peritoneum, subsequent invasion and growth appears to be regulated by matrix metalloproteinases (MMPs) and their tissue inhibitors (70,71).

There is increasing evidence that local inflammation and secretion of prostaglandins (PG) is related to differences in endometrial aromatase activity between women with and without endometriosis. Expression of aromatase cytochrome P450 protein and mRNA was observed in human endometriotic implants but not in normal endometrium, suggesting that ectopic endometrium produces estrogens, which may be involved in the tissue growth interacting with the estrogen receptor (72). Inactivation of 17 β -estradiol has been reported to be impaired in endometriotic tissues because of deficient expression of 17 β -hydroxysteroid dehydrogenase type 2, which is normally expressed in eutopic endometrium in response to progesterone (73). Finally, the inappropriate aromatase expression in endometriosis lesions can be stimulated by prostaglandin E₂ (PGE₂). This also leads to local production of E₂, which also stimulates PGE₂ production, resulting in a positive-feedback system between local inflammation and estrogen-driven local growth of ectopic endometrium (74).

Environmental Factors and Dioxin

There is an increasing awareness of potential links between reproductive health, infertility, and environmental pollution. Attention has been directed to the potential role of dioxins in the pathogenesis of endometriosis, but the issue remains controversial.

A 1976 explosion of a factory in Seveso (Italy) resulted in the highest levels of dioxin exposure recorded in humans (75), but so far no data have been published. The Seveso Women's Health Study will correlate prospective individual data on exposure to dioxin with reproductive endpoints such as the incidence of endometriosis, infertility, and decreased sperm quality. Thus far, one case-control study has failed to show in the general population an association between endometriosis and exposure to polychlorinated biphenyl and chlorinated pesticides during adulthood: no differences in mean plasma concentrations of 14 polychlorinated biphenyl and 11 chlorinated pesticides were found between women with and without endometriosis (76).

Genetic mechanisms may play a role in dioxin exposure and the development of endometriosis. Transcripts of the *CYP1A1* gene, a dioxin-induced gene, have been reported to be significantly higher (9 times higher) in endometriotic tissues than in eutopic endometrium (77). Other investigators have reported a similar expression of arylhydrocarbon receptor and dioxin-related genes (using semiquantitative reverse transcriptase polymerase chain reaction) in the endometrium from women with or without endometriosis (78). In Japanese subjects, no association was found between endometriosis prevalence or severity and polymorphisms for arylhydrocarbon receptor repressor, arylhydrocarbon (x2) receptor, and arylhydrocarbon nuclear translocator or *CYP1A1* genes (79). Based on these data, there is insufficient

evidence supporting the association between endometriosis and dioxin exposure in humans.

Primates

An initial retrospective case-control study reported that the prevalence of endometriosis was not statistically different (Fisher exact test, $p = 0.08$) between monkeys chronically exposed to dioxin during 4 years (11 of 14, 79%) and in nonexposed animals (2 of 6, 33%) after a period of 10 years. However, a positive correlation was found between the severity of endometriosis and dioxin dose, serum levels of dioxin, and dioxin-like chemicals (80,81). Two prospective studies have evaluated the association between dioxin exposure and development of endometriosis in Rhesus monkeys. In the most recent study (82), monkeys exposed over 12 months to low-dose dioxin (0.71 ng/kg/d) had endometriosis implants with smaller maximal and minimal diameters and similar survival rate when compared with endometriotic lesions in unexposed controls, suggesting no effect of dioxin on endometriosis. However, after 12 months of exposure to high-dose dioxin (17.86 ng/kg/d), larger diameters and a higher survival rate of endometriosis implants were observed in exposed Rhesus monkeys compared with nonexposed controls. The second randomized controlled study performed in 80 Rhesus monkeys compared those with no treatment with those treated with 0, 5, 20, 40, and 80 μg of Aroclor (1,254/kg/d) for 6 years. Endometriosis occurred in 37% of controls and in 25% of treated monkeys as determined by laparoscopy and necropsy data (83). No association was observed between endometriosis severity and polychlorinated biphenyl exposure. These data question the importance of dioxin exposure in the development of endometriosis in primates, except at high doses.

Rodents

Continuous exposure to 2,3,7,8-tetrachlorodibenzo-P-dioxin inhibited the growth of surgically induced endometriosis in ovariectomized mice treated with high-dose estradiol. No correlation was observed between the dose of dioxin and survival of endometrial implants, adhesions, and serum E_2 levels (84). In ovariectomized mice induced with endometriosis, similar stimulating effects of estrone and 4-chlorodiphenyl ether (4-CDE) were observed on survival rates of endometriotic mice, suggesting an estrogen-like effect of 4-CDE (85). Potential mechanisms mediating dioxin action to promote endometriosis in rodents are complex and probably different in rats and mice, not to mention women. The mouse appears to be a better model to elucidate these mechanisms (86), but both models have important limitations.

Future Research

The study of endometriosis is compounded by the need to exclude other causes and to assess symptoms within the context of the pelvic condition (i.e., the presence or absence of pathology). The pathogenesis of endometriosis, the pathophysiology of related infertility, and the spontaneous evolution of endometriosis are still being investigated. At the time of diagnosis, most patients with endometriosis have had the disease for an unknown period, making it difficult to initiate any clinical experiments that would determine definitely the etiology or progression of the disease (3). Because endometriosis occurs naturally only in women and primates and invasive experiments cannot be performed easily, it is difficult to undertake properly controlled studies. Thus, there is a need for the development of a good animal model with spontaneous endometriosis.

The main advantage of the rat and rabbit animal models used to study endometriosis is their low cost relative to primates. The disadvantages are numerous, however. Rodents lack a menstrual cycle comparable to that of primates and do not have spontaneous endometriosis. Whereas the rat ovulates spontaneously, it has a shorter luteal phase than humans. The reproductive pattern of the rabbit lacks a luteal phase. There is a wide phylogenetic gap between these two species and the human. In both rodent models, the type of lesions appear to be quite different from the variety of pigmented and nonpigmented lesions observed in women (88,89 and 90).

Primates, conversely, are phylogenetically close to humans, have a comparable menstrual cycle, are afflicted with spontaneous endometriosis, and when induced with endometriosis, develop macroscopic lesions that are similar to those found in human disease (12,91,92,93,94 and 95). Although the great apes are closest to humans in many anatomic and physiologic aspects of reproduction, they are not practical models for study; therefore, Rhesus and cynomolgus monkeys have been used. Baboons may be a better choice for study because they are continuous breeders, are phylogenetically very close to humans, and have similar reproductive anatomy and physiology with regard to menstrual cycle characteristics and regularity, embryo implantation, and fetal development (91). In addition, spontaneous endometriosis in the baboon has been found to be both minimal and disseminated, similar to the different stages of endometriosis in women (91,96,97). Experimental endometriosis can be successfully induced by the intrapelvic injection of menstrual endometrium (11). In recent years, the baboon has been established in about 30 peer reviewed articles as an excellent model for endometriosis research (98).

Prevalence

Endometriosis is predominantly found in women of reproductive age but has been reported in adolescents and in postmenopausal women receiving hormonal replacement (99). It is found in women of all ethnic and social groups. In women with pelvic pain or infertility, a high prevalence of endometriosis (from a low of 20% to a high of 90%) has been reported (2,100). In asymptomatic women having tubal ligation (women of proven fertility), the prevalence of endometriosis ranges from 3% to 43% (5,101,102,103,104 and 105). This great variation in the reported prevalence may be explained by several factors. First, it may vary with the diagnostic method used: laparoscopy, the operation of choice for diagnosis, is generally accepted to be a better method than laparotomy for diagnosing minimal to mild endometriosis. Second, minimal or mild endometriosis may be more thoroughly noted in a symptomatic patient being given general anesthesia than in an asymptomatic patient during tubal sterilization. Third, the experience of the surgeon is important because there is a wide variation in the appearance of subtle endometriosis implants, cysts, and adhesions. Most studies that evaluate the prevalence of endometriosis in women of reproductive age lack histologic confirmation (5,101,102,105,106,107,108,109 and 110).

Diagnosis

Clinical Presentation

Endometriosis should be suspected in women with subfertility, dysmenorrhea, dyspareunia, or chronic pelvic pain. However, endometriosis may be asymptomatic.

Risk factors for endometriosis include short cycle length (111), heavier menstruation, and longer flow duration (16,112), probably related to a higher incidence of retrograde menstruation. Patient height and weight are positively and negatively, respectively, associated with the risk for endometriosis (113).

Endometriosis can be associated with significant gastrointestinal symptoms (pain, nausea, vomiting, early satiety, bloating and distention, altered bowel habits). A characteristic motility change (ampulla of Vater–duodenal spasm, a seizure equivalent of the enteric nervous system), along with bacterial overgrowth, has been documented in most women with the disease (114). Women of reproductive age with endometriosis are not osteopenic (115).

The average delay between onset of pain symptoms and surgically confirmed endometriosis is quite long: ± 8 years in the United Kingdom and ± 9 to 12 years in the United States (116). A delay in diagnosis of endometriosis of 6 and 3 years in women with pain and women with infertility, respectively, has been reported. Over the past two decades, there has been a steady decrease in the delay in diagnosis and a decline in the prevalence of advanced endometriosis at first diagnosis (117). At the same time, patient awareness of endometriosis has increased. For many patients, endometriosis becomes a chronic disease, affecting quality of life resulting from pain, emotional impact of subfertility, anger about disease recurrence, and uncertainty about the future regarding repeated surgeries or long-term medical therapy and its side effects. Therefore, there is a need to look at endometriosis, at least in a subset of highly symptomatic women, as a chronic disease. Quality-of-life issues should, therefore, be addressed and studied using reliable and valid questionnaires (118).

Pain

In adult women, dysmenorrhea may be especially suggestive of endometriosis if it begins after years of pain-free menses. Dysmenorrhea often starts before the onset of menstrual bleeding and continues throughout the menstrual period. In adolescents, the pain may be present after menarche without an interval of pain-free menses. The distribution of pain is variable but most often is bilateral.

Local symptoms can arise from rectal, ureteral, and bladder involvement. Lower back pain can occur. Most studies have failed to detect a correlation between the degree of pelvic pain and the severity of endometriosis (103). Some women with extensive disease have no pain, whereas others with only minimal disease may experience severe pelvic pain. Severe pelvic pain and dyspareunia may be associated with deep infiltrating subperitoneal endometriosis (100,110). Possible mechanisms causing pain in patients with endometriosis include local peritoneal inflammation, deep infiltration with tissue damage, adhesion formation, fibrotic thickening, and collection of shed menstrual blood in endometriotic implants, resulting in painful traction with the physiologic movement of tissues (110,119).

In rectovaginal endometriotic nodules, a close histologic relationship has been observed between nerves and endometriotic foci and between nerves and the fibrotic component of the nodule (120).

Subfertility

An association between endometriosis and subfertility is generally accepted, but most of the studies suggesting this link have been based on retrospective or cross-sectional analysis. When endometriosis is moderate or severe, involving the ovaries and causing adhesions that block tuboovarian motility and ovum pickup, it is associated with subfertility (121). This effect has also been shown in primates, including cynomolgus monkeys and baboons (94,122). Although numerous mechanisms (ovulatory dysfunction, luteal insufficiency, luteinized unruptured follicle syndrome, recurrent abortion, altered immunity, and intraperitoneal inflammation) have been proposed (123), the association between fertility and minimal or mild endometriosis remains controversial (121).

Infertility Based on the number of asymptomatic women who are found to have endometriosis during tubal ligation, it would appear that the prevalence of endometriosis is not necessarily higher in infertile than in fertile women with endometriosis (5). In fertile women, endometriosis has been reported to be minimal or mild in 80% and moderate or severe in 20% (5,101,102,103,104 and 105).

In women with mild disease, some studies have reported a lower spontaneous *monthly fecundity rate* (MFR), which is the total number of pregnancies divided by the number of months of pregnancy exposure (i.e., 5% to 11% compared with 25% in a normally fertile population) (123). Other studies using artificial insemination with donor semen have reported that the MFR in women with minimal and mild endometriosis is either reduced (4%) or normal (20%) (124,125,126 and 127). Fertility is not reduced in baboons with spontaneous minimal endometriosis (122,128). In one study, the fecundity rate (probability of becoming pregnant in the first 36 weeks after laparoscopy and carrying the pregnancy to \geq 20 weeks) was 18% in infertile women with minimal to mild endometriosis and 23.7% in women with unexplained infertility (no significant difference). None of these women had been surgically treated for endometriosis during the diagnostic laparoscopy. However, 10% of women in each group had been treated with intrauterine insemination, *in vitro* fertilization (IVF) or cystectomy-myomectomy (129). It remains unclear whether the mere presence of peritoneal endometriosis directly correlates with infertility.

Spontaneous Abortion A possible association between endometriosis and spontaneous abortion has been suggested in mostly uncontrolled or retrospective studies. Some controlled studies evaluating the association between endometriosis and spontaneous abortion have important methodologic shortcomings: heterogeneity between cases and controls, analysis of the abortion rate before the diagnosis of endometriosis, and selection bias of study and control groups (357). Based on controlled prospective studies, there is no evidence that endometriosis is associated with (recurrent) pregnancy loss (132), or that medical or surgical treatment of endometriosis reduces the spontaneous abortion rate (133,134).

Endocrinologic Abnormalities

Endometriosis has been associated with anovulation, abnormal follicular development with impaired follicle growth, reduced circulating E_2 levels during the preovulatory phase, disturbed luteinizing hormone (LH) surge patterns, premenstrual spotting, the luteinized unruptured follicle syndrome, and galactorrhea and hyperprolactinemia (135). Increased incidence and recurrence of the luteinized unruptured follicle syndrome has been reported in baboons with mild endometriosis, but not in primates with minimal endometriosis or a normal pelvis (136). Luteal insufficiency with reduced circulating E_2 and progesterone levels, out-of-phase endometrial biopsies, and aberrant integrin expression has been reported in the endometrium of women with endometriosis by some researchers (135,137), but these findings have not been confirmed by other investigators (138). Therefore, no convincing data exist to conclude that the incidence of these endocrinologic abnormalities is increased in women who have endometriosis.

Extrapelvic Endometriosis

Extrapelvic endometriosis, although often asymptomatic, should be suspected when symptoms of pain or a palpable mass occur outside the pelvis in a cyclic pattern. Endometriosis involving the intestinal tract (especially colon and rectum) is the most common site of extrapelvic disease and may cause abdominal and back pain, abdominal distention, cyclic rectal bleeding, constipation, and obstruction. Ureteral involvement can lead to obstruction and result in cyclic pain, dysuria, and hematuria. Pulmonary endometriosis can manifest as pneumothorax, hemothorax, or hemoptysis during menses. Umbilical endometriosis should be suspected when a patient has a palpable mass and cyclic pain in the umbilical area (18).

Clinical Examination

In many women with endometriosis, no abnormality is detected during the clinical examination. The vulva, vagina, and cervix should be inspected for any signs of endometriosis, although the occurrence of endometriosis in these areas is rare (e.g., episiotomy scar).

Other possible signs of endometriosis include uterosacral or cul-de-sac nodularity, lateral or cervical displacement due to uterosacral scarring (139), painful swelling of the rectovaginal septum, and unilateral ovarian (cystic) enlargement. In more advanced disease, the uterus is often in fixed retroversion, and the mobility of the ovaries and fallopian tubes is reduced. Evidence of deeply infiltrative endometriosis (deeper than 5 mm under the peritoneum) in the rectovaginal septum with cul-de-sac obliteration or cystic ovarian endometriosis should be suspected by clinical documentation of uterosacral nodularities during menses, especially if CA125 serum levels are higher than 35 IU/mL (140,141 and 142).

The clinical examination may have false-negative results. Therefore, the diagnosis of endometriosis should always be confirmed by biopsy of suspicious lesions that are obtained laparoscopically.

Imaging and Endometriosis

When filling defects (presence of hypertrophic or polypoid endometrium) are observed at hysterosalpingography (143), there is a significant positive correlation with endometriosis with a positive predictive value of 84% and negative predictive value of 75%.

Gynecologic transvaginal (144) or transrectal ultrasonography (145) is an important diagnostic tool in the assessment of ovarian endometriotic cysts (differentiation from other adnexal masses) and of rectovaginal endometriosis (sensitivity, 97%; specificity, 96%).

Other imaging techniques, including computed tomography (CT) and magnetic resonance imaging (MRI), can be used to provide additional and confirmatory information, but they cannot be used for determining the primary diagnosis (146). These techniques are more costly than ultrasound, and their added value is not clear.

CA125

There is no blood test available for the diagnosis of endometriosis. Levels of CA125, a marker found on derivatives of the coelomic epithelium and common to most nonmucinous epithelial ovarian carcinomas, have been found to be significantly higher in women with moderate or severe endometriosis and normal in women with minimal or mild disease (147,148). During menstruation, an increase in CA125 levels has been shown in women with and without endometriosis (149,150,151,152 and 153). Other studies have not found an increase during menses (154,155) or have found an increase only with moderate to severe endometriosis (156,157). The levels of CA125 vary widely, not only in patients without endometriosis (8 to 22 U/mL in the nonmenstrual phase), but also in those with minimal to mild endometriosis (14 to

31 U/mL in the nonmenstrual phase) and in those with moderate to severe disease (13 to 95 U/mL in the nonmenstrual phase).

The reason CA125 levels are increased in moderate to severe endometriosis is unclear. It has been hypothesized that endometriosis lesions contain a greater amount of CA125 than normal endometrium and that the associated inflammation could lead to an increased shedding of CA125 (148).

The specificity of CA125 has been reported to be higher than 80% in most studies. This high level of specificity is achieved in selected women with infertility or pain who are known to be at risk for endometriosis. The low level of sensitivity of CA125 (20% to 50% in most studies) poses limitations for the clinical use of this test for diagnosis of endometriosis. Theoretically, the sensitivity might increase during the menstrual period, when the increase in CA125 levels is more pronounced in women who have endometriosis. However, studies using cutoff levels of 35 U/mL (156,157) or 85 U/mL (158) have not found a significant improvement in sensitivity. A sensitivity of 66% was found when CA125 was determined during both the follicular phase and the menstrual phase in each patient and when the ratio of menstrual versus follicular values (>1.5) was used instead of one CA125 level (157). More recent studies reported that the value of CA125 in diagnosis of endometriosis is limited but higher for moderate to severe disease, especially if serum CA125 concentrations are measured during the midfollicular phase (159,160).

Serial CA125 determinations may be useful to predict the recurrence of endometriosis after therapy (161,162). CA125 levels decrease after combined medical and surgical therapy or during medical treatment of endometriosis with danazol, gonadotropin-releasing hormone (GnRH) analogues, or gestrinone, but not with medroxyprogesterone acetate (MPA) or placebo (163,164 and 165). CA125 levels have been reported to increase to pretreatment levels as early as 3, 4, or 6 months after the cessation of therapy with danazol, GnRH analogs, or gestrinone (153,164,165,167 and 168). Posttreatment increases in CA125 levels have been reported to correlate with endometriosis recurrence (152,162,169). However, other studies have not substantiated a correlation between posttreatment CA125 levels and disease recurrence (163,166,170).

Laparoscopic Findings During diagnostic laparoscopy, the pelvic and abdominal cavity should be systematically investigated for the presence of endometriosis. This examination should include a complete inspection and palpation in a clockwise or counterclockwise fashion with a blunt probe of the bowel, bladder, uterus, tubes, ovaries, cul-de-sac, and broad ligament (Fig. 26.1).

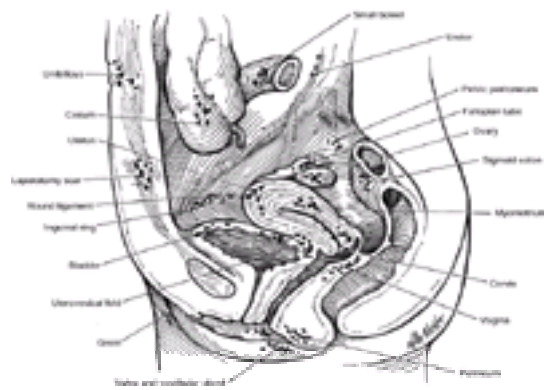

Figure 26.1 Pelvic localization of endometriosis.

Characteristic findings include typical (“powder-burn,” “gunshot”) lesions on the serosal surfaces of the peritoneum. These are black, dark brown, or bluish nodules or small cysts containing old hemorrhage surrounded by a variable degree of fibrosis (Fig. 26.2). Endometriosis can appear as subtle lesions (Fig. 26.3), including red implants (petechial, vesicular, polypoid, hemorrhagic, red flamelike), serous or clear vesicles, white plaques or scarring, yellow-brown discoloration of the peritoneum, and subovarian adhesions (89,90 and 91,171,172). Histologic confirmation of the laparoscopic impression is essential for the diagnosis of endometriosis (173), not only for subtle lesions but also for typical lesions reported to be histologically negative in 24% of cases (174).

Figure 26.2 Subtle and typical endometriotic lesions. **A:** Clear translucent vesicle on pelvic peritoneum. **B:** Red polypoid lesions and petechial and hemorrhagic areas on pelvic peritoneum. **C:** Typical black-puckered lesions on uterosacral ligaments. **D:** Combination of typical black-puckered lesions on left uterosacral ligament and red polypoid lesions in cul-de-sac.

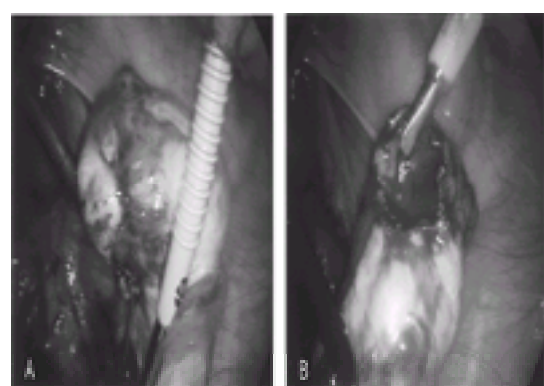

Figure 26.3 Ovarian endometriosis: endometriotic cyst (endometrioma) on the left ovary.

Mild forms of deep endometriosis may only be detected by palpation under an endometriotic lesion or by discovery of a palpable mass beneath visually normal peritoneum, most notably in the posterior cul-de-sac (141) (Fig. 26.4). Reduced Douglas depth and volume in women with deep endometriosis suggest that such lesions develop not in the rectovaginal septum but intraperitoneally and that burial by anterior rectal wall adhesions creates a false bottom, giving an erroneous impression of xtraperitoneal origin (175).

Figure 26.4 Laparoscopic excision of deep endometriosis from the cul-de-sac.

The diagnosis of ovarian endometriosis is facilitated by careful inspection of all sides of both ovaries, which may be difficult when adhesions are present in more advanced stages of disease (Fig. 26.5). With superficial ovarian endometriosis, lesions can be both typical and subtle. Larger ovarian endometriotic cysts (endometrioma) are usually located on the anterior surface of the ovary and are associated with retraction, pigmentation, and adhesions to the posterior peritoneum. These ovarian endometriotic cysts often contain a thick, viscous dark brown fluid (“chocolate fluid”) composed of hemosiderin derived from previous intraovarian hemorrhage. Because this fluid may also be found in other conditions, such as in hemorrhagic corpus luteum cysts or neoplastic cysts, biopsy and preferably removal of the ovarian cyst for histologic confirmation are necessary for the diagnosis in the revised endometriosis classification of the American Society for Reproductive Medicine. If that is not possible, the presence of an ovarian endometriotic cyst should be confirmed by the following features: cyst diameter of less than 12 cm, adhesion to pelvic sidewall or broad ligament, endometriosis on surface of ovary, and tarry, thick, chocolate-colored fluid content (176). Ovarian endometriosis appears to be a marker for more extensive pelvic and intestinal disease. Exclusive ovarian disease is found in only 1% of endometriosis patients, with the remaining patients having mostly extensive pelvic or intestinal endometriosis (177).

Stage	Location	Characteristics
I	Superficial	Endometrial implants on the surface of the peritoneum, ovaries, or fallopian tubes.
II	Deep	Endometrial implants extending into the muscular layers of the peritoneum, ovaries, or fallopian tubes.
III	Advanced	Endometrial implants with associated adhesions and cysts.
IV	Severe	Endometrial implants with extensive adhesions and cysts, often involving the uterus and fallopian tubes.

Histologic Confirmation

Histologic confirmation is essential in the diagnosis of endometriosis. In a study of 44 patients with chronic pelvic pain, endometriosis was laparoscopically diagnosed in 36%, but histologic confirmation was obtained in only 18%. This resulted in a low diagnostic accuracy of laparoscopic inspection with a positive predictive value of only 45%, explained by a specificity of only 77% (178).

Microscopically, endometriotic implants consist of endometrial glands and stroma with or without hemosiderin-laden macrophages (Fig. 26.6). It has been suggested, however, that using these stringent and unvalidated histologic criteria may result in significant underdiagnosis of endometriosis (2). Furthermore, problems in obtaining biopsies (especially small vesicles) and variability in tissue processing (step or partial instead of serial sectioning) may contribute to false-negative results. Endometrioid stroma may be more characteristic of endometriosis than endometrioid glands (179). Stromal endometriosis, which contains endometrial stroma with hemosiderin-laden macrophages or hemorrhage, has been reported in women (173,174) and in baboons (97) and may represent a very early event in the pathogenesis of endometriosis. Isolated endometrial stromal cell nodules, immunohistochemically positive for vimentin and estrogen receptor, can be found without endometrial glands along blood or lymphatic vessels (180).

Figure 26.6 Histologic appearance of endometriosis: endometrial glandular epithelium, surrounded by stroma in (A) typical lesion and (B) clear vesicle.

Different types of lesions may have different degrees of proliferative or secretory glandular activity (179). Vascularization, mitotic activity, and the three-dimensional structure of endometriosis lesions are key factors (181,182 and 183). Deep endometriosis has been described as a specific type of pelvic endometriosis characterized by proliferative strands of glands and stroma in dense fibrous and smooth muscle tissue (110). However, smooth muscles are also frequent components of endometriotic lesions on the peritoneum, ovary, rectovaginal septum, and uteroasacral ligaments (184).

Microscopic endometriosis is defined as the presence of endometrial glands and stroma in macroscopically normal pelvic peritoneum. It is believed to be important in the histogenesis of endometriosis and its recurrence after treatment (185,186). The clinical relevance of microscopic endometriosis is controversial because it has not been observed uniformly. Using undefined criteria for what constitutes normal peritoneum, peritoneal biopsy specimens of 1 to 3 cm were obtained during laparotomy from 20 patients with moderate to severe endometriosis (186). Examination of the biopsy results with low-power scanning electron microscopy revealed unsuspected microscopic endometriosis in 25% of cases not confirmed by light microscopy. Peritoneal endometriotic foci have been demonstrated by light microscopy in areas that show no obvious evidence of disease (187). In serial sections of laparoscopic biopsies of normal peritoneum, 10% to 15% of women were shown to have microscopic endometriosis, and endometriosis was found in 6% of those without macroscopic disease (172,188,189).

In contrast, other studies have been unable to detect microscopic endometriosis in 2-mm biopsy specimens of visually normal peritoneum (88,190,191 and 192). Examination of larger samples (5 to 15 mm) of visually normal peritoneum has revealed microscopic endometriosis in only 1 of 55 patients studied (193). Similarly, a histologic study of serial sections through the entire pelvic peritoneum of visually normal peritoneum from baboons with and without disease indicated that microscopic

endometriosis is a rare occurrence (194). Therefore, it appears that macroscopically appearing normal peritoneum rarely contains microscopic endometriosis (193).

Classification

The current classification system of endometriosis is the former American Fertility Society (AFS) system (Fig. 26.5), which has been revised without major changes (121). It is based on the appearance, size, and depth of peritoneal and ovarian implants; the presence, extent, and type of adnexal adhesions; and the degree of cul-de-sac obliteration. **In the new classification system, the morphology of peritoneal and ovarian implants should be categorized as red (red, red-pink, and clear lesions), white (white, yellow-brown, and peritoneal defects), and black (black and blue lesions).**

This system reflects the extent of endometriotic disease but has considerable intraobserver and interobserver variability (195,196). Because the revised classification of endometriosis is the only internationally accepted system, it appears to be the best available tool to describe objectively the extent of endometriosis and relate it to spontaneous evolution and to therapeutic outcomes (pain relief, enhancement of fertility).

The classification system has also been criticized because several investigators failed to find a correlation between it and endometriosis-related pain or infertility, as will be reviewed in the section, Results of Surgical Treatment.

Spontaneous Evolution

Endometriosis appears to be a progressive disease in a significant proportion (30% to 60%) of patients. During serial observations, deterioration (47%), improvement (30%), or elimination (23%) was documented over a 6-month period (197). In another study, endometriosis progressed in 64%, improved in 27%, and remained unchanged in 9% of patients over 12 months (198). A third study of 24 women reported 29% with disease progression, 29% with disease regression, and 42% with no change over 12 months. Follow-up studies in both baboons and women (200,201) with spontaneous endometriosis over 24 months have demonstrated disease progression in all baboons and in 6 of 7 women. Several studies have reported that subtle lesions and typical implants may represent younger and older types of endometriosis, respectively. In a cross-sectional study, the incidence of subtle lesions decreased with age (203). This was recently confirmed by a 3-year prospective study that reported that the incidence, overall pelvic area involved, and volume of subtle lesions decreased with age, but in typical lesions, these parameters and the depth of infiltration increased with age (100). Remodeling of endometriotic lesions (transition between typical and subtle subtypes) has been reported to occur in women and in baboons, indicating that endometriosis is a dynamic condition (202,204). Several studies in women, cynomolgus monkeys, and rodents have shown that endometriosis is ameliorated after pregnancy (204,205).

The characteristics of endometriosis are variable during pregnancy, and lesions tend to enlarge during the first trimester but regress thereafter (208). Studies in baboons have revealed no change in the number or surface area of endometriosis lesions during the first two trimesters of pregnancy (209). These results do not exclude a beneficial effect that potentially may occur during the third trimester or in the immediate postpartum period. Establishment of a “pseudopregnant state” with exogenously administered estrogen and progestins was based on the belief that symptomatic improvement may result from decidualization of endometrial implants during pregnancy (210). This hypothesis, however, has not been substantiated.

Treatment

Prevention

No strategies to prevent endometriosis have been uniformly successful. Although a reduced incidence of endometriosis has been reported in women who engaged in aerobic activity from an early age (16), the possible protective effect of exercise has not been investigated thoroughly. There also is insufficient evidence that oral contraceptive use offers protection against the development of endometriosis. In contrast, a recent report (211) showed an increased risk for endometriosis development in a select population of women taking oral contraceptives.

Regardless of the clinical profile (subfertility, pain, asymptomatic findings), treatment of endometriosis may be justified because endometriosis appears to progress in 30% to 60% of patients within a year of diagnosis and because it is not possible to predict in which patients it will progress (198). **Unfortunately, elimination of the endometriotic implants by surgical or medical treatment often provides only temporary relief. Therefore, the goal should be to eliminate the endometriotic lesions and, more importantly, to treat the sequelae (pain and subfertility) often associated with this disease.**

Surgical Treatment

In most women with endometriosis, preservation of reproductive function is desirable. Therefore, the least invasive and least expensive approach that is effective should be used. The goal of surgery is to excise or coagulate all visible endometriotic lesions and associated adhesions—peritoneal lesions, ovarian cysts, deep rectovaginal endometriosis—and to restore normal anatomy. Laparoscopy can be used in most women, and this technique decreases cost, morbidity, and the possibility of recurrence of adhesions postoperatively. **Laparotomy should be reserved for patients with advanced-stage disease who cannot undergo a laparoscopic procedure and for those in whom fertility conservation is not necessary.**

Peritoneal Endometriosis Endometriosis lesions can be removed during laparoscopy by surgical excision with scissors, bipolar coagulation, or laser methods (CO₂ laser, potassium-titanyl-phosphate laser, or argon laser). Although some surgeons claim that the CO₂ laser is superior because it causes only minimal thermal damage, no evidence is available to show that one technique is better than the other. Comparable cumulative pregnancy rates have been reported after treatment of mild endometriosis with laparoscopic excision and electrocoagulation (212).

Ovarian Endometriosis Superficial ovarian lesions can be vaporized. Small ovarian endometrioma (<3 cm in diameter) can be aspirated, irrigated, and inspected with ovarian cystoscopy for intracystic lesions; their interior wall can be vaporized to destroy the mucosal lining of the cyst (213). **Large (>3 cm in diameter) ovarian endometrioma should be aspirated, followed by incision and removal of the cyst wall from the ovarian cortex. To prevent recurrence, the cyst wall of the endometrioma must be removed, and normal ovarian tissue must be preserved.**

Although as little as one tenth of an ovary is enough to preserve function and fertility (214), there is increasing concern that ovarian cystectomy with concomitant removal or destruction of primordial follicles may reduce ovarian volume and reserve and diminish fertility. A recent study reported reduced follicular response in natural and clomiphene citrate-stimulated cycles, but not in gonadotropin-stimulated cycles, in women younger than 35 years of age who underwent cystectomy compared with controls of similar age with normal ovaries (215). Therefore, it has been proposed to replace cystectomy by fenestration and coagulation of the inner wall of the endometriotic ovarian cyst. In one study, cumulative clinical pregnancy rates and recurrence rates were comparable in women treated with cystectomy and with fenestration and coagulation after 36 months, but conception occurred more quickly in the fenestration and coagulation group (216). A more recent case-control study in 231 patients reported a lower cumulative reoperation rate in the cyst excision group than in the fenestration and coagulation group after 18 (6% versus 22%) and 42 (24% versus 59%) months of follow-up (217). A randomized controlled trial demonstrated that pain and subfertility caused by ovarian endometrioma were improved more by cystectomy than by fenestration and coagulation (218). A reduced recurrence of pain after 2 years [odds ratio (OR), 0.2; confidence interval (CI), 0.05 to 0.77], an increased pain-free interval after operation (19 months versus 9.5 months), and an increased pregnancy rate (67% versus 23%) were found in the cystectomy group when compared with the fenestration and coagulation group (218). Therefore, based on the current evidence, ovarian cystectomy appears to be the method of choice.

Adhesiolysis The removal of endometriosis-related adhesions (adhesiolysis) should be performed carefully as described in Chapter 21. Routine use of pharmacologic or liquid agents to prevent postoperative adhesions after fertility surgery cannot be recommended based on evidence from randomized controlled trials (219).

Preoperative Hormonal Treatment In patients with severe endometriosis, it has been recommended that surgical treatment be preceded by a 3-month course of medical treatment to reduce vascularization and nodular size (141). However, a recent randomized study comparing 3 months of preoperative treatment with GnRH and no treatment in 75 women with moderate to severe endometriosis failed to show a significant difference in ease of surgery between the two groups (220).

Deep Rectovaginal and Rectosigmoidal Endometriosis The surgical excision of deep rectovaginal and rectosigmoidal endometriosis is difficult and can be

associated with major complications. Postoperative bowel perforations with peritonitis have been reported in 2% to 3% of cases ([221](#)).

Preoperative investigations, including gynecologic ultrasound, intravenous pyelography (to exclude ureteral endometriosis), and colon contrast radiography (to exclude transmural rectosigmoidal endometriosis), are essential. Preoperative laxatives, starch-free diet, and full bowel preparation are needed to allow perioperative bowel suturing, if needed. To allow complete excision of rectovaginal endometriosis, 6% of patients needed bowel wall resection, and 14% required partial resection of the posterior vaginal fornix ([221](#)). Segmental rectosigmoid resection can be performed by laparotomy, laparoscopy with intracorporeal suturing, or by laparoscopically assisted vaginal technique ([222](#)). The latter technique appears to be faster than laparoscopy with intracorporeal suturing and cheaper than laparotomy because of decreased hospital stay and lower operating room charges ([222](#)). Ureter stents may be required before excision of peritoneal endometriosis surrounding the ureter. A multidisciplinary approach involving gynecologic and gastroenterologic surgeons and urologists is desirable.

Oophorectomy and Hysterectomy Radical procedures such as oophorectomy or total hysterectomy are indicated only in severe situations and can be performed either laparoscopically or, more commonly, by laparotomy. However, it is important to note that women aged 30 years or younger at the time of hysterectomy for endometriosis-associated pain are more likely than older women to have residual symptoms, to report a sense of loss, and to report more disruption from pain in different aspects of their lives ([223](#)).

Postoperative Hormone Replacement Postoperative hormone replacement with estrogen is required after bilateral oophorectomy, and there is a negligible risk for renewed growth of residual endometriosis. To reduce this risk, hormone replacement therapy should be withheld until 3 months after surgery. The addition of progestins to this regimen protects the endometrium. Some cases of adenocarcinoma have been reported, presumably arising from endometriosis lesions left in women treated with unopposed estrogen ([214](#)).

Results of Surgical Treatment

Pain

The outcome of surgical therapy in patients with endometriosis and pain is influenced by many psychological factors relating to personality, depression, and marital and sexual problems. **There is a significant placebo response to surgical therapy: diagnostic laparoscopy without complete removal of endometriosis may alleviate pain in 50% of patients** ([224,225](#) and [226](#)). Similar results have been reported using oral placebos ([227](#)). Although some reports have claimed pain relief with laser laparoscopy in 60% to 80% of patients with very low morbidity, none was prospective or controlled and, thus, did not allow a definitive conclusion regarding treatment efficacy ([141,228,229,230](#) and [231](#)).

Endometriosis Stage and Pain Relief after Surgery In patients with pain, the endometriosis stage was not related to pain symptoms in several studies ([232,233](#)). However, more recent studies reported a positive correlation between endometriosis stage and endometriosis-related dysmenorrhea or chronic pelvic pain ([234,235](#)).

In a prospective, controlled, randomized, double-blind study, surgical therapy has been shown to be superior to expectant management 6 months after treatment of mild and moderate endometriosis ([224](#)). In women with mild and moderate disease treated with laser, 74% achieved pain relief. Treatment was least effective in women with minimal disease. There were no reported operative or laser complications ([224](#)). One year later, symptom relief was still present in 90% of those who initially responded ([199](#)). Patients with severe disease were not included because it had previously been shown that surgery resulted in pain relief in 80% of patients who did not respond to medical therapy ([236](#)).

These results suggest that laser laparoscopy may be effective for the treatment of pain associated with mild to severe endometriosis. In women with minimal endometriosis, laser treatment may limit progression of disease.

Effects of Postoperative Hormonal Treatment on Pain Substantial evidence from randomized controlled trials supports the postoperative medical treatment of endometriosis-associated pain for 6 to 12 months. Postoperative GnRH treatment resulted in reduced pain scores and in a delay of pain recurrence for more than 12 months if the agonists were given for 6 months but not if they were only administered for 3 months ([237,238](#) and [239](#)). Similarly, postoperative hormonal treatment with *danazol*, 100 mg/d (low dose), for 12 months after surgery for moderate to severe endometriosis resulted in a significantly lower pain score in the treated group when compared with the placebo group. In contrast, postoperative high-dose *danazol*, 600 mg/d for 3 months, was not superior to expectant management with respect to pain recurrence in an identical patient population ([240](#)).

Subfertility

Endometriosis Stage and Pregnancy Outcome after Surgery When endometriosis causes mechanical distortion of the pelvis, surgery should be performed if reconstruction of normal pelvic anatomy can be achieved. The success of surgery in relieving infertility is probably related to the severity of endometriosis. A recent retrospective multicenter analysis ([241](#)) reported cumulative pregnancy rates of 39%, 31%, 30%, and 25% in patients with endometriosis stages I, II, III, and IV, respectively, 12 months after surgical treatment. Although there appeared to be a negative correlation between stage of endometriosis and fertility outcome, no significant difference was found between the four groups in this study. However, the study had many limitations, including retrospective design, lack of well-defined definition of male factor infertility as potential bias, multicenter data with significant interobserver variability, inclusion of only a limited number of patients with substantial adhesive disease, variable infertility treatment after 6 months of follow-up, and absence of a control group. A somewhat higher cumulative intrauterine pregnancy rate has been reported in 30 women with deep uterosacral endometriosis after surgery: 48% after 12 months (47% for AFS stages I to II and 46% for AFS stages III to IV) ([242](#)). A cumulative pregnancy rate of 24% was reported in patients 9 months after undergoing reoperation for stage III to IV endometriosis ([243](#)).

Other investigators reported a negative correlation between stage of endometriosis and fertility after surgical treatment. In an older study, using an older classification system, a significant decrease in fecundability was seen in women with severe or extensive endometriosis compared with women with mild or moderate disease ([244,245](#)). Other studies have reported a significant negative correlation between endometriosis stage and pregnancy rate and decreased pregnancy rates when the revised scores exceeded 70 ([246,247](#)).

Preoperative and Postoperative Medical Treatment Preoperative medical treatment with *danazol*, GnRH agonists, or progestins may be useful to reduce the extent of endometriosis in patients with advanced disease. Postoperative medical treatment is rarely indicated because it does not work based on randomized trials, because it prevents pregnancy, and because the highest pregnancy rates occur during the first 6 to 12 months after conservative surgery ([238,239](#)). If pregnancy does not occur within 2 years of surgery, there is little chance of subsequent fertility ([248](#)).

Minimal to Mild Endometriosis and Fertility after Surgery Surgical management of infertile women with minimal to mild endometriosis is controversial. The cumulative pregnancy rate after 5 years without therapy has been reported to be as high as 90% in women with minimal or mild endometriosis ([249](#)). This is comparable to the 93% rate reported in women who do not have endometriosis. Laparoscopic destruction of endometriosis has been reported to improve fertility in patients with minimal to mild disease ([250,251](#) and [252](#)), but not all investigators share this conclusion ([253,254](#) and [255](#)). It has been hypothesized that the MFR is higher during the first 6 to 12 months after laparoscopic surgery than with expectant management ([256,257](#)).

Two randomized controlled studies have evaluated the effect of surgical treatment of endometriosis on fertility parameters ([133,134](#)). Marcoux and coworkers ([133](#)) reported that laparoscopic surgery enhanced fecundity in infertile women with minimal or mild endometriosis. They studied 341 infertile women, 20 to 39 years of age, with minimal or mild endometriosis. During diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. They were followed for 36 weeks after the laparoscopy or, for those who became pregnant during that interval, for up to 20 weeks of pregnancy. The study objects were recruited among infertile women scheduled for diagnostic laparoscopy with strict eligibility criteria. There was no previous surgical treatment for endometriosis and no medical treatment for endometriosis in the previous 9 months. There was no other medical or surgical treatment for infertility in the previous 3 months. They had no history of pelvic inflammatory disease and no severe pelvic pain precluding expectant management. The diagnosis of endometriosis required the presence of one or more typical bluish or black lesions. The stage of endometriosis was determined according to the revised AFS classification. During the diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. They found that resection or ablation of minimal and mild endometriosis increased the likelihood of pregnancy in infertile women. In the treated group, 31% of the patients became pregnant, compared with 18% in the nontreated group ($p = 0.006$).

In a multicenter Italian study, a similar study design was used to compare the effect of diagnostic laparoscopy with surgical resection and ablation of visible

endometriosis (on fertility parameters) in infertile women with minimal to mild endometriosis (134). Eligible patients were women aged less than 36 years who were trying to conceive and had a laparoscopically confirmed diagnosis of minimal or mild endometriosis, according to the revised AFS classification system. None of the women had had therapy for endometriosis or infertility. Treatment was randomly allocated during laparoscopy. There was a follow-up period of 1 year after the laparoscopy. The results of this study did not show a beneficial effect of surgery regarding fertility. During the follow-up period after laparoscopy, no statistically significant differences in conception and live-birth rates were observed in the treated group (24% and 20%, respectively) and in the control group (29% and 22%, respectively).

Based on these studies, and taking into account the larger patient population in the Canadian multicenter study, **surgical treatment of minimal to mild endometriosis appears to offer a small but significant benefit with regard to fertility outcome.** Furthermore, the surgical removal of peritoneal endometriosis may also be important to prevent progression of endometriosis. However, care is needed to prevent adhesion formation that could result as a consequence of overenthusiastic excision of minimal to mild endometriosis.

Medical Treatment

Because estrogen is known to stimulate the growth of endometriosis, hormonal therapy has been designed to suppress estrogen synthesis, thereby inducing atrophy of ectopic endometrial implants or interrupting the cycle of stimulation and bleeding. Implants of endometriosis react to gonadal steroid hormones in a manner similar but not identical to normally stimulated ectopic endometrium. Ectopic endometrial tissue displays histologic and biochemical differences from normal ectopic endometrium in characteristics such as glandular activity (proliferation, secretion), enzyme activity (17 β -hydroxysteroid dehydrogenase), and steroid (estrogen, progesterin, and androgen) hormone receptor levels. The use of *diethylstilbestrol*, *methyltestosterone*, or other androgens is no longer advocated because they lack efficacy, have significant side effects, and pose risks to the fetus if pregnancy occurs during therapy. A new generation of aromatase inhibitors, estrogen receptor modulators, and progesterone antagonists may offer new hormonal treatment options in the future. Recent progress in the understanding of the pathogenesis of endometriosis has led to the expectation that new pharmaceutical agents affecting inflammation, angiogenesis, and MMP activity may prevent or inhibit the development of endometriosis.

Oral Contraceptives

Continuous Administration Manipulation of the endogenous hormonal milieu is the basis for the medical management of endometriosis. The treatment of endometriosis with continuous low-dose monophasic combination contraceptives (one pill per day for 6 to 12 months) was originally used to induce pseudopregnancy caused by the resultant amenorrhea and decidualization of endometrial tissue (210). Kistner was the first to introduce the concept of an adynamic endometrium through elimination of the normal cyclic hormonal changes characteristic of the menstrual cycle (258). This induction of a pseudopregnancy state with combination oral contraceptive pills has been shown to be effective in reducing dysmenorrhea and pelvic pain. In addition, the subsequent amenorrhea induced by oral contraceptives could potentially reduce the amount of retrograde menstruation (one of the many risk factors proposed in the etiology of endometriosis), decreasing the risk for disease progression. Pathologically, oral contraceptive use is associated with decidualization of endometrial tissue, necrobiosis, and possibly absorption of the endometrial tissue (259). Unfortunately, there is no convincing evidence that medical therapy with oral contraceptives offers definitive therapy. Instead, the endometrial implants survive the induced atrophy and, in most patients, reactivate after termination of treatment.

Any low-dose combination oral contraceptive containing 30 to 35 mg of ethinyl estradiol used continuously can be effective in the management of endometriosis. The objective of the treatment is the induction of amenorrhea, which should be continued for 6 to 12 months. Symptomatic relief of dysmenorrhea and pelvic pain is reported in 60% to 95% of patients (260,261). After a first-year recurrence rate of 17% to 18%, a 5% to 10% annual recurrence rate has been observed. In addition, a posttreatment pregnancy rate of up to 50% can be expected. Although oral contraceptives are effective in inducing a decidualized endometrium, the estrogenic component in oral contraceptives may potentially stimulate endometrial growth and increase pelvic pain in the first few weeks of treatment. The long-term significance of this effect remains to be determined. Oral contraceptives are less costly than other treatments and may be helpful in the short-term management of endometriosis with potential long-term benefits in some women.

Cyclic Administration There is no convincing evidence that cyclic use of combination oral contraceptives provides prophylaxis against either the development or recurrence of endometriosis. Estrogens in oral contraceptives potentially may stimulate the proliferation of endometriosis. The reduced menstrual bleeding that often occurs in women taking oral contraceptives may be beneficial to women with prolonged, frequent menstrual bleeding, which is a known risk factor for endometriosis (16). Further research is warranted to assess the effect of low-dose oral contraceptives in preventing endometriosis and in treating associated pain. In a recent randomized controlled study, a cyclic 2-day oral contraceptive (*ethinyl estradio* 20 μ g + *desogestrel* 0.15 mg) combined with very-low-dose danazol (50 mg/d) was less effective in relief of dysmenorrhea than depot *medroxyprogesterone acetate* (150 mg every 3 months) (262).

Progestins

Progestins may exert an antiendometriotic effect by causing initial decidualization of endometrial tissue followed by atrophy. They can be considered as the first choice for the treatment of endometriosis because they are as effective as *danazol* or GnRH analogues and have a lower cost and a lower incidence of side effects than these agents (263).

There is no evidence that any single agent or any particular dose is preferable to another. The effective doses of several progestins are summarized in Table 26.1. In most studies, the effect of treatment has been evaluated after 3 to 6 months of therapy. *MPA* has been the most studied agent. It is effective in relieving pain starting at a dose of 30 mg/d and increasing the dose based on the clinical response and bleeding patterns (264,265). However, a recent randomized placebo controlled study reported a significant reduction in stages and scores of endometriosis in both the placebo group and the group treated with *MPA*, 50 mg/d, and placebo at laparoscopy within 3 months after cessation of therapy (266). These findings raise questions about the need for medical therapy.

	Administration	Dose	Frequency
Progestins			
<i>Medroxyprogesterone acetate</i>	PO	30 mg	Daily
<i>Megestrol acetate</i>	PO	40 mg	Daily
<i>Lynestrenol</i>	PO	30 mg	Daily
<i>Dydrogesterone</i>	PO	20–30 mg	Daily
Androgens			
<i>Testosterone</i>	PO	1.25 or 2.5 mg	Twice weekly
<i>Danazol</i>	PO	400 mg	Daily
Gonadotropin-Releasing Hormone			
<i>Leuprolide</i>	SC	500 mg	Daily
	IM	3.75 mg	Monthly
<i>Goserelin</i>	SC	3.6 mg	Monthly
<i>Buserelin</i>	IN	300 μ g	Daily
	SC	200 μ g	Daily
<i>Nafarelin</i>	IN	200 μ g	Daily
<i>Triptorelin</i>	IM	3.75 mg	Monthly

PO, oral; SC, subcutaneous; IM, intramuscular; IN, intranasal.

Table 26.1. Medical Treatment of Endometriosis-Associated Pain: Effective Regimens (Usual Duration: 6 Months)

Medroxyprogesterone acetate (150 mg) given intramuscularly every 3 months is also effective for the treatment of pain associated with endometriosis, but it is not indicated in infertile women because it induces profound amenorrhea and anovulation, and a varying length of time is required for ovulation to resume after discontinuation of therapy. *Megestrol acetate* has been administered in a dose of 40 mg/d with good results (276). Other treatment strategies have included *dydrogesterone* (20 to 30 mg/d, either continuously or on days 5 to 25) and *lynestrenol* (10 mg/d). The effectiveness of natural progesterone has not been evaluated.

Side effects of progestins include nausea, weight gain, fluid retention, and breakthrough bleeding due to hypoestrogenemia. Breakthrough bleeding, although common, is usually corrected by short-term (7-day) administration of estrogen. Depression and other mood disorders are a significant problem in about 1% of women taking these medications.

Local progesterone treatment of endometriosis-associated dysmenorrhea with a *levonorgestrel*-releasing intrauterine system for 12 months has resulted in a

significant reduction in dysmenorrhea, pelvic pain, and dyspareunia; a high degree of patient satisfaction; and a significant reduction in the volume of rectovaginal endometriotic nodules ([267,268](#)). Although the results are promising, none of these pilot studies included a control group. Further randomized evidence is needed to determine whether intrauterine progesterone treatment is effective in the suppression of endometriosis.

Progesterone Antagonists

Progesterone antagonists and progesterone receptor modulators may suppress endometriosis based on their antiproliferative effects on the endometrium, without the risk for hypo-estrogenism or bone loss that occurs with GnRH treatment. These products are soon to be introduced in the United States, but their clinical effectiveness remains to be proved.

Mifepristone Mifepristone (RU-486) is a potent antiprogesterone with a direct inhibitory effect on human endometrial cells and, in high doses, an antiglucocorticoid action ([269](#)). The recommended dose for endometriosis is 25 to 100 g/d. In uncontrolled studies, *mifepristone*, 50 to 100 mg/d, reduced pelvic pain and induced 55% regression of the lesions without significant side effects ([270,271](#)). In an uncontrolled pilot study, *mifepristone*, 5 mg/d, resulted in pain improvement, but there was no change in endometriosis lesions, suggesting that this dosage is probably too low ([272](#)).

Onapristone Progesterone antagonists *onapristone* (ZK98299) and ZK136799, used in the treatment of rats with surgically induced endometriosis, resulted in a remission in 40% to 60% of treated animals. In animals with persistent endometriosis, growth inhibition was obtained in 48% and 85% of endometriotic lesions after therapy with *onapristone* and ZK136799, respectively ([273](#)).

Other Progesterone Antagonists The chemical synthesis and pharmacologic characterization of a highly potent progesterone antagonist, ZK230211, have been reported, with little or no other endocrinologic effects. ZK230211 is active on both progesterone receptors A and B ([274](#)). In primates, this drug has been reported to block ovulation and menstruation at all effective doses ([275](#)), whereas another progesterone antagonist, ZK137316, allowed ovulation but blocked menstruation in a dose-dependent fashion. All progesterone antagonist-treated animals maintained normal follicular phase concentration of estradiol and returned to menstrual cyclicity within 15 to 41 days after treatment ([275](#)). Both progesterone antagonists block unopposed estrogen action on the endometriosis through their antiproliferative effect.

Gestrinone

Gestrinone is a 19-nortestosterone derivative with androgenic, antiprogesterone, antiestrogenic, and antigonadotropic properties. It acts centrally and peripherally to increase free testosterone and reduce sex hormone-binding globulin levels (androgenic effect), reduce serum estradiol values to early follicular phase levels (antiestrogenic effect), reduce mean LH levels, and obliterate the LH and follicle-stimulating hormone (FSH) surge (antigonadotropic effect). *Gestrinone* causes cellular inactivation and degeneration of endometriotic implants but not their disappearance ([277](#)). Amenorrhea occurs in 50% to 100% of women and is dose dependent.

Resumption of menses generally occurs 33 days after discontinuing the medication ([278,279](#)). An advantage of gestrinone is its long half-life (28 hours) when given orally. The standard dose has been 2.5 mg twice a week. Although it has been reported that 1.25 mg twice weekly is equally effective ([280](#)), a more recent randomized study demonstrated in women with mild to moderate endometriosis that 2.5 mg *gestrinone*, twice weekly for 24 weeks, is more effective and has a better effect on bone mass (+7% versus -7%) when compared with 1.25 mg *gestrinone*, 2 times weekly for 24 weeks ([281](#)).

The clinical side effects of gestrinone are dose dependent and similar to but less intense than those caused by *danazol* ([278](#)). They include nausea, muscle cramps, and androgenic effects such as weight gain, acne, seborrhea, and oily hair and skin.

In a multicenter, randomized, double-blind study, *gestrinone* was as effective as GnRH for the treatment of pelvic pain associated with endometriosis ([282](#)). However, *gestrinone* has fewer side effects and has the added advantage of twice-weekly administration. Pregnancy is contraindicated while taking gestrinone because of the risk for masculinization of the fetus.

Danazol

Danazol is not more effective than other available medications to treat endometriosis. Recognized pharmacologic properties of *danazol* include suppression of GnRH or gonadotropin secretion, direct inhibition of steroidogenesis, increased metabolic clearance of estradiol and progesterone, direct antagonistic and agonistic interaction with endometrial androgen and progesterone receptors, and immunologic attenuation of potentially adverse reproductive effects ([283,284](#)). The multiple effects of *danazol* produce a high-androgen, low-estrogen environment (estrogen levels in the early follicular to postmenopausal range) that does not support the growth of endometriosis, and the amenorrhea that is produced prevents new seeding of implants from the uterus into the peritoneal cavity.

The immunologic effects of danazol have been studied in women with endometriosis and adenomyosis and include a decrease in serum immunoglobulins, a decrease in serum C3, a rise in serum C4 levels, decreased serum levels of autoantibodies against various phospholipid antigens, and decreased serum levels of CA125 during treatment ([152,153,165,166,167](#) and [168,285,286](#)). *Danazol* inhibits peripheral blood lymphocyte proliferation in cultures activated by T-cell mitogens but does not affect macrophage-dependent T-lymphocyte activation of B lymphocytes ([284](#)). *Danazol* inhibits interleukin-1 and TNF production by monocytes in a dose-dependent manner, and suppresses macrophage- and monocyte-mediated cytotoxicity of susceptible target cells in women with mild endometriosis ([287](#)). These immunologic findings may be important in the remission of endometriosis with danazol treatment and may offer an explanation of the effect of *danazol* in the treatment of a number of autoimmune diseases, including hereditary angioedema ([289](#)), autoimmune hemolytic anemia ([290](#)), systemic lupus erythematosus ([291](#)), and idiopathic thrombocytopenic purpura ([292,293](#)). Doses of 800 mg/d are frequently used in North America, whereas 600 mg/d is commonly prescribed in Europe and Australia. It appears that the absence of menstruation is a better indicator of response than drug dose. A practical strategy for the use of *danazol* is to start treatment with 400 mg daily (200 mg twice a day) and increase the dose, if necessary, to achieve amenorrhea and relieve symptoms ([279](#)).

The significant adverse side effects of *danazol* are related to its androgenic and hypoestrogenic properties. The most common side effects include weight gain, fluid retention, acne, oily skin, hirsutism, hot flashes, atrophic vaginitis, reduced breast size, reduced libido, fatigue, nausea, muscle cramps, and emotional instability. Deepening of the voice is another potential side effect that is nonreversible. Although *danazol* can cause increased cholesterol and low-density lipoprotein levels and decreased high-density lipoproteins levels, it is unlikely that these short-term effects are clinically important. *Danazol* is contraindicated in patients with liver disease because it is largely metabolized in the liver and may cause hepatocellular damage. *Danazol* is also contraindicated in patients with hypertension, congestive heart failure, or impaired renal function because it can cause fluid retention. The use of danazol is contraindicated in pregnancy because of its androgenic effects on the fetus.

Because the many side effects of oral *danazol* limit its use, alternative routes of administration have been studied. In an uncontrolled pilot study, local *danazol* treatment using a vaginal *danazol* ring (1,500 mg) has been shown to be effective for pain relief in deeply infiltrative endometriosis without the classic *danazol* side effects, or detectable serum *danazol* levels, while allowing ovulation and conception ([294](#)).

Gonadotropin-releasing Hormone Agonists

GnRH agonists bind to pituitary GnRH receptors and stimulate LH and FSH synthesis and release. However, the agonists have a much longer biologic half-life (3 to 8 hours) than endogenous GnRH (3.5 minutes), resulting in the continuous exposure of GnRH receptors to GnRH agonist activity. This causes a loss of pituitary receptors and downregulation of GnRH activity, resulting in low FSH and LH levels. Consequently, ovarian steroid production is suppressed, providing a medically induced and reversible state of pseudomenopause. A direct effect of GnRH agonists on ectopic endometrium is also possible because expression of the GnRH receptor gene has been documented in ectopic endometrium and because direct inhibition of endometriosis cells has been demonstrated *in vitro* ([295](#)). Furthermore, in rat models for surgical adhesion formation and endometriosis, GnRH agonist therapy decreased activity of plasminogen activators and matrix MMPs and increased the activity of their inhibitors, suggesting potential GnRH agonist-regulated mechanisms for reducing adhesion formation ([296](#)).

Various GnRH agonists have been developed and used in treating endometriosis. These agents include *leuprolide*, *buserelin*, *nafarelin*, *histrelin*, *goserelin*, *deslorelin*, and *triptorelin*. These drugs are inactive orally and must be administered intramuscularly, subcutaneously, or by intranasal absorption. The best therapeutic effect is often associated with an *estradiol* dose of 20 to 40 pg/mL (75 to 150 pmol/L). These so-called depot formulations are attractive because of the reduced frequency of administration and because nasal administration can be complicated by variations in absorption rates and problems with patient compliance ([279](#)). The results with

GnRH agonists are similar to those with *danazol* or progestin therapy.

Although GnRH agonists do not have an adverse effect on serum lipids and lipoproteins, their side effects are caused by hypoestrogenism and include hot flashes, vaginal dryness, reduced libido, and osteoporosis (6% to 8% loss in trabecular bone density after 6 months of therapy). Reversibility of bone loss is equivocal and therefore of concern (297,298), especially because treatment periods of longer than 6 months may be required. The goal is to suppress endometriosis and maintain serum estrogen levels of 30 to 45 pg/mL. More extreme estradiol suppression will induce bone loss (297). The dose of daily GnRH agonist can be regulated by monitoring estradiol levels, by the addition of low-dose progestin or estrogen-progestin in an add-back regimen, or by draw-back therapy. The goal of add-back therapy is to treat endometriosis and endometriosis-associated pain effectively, while preventing vasomotor symptoms and bone loss related to the hypoestrogenic state induced by GnRH analogues. Add-back therapy can be achieved by administering progestogens only, including *norethisterone*, 1.2 mg, and *norethindrone acetate*, 5 mg, but bone loss is not prevented by *medrogestone*, 10 mg/d (298,299 and 300). Add-back therapy can also be achieved by tibolone, 2.5 mg/d (301,302), or by an estrogen-progestin combination (i.e., conjugated estrogens, 0.625 mg, combined with *medroxyprogesterone acetate*, 2.5 mg, or with *norethindrone acetate*, 5 mg, estradiol, 2 mg, and *norethisterone acetate*, 1 mg) (299,300,301,302 and 303). However, some concern remains about the long-term effects of GnRH analogues on bone loss. In one report, bone mineral density reduction occurred during long-term GnRH agonist use and was not fully recovered up to 6 years after treatment (304). Use of add-back therapy (2 mg *estradiol* and 1 mg *norethisterone acetate*) did not affect this process (304).

Draw-back therapy has recently been suggested as an alternative in a study showing that 6 months of intake of 400 µg/d of *nafarelin* was as effective as a draw-back regimen consisting of 1 month of intake of 400 µg/d of *nafarelin* followed by 5 months of 200 µg/d of *nafarelin*, with similar estradiol levels (30 pg/mL) but less loss of bone mineral density (305).

Aromatase Inhibitors

Treatment of rats with induced endometriosis using the nonsteroidal aromatase inhibitor *fadrozole hydrochloride* (306) or YM511 (307) resulted in a dose-dependent volume reduction of endometriosis transplants, but these products have so far not been used in published human studies. Treatment of severe postmenopausal endometriosis with an aromatase inhibitor, *anastrozole*, 1 mg/d, and elemental *calcium*, 1.5 g/d for 9 months, resulted in hypoestrogenism, pain relief after 2 months, and after 9 months a 10-fold reduction in the 30-mm diameter size of red, polypoid vaginal lesions, along with remodeling to gray tissue. No other data are available, except this case report (308).

Selective Estrogen Receptor Modulators

Raloxifen In animal models, *raloxifene* therapy resulted in regression of endometriosis. The effect was seen in both a surgically prepared, rat uterine explant model and in Rhesus macaques diagnosed with spontaneous endometriosis before exposure (309).

Nonhormonal Medical Therapy

Modulation of Cytokines In rats with experimental endometriosis, recombinant human TNF- α -binding protein can reduce 64% of the size of endometriosis-like peritoneal lesions (310). Similarly, a recent prospective randomized placebo- and drug-controlled study in baboons showed that recombinant human TNF- α -binding protein effectively inhibits the development of endometriosis and endometriosis-related adhesions (311).

In mice with experimental endometriosis, a placebo-controlled double-blind study showed that intraperitoneal or subcutaneous injection of recombinant interferon- α 2B resulted in smaller endometriotic lesions when compared with the placebo control group (312). In rats with experimental endometriosis, regression of endometrial explants was observed after treatment with immune-enhancing modulators *loxoribine* and *levamisole* (313).

Antiinflammation In the future, leukotriene receptor antagonists could be of use in patients with endometriosis who do not respond to prostaglandin synthetase inhibitors (314). In humans, a randomized placebo-controlled trial of oral *pentoxifylline*, 800 mg/d for 12 months, reported after life-table analysis a similar overall pregnancy rate in treated patients (31%) and in controls (18.5%) (315).

Inhibition of Matrix Metalloproteinase In nude mice, suppression of MMPs by progesterone or by a natural inhibitor slows the establishment of ectopic lesions by human endometrium (316). Thus far, no clinical reports have been published.

Efficacy of Medical Treatment

Pain Medical treatment with progestins, *danazol*, *gestrinone*, or GnRH agonists is effective in treating pain associated with endometriosis, as shown in several prospective, randomized, placebo-controlled double-blind studies (197,226,317,318). Based on published studies, *medroxyprogesterone acetate*, *danazol*, *gestrinone*, and GnRH agonists have similar efficacy in resolution of the laparoscopically documented disease and in pain alleviation (278). Postoperative medical therapy may be required in patients with incomplete surgical resection and persistent pain. Treatment should last at least 3 to 6 months, and pain relief may be of short duration, presumably because endometriosis recurs. Disadvantages of medical therapy over surgical therapy include the high cost of hormone preparations, the high prevalence of side effects, and the higher recurrence rate of endometriosis.

Subfertility Conception is either impossible or contraindicated during medical treatment of endometriosis. There is no evidence that medical treatment of minimal to mild endometriosis leads to better chances of pregnancy than expectant management (197,249, 317,318,319,320,321,322 and 323).

Adolescent Endometriosis The incidental finding of minimal to mild endometriosis in a young woman without immediate interest in pregnancy is a common clinical problem. Seventy percent of girls with chronic pelvic pain unresponsive to oral contraceptives (OAC) or nonsteroidal antiinflammatory drugs are affected by endometriosis (324). Mild disease can be treated by surgical removal of implants at the time of diagnosis, followed by administration of continuous low-dose combination oral contraceptives to prevent recurrence. More advanced disease can be treated medically for 6 months, followed by continuous oral contraceptives to prevent progression of disease. GnRH agonists with add-back therapy can be considered for adolescents older than 16 years of age who have completed pubertal maturation (324).

Recurrence

Endometriosis tends to recur unless definitive surgery is performed. The recurrence rate is about 5% to 20% per year, reaching a cumulative rate of 40% after 5 years. The rate of recurrence increases with the stage of disease, the duration of follow-up, and the occurrence of previous surgery (325,326,327,328 and 329). The likelihood of recurrence appears to be lower when endometriosis is located only on the right side of the pelvis than when the left side is involved (330).

In a recent randomized controlled trial, postoperative low-dose cyclic oral contraceptive use resulted in a significantly lower cumulative recurrence rate after 1 year, but not after 2 to 3 years (331). In women treated with a second operation for recurrent endometriosis, the cumulative recurrence rate was comparable to those rates after laparoscopy or laparotomy (332).

The recurrence rates reported in women 5 years after therapy with various GnRH agonists were 37% for minimal disease and 74% for severe disease (325). In women treated with GnRH agonists or *danazol* for endometriosis associated with pelvic pain, the recurrence rates of endometriosis were similar, and associated pain symptoms usually returned after cessation of therapy (333). Pain recurs within 5 years in about one in five patients with pelvic pain treated by complete laparoscopic excision of visible endometriotic lesions (334).

Assisted Reproduction and Endometriosis

The treatment of endometriosis-related infertility is dependent on the age of the woman, the duration of infertility, the stage of endometriosis, the involvement of ovaries, tubes, or both in the endometriosis process, previous therapy, associated pain symptoms, and the priorities of the patient, taking into account her attitude toward the disease, the cost of treatment, her financial means, and the expected results. Assisted reproduction, including controlled ovarian hyperstimulation with

intrauterine insemination, IVF, and gamete intrafallopian transfer, may be options for infertility treatment in addition to surgical reconstruction and expectant management. IVF is the method of choice when distortion of the tuboovarian anatomy contraindicates the use of superovulation with intrauterine insemination or gamete intrafallopian transfer.

Intrauterine Insemination

Endometriosis-associated infertility can be successfully treated with intrauterine insemination. A recent randomized study (335) compared controlled ovarian hyperstimulation with FSH and intrauterine insemination with no treatment during 311 cycles in 103 couples with minimal to mild endometriosis as the only infertility factor. This study reported a significantly higher live-birth rate per cycle in the treated group (11%) than in the control group (2%) (OR, 5.6; 95% CI, 1.8 to 17.4). However, there is clear evidence that the pregnancy rate in an insemination program is lower in women with endometriosis than in women with unexplained infertility (336,337). In a recent metaanalysis of 5,214 cycles by stepwise logistic regression (338), evaluating the effectiveness of ovulation induction and intrauterine insemination in the treatment of persistent infertility, the OR for pregnancy associated with endometriosis was 0.45 (95% CI, 0.27 to 0.76) and for male factor was 0.48 (95% CI, 0.37 to 0.61).

In Vitro Fertilization

Based on several retrospective studies, several investigators (130,135) have suggested that the pregnancy rate after IVF may be lower in women with endometriosis than in women without the disease. In earlier studies, this had been ascribed to a reduced oocyte quality and decreased fertilization rate in women with endometriosis. However, these findings were not confirmed in more recent studies that reported a normal fertilization rate but a reduced implantation rate per embryo transferred also in women obtaining oocytes from oocyte donors with endometriosis (339,340). This reduced implantation rate could possibly be related to increased interleukin-6 levels in follicular fluid of women with endometriosis when compared with controls (341). However, in a more recent case-control study in an IVF egg-donation program comparing oocyte receptors in patients with endometriosis stage III or IV (cases) with oocyte receptors in patients without endometriosis (controls), a similar implantation rate, miscarriage rate, and pregnancy rate was observed in cases and controls, suggesting that there is no endometrial implantation problem in women with endometriosis stage III or IV treated with IVF (342). In another case-control study, the cumulative pregnancy rate and live-birth rate was comparable after five cycles of IVF in women with ovarian endometriosis and those with tubal infertility: 63% versus 63% (CPR) and 47% versus 51% (CLBR), but women with ovarian endometriosis had poorer responses and needed higher gonadotropin therapy (343).

When endometriosis was assigned a stage, the pregnancy rate after IVF was decreased in patients with stage IV endometriosis but normal in women with less advanced disease (344,345,346,347,348,349 and 350). However, some studies have been unable to demonstrate a significant negative correlation between either the presence or stage of endometriosis and the pregnancy rate per cycle (351,352). The use of *danazol*, *gestrinone*, or GnRH agonists in women with endometriosis before IVF has been reported to improve the pregnancy rate by some (350,354) but not all investigators (352).

Intracytoplasmic Sperm Injection

A recent well-controlled study in intracytoplasmic sperm injection (ICSI) patients (353) reported a reduced number of oocytes recovered after ovarian aspiration but a normal fertilization rate, implantation rate, and pregnancy rate in women with endometriosis when compared with controls. These normal fertilization, implantation, and pregnancy rates also were reported in another recent ICSI study (355).

Gamete Intrafallopian Transfer

The use of gamete intrafallopian transfer in patients with endometriosis is reported to result in a higher monthly fecundity rate (25%) than with IVF (14%), but this difference may be related to selection bias because less severe forms of endometriosis may have been more likely to be treated with gamete intrafallopian transfer, reserving IVF for more advanced stages of disease (257). In one study, the gamete intrafallopian transfer pregnancy rate in patients with a primary diagnosis of endometriosis (32.5%) was lower than in matched controls (356).

The current evidence suggests that patients with endometriosis have a poorer ovarian response and need a higher dose of gonadotropin therapy in IVF or ICSI programs, but no reduced endometrial implantation. It remains unclear whether the presence or degree of endometriosis is associated with impaired oocyte quality, fertilization rate, and implantation rate. Future studies evaluating the association between endometriosis and reproductive outcome after assisted reproduction should be prospective and should include the following components (131):

- Accurate and recent laparoscopic description of the stage of endometriosis
- Date, number of procedures, and interval between surgery
- Ultrasonographic evidence of endometriosis, confirmed by cytology or histology when endometriotic cysts are aspirated during oocyte aspiration
- Effectiveness of interim suppressive therapy between diagnosis and treatment with assisted reproduction
- Reliability and date of negative diagnosis
- Clear definition of implantation rate, pregnancy rate, abortion rate, and live-birth rate per started cycle, per oocyte aspiration, and per embryo transfer

Infertility is defined as 1 year of unprotected intercourse without pregnancy. This condition may be further classified as *primary infertility*, in which no previous pregnancies have occurred, and *secondary infertility*, in which a prior pregnancy, although not necessarily a live birth, has occurred. *Fecundability* is the probability of achieving pregnancy within a single menstrual cycle, and *fecundity* is the probability of achieving a live birth within a single cycle. The fecundability of a normal couple has been estimated at 20% to 25% (1). **On the basis of this estimate, about 90% of couples should conceive after 12 months of unprotected intercourse.**

Infertility affects about 10% to 15% of reproductive-age couples in the United States. Despite the relatively stable prevalence of infertility in the United States, the use of infertility services has increased significantly. Between 1968 and 1984, the number of office visits for infertility increased nearly threefold to the current 1.6 million visits annually (2). There are several reasons for this increase. Recent media coverage of assistive reproductive technology (ART) and other fertility treatments has heightened awareness of the problem and its treatment; the aging of the post–World War II “baby boomers” has led to an increase in the number of reproductive-age women; and sociologic changes have led to delayed marriage with a consequent postponement of childbearing. Still, despite an increased awareness of available therapies, only 43% of infertile couples seek treatment, and only 24% seek specialized care. Fewer than 2% use *in vitro* fertilization (IVF) or other ART methods. The women most likely to obtain specialized treatment are 30 years of age or older, white, married, and of relatively high socioeconomic status (3).

Epidemiology

Data from the U.S. National Survey of Family Growth indicate that the prevalence of infertility among women who had not been surgically sterilized was 13.3% in 1965, 13.9% in 1982, and 13.7% in 1988 (4). In 1990, about 1 in 3 women in the United States reported 12 consecutive months of unprotected coitus without pregnancy at some time in her life (5).

A number of demographic variables, including age and socioeconomic status, have been associated with infertility. The delay in childbearing in the United States population has led to attempts to conceive by a higher percentage of women in the older reproductive age groups. **As a result, although the overall prevalence of infertility has not changed in the United States since 1965, the percentage of women with primary infertility has increased significantly.** In 1965, only one of six infertile women was nulliparous, whereas in 1988, more than half of infertile women had never been pregnant (6). The prevalence of infertility does not differ significantly among racial and ethnic groups. Although patients seeking treatment for infertility are predominantly of high socioeconomic status, infertility is more common among groups of relatively low socioeconomic status (6). Improved familiarity with and access to infertility services among the affluent and better-educated patients probably accounts for their greater use of these medical resources.

The Infertile Couple

Initial Visit

The physician's initial encounter with the infertile couple is the most important one because it sets the tone for subsequent evaluation and treatment. **The male partner should be present at this first visit because his history is a key component in the selection of diagnostic and therapeutic plans. It cannot be overemphasized that infertility is a problem of the couple. The presence of the male partner beginning with the initial evaluation involves him in the therapeutic process.** This essential involvement demonstrates that the physician is receptive to the male partner's needs as well as to those of the female partner, while allowing the male partner an opportunity to ask questions and to voice any concerns.

The physician should obtain a complete medical, surgical, and gynecologic history from the woman. Specifically, information regarding menstrual cyclicity, pelvic pain, and obstetric history is important. Risk factors for infertility, such as a history of pelvic inflammatory disease (PID), intrauterine device use, or pelvic surgery, should be reviewed. A history of intrauterine exposure to diethylstilbestrol (DES) is significant. In addition, questions should be asked about pituitary, adrenal, and thyroid function. A directed history, including past genital surgery, infections (including mumps orchitis), and previous genital trauma, should be obtained from the male partner. A history of occupational exposures that might affect the reproductive function of either partner is also important. Additionally, the interviewer should obtain information about coital frequency, dyspareunia, and sexual dysfunction.

The initial interview provides the physician with the opportunity to assess the emotional impact of infertility on the couple. It further gives the physician a chance to emphasize the emotional support available to the couple as they proceed with the diagnostic evaluation and suggested treatments. In some cases, referral to a trained social worker or psychologist at this point may be beneficial.

The physical examination of the female should be thorough, with particular attention given to height, weight, body habitus, hair distribution, thyroid gland, status with regard to galactorrhea, and findings of the pelvic examination. Referral of the male to a urologist for examination is often beneficial if historic information or subsequent evaluation suggests an abnormality. The initial encounter also gives the doctor the opportunity to outline the general causes of infertility and to discuss subsequent diagnostic and treatment plans. (Fig. 27.1, Fig. 27.2, Fig. 27.3, Fig. 27.4 and Fig. 27.5).

Figure 27.5 Diagnostic and treatment algorithm: tubal factor. (From eries Yao M. Clinical management of infertility. Washington, DC: The Advisory Board: 2000, with permission.)

Causes of Infertility

The main causes of infertility include the following:

1. Male factor
2. Decreased ovarian reserve
3. Ovulatory disorders (ovulatory factor)
4. Tubal injury, blockage, or paratubal adhesions (including endometriosis with evidence of tubal or peritoneal adhesions)
5. Cervical and immunologic factors
6. Uterine factors
7. Conditions such as immunologic aberrations, infections, and serious systemic illnesses
8. Unexplained factors (including endometriosis with no evidence of tubal or peritoneal adhesions)

Factors from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatment. In some cases, no specific cause is detected despite an extensive and complete evaluation. The relative prevalence of the different causes of infertility varies widely among patient populations ([Table 27.1](#)).

Relative prevalence of the etiologies of infertility (%)	
Male factor:	25-40
Both male and female factors:	10
Female factor:	40-55
Unexplained infertility:	10
Approximate prevalence of the causes of infertility in the female (%)	
Ovulatory dysfunction:	30-40
Tubal or peritoneal factor:	30-40
Unexplained infertility:	10-15
Miscellaneous causes:	10-15

Table 27.1. Causes of Infertility

Very few couples have absolute infertility, which can result from congenital or acquired irreversible loss of functional gametes in either partner or the absence of a uterus in the female. These specific couples should be counseled regarding their options of adoption, the use of donor gametes, or surrogacy. Rather, most couples who have difficulty conceiving have subfertility. According to this fundamental concept, most couples could conceive spontaneously in time, but because of known or unidentifiable causes, their spontaneous fecundity rate is so low that medical management is warranted. Another reason to seek medical attention, particularly among older women, is that as time passes during unsuccessful spontaneous attempts, fecundability will be further compromised by increasing age and concomitantly decreasing ovarian reserve. Although identification of apparent causes of subfertility (such as anovulation or oligospermia) allows treatment to be targeted, effective empiric treatments greatly increase the chance of a pregnancy even when no distinct cause is identified. Overall, these treatments aim at increasing the probability of conception and implantation by optimizing gamete (sperm and oocyte) and uterine factors.

The next section of this chapter outlines causes of male and female infertility, their methods of diagnosis, and the specific treatments for these conditions. The basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency by hysterosalpingography (HSG). Some treatments, especially ART, are indicated for more than one diagnosis and are discussed in greater detail. Often, more than one cause is identified in a couple. For this reason, multiple directions of investigation and treatment may be undertaken in parallel.

Male Factor

The combined effects of our increased understanding of genetic causes in male factor infertility and the efficacy of intracytoplasmic sperm injection (ICSI) in ART have revolutionized modern treatment of male factor infertility. For men, semen analysis as the initial step in their diagnostic evaluation for infertility is a fairly simple one. Semen analysis is inexpensive and noninvasive, and it should be included at the initiation of every infertility workup. The assessment of semen parameters, however, is confounded by controversies regarding the proper range of normal values. Semen parameters in normal fertile men vary considerably over time and may even drop below established norms; this situation makes evaluation of the male patient more difficult. The value and interpretation of the semen analysis and other tests for male infertility should be considered within the context of male reproductive physiology.

Physiology

The male reproductive tract consists of the testis, epididymis, vas deferens, prostate, seminal vesicles, ejaculatory duct, bulbourethral glands, and urethra. The testes contain two cell types: the Sertoli cells, which line the seminiferous tubules (the site of spermatogenesis), and the Leydig cells (the site of androgen synthesis). In the male, the pituitary gland secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which act on the testes. LH stimulates the synthesis and secretion of testosterone by the Leydig cells, and FSH stimulates the Sertoli cells to secrete inhibin. FSH and testosterone act on the seminiferous tubules to stimulate spermatogenesis. In humans, it takes about 75 days for spermatogonia to develop into mature sperm cells. The immature spermatogonia undergo mitotic division, giving rise to spermatocytes. These spermatocytes subsequently undergo meiosis, or reduction division, which gives rise to spermatids containing 23 (rather than 46) chromosomes. Upon maturation, spermatids become spermatozoa, which enter the epididymis, where they continue to mature and become progressively more motile during the 12 to 21 days that is required to traverse this tortuous structure.

During ejaculation, mature spermatozoa are released from the vas deferens along with fluid from the prostate, seminal vesicles, and bulbourethral glands. The semen released is a gelatinous mixture of spermatozoa and seminal plasma; however, it thins out 20 to 30 minutes after ejaculation by a process called *liquefaction*. Liquefaction occurs secondary to the presence of proteolytic enzymes within the prostatic fluid. The released spermatozoa are not usually capable of fertilization. Instead, a series of complex biochemical and electrical events, termed *capacitation*, must take place within the sperm's outer surface membrane before fertilization can occur. Normally, capacitation occurs in the cervical mucus; however, it can occur in physiologic media *in vitro*. Finally, as part of fertilization, the sperm must undergo the acrosome reaction, in which the release of enzymes of the inner acrosomal membrane results in the breakdown of the outer plasma membrane and its fusion with the outer acrosomal membrane (7). Several of the enzymes within the acrosome appear to be important to the sperm's penetration of the egg's zona pellucida. As the sperm penetrates the egg, it initiates a hardening of the zona pellucida (cortical reaction), which prevents penetration by additional sperm (8).

Semen Analysis

The basic semen analysis measures semen volume, sperm concentration, sperm motility, and sperm morphology. In addition, many laboratories measure pH, fructose levels, and white blood cell counts within the semen. Normal values suggested by the World Health Organization (WHO) are listed in [Table 27.2 \(18\)](#). These values represent only general guidelines, and normal values should be separately established by individual andrology laboratories.

Volume	>20 mL
Sperm concentration	>20 million/mL
Motility	>50%
Morphology	>30% normal forms

From World Health Organization. *Laboratory manual for the examination of human semen and sperm-cervical interaction*. Cambridge, England: Cambridge University Press, 1992, with permission.

Table 27.2. Normal Values for a Semen Analysis

Specimen Collection The method used for semen specimen collection is important to the achievement of accurate results. The optimal period of abstinence before semen collection is unknown; however, because a decrease in sperm concentration is associated with frequent ejaculation, a period of 2 to 3 days usually is recommended. The specimen should be obtained by masturbation and collected in a clean container. Because of the presence of spermicidal agents, collection into condoms is generally unacceptable, although special sheaths that do not contain spermicides are available for semen collection. All semen specimens should be taken to the laboratory within 1 to 2 hours of collection. Even when collection is done under optimal circumstances, interpretation of the results of the semen analysis is complicated by wide differences in normal semen parameters (9), seasonal variability (10), variations among laboratories or technicians (11), and inconsistent correlation with fertility outcome. Semen parameters also may vary widely from one man to another and among men with proven fertility. In many circumstances, several specimens are necessary to verify an abnormality.

Sperm Volume The normal ejaculated volume of semen is 2 to 6 mL. Volumes may be abnormally low in cases of retrograde ejaculation, and high volumes usually reflect relatively long periods of abstinence or inflammation of the accessory glands. Absence of fructose or high pH may be associated with ejaculatory tract obstruction or seminal vesicle dysfunction.

Sperm Concentration Sperm concentration or density is defined as the number of sperm per milliliter in the total ejaculate. Establishing a lower limit of normal for sperm concentration is difficult. Historically, cutoffs of 60 million sperm per milliliter for normal fertility have been advocated, but most WHO laboratories recognize the value of 20 million sperm per milliliter as a lower limit of normal (12). Some have advocated concentrations of 5 million sperm per milliliter as a lower limit of normal (13,14).

Sperm Motility An equally important parameter in the semen analysis is sperm motility, which is defined as the percentage of progressively motile sperm in the ejaculate. Lower limits of normal vary considerably and depend on the local laboratory's experience. The WHO and many laboratories use a cutoff of 50% motility as the lower limit of normal; whereas others requires 40% motility as a criterion for defining male factor infertility (15). Computer-assisted semen analysis, in which computer-generated images of sperm specimens quantitate both sperm counts and sperm motility, may yield results very different from those of nonautomated semen analyses. Regardless of how motility is assessed, the interpretation of sperm motility—as with sperm concentration—is hampered by both significant variability among repeat samples obtained from a single individual and poor correlation of motility with fertility.

Sperm Morphology The WHO uses a fairly permissive visual assessment of sperm within a semen specimen to assess morphology values; greater than 30% normal forms is defined as acceptable. More stringent criteria have evolved from other sources. The strict Tygerberg criteria were introduced by Kruger and Menkveld in 1986 to assess sperm morphology (16). Using this system, the entire spermatozoon—including the head, midpiece, and tail—is assessed, and even mild abnormalities in head forms are classified as abnormal. Most sperm from normal men exhibit minor abnormalities when subjected to Tygerberg standards. One advantage of these strict criteria, however, is that the Tygerberg classification correlates with prognosis in IVF treatment. For example, greater than 14% normal morphology is associated with normal rates of fertilization in IVF programs; 4% to 14% normal morphology is associated with a “good prognosis.” Values of less than 4% normal sperm morphology are associated with poor prognosis for fertilization and pregnancy in IVF (17). In some studies, this sperm morphology classification has also been found to be predictive of pregnancy outcomes after intrauterine insemination (IUI) treatment, especially when the total motile sperm count is less than 1×10^6 (18). The disparity in assessment criteria for semen morphology mandates that to interpret semen analysis results properly, the clinician must thoroughly understand the methodology used by the local andrology laboratory.

White Blood Cells Although measurements of semen volume, sperm concentration, sperm motility, and sperm morphology make up the standard semen analysis, some laboratories also report numbers of round cells. These cells, which may be lymphocytes, can signify the presence of prostatitis or, alternatively, may actually be immature germ cells. These two cell types can be distinguished by an immunoperoxidase staining technique that identifies leukocytes (Endtz test) (19). The WHO views ejaculates with more than 5 million round cells per milliliter or more than 1 million leukocytes per milliliter as abnormal (20); however, the prognostic significance of leukocytes in the semen is controversial. The presence of immature sperm cells in the ejaculate suggests a defect in spermatogenesis and, therefore, may signify a relatively poor prognosis for fertilization (21). Although the standard semen analysis and associated tests provide a fairly reasonable picture of semen quality, they yield little information about sperm function. Consequently, several tests of sperm function have been devised in an effort to assess the physiologic properties of sperm and thereby predict the likelihood of fertilization of normal oocytes.

Sperm Penetration Assay The most commonly used test of sperm function is the *sperm penetration assay* (SPA), or hamster egg penetration test (22). This test attempts to measure the ability of an individual patient's sperm to undergo capacitation (i.e., the acrosome reaction), to fuse with and penetrate the oocyte membrane, and to undergo nuclear decondensation. In the SPA, golden hamsters are superovulated, and their eggs are collected and treated with enzymes to remove the cumulus and zona pellucida. Meanwhile, sperm are isolated from the patient's semen and placed in a protein-rich environment that promotes capacitation. Sperm from normal fertile men are used as positive controls. After this incubation, the zona-free eggs are exposed to patient and control sperm. The presence of one or more swollen sperm heads within the hamster oocyte after exposure to sperm demonstrates penetration. Most laboratories report the percentage of eggs successfully penetrated; however, some laboratories count the number of penetrations per egg (usually two or more is considered normal). Cutoff values for the lower limit of normal in the SPA differ remarkably among laboratories.

The prognostic value of the SPA has been controversial almost since its inception. On the basis of a metaanalysis of the SPA, the test does not discriminate between fertile and infertile men (23). The value of the test as a predictor of success in IVF has been no less controversial. In most evaluations of the male partner, the SPA offers little definitive information; however, it may uncover sperm abnormalities in couples with otherwise unexplained infertility.

Several other tests attempt to correlate sperm function with fertility prognosis. The human zona-binding assay (the *Hemizone tes*) examines the ability of the sperm to bind to zona. In this assay, human zona are bisected; half of the zona is exposed to the patient's sperm, and half is exposed to sperm from a known fertile donor control (24). Results compare the binding ability of samples of patients to those of controls. The hypoosmotic swelling test examines the normality of the sperm tail. When placed in a hypoosmotic solution of sodium citrate and fructose, the normal sperm tail swells and coils; when there is an abnormality in fluid transport across the tail membrane, the sperm tail fails to swell (25). To detect the acrosome reaction, some investigators have used monoclonal antibodies (26), whereas others have measured adenosine triphosphate (ATP) content in the semen (27). These functional tests should be considered experimental until more definitive evidence demonstrates their utility in clinical settings.

Further Evaluation If abnormalities in the semen are detected, further evaluation of the male partner by a urologist is indicated to diagnose the defect. Table 27.3 lists the differential diagnoses for male factor infertility (40). Several groups have attempted to assess the distribution of male infertility diagnoses; two such distributions are shown in Table 27.4 (24,28). The first is the result of a WHO study of 7,057 men with complete diagnoses based on the WHO standard investigation of the infertile couple (28). The figures include data from cases in which the male partner was normal and the presumed cause of the couple's infertility was a female factor. The second distribution is the result of a study of 425 subfertile male patients (24). Although the two studies represent different populations (one is from a study of couples, the other from a urologic practice) and differ in their distribution of male infertility diagnoses, idiopathic male factor and varicocele predominate. Other anatomic and endocrine causes occur less frequently.

Table 27.4. Frequency of Some Etiologies in Male Factor Infertility

The widely accepted concept of a global decline in sperm counts needs to be reassessed (9,30). A number of recent analyses reported no decrease in sperm counts over time (31,32 and 33). Geographic differences in the results of semen analyses do seem to exist, but a global trend toward decreasing semen quality does not (34,53 and 36). Furthermore, the rate of male factor infertility has not increased significantly in recent decades. Thus, even if semen characteristics are changing, these changes do not appear to be having a dramatic clinical effect. Nevertheless, exposures to environmental toxins may certainly be harmful to sperm, and the incidence of some exposures (e.g., phytoestrogens) may be on the rise. Marijuana and cocaine use can reduce sperm concentration (37,38). Certain drugs, such as anabolic steroids, chemotherapeutic agents, cimetidine, erythromycin, nitrofurans, spironolactone, sulfasalazine, and tetracycline, also may reduce semen parameters. Finally, commonly ingested agents present in cigarettes and coffee have been associated with diminished semen quality (39).

Treatment

Treatment of male factor infertility may be classified as medical, surgical, or ART-related therapies. Further, the diagnosis and treatment of azoospermia (no sperm on semen analysis) will be discussed separately from other forms of male factor infertility.

Medical therapies for male factor infertility are severely limited. Medical correction of underlying treatable endocrine or infectious causes of subfertility tends to be efficacious. These conditions may include sexually transmitted diseases, thyroid disorders, and other rare causes of male infertility. Clomiphene citrate, an estrogen agonist and partial antagonist, has often been used to treat male infertility of idiopathic origin. Clomiphene citrate acts on the hypothalamic-pituitary axis and, in men, increases serum levels of LH, FSH, and testosterone (41). Although efficacy of clomiphene for male factor infertility is controversial, most studies have shown little improvement in semen parameters and no improvement in pregnancy rates (42). However, severe idiopathic male factor infertility has been treated with pure FSH, with no notable improvement in semen parameters but a significant increase in fertilization rates during ART (43).

Surgical approaches to male factor infertility include procedures to correct varicocele, artificial insemination, and ART.

Varicocele

A varicocele is an abnormal dilation of the veins within the spermatic cord. Varicoceles nearly always occur on the left side, presumably because of the direct insertion of the spermatic vein into the renal vein on that side. The pathophysiologic effects of varicocele on testicular function are uncertain but appear to be mediated by an associated rise in testicular temperature or a reflux of toxic metabolites from the left adrenal or renal veins (44). In either event, the effect on sperm production is bilateral. Our understanding of the role of varicoceles in infertility is complicated by two issues: the prevalence of varicoceles in the normal male population and the efficacy of varicocele repair in infertile men. One WHO study found varicocele to be present in 25.4% of men with abnormal semen analyses, as opposed to 11.7% of men with normal semen (45). This study failed to demonstrate a difference in the frequency of spontaneous pregnancies among couples in which the men did or did not have varicoceles. The presence of a varicocele was, however, associated with decreased testicular volume, impaired semen quality, and a reduction in serum testosterone levels.

Varicocele repair involves interruption of the internal spermatic vein and is commonly performed in the 40% of infertile men with clinically evident varicoceles. Currently, it is performed as an outpatient procedure and may involve laparoscopy, open surgery, or the injection of embolizing agents. Despite its widespread use, the therapeutic benefits of varicocele repair have remained controversial. Two multicenter trials have shown that pregnancy rates are significantly increased after varicocelectomy (46,47). However, the validity of the control groups in each of these trials has been criticized (48). A more recent metaanalysis on four randomized, controlled trials involving a total of 385 patients failed to demonstrate significantly altered pregnancy rates after varicocelectomy (48,49,50,51 and 52).

Artificial Insemination

Artificial insemination encompasses a variety of procedures. All involve the placement of whole semen or processed sperm into the female reproductive tract, which permits sperm-ovocyte interaction in the absence of intercourse. The placement of whole semen into the vagina as a mode of fertility treatment is now rarely performed. Exceptions include cases of severe coital dysfunction, including those involving severe hypospadias, retrograde ejaculation, erectile abnormalities, and psychosocial dysfunction precluding intercourse. Currently, all of the common forms of artificial insemination involve processed sperm obtained from the male partner or a donor before its use. Artificial insemination has mainly been used to treat unexplained infertility (usually combined with superovulation) and male factor infertility. The efficacy of each type of insemination method should be assessed separately for each of these two diagnoses.

Types of Insemination for Unexplained Infertility Many techniques for artificial insemination have been described. Of intracervical, intrauterine, intraperitoneal, and intrafollicular insemination and fallopian tube sperm perfusion, only the first two methods have been routinely employed. **Intrauterine insemination (IUI) is the best studied and most widely practiced of all the insemination techniques.** It involves placement of about 0.3 mL of washed, processed, and concentrated sperm into the intrauterine cavity by transcervical catheterization. In contrast with IUI, intracervical insemination may be performed either with unwashed or with processed specimens. The success rates with intracervical insemination are consistently lower than those with IUI (53).

Fallopian tube sperm perfusion (FSP) differs from IUI in that a large volume of washed sperm (about 4 mL) is injected into the intrauterine cavity. This is a more expensive procedure because larger volumes of media are required during sperm processing. Technical performance of FSP may be complicated by efflux of sperm through the vagina during the intrauterine injection of such large volumes of fluid. Among several techniques of efflux prevention, use of an intrauterine Foley catheter with balloon inflation is most commonly described. Although many have demonstrated that fallopian tube sperm perfusion does not offer any general advantage over IUI (54,55,56 and 57), its benefit in the treatment of unexplained infertility remains controversial. Several prospective randomized trials have reported higher pregnancy

rates among patients with unexplained infertility in cycles treated with FSP compared with those using IUI (58,59,60 and 61). One recent metaanalysis found that FSP significantly improves pregnancy rates in patients with unexplained infertility undergoing controlled ovarian hyperstimulation (COH)/insemination with an odds ratio (OR) of 1.9 and a 95% confidence interval (CI) of 1.2 to 3 (60) (see [Controlled Ovarian Hyperstimulation](#)).

Direct intraperitoneal insemination involves the injection of washed, processed sperm into the intraperitoneal cavity by puncture of the posterior vaginal cul-de-sac. Evidence from prospective randomized trials showed that direct intraperitoneal insemination offers no advantage over IUI (62,63,64 and 65). Intrafollicular insemination as a treatment of male factor infertility has also been reported (66), but in a series of 50 patients with unexplained infertility, only one intrauterine pregnancy resulted (67). Its low efficacy has deterred further investigation of this technique. In summary, IUI is the best-studied insemination technique, with proven superiority to intracervical insemination in the treatment of unexplained infertility (53). FSP appears to be a viable alternative to IUI with COH/insemination in couples with unexplained infertility. However, the potential increase in pregnancy rates using FSP over IUI is unlikely to be as great as that of IVF/ICSI over IUI. Therefore, although COH/FSP may be chosen instead of COH/IUI in a center where FSP gives a higher pregnancy rate, there is no benefit to switch from COH/IUI to COH/FSP after three cycles of failed COH/IUI in patients with unexplained infertility. IVF/ICSI remains the best available treatment option in patients with unexplained infertility who have not become pregnant with COH/IUI treatment.

Processing Semen Two important issues regarding the use of artificial insemination procedures are the mode of semen processing and the number and timing of inseminations. Many protocols have been developed for sperm preparation. Seminal fluid usually is prevented from reaching the intrauterine cavity and intraabdominal space by the cervical barrier. The introduction of seminal fluid past this barrier may be associated with severe uterine cramping or anaphylactoid reactions, possibly mediated by seminal factors such as prostaglandins. Thus, protocols for processing whole semen include the washing of specimens to remove seminal factors and to isolate pure sperm. Some semen preparation methods attempt to enhance sperm motility or morphology further by using additional separation protocols. These methods include centrifugation through density gradients, sperm migration protocols, and differential adherence procedures. Finally, phosphodiesterase inhibitors, such as pentoxifylline, have been used during semen processing in an attempt to enhance sperm motility, fertilization capacity, and acrosome reactivity for IVF procedures (68).

IUI as Treatment of Male Factor Infertility Studies of the efficacy of IUI in the treatment of male factor infertility have been generally difficult to assess because of variations in inclusion criteria. Further, sperm function tests are not consistently used in these studies, nor is their use standardized. Considering these limitations, the benefits of IUI in male factor infertility have been accepted because IUI appears to result in higher pregnancy rates than natural intercourse or intracervical insemination (OR, 2.20;95% CI, 1.43 to 3.39) (69). However, the IUI pregnancy rates are generally lower in couples with male factor infertility than in couples with unexplained infertility (4.8% versus 11.6%) (69). In a retrospective analysis of 1,841 couples undergoing 4,056 cycles of IUI for male factor infertility, pregnancy rates were found to be related to total motile sperm count. Optimal pregnancy rates (>8.2% per cycle) were reached with initial total motile sperm counts of greater than or equal to 5.0×10^6 . Higher counts did not necessarily yield higher pregnancy rates. The minimal total motile sperm count that resulted in a pregnancy was 1.6×10^6 (70).

Some couples with male factor infertility fail treatment with artificial insemination, and some have initial semen parameters that make insemination a suboptimal approach. In these couples, use of ART, especially with ICSI, may be superior treatment options. The efficacy of ICSI in ART allows almost all cases of male factor infertility to be highly treatable. ICSI only requires that viable sperm be present. Therefore, ICSI should be considered if the total motile sperm count is less than 0.5×10^6 because the IUI success rates are extremely low with such sperm counts (71). Finally, ICSI should be recommended after a maximum of three IUI cycles have failed in a couple with male factor infertility.

Azoospermia: Classification and Treatment

Azoospermia is the absence of spermatozoa in the ejaculate. Azoospermia is found on semen analysis in about 5% of all couples being investigated for infertility (72), and its incidence is 10% to 20% among infertile men who have abnormal semen analysis (73). Traditionally, azoospermia has been classified as obstructive or nonobstructive. However, an increased understanding of the various etiologies of azoospermia and treatment advances using surgical sperm retrieval and ART have prompted a reclassification. The new classification system, advocated by Sharif and others, may better reflect the etiology, prognosis, and treatment of azoospermia (74,75 and 76). It separates azoospermic patients into those with pretesticular, testicular, and posttesticular causes.

Pretesticular Azoospermia

Pretesticular azoospermia represents those conditions in which the hypothalamic–pituitary axis fails to stimulate spermatogenesis within the testis. Congenital, acquired, and idiopathic etiologies of hypogonadotropic hypogonadism are included in this category. A full endocrine history, including information on puberty and growth and a review of endocrine systems, should guide the physician in the evaluation of the hypogonadotropic hypogonadal patient. Laboratory investigations of particular benefit in this population include measurement of serum LH, FSH, testosterone, and prolactin levels and imaging of the pituitary gland. Low levels of gonadotropins (LH and FSH) and low serum levels of testosterone are characteristic.

Hormonal treatment of hypogonadotropic hypogonadism has been conclusively demonstrated to be efficacious. In fact, pulsatile gonadotropin-releasing hormone (GnRH) therapy is both conceptually indicated and effective in infertile men with hypothalamic dysfunction (77), including those patients with Kallmann's syndrome. Infertile males with hypogonadotropic hypogonadism secondary to panhypopituitarism also may respond to GnRH therapy (78). An alternative treatment uses human chorionic gonadotropin (hCG), 1,000 to 2,500 IU twice a week, with the dose titrated to maintain serum testosterone and estradiol levels within the normal range. Treatment with hCG is then combined with human menopausal gonadotropin (hMG), which is given at a dose of 150 IU three times weekly (79,80). Spermatogenesis and pregnancy can be achieved in up to 80% to 88% of patients after 1 year of therapy (79,80).

Testicular Azoospermia

Gonadal failure is the hallmark of testicular azoospermia. Causes of this condition may be congenital or genetic (e.g., Klinefelter's syndrome, microdeletion of Y chromosome), acquired (e.g., radiation therapy, chemotherapy, testicular torsion, or mumps orchitis), or developmental (e.g., testicular maldescent). The latter disorder may be associated most closely with male factor infertility in the absence of complete testicular azoospermia. A large observational cohort study suggested that infertility was, in fact, associated with congenital bilaterally maldescended testes, but that men with congenital unilaterally maldescended testes did not have decreased fertility when compared with controls (81).

Men with hypergonadotropic hypogonadism (elevated levels of LH and FSH with low serum levels of testosterone) **generally have primary gonadal failure.** A karyotype should be obtained in such cases to detect chromosomal abnormalities such as Klinefelter's syndrome (47, XXY). Acquired causes of primary gonadal failure are usually evident on history, but they should be confirmed by assessment of the serum hormonal profile and biopsy. If the diagnosis of gonadal failure is confirmed on biopsy, endocrine therapy is contraindicated.

It is becoming increasingly evident that some cases of male factor infertility that have previously been categorized as idiopathic are actually the result of genetic defects on the Y chromosome. The two most commonly implicated candidate gene families are the RNA-binding motif (RBM) and the “deleted in azoospermia” (DAZ) families, but microdeletions at various loci on the Y chromosome have been described. For example, microdeletions in Yq11.23 have been found in 10% to 20% of men with idiopathic azoospermia or severe oligospermia (82,83). In another study involving 200 infertile men, 7% were found to have microdeletions in the Y chromosome (84). Semen analyses in affected men varied between oligospermia and azoospermia. Interestingly, 2% of fertile men also have microdeletions in the Y chromosome. These microdeletions can be transmitted to the male offspring, who may then also suffer from infertility. Therefore, screening for genetic causes is indicated in nonacquired cases of testicular azoospermia so that proper genetic counseling can be provided before treatment. Treatment is focused on surgical retrieval of spermatozoa with subsequent fertilization of the oocyte by ICSI. These approaches have made fertility possible for some men with testicular azoospermia.

Intracytoplasmic Sperm Injection ICSI is a micromanipulation technique commonly used in some ART procedures. It was first reported to result in human pregnancies in 1992 (85). ICSI is performed to increase the fertilization rate of oocytes retrieved during ART. The procedure involves stripping the aspirated cumulus complex of all surrounding granulosa cells, so that micromanipulation can be performed on the egg itself. A holding pipette is used to stabilize the egg while an injection pipette is used to insert a viable sperm into the cytoplasm of the egg (ooplasm). This procedure is thought to bypass some of the physiologic events, such as capacitation and the acrosome reaction, that are normally required for fertilization *in vivo*.

In general, ICSI has allowed couples with male factor infertility to achieve ART pregnancy outcomes that are comparable with those of couples with non–male factor infertility using conventional IVF treatment. The indications of ICSI have evolved since its introduction. They will most likely continue to evolve as more is learned

about risks and benefits of ICSI. One absolute indication for ICSI is severe male factor infertility as demonstrated by total progressively motile sperm counts ($0.5 \times 10^6/\text{mL}$ and $<3\%$ normal morphology according to strict Tygerberg criteria) (71). Sperm counts of less than $0.5 \times 10^6/\text{mL}$ are associated with poor fertilization rates in IVF, and this finding alone is also an indication for ICSI (86). Other indications for ICSI include the sole presence of spermatozoa lacking an acrosome or those that are completely immotile, as well as the use of surgically recovered epididymal or testicular sperm. Other absolute indications for ICSI are non-male factor-related and include a history of two previous fertilization failures with conventional IVF and the fertilization of oocytes before reimplantation genetic diagnosis (87). The benefit of combined IVF/ICSI in ART for unexplained infertility also is described under *Unexplained Infertility*.

Micromanipulation is a highly skilled technique. When performed by specially trained embryologists, the immediate risk for damaging the manipulated oocyte is less than 10% (71). Normal physiologic processes—capacitation, zona binding, and penetration of the oolemma—are bypassed by the spermatozoa used in ICSI. Because the particular spermatozoa used for ICSI might otherwise be incapable of fertilization, concerns have been voiced regarding possible increased risks for congenital abnormalities among ICSI offspring. Several large series have followed 1,987 (88), 1,139 (89), and 730 (90) children born after ICSI. Each has reported no increase in major or minor congenital malformations among offspring produced by ICSI when compared with the general population (88,89 and 90) and when adjusted for multiple gestation (89). However, an increased incidence of sex chromosome karyotypic abnormalities (88,91) and hypospadias (89) has been suggested. Because the prevalence of sex chromosome karyotypic abnormalities and other genetic etiologies is increased in infertile men with severe oligospermia or azoospermia, genetic counseling should be offered before treatment with ART (92).

Posttesticular Azoospermia

In posttesticular azoospermia, the hypothalamic–pituitary axis and spermatogenesis are normal. No sperm appear in the ejaculate secondary to congenital absence or obstruction of the vas deferens or ejaculatory ducts, acquired obstruction of these ducts, or ductal dysfunctions, including retrograde ejaculation. Although low seminal pH (6.7 to 8.0) or low seminal fructose may signal the congenital absence or obstruction of the vas deferens, the diagnosis is confirmed by vasography. In some cases, testicular biopsy may be indicated to differentiate between primary testicular damage and outflow obstruction. Congenital bilateral absence of the vas deferens (CABVD) is found in 1% to 2% of infertile men and 95% of men with cystic fibrosis (93). Common mutations of the cystic fibrosis transmembrane conductance regulator gene (*CFTR*), which encodes a cyclic adenosine monophosphate (cAMP)-regulated chloride channel, can be found in some infertile men with CABVD, despite the absence of clinical symptoms of cystic fibrosis. Therefore, screening for mutations in the *CFTR* gene is indicated if men with CABVD plan to undergo sperm retrieval and ICSI in order to conceive using their own sperm. One cost-effective screening method addressing this problem involves screening the female partner for the three most common mutations in the *CFTR* gene. If negative, the couple has a risk of less than 1 in 1,500 for conceiving a child with cystic fibrosis, regardless of the paternal genotype (40).

Prior vasectomy is probably the most common cause of posttesticular azoospermia in infertile men. The reversal of vasectomy by microsurgical vasovasostomy is quite effective. In one study, vas deferens patency was obtained in 86% of cases, and pregnancy was achieved in 52% of cases after primary procedures (94). Rates of patency and pregnancy vary inversely with the length of time from vasectomy. For those patients with azoospermia 3 months after the reversal procedure, either the reanastomosis has failed or the epididymis is obstructed. Repeat vasovasostomy is associated with patency rates of 75% and pregnancy rates of 43% (94).

Epididymal obstruction is best diagnosed by vasography or documentation of normal spermatogenesis on testicular biopsy. There are two approaches to the treatment of posttesticular obstruction if the use of donor sperm is not being considered. Epididymal aspiration proximal to the obstruction may be used in cases of epididymal or vas deferens obstruction in order to obtain sperm for use in ART. Alternatively, microsurgical vasoepididymostomy is associated with patency rates of 70% and postoperative pregnancy rates of 44% at 1 year if no other infertility factor is present (95).

Some men with reduced semen volume may have retrograde ejaculation, in which sperm is propelled into the bladder during ejaculation rather than through the urethra. This diagnosis can be confirmed by examination of a postejaculatorily voided or catheterized urine specimen. This condition occurs in rare cases of patients with diabetes mellitus, in certain neurologic conditions, and after bladder or prostatic surgery. For subfertile men with retrograde ejaculatory dysfunction, α -adrenergic agonists such as phenylephrine have been reported to strengthen internal urethral sphincter tone (96). Sperm may also be isolated from the neutralized urine of men with retrograde ejaculation and processed for insemination or for ART (97).

Surgical Sperm Recovery for ICSI Among the many surgical methods for sperm recovery, the most widely described are microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), testicular sperm extraction (TESE), and percutaneous testicular sperm fine-needle aspiration (TESA, also called *fine-needle aspiration*, or FNA) (98). The choice of surgical sperm recovery method depends on the underlying diagnosis, whether the goal of the procedure is diagnostic or therapeutic, and whether isolated sperm will be used immediately or will be cryopreserved.

TESA may be used to recover sperm in cases of posttesticular azoospermia (in which spermatogenesis is expected to be normal), with a successful sperm recovery in 96% of patients (99). TESA is usually well tolerated by patients. It is typically performed with a 21-gauge needle with no anesthesia or with a 19-gauge needle or biopsy gun using local anesthesia. Fertilization and implantation rates have been reported to be similar in a retrospective analysis comparing TESA with open biopsy using TESE (99). Alternatively, if the nature of the obstruction needs to be investigated by a full scrotal exploration, or if attempted surgical correction of the obstruction will be performed at the time of sperm recovery, MESA may be the preferred procedure. MESA is performed with general or regional anesthesia using a microsurgical approach. One advantage of MESA is that a very large number of spermatozoa are usually retrieved, so that cryopreservation and avoidance of repeat surgery may be possible (100). Fresh and frozen-thawed epididymal (101) or testicular spermatozoa (102) appear to have comparable fertilization and ongoing pregnancy rates when used for ICSI.

Sperm retrieval using PESA is another option for the treatment of posttesticular azoospermia. PESA is performed using a 19-gauge needle with local or regional anesthesia. A sperm recovery rate of greater than 80% has been reported with 55% fertilization and 33% ongoing pregnancy rates after ICSI (103). Although this procedure appears less invasive than some of its alternatives, it is performed blindly. Bleeding and epididymal injury are possible, and postsurgical fibrosis may result (104). In contrast, men with testicular azoospermia or gonadal failure require TESE, and possibly multiple biopsies, to retrieve sperm (105). TESE followed by ICSI has resulted in ongoing pregnancies, even for patients with 47, XXY Klinefelter's syndrome (106,107). However, the sperm recovery rate with TESE is only about 50%, and clinical outcomes for ICSI after TESE among patients with testicular azoospermia are variable.

Lower fertilization rates but comparable ongoing pregnancy rates have been reported for ICSI using testicular spermatozoa recovered from testicular azoospermia, compared with epididymal spermatozoa, posttesticular azoospermia (91,108). In addition, if an associated histologic diagnosis of testicular aplasia, Sertoli cell-only syndrome, or spermatogenesis arrest is noted, all measures of success are reduced when compared with patients who have normal testicular histology (109). These measures of success include the following: lower sperm recovery rates (110), lower ongoing pregnancy rates (18% to 19% versus 33.5%), and lower implantation rates (5% to 9% versus 12%) (107,109). Despite these findings, the histologic diagnosis alone should not be used to exclude patients from ICSI treatment. Among patients with testicular azoospermia, surgically recovered sperm may be at various stages of maturation arrest (i.e., round spermatid, elongated spermatid, and motile and immotile spermatozoa). Sperm at all stages have been used to establish successful pregnancies using ICSI (71,111). However, the fertilization and pregnancy rates associated with maturation-arrested spermatid are very low, and couples should be properly counseled regarding their prognosis and alternative options (112,113 and 114). Finally, cryopreservation of testicular tissues and of spermatozoa for use in subsequent ICSI treatment cycles has been reported (115). Fertilization rates of 48%, ongoing pregnancy rates of 16%, and implantation rates of 9% were documented using cryopreservation in a mixed population of 246 patients diagnosed with testicular and posttesticular azoospermia (115).

Donor Insemination For men with azoospermia, couples with significant male factor infertility who do not desire ART, or women seeking pregnancy without a male partner, therapeutic donor insemination offers an effective option. A number of important issues surround the use of this form of artificial insemination. First, despite reports that the use of fresh donor semen is associated with higher pregnancy rates than the use of frozen specimens (116), both the Centers for Disease Control and Prevention (CDC) and the American Society for Reproductive Medicine recommend the use of frozen samples (117). This recommendation stems from the increasing incidence of human immunodeficiency virus (HIV) infection in the general population and the lag time between HIV infection and seroconversion. Currently, semen donors are screened for HIV infection, hepatitis B, hepatitis C, syphilis, gonorrhea, chlamydia, and cytomegalovirus infections, all of which may be transmitted through the semen vector. All cryopreserved samples are quarantined for 6 months, and the donor is retested for HIV before clinical use of the specimen. Donors are likewise questioned about any family history of genetically transmitted disorders, including both mendelian (e.g., hemophilia, Tay-Sachs disease, thalassemia, cystic fibrosis, congenital adrenal hyperplasia, Huntington's disease) and polygenic-multifactorial (e.g., mental retardation, diabetes, heart malformation, spina bifida) conditions. Those with positive family histories conditions are eliminated as donor candidates.

A second issue surrounding the use of therapeutic donor insemination—that which is most important to the patient—is the success rate of treatment. In patients

younger than 30 years of age who have no other infertility factors, conception rates approach 62% after 12 cycles of treatment with frozen sperm ([118](#)).

IUI was superior to intracervical insemination for donor insemination in several prospective randomized or crossover trials. Overall, the cycle fecundity rates ranged from 9.7% to 24% for IUI to 3.9% to 17.9% for intracervical insemination ([119,120,121,122,123,124](#) and [125](#)). A metaanalysis concluded that IUI had a significantly higher cycle fecundity rate when compared with ICSI (OR, 2.4; 95% CI, 1.5% to 3.8) ([126](#)). Moreover, the concomitant use of clomiphene citrate or gonadotropin (hMG) for COH did not result in higher fecundity rates ([126](#)).

The length of recommended treatment also should be considered. When frozen donor semen is used, more than 80% of consequent pregnancies will occur during the first 12 months of treatment ([127](#)). Thus, patients who do not conceive within 6 to 12 months should be assessed for female factors and encouraged to terminate treatment or move to alternative forms of therapy.

Last, but not least, one must consider the psychosocial aspects of pregnancies involving donor gametes. Among patients without a male partner, the potential repercussions of becoming a single mother and the issue of telling others about the father of the child must be discussed. If the couple is married, it is imperative that the husband be aware of the process of using donor gametes, and most programs require that the husband sign a consent form. A skilled infertility social worker or psychologist can be immeasurably helpful in addressing these concerns.

Age and Decreased Ovarian Reserve

An association between the age of the woman and reduced fertility has been well documented, with the decline in fecundability beginning in the early 30s but accelerating during the late 30s and early 40s. Chronologic age is the strongest determinant of reproductive success in spontaneous and ART cycles because it is a predictor of ovarian reserve ([128,129](#)). However, age has traditionally not been considered a “cause” of infertility, probably because it represents a physiologic rather than a pathologic state.

Data from rural Senegal, in which each female gives birth to an average of 7.9 children, show declining fertility rates with a peak of fertility at 25 years of age and a steep decline after 35 years of age ([130](#)) ([Fig. 27.6](#)). Similarly, among the Hutterites, a communal sect living in the Dakotas and Montana that practices no contraception and has large families, fertility peaks by 25 years of age, and one third of women are no longer fertile by 40 years of age ([131](#)). The fecundability of women undergoing donor insemination whose husbands are azoospermic provides insight into the effects of age on the fertility of the female alone. A French group that studied women enrolled in artificial insemination programs found that fertility rates begin to drop after 30 years of age. The pregnancy rate after 1 year of inseminations was 74% in women aged 30 years and younger, 62% in women aged 30 to 35 years, and 54% in women older than 35 years of age ([132](#)).

Figure 27.6 Age pattern of male and female fertility in a transitional society (Senegal).

The physiology of declining fertility in older women is better understood in light of data from oocyte donation programs. When embryos produced from oocytes retrieved from younger women are transferred into older women, the pregnancy rates among the older women approximate those of the younger women ([133](#)), and variations in pregnancy rates are directly dependent on the age of the donors, not that of the recipients ([133,134](#) and [135](#)). In fact, among 260 egg donors (mean age of 30 years) who underwent controlled ovarian stimulation (COH with exogenous gonadotropins), the number of oocytes retrieved per cycle decreased steadily at the rate of 0.24 oocyte per year of increasing age ([135](#)). In another study, the use of oocytes from young donors provided cycle fecundity rates of 50% per cycle. The accumulated pregnancy and live birth rates in this investigation reached 95% and 89%, respectively, after up to four cycles of ART ([136](#)). **These observations strongly support that it is the age of the oocyte, rather than the age of the endometrium, that accounts for the age-related decline in female fertility.**

This oocyte-related decline in fertility is also known as *decreased ovarian reserve*. Absolute evidence of decreased ovarian reserve often can be ascertained only after ART treatment shows decreased ovarian responsiveness to COH. In ART, decreased ovarian reserve is reflected by an increased requirement for gonadotropins (FSH ± LH), small numbers of ovarian follicles and oocytes, and low serum estradiol levels during exogenous stimulation of folliculogenesis. These clinical outcomes probably reflect a decreased number of ovarian antral follicles as well as poor quality of granulosa cells and oocytes ([137](#)). Although age is the best predictor of ovarian reserve as reflected by ovarian responsiveness to COH, there is a subset of women who demonstrate an ovarian reserve that is prematurely diminished based on their chronologic age. Similarly, there are women who respond well to COH and achieve pregnancies despite their advanced age. Therefore, tremendous efforts have been expended to identify an ovarian reserve test that can be used to counsel patients and to guide their management.

Ovarian reserve screening tests that have been proposed include serum day 3 FSH, *clomiphene citrate* challenge test (CCCT), serum inhibin B, and transvaginal ultrasound to assess antral follicle number or ovarian size ([138,139](#) and [140](#)). Measurement of day 3 FSH is based on evidence that small increases in basal serum FSH levels correlate with the decreased fecundability seen among women in their late 30s. *Clomiphene citrate* is thought to have antiestrogenic effects in the hypothalamic–pituitary axis, resulting in a decrease in suppression of FSH production by the pituitary. In the CCCT, serum FSH is drawn on day 3, and again on day 10 after administration of *clomiphene citrate* (100 mg orally each day) from days 5 to 9. FSH levels vary depending on the assay used and the population being screened; therefore, each ART center typically sets its own reference range for evaluating the results of a CCCT. In a general infertility patient population, the incidence of an abnormal CCCT rises from less than 10% in patients younger than 35 years of age to 26% in patients older than 40 years of age ([141](#)). However, the results of day 3 FSH levels and CCCT must be interpreted with caution. These tests have mainly been studied in women with subfertility. Among these patients, day 3 FSH testing has a sensitivity of 8% in identifying women who will not conceive with subsequent IVF treatment. Day 3 FSH and CCCT each displays a high specificity (96%) in predicting IVF outcome; however, addition of the CCCT to a day 3 FSH assessment only increases the sensitivity of prediction to 26% ([142,143](#) and [144](#)). Although abnormal CCCT results portend poor prognosis for pregnancy independent of age, older patients with normal CCCT still have significantly decreased pregnancy rates. Because among older patients even a normal CCCT is not reassurance of good prognosis, chronologic age must still be considered a salient, independent predictor of treatment outcome ([129](#)).

A great deal of emotional, physical, temporal, and financial effort is involved in the process of fertility treatments involving ART. Day 3 FSH and CCCT results can be used to counsel patients regarding their potential for pregnancy with IVF treatment. In one study, 5% of 435 women beginning their first IVF cycle had a day 3 FSH level greater than 15 IU/L ([145](#)). These women were 3.9 times more likely to have an unsuccessful treatment cycle. Similarly, among 175 IVF cycles involving women older than 40 years of age, no pregnancies resulted when testing revealed a day 3 FSH greater than 11.1 mIU/mL or a day 10 FSH greater than 13.5 mIU/mL after CCCT ([146](#)). Therefore, it is reasonable to advise women with advanced age (>40 years) and abnormal day 3 FSH or CCCT results to strictly limit the number of IVF cycle attempts because of their overall poor prognosis. These tests should not, however, be used as the sole basis to exclude women from IVF treatment ([142](#)).

Recently, serum inhibin B has also been proposed as a potential screening test for ovarian reserve. Inhibin B is produced by ovarian granulosa cells predominantly during the follicular phase of the menstrual cycle. Inhibin B suppresses the production of FSH by the pituitary gland. The normal rise in circulating levels of FSH associated with menopause is thought to be secondary to the decrease in inhibin B production accompanying the age-related depletion of functional ovarian follicles. In fact, in the CCCT, the main mechanism by which FSH is normally suppressed is via inhibin B production by granulosa cells. Women with decreased ovarian reserve have a lower rise in the day 10 serum inhibin B levels in response to the CCCT ([147](#)). In addition, women who have clinical evidence of diminished ovarian reserve and normal day 3 FSH levels have been found to have decreased day 3 inhibin B levels. This observation suggests that a decrease in day 3 serum inhibin B

levels may precede detectable changes in day 3 FSH levels (140). Although the degree of elevation in serum inhibin B levels 24 hours after administration of exogenous FSH appears to be positively predictive of good ovarian response (148), clinical application of serum inhibin B still requires further evaluation. In particular, basal inhibin B levels do not provide additional age-independent prognostic value for predicting pregnancy outcomes after ART (128). One possible reason for this is that levels of inhibin B may reflect granulosa cell function and thereby only forecast ovarian response in ART. Although granulosa cell competence is certainly associated with oocyte quality, clinical application of serum inhibin B testing will also depend on whether levels are predictive of normal meiotic division of the oocyte because fetal karyotype is an important determinant of pregnancy outcome (149).

Spontaneous Abortion

Another factor contributing to the decreased fecundity among older reproductive-age women is the increased risk for spontaneous abortion in this population. A large study based on the Danish national registry estimated the rates of clinically recognized spontaneous abortion for various age groups to be 13.3% (12 to 19 years), 11.1% (20 to 24 years), 11.9% (25 to 29 years), 15.0% (30 to 34 years), 24.6% (35 to 39 years), 51.0% (40 to 44 years), and 93.4% (>45 years) (150). In addition, using sensitive hCG assays in women during their reproductive years, 22% of all pregnancies were found to be lost before they could be clinically diagnosed (151). One might predict that this proportion would be increased among older women attempting pregnancy, making subclinical spontaneous pregnancy loss a significant consideration among older women who are thought to be having difficulty conceiving.

One major cause for the increase in spontaneous losses among older women is their increased incidence of chromosomally abnormal fetuses. A cytogenetic analysis of 750 spontaneous abortions revealed that the increase in chromosomally abnormal conceptuses seen with increased maternal age was mainly due to an increase in chromosomal trisomies. In particular, the incidence of trisomies 16, 21, 22, 18, and 20 were significantly increased, with 18 and 20 being the most dramatic. In contrast, the risk for monosomy X and polyploidy did not increase with advanced maternal age (152). In conclusion, an increased spontaneous loss rate, coupled with a reduced conception rate, significantly decreases the chance of a live birth among women older than 40 years of age.

Age of Male Partner

There is little doubt that increasing age is accompanied by reduced female fecundity; however, the age-related decline in fecundity for men is more controversial. Male fertility peaks at about 35 years of age and declines sharply after 45 years of age; however, men have reportedly fathered children into their 80s (6). Also, the risk for chromosomal trisomies appears to be related, at least in part, to increased paternal age (153). Recent observations have demonstrated an increase in the rate of autosomal recessive disorders among the progeny of men 35 years of age and older (154,155). These findings suggest an age-related decline in gamete quality among men, albeit one that is more subtle than that experienced by women.

Ovulatory Factor

Disorders of ovulation account for about 30% to 40% of all cases of female infertility. These disorders are generally among the most easily diagnosed and most treatable causes of infertility. The normal length of the menstrual cycle in reproductive-age women varies from 25 to 35 days; most women have cycle lengths of 27 to 31 days. Figure 27.7 shows the fluctuations of estradiol, progesterone, FSH and LH in a normal, 28-day ovulatory cycle. Women who have regular monthly menses (about every 4 weeks) with minimal symptoms, such as premenstrual breast swelling and dysmenorrhea, almost invariably have ovulatory cycles. Because ovulation is an obligatory prerequisite to conception, ovulation must be documented as part of the basic assessment of the infertile couple. Initial diagnoses among women with ovulatory factor infertility may include anovulation (complete absence of ovulation) or oligoovulation (infrequent ovulation).

Figure 27.7 Relative hormonal fluctuations in a normal, ovulatory, 28-day menstrual cycle.

Methods to Document Ovulation

Luteinizing Hormone Monitoring Documentation of the LH surge represents a remarkably reproducible method of predicting ovulation. Ovulation occurs 34 to 36 hours after the onset of the LH surge and about 10 to 12 hours after the LH peak (156,157). Commercially available kits for documenting the LH surge are generally accurate, quick, convenient, and relatively inexpensive enzyme-linked immunosorbent assays (ELISAs) using 40 mIU/mL as the threshold for detection (158,159). The positive and negative predictive values of these kits have been described to be 90% and 96%, respectively (160). A 100% correlation between urinary LH prediction of ovulation and transvaginal ultrasound diagnosis of ovulation has further confirmed the value of urine LH detection kits for home ovulation detection (161). Still, there may be up to 5% to 10% of women for whom this ELISA test cannot detect urinary LH, probably either because of failed recognition by the antibody used or because their peak urinary LH concentration does not rise above the threshold set by the kit manufacturers. Serum LH measurements may be necessary to predict ovulation in such cases.

Basal Body Temperature The least expensive method of confirming ovulation is for the patient to record her temperature each morning on a basal body temperature (BBT) chart. The oral or rectal temperature should be determined before the patient arises, eats, or drinks. Smoking is forbidden before temperature measurement, and irregular sleep patterns can interfere with the test results. Patients monitoring BBT record their temperature daily but also record times when coitus occurs. Use of a BBT is preferred to use of a conventional thermometer because of the BBT instrument's precision in the temperature range under consideration. The principle behind temperature charting as a means to document ovulation is simple. Significant progesterone secretion by the ovary generally occurs only after ovulation. Progesterone is a thermogenic hormone. The secretion of progesterone causes a temperature increase of about 0.58°F over the baseline temperature of 97° to 98.8°F typically recorded during the follicular phase of the menstrual cycle. Charting of daily BBTs produces a characteristic biphasic pattern in women with ovulatory cycles. Frequently, a nadir in charted BBT is noted at the time of the LH surge, but this finding is inconsistent. A normal luteal phase is characterized by a documented temperature elevation lasting at least 10 days.

BBT charting for documentation of ovulation, although simple, has several drawbacks. Presumptive ovulation can be identified only retrospectively (i.e., the test merely confirms rather than predicts ovulation). Even retrospectively, the exact time of ovulation is difficult to determine using BBTs, although in most instances, it is probably 1 day before documented temperature elevation. An unequivocal temperature rise generally occurs 2 days after the LH surge and correlates with serum progesterone levels of 0.4 ng/mL (162). Also, in a small percentage of patients, BBT charts are monophasic, despite the documentation of ovulation by other methods. Further, BBT charting is correlated with transvaginal ultrasound evidence of ovulation in only 30.4% of cases (161). Despite its limitations, for many patients, BBT charting is a simple way to document ovulation, and unequivocal biphasic cycles are almost certainly ovulatory. Patients with monophasic cycles require confirmation of ovulation using alternative methods.

Midluteal Serum Progesterone Elevations in serum levels of progesterone constitute indirect evidence of ovulation. When used to document ovulation, serum progesterone measurement should coincide with peak progesterone secretion in the midluteal phase (typically on days 21 to 23 of an ideal 28-day cycle). The lower limit of progesterone levels in the luteal phase varies among laboratories, but a level above 3 ng/mL (10 nmol/L) typically confirms ovulation. However, an appropriate interpretation of isolated luteal-phase measurements of serum progesterone is complicated by the frequent pulses that characterize the secretion of this hormone (163). Although ovulatory levels are often considerably higher than 3 ng/mL, low midluteal serum levels of progesterone are not necessarily diagnostic of anovulation.

Ultrasound Monitoring Ovulation can also be documented by monitoring the development of a dominant follicle by ultrasound until ovulation takes place.

Ovulation is characterized both by a decrease in the size of a monitored ovarian follicle and by the appearance of fluid in the cul-de-sac (164). It most often occurs when follicular size reaches about 21 to 23 mm, although it may occur with follicles as small as 17 mm or as large as 29 mm (165,166). Because of the inconvenience and expense of serial measurements, routine use of ultrasound for documenting ovulation is discouraged. Instead, it is recommended that its use be confined to the monitoring of ovulation induction.

Follow-up Tests If tests confirm that a patient is anovulatory or oligoovulatory, then diagnoses such as hypothalamic–pituitary disorder, hypothyroidism, anorexia nervosa, polycystic ovarian syndrome (PCOS), and premature ovarian failure need to be considered. In addition to history and physical examination, the basic investigations typically used to assess further these potential diagnoses include serum FSH, prolactin, and thyroid-stimulating hormone (TSH) testing. These three investigations are often sufficient to guide the initial management plan.

Polycystic Ovarian Syndrome

PCOS is the most common cause of oligoovulation and anovulation—both in the general population and among women presenting with infertility. The diagnosis of PCOS is determined by a history of oligoovulation or anovulation in conjunction with physical evidence of hyperandrogenism. The exclusion of pregnancy, hypothalamic–pituitary disorders, or other causes of hyperandrogenism (e.g., androgen-secreting tumors or nonclassical congenital adrenal hyperplasia) may be indicated in some patients presenting with presumptive ovulatory disorders and infertility. However, once other causes of oligoovulation or anovulation have been excluded, biochemical evidence consistent with PCOS—including serum LH-to-FSH ratios and hyperinsulinemia—is not required before initiation of infertility treatment. Because oligomenorrheic women with PCOS are at risk for endometrial hyperplasia, it may be prudent to perform an endometrial biopsy before beginning ovulation induction therapy.

Ovulation Induction in Women with PCOS

Despite the use of similar medications, the indications and goals of ovulation induction should be distinguished from those of superovulation. Ovulation induction refers to the therapeutic restoration of the release of one egg per cycle in a woman who either has not been ovulating regularly or has not been ovulating at all. Although it is usually acceptable for ovulation induction to result in the release of two eggs, one should avoid the ovulation of more than two eggs in an effort to minimize the risk for ovarian hyperstimulation syndrome (OHSS) and multiple pregnancies. In contrast, superovulation is indicated for the treatment of women with unexplained infertility who have been unable to conceive despite regular, monthly ovulation. The explicit goal of superovulation is to cause more than one egg to be ovulated, thereby increasing the probability of conception.

Ovulation induction can be achieved either medically or surgically in women with PCOS. There is no fixed protocol on how to approach ovulation induction in these patients, although there exists a reasonable tendency to progress from the least to the most invasive therapies. Appropriate patient selection for various therapies can be a significant determinant of successful ovulation induction among PCOS patients.

Regardless of which treatment is employed, one important concept to convey to couples is that pregnancy is a cumulative probability. Once ovulation has been documented for a particular treatment, patients should be mentally prepared to continue with that regimen for at least three cycles because, for most treatments, the rate of a pregnancy occurring per therapeutic cycle is the same for each of the first three cycles. When counseling patients, it is often helpful to remind them that even **a couple with no fertility problems has a fecundity rate of only 20% to 25% per cycle (1)**. A good rule of thumb involves review of the patient management plan at least once every 3 cycles and more frequently if side effects are present. This plan should be explicitly discussed with patients, thereby promoting education, communication, and informed compliance.

Weight Loss A body mass index (BMI) above 27 kg/m² is considered excessive; moreover, an increase in BMI is associated with an increased risk for insulin resistance. There are several excellent reasons for recommending weight loss among overweight infertile patients. Using hypocaloric diets, weight loss of 20 kg (mean pretreatment weight, 77 kg) in one study and 10 kg (mean pretreatment BMI, 32 kg/m²) in another study, resulted in a decrease in plasma testosterone, androstenedione, LH, and fasting insulin levels (167,168). Significant improvement in these parameters, which are thought to play a role in the pathogenesis of PCOS, helps restore spontaneous ovulation in many patients. In a study of 67 overweight women who had a mean weight loss of 10.2 kg/m², spontaneous ovulation and pregnancy occurred in 90% and 30%, respectively (169). Obese patients are at increased risk for medical conditions such as diabetes, hypertension, and cardiovascular disease. Because obesity also is a risk factor for obstetric complications, there should be tremendous incentive for the infertile patient to reduce weight (170). As with any other lifestyle change, promotion of weight loss can be difficult and frustrating for both patient and practitioner. Weight loss often requires multidisciplinary efforts, including the involvement of an experienced dietitian and promotion of an effective exercise program. Many women may be discouraged by the time it takes to reduce their weight and the uncertainty of successful weight reduction; thus, it is reasonable to pursue medical options in parallel with lifestyle changes.

Clomiphene Citrate Traditionally, *clomiphene citrate* (*Clomid*, *Serophene*) has been the first-line intervention for medical induction of ovulation in PCOS patients. *Clomiphene citrate* is a weak synthetic estrogen, but it mimics the activity of an estrogen antagonist when given at typical pharmacologic doses for the induction of ovulation. A functional hypothalamic–pituitary–ovarian axis is required for appropriate *clomiphene citrate* activity. More specifically, *clomiphene citrate* is thought to bind and block estrogen receptors in the hypothalamus for prolonged periods, thereby decreasing the normal ovarian–hypothalamic estrogen feedback loop (171). This blockade increases GnRH pulse amplitude in some anovulatory women (172). Increases in GnRH then feed forward to cause increased gonadotropin secretion by the pituitary, promoting ovarian follicular development. *Clomiphene citrate* also may affect ovulation through direct action on the pituitary (173) or the ovary (174,175). Unfortunately, the antiestrogenic effects of *clomiphene citrate* at the level of the endometrium (176) or the cervix (177) may have adverse effects on fertility in a minority of individuals (178,179).

Use of *clomiphene citrate* for ovulation induction is generally associated with excellent outcomes. In fact, in some populations, 80% to 85% of treated women will ovulate and 40% will conceive (180,181). Discrepancies between ovulatory rates and conception rates are most likely associated with the number of cycles attempted or are secondary to the presence of additional, nonovulatory infertility factors among treated women. Most pregnancies resulting from induction of ovulation with *clomiphene citrate* occur during the first 6 months of therapy (180). Side effects of *clomiphene citrate* therapy include infrequent OHSS, vasomotor flushes, nausea, pelvic discomfort, and breast pain (173). In the presence of visual abnormalities, *clomiphene citrate* should be promptly discontinued. Use of *clomiphene citrate* is associated with a 35% to 60% incidence of multiple follicular recruitments (182); however, the incidence of multiple gestation with this agent is only about 5% to 8%. Most of these multiple gestations are twin pregnancies; triplet pregnancies occur infrequently. Rates of spontaneous abortion and teratogenicity in humans are not increased with the use of *clomiphene citrate* (183).

***Clomiphene citrate* is typically used for ovulation induction in the following manner:**

1. The drug is supplied in 50-mg tablets; the usual starting dosage is 50 mg/d. Therapy is typically begun on the fifth day after the onset of a spontaneous or progesterone-induced menses and is continued through day 9 of the menstrual cycle. Treatment on days 2 to 6 after onset of menses has also been advocated (184). Some patients respond to a dosage as low as 25 mg/d.
2. Ovulation should be documented using a home urine LH kit. This information is valuable for future therapeutic planning because failure to conceive despite successful ovulation has different implications than failure to conceive because of failed ovulation induction. If ovulation does not occur at the initial dosage of *clomiphene citrate*, the dosage is increased in each subsequent cycle by 50 mg/d. The U.S. Food and Drug Administration recommends a maximum dosage of 100 mg/d; however, in patients who ovulate as a result of *clomiphene citrate* treatment, 11.8% do so only at doses of 150 mg/d or more (180). Considerable clinical experience with *clomiphene citrate* indicates that a dosage of up to 250 mg/d is safe.
3. Ovulation is expected to occur 5 to 10 days after the last day of therapy; thus, with standard *clomiphene citrate* regimens, ovulation testing should begin on day 12 or 13 and continued daily until results are positive. Once a pattern is established, ovulation testing can be confined to a 5-day period in subsequent months. Intercourse every other day for 1 week beginning a day or two before anticipated ovulation is recommended. Alternatively, daily intercourse for 3 days beginning on the day of a positive urine LH test will also maximize the chance of a pregnancy.
4. If ovulation cannot be induced despite the use of increasing amounts of *clomiphene citrate*, ultrasound can be used to monitor follicular development during the treatment cycle. If a dominant follicle develops, but there is no spontaneous LH surge, hCG (10,000 units given intramuscularly) can be used for final follicular maturation/ovulation, followed by timed intercourse or IUI. The number of *clomiphene citrate*-treated and ovulatory cycles should not exceed six cycles because the maximum cumulative pregnancy rate has been achieved by that point, and further treatment with *clomiphene citrate* would have minimal predicted benefit.

Despite the high therapeutic success rates of *clomiphene citrate* in most anovulatory women, treatment has relatively low success in inducing ovulation in women with PCOS and insulin resistance, in whom obesity or elevated BMI also is evident. Before initiating therapeutic changes in such women, differential diagnoses should be reviewed and endocrinologic investigations repeated if necessary. *Dexamethasone*, 0.5 mg/d at bed time, combined with typical *clomiphene citrate* regimens may induce ovulation in patients who have elevated serum dihydroepiandrosterone sulfate (DHEAS) (185). At this low dosage, *dexamethasone* therapy is associated with minimal adverse effects. Alternatively, there is now increasing evidence that insulin sensitizers are particularly effective in inducing ovulation in PCOS women with insulin resistance.

Insulin Sensitizers PCOS is currently viewed as a disease that can result from different genetic causes with possible modification by environmental factors (186). Insulin resistance is thought to play a central role in the pathogenesis of PCOS in the subset of patients characterized by increased BMI, hyperinsulinemia, and significant hyperandrogenism (Table 27.5)(186). It is also thought that a different form of insulin resistance intrinsic to PCOS is part of the underlying disease mechanism in thin women with PCOS (187,188). *Metformin* and *troglitazone* are the best-studied of the insulin sensitizers used for ovulation induction.

Physical findings associated with insulin resistance
Body mass index >27 kg/m ²
Waist-to-hip ratio >0.85
Waist >100 cm
Acanthosis nigricans
Numerous acrochordons (skin tags)

From Barbieri RL. Induction of ovulation in infertile women with hyperandrogenism and insulin resistance. *Am J Obstet Gynecol* 2000;182:412-418, with permission.

Table 27.5. Clinical Findings That Suggest Insulin Resistance and Hyperinsulinemia

Metformin is an oral biguanide that is approved for the treatment of non-insulin-dependent diabetes. *Metformin* acts by several mechanisms, including inhibition of gluconeogenesis in the liver and an increase in the uptake of glucose in the periphery (189). When women with PCOS, hyperandrogenism, and hyperinsulinemia are treated with metformin for 12 weeks, their fasting insulin and total testosterone levels, free testosterone index, BMI, waist-to-hip ratio, hirsutism, and acne all decrease significantly (190). Moreover, among women who have PCOS, a BMI greater than 28 kg/m², and hyperandrogenemia, 89% ovulate after treatment with a combination of *metformin* and *clomiphene citrate*. This rate is significantly higher than the 12% of patients who ovulated during combined treatment with placebo and *clomiphene citrate* (191). Although *metformin* alone has also been reported to induce spontaneous ovulation, this monotherapy has not been compared with *metformin* plus *clomiphene citrate* or placebo in a prospective, randomized trial (187). Similarly, *troglitazone*, an insulin sensitizer under the category of thiazolidinediones, has beneficial effects on plasma androgen and fasting insulin levels, and increases the rate of spontaneous ovulation in obese women with hyperandrogenemia and insulin resistance, even in the absence of weight loss (192,193). *Troglitazone*, however, has recently been withdrawn from the market because it carries a 1 in 50,000 chance of fatal liver failure. In contrast, *metformin* has an excellent safety profile. Gastrointestinal complaints are its most common side effects, although isolated cases of fatal lactic acidosis have been reported in patients with underlying renal compromise. *Metformin* is typically discontinued once pregnancy has been established; however, it is a category B drug and its administration during pregnancy is not known to confer specific risk to the fetus. Two new insulin sensitizers have recently been approved for treatment of diabetes: *rosiglitazone* and *pioglitazone*. The safety and efficacy of these medications has not yet been assessed for use in ovulation induction.

A typical treatment regimen using *metformin* with or without *clomiphene citrate* for ovulation induction in PCOS patients follows (187):

1. Select PCOS patients. Failure of ovulation induction with clomiphene citrate alone is an indication but not a requirement for the use of metformin.
2. Confirm normal liver and renal function (serum creatinine <1.4 mg/dL). Serum hCG testing to exclude pregnancy, followed by a progestin withdrawal-induced menses, can be undertaken if indicated.
3. Start *metformin* therapy as follows:
 - *Metformin*, 500 mg once a day with breakfast for 4 days
 - *Metformin*, 500 mg twice a day with breakfast and dinner for 4 days
 - *Metformin*, 500 mg with breakfast and 1,000 mg with dinner for 4 days
4. Thereafter, give *metformin*, 1,000 mg twice a day (at breakfast and dinner).
5. If a trial of *metformin* alone is chosen, evaluate single serum progesterone levels weekly to detect the occurrence of ovulation. It may take up to 2 months of therapy before spontaneous ovulation occurs.
6. If *metformin* plus *clomiphene citrate* is the desired regimen, add *clomiphene citrate* at the usual starting dosage of 50 to 100 mg once a day from days 5 to 9 when the full dose of *metformin* has been reached, and if spontaneous ovulation has not occurred. Home LH detection kits can then be used to predict ovulation and time intercourse.
7. *Clomiphene citrate* can be increased incrementally by 50 mg once a day in subsequent cycles if ovulation still does not occur. Once ovulation occurs, the ovulatory dosage of *clomiphene citrate* can be used in combination with *metformin* for up to 3 to 6 cycles (in conjunction with ovulation detection and timed intercourse or inseminations).

Metformin is usually discontinued once pregnancy is confirmed. It has been suggested that continuation of metformin in early pregnancy may decrease the risk for spontaneous abortion in PCOS patients (194). At present, this finding needs to be confirmed by a prospective, randomized trial before being widely accepted. If the combination of *metformin* and *clomiphene citrate* fails to induce ovulation, the diagnosis should be reviewed. Other treatment options, including gonadotropin therapy (see section on [Gonadotropin Therapy](#)) and surgical ovarian diathermy, may be considered.

Surgical Treatment Pathophysiologic changes in the polycystic ovary have been the subject of many years of intense investigation. As early as 1935, with the initial description of the syndrome, ovarian surgical treatment of PCOS was considered (195). Initial surgical management of PCOS involved wedge resection of the ovaries in an effort to reduce the volume of androgen-producing tissue and thereby alleviate hyperandrogenic abnormalities. In fact, ovarian wedge resection does decrease circulating levels of testosterone (196), and this therapy is associated with resumption of menses in 91% of treated PCOS patients (197). Unfortunately, many patients treated with ovarian wedge resection suffer from postoperative intrapelvic adhesions, often leading to iatrogenic tubal factor infertility (197,198).

Laparoscopic techniques aimed at treating PCOS appear to be associated with less adhesion formation in the pelvis than noted after ovarian wedge resection by laparotomy (199,200), while maintaining similar improvements in hormonal profiles (201,202). Compared with controls, patients undergoing laparoscopic ovarian diathermy (or ovarian drilling) have higher rates of subsequent ovulation and a lower resistance to standard ovulation induction agents (203,204). In further support of this concept, 112 women with PCOS and anovulatory infertility in whom previous ovulation induction attempts using clomiphene citrate (up to 200 mg once a day) were unsuccessful were treated with laparoscopic ovarian diathermy. This surgical therapy resulted in a significant decrease in serum levels of LH, testosterone, DHEAS, and androstenedione and in the LH-to-FSH ratio (205). Further, 73% of these patients ovulated spontaneously, 24% ovulated with clomiphene citrate therapy, and 1.8% ovulated only with gonadotropin use. The cumulative probabilities of pregnancy were 54%, 68%, and 82% at 12, 18, and 24 months of follow-up, respectively. The median time to conception was 10.2 months. Thus, laparoscopic ovarian diathermy may have particular application in ovulation induction among PCOS patients who are resistant to treatment with clomiphene citrate.

Laparoscopic ovarian diathermy appears to have an effect on IVF outcomes as well. In a prospective trial comparing IVF outcomes in PCOS patients with and without prior surgical intervention, both a higher ongoing pregnancy rate and lower peak estradiol levels were documented in PCOS patients with prior laparoscopic ovarian diathermy (206). If one interprets these results as an indication that laparoscopic ovarian diathermy favorably alters the response of PCOS patients to COH with gonadotropin therapy, then its effect on reducing the risk for OHSS among PCOS patients treated with these medications certainly warrants further investigation. It is of interest that laparoscopic ovarian diathermy has been linked to a decrease in the elevated rates of spontaneous abortions documented in PCOS patients (205,206).

A variety of techniques have been described for laparoscopic destruction of ovarian tissue in the treatment of PCOS, including the use of laser, unipolar cautery, and bipolar cautery. Although no single technique has been proved superior using randomized studies, recent reports have advocated diathermy by electrocautery (205,206 and 207). In this technique, the ovary is immobilized, and an insulated needle is inserted into the ovary in a direction perpendicular to the ovarian surface using a short duration of cutting current at 100 W. Coagulating current at 40 W is then applied for about 2 seconds. The needle is withdrawn, and the process is repeated at up to 15 puncture sites per ovary. At the end of the procedure, the ovaries are lavaged with copious amounts of normal saline (205).

In addition to the usual risks associated with laparoscopic surgery, laparoscopic ovarian diathermy involves the rare but potential risk for surgically induced premature ovarian menopause via inadvertent disruption of ovarian vascular supply. More common, however, is the possible formation of adnexal adhesions, which may further compromise fertility. In one study, 19% of the patients who had second-look laparoscopy after laparoscopic ovarian diathermy had adhesions (200). In a series of 112 PCOS patients reported (205), filmy adhesions confined to the ovarian surface were reported in 4 of 15 women who had not conceived at 1 year and who underwent second-look laparoscopy. At present, the impact of postsurgical adhesion formation on subsequent fertility and defined indications for use of second-look laparoscopy in treated patients remains undetermined.

Gonadotropin Therapy for PCOS Patients Anovulatory PCOS patients who fail to ovulate or conceive after surgery or medical treatment with *metformin* and *clomiphene citrate* should be considered for ovulation induction with gonadotropin therapy (with or without GnRH agonist downregulation). A complete protocol is described in the section on *Gonadotropin Therapy*. This treatment involves daily injection of gonadotropins and close monitoring using serum estradiol measurements and transvaginal ultrasound monitoring of follicular development. IUI often is recommended in conjunction with ovulation induction to optimize the chances of pregnancy using this intense treatment. It is important to remember that PCOS patients tend to have a high number of small antral follicles in the unstimulated state. These follicles have the potential for stimulation by exogenous gonadotropin therapy. This effect could be potentially problematic because the goal of gonadotropin therapy in these patients, unlike that in ovulatory patients with unexplained infertility, is not to produce many eggs but rather to induce the release of only 1 or 2 oocytes. Treatment should therefore be monitored by an experienced physician because the risks for OHSS and multiple gestation are significantly increased when using gonadotropins in this patient population.

Ovulation Induction for Other Anovulatory Disorders

Hyperprolactinemia Hyperprolactinemia can be associated with ovulatory factor infertility. After exclusion of a pituitary macroadenoma or other intracranial pathology, correction of the hyperprolactinemic state with *bromocriptine* is followed by restoration of ovulation in 90% of patients (208). *Cabergoline* has similarly high efficacy, but it has the advantage of a twice-weekly dosing schedule. More controversial is the use of bromocriptine alone or the addition of *bromocriptine* to *clomiphene citrate* therapy in patients with normal or minimally elevated serum prolactin levels. Such therapy has, however, been associated with improved pregnancy rates among normoprolactinemic women with unexplained infertility and galactorrhea (209).

Hypogonadotropic Hypogonadism Anovulation in the presence of low serum LH, FSH, and estradiol levels defines hypogonadotropic hypogonadism and reflects dysfunction within the hypothalamic–pituitary axis. Causes of hypogonadotropic hypogonadism, including craniopharyngiomas, pituitary adenomas, arteriovenous malformations, or other central space-occupying lesions, should be excluded using magnetic resonance imaging.

There is now increasing evidence for genetic and physiologic mechanisms linking the regulation of body fat content, caloric intake, and hypothalamic control of reproduction. For instance, leptin and its receptor have recently been demonstrated to have critical functions in body mass regulation, glucose homeostasis, and reproductive function at the hypothalamic level. Among other characteristic metabolic abnormalities, gene-targeted mice lacking leptin or leptin receptor were infertile secondary to hypogonadotropic hypogonadism (210). Homozygous mutation in the human leptin receptor gene also has been identified. In humans, abnormalities in leptin receptor function lead to early-onset morbid obesity and absent pubertal development, presumably secondary to defective hypothalamic function (210).

Low BMI also can cause anovulation and infertility in women, possibly by disrupting hypothalamic function (211). Examples of conditions characterized by low BMI include anorexia nervosa, professional athletic training, and malnutrition. In most patients with these conditions, weight gain is the ideal treatment for ovulatory dysfunction, avoiding the use of ovarian stimulatory medications and their complications. Other health benefits, including the reduction of complications from pregnancy and osteoporosis, can result from correction of an abnormally low BMI. In one study, increased caloric intake and weight gain alone resulted in the resumption of menses in 90% patients with amenorrhea related to low BMI; 73% had spontaneous conception (212). In another study, a mean weight gain of 3.6 kg was sufficient to promote the resumption of spontaneous ovulation (213).

Other conditions of hypothalamic dysfunction, such as congenital hypothalamic failure (*Kallmann's syndrome*), can be treated using pulsatile GnRH therapy if the pituitary–ovarian axis is intact. Gonadotropin therapy should be chosen for patients in whom pituitary dysfunction is present, such as those with empty sella syndrome. Each of these treatment modalities is discussed in greater detail under *Gonadotropin Therapy*.

Hypothyroidism The prevalence of abnormal TSH levels in the general infertility population has been reported to be 6.3%, 4.8%, 2.6%, and 1.5% for women from couples diagnosed with anovulatory infertility, unexplained infertility, tubal infertility, and male infertility, respectively (214). This diagnosis is significant in the management of infertility. For instance, one study reported that among 171 women with hypothyroidism, 23% had irregular menses, likely resulting from anovulation (215). Spontaneous ovulatory cycles typically resume when euthyroid status is achieved using *thyroxine* supplementation.

In contrast to the causal relationship between hypothyroidism and anovulation, the association between hypothyroidism or thyroid antibodies and spontaneous abortion is still unclear. Although hypothyroidism has been associated with increased fetal wastage in some studies (216,217), thyroid antibody status was not associated with pregnancy loss in women with unexplained recurrent miscarriage (218), nor did it affect pregnancy rates with IVF treatment (219). Others, however, have reported conflicting results, indicating that thyroid antibodies occur at a higher than average frequency in women with recurrent pregnancy loss, but not among women undergoing ART for infertility (220,221).

Tubal, Paratubal, and Peritoneal Factors

Tubal and peritoneal factors account for 30% to 40% of cases of female infertility. Tubal factors include damage or obstruction of the fallopian tubes and are usually associated with previous PID or previous pelvic or tubal surgery. Peritoneal factors include peritubal and periovarian adhesions, which generally result from PID, surgery, or endometriosis. The risk for infertility after a single bout of PID is surprisingly high and increases rapidly with subsequent episodes. In fact, the incidence of tubal infertility has been reported to be 12%, 23%, and 54% after one, two, and three episodes of PID, respectively (222). Still, about half of patients with documented tubal damage have no identifiable risk factors for tubal disease (223). Most of these women are presumed to have had subclinical chlamydial infections.

Hysterosalpingography HSG is the initial diagnostic test used to assess tubal patency because it has a sensitivity of 85% to 100% in identifying tubal occlusion. The particular specificity of HSG in identifying PID-related tubal occlusion approaches 90% (224,225). Other causes of apparent tubal blockage include salpingitis, isthmica nodosa, benign polyps within the tubal lumen, tubal endometriosis, tubal spasm, and intratubal mucous debris (226). Bilateral tubal pathology documented on HSG is associated with significantly reduced fecundity rates and warrants further evaluation using falloscopy, selective salpingography, or laparoscopy.

HSG is usually performed between cycle days 6 and 11. To reduce the chance of iatrogenic infection, HSG should ideally follow the cessation of menstrual flow; to avoid possible fetal irradiation and interference with conception, HSG should precede ovulation. It is estimated that infection follows 1% to 3% of HSG procedures and occurs almost exclusively in women with hydrosalpinges or with current or prior pelvic infection. Therefore, known hydrosalpinges, current PID or cervicitis, and palpable adnexal masses or tenderness on bimanual examination all constitute contraindications to HSG. Because there is a high prevalence of current or past chlamydial infection among infertile women and complications of HSG-associated pelvic infection could further compromise fertility, it is reasonable to prescribe antibiotic prophylaxis to patients scheduled for HSG. One typical regimen uses *doxycycline*, 100 mg twice daily, beginning the day before HSG and continuing for 3 to 5 days. Other rare complications of HSG include uterine perforation, hemorrhage, and allergic reaction to the contrast dye. HSG often causes uterine cramping, and prophylaxis with a nonsteroidal antiinflammatory drug may minimize this discomfort.

Performing the HSG procedure itself is fairly straightforward. After a bimanual examination and vaginal cleansing, an acorn (Jarcho) cannula, a pediatric Foley catheter, or some other injection device is introduced into the uterine cervix. A paracervical anesthetic block is not routinely needed but may be used in selected patients. Either a water-soluble contrast medium, such as meglumine *diatrizoate* (*Renografin-60*), or a low-viscosity oil-based dye, such as *ethiodized oil* (*Ethiodol*), may be used for the procedure. Each contrast material has advantages. Water-soluble contrast material is more rapidly absorbed than oil-based dyes and does not

carry the risk for either lipid embolism due to dye extravasation or lipid granuloma formation. Oil-based dyes are associated with less uterine cramping, better resolution of tubal architecture, and a higher postprocedure pregnancy rate (227). A recent update of a 1994 metaanalysis has found that the use of oil-soluble media to flush the tubes during HSG significantly increases subsequent pregnancy rates (OR, 1.8; 95% CI, 1.29 to 2.50). Similar therapeutic benefit has not been demonstrated using water-soluble contrast media (228).

HSG should be performed using fluoroscopy, with care taken to minimize ovarian exposure to x-rays. Careful and slow initial injection of 3 to 4 mL of contrast media should give a clear outline of the uterine cavity. Further injection of about 5 to 10 mL of contrast media is usually sufficient to demonstrate bilateral tubal patency or tubal obstruction. Generally, only two radiographic views are needed, one demonstrating the filling of the uterine cavity and the other (at the completion of the procedure) showing tubal findings. The radiation exposure required for the completion of an HSG examination has been shown to be well below the documented limiting ovarian dose of 10 cGy (229).

Laparoscopy The best technique for diagnosing tubal and peritoneal disease is laparoscopy. It allows visualization of all pelvic organs and permits detection of intramural and subserosal uterine fibroids, peritubal and periovarian adhesions, and endometriosis. Abnormal findings on HSG can be verified by direct visualization on laparoscopy. For instance, tubal patency may be confirmed at laparoscopy by observation of the passage of a dye, such as methylene blue or indigo carmine, through the fimbrial openings of the tubes. Unlike HSG, laparoscopy allows careful assessment of the external architecture of the tubes and, in particular, visualization of the fimbria. Identified abnormalities, including tubal obstruction, pelvic adhesions, and endometriosis, can be treated laparoscopically at the time of diagnosis.

Other Diagnostic Modalities Successful evaluation of proximal tubal obstruction using selective *salpingography* and *fallopscopy* has been described. Based on techniques derived from coronary angioplasty, salpingography uses small guidewires to permit selective tubal cannulization and radiographic visualization under fluoroscopy. Fallopscopy is based on similar principles, but allows direct fiberoptic visualization of tubal ostia and intratubal architecture. Fallopscopy allows the visual identification of tubal ostial spasm, abnormal tubal mucosal patterns, and even intraluminal debris causing tubal obstruction. In fact, a tubal disease scoring system based on falloposcopic examination has been suggested to identify patients with poor prognoses for spontaneous conception (230). Complications associated with fallopscopy include a 5.1% rate of pinpoint perforations of the tube.

Abdominal and transvaginal, ultrasound-guided tubal cannulations have also been used to identify tubal blockage. Each reports high diagnostic sensitivity and specificity. Alternatively, sonohysterography with contrast media offers a much less invasive method of diagnosing fallopian tubal obstruction while maintaining a sensitivity and specificity similar to that of laparoscopic chromotubation (231). Further prospective evaluation and cost analyses are necessary to determine the utility of tubal cannulation and sonohysterography with contrast media.

Treatment of Tubal Factor Infertility

Therapies that directly address correcting tubal factor infertility are entirely surgical and include (a) correction of periadnexal disease; (b) correction of proximal, distal, or combined tubal disease; and (c) correction of iatrogenic tubal abnormalities (e.g., tubal sterilization). **As success rates continue to improve in ART, the indications for surgical approaches in the treatment of tubal factor infertility may become increasingly limited.** Still, a number of the principles underlying surgical management remain important. Surgical treatment of periadnexal disease causing tubal factor infertility has been proved effective, regardless of whether the approach is by laparotomy (232) or laparoscopy (233). Adhesion prevention, however, becomes particularly vital when surgery is used to address prior adhesive disease causing infertility. The relative value of laparotomy versus laparoscopy for the treatment of tubal infertility has received considerable attention, as have their respective effects on postoperative adhesion formation. For example, one study comparing laparoscopy and laparotomy for the treatment of ectopic pregnancy demonstrated that adhesion formation occurred more frequently after laparotomy, even when meticulous technique was maintained during all procedures (234). Many adjuncts for postoperative adhesion prevention have been proposed, including the use of antiinflammatory agents, barrier agents, fibrinolytic substances, and anticoagulants. However, none of these interventions has consistently altered postoperative adhesive complications. Thus, careful hemostatic surgical technique and judicious use of the laparoscopic approach remain the only generally recommended principles guiding surgical treatment of tubal factor infertility.

Proximal Tubal Occlusion Correction of proximal tubal occlusion may involve the use of those same techniques employed in establishing its diagnosis. For instance, selective salpingography performed under fluoroscopy may be used to inject contrast media directly into the tubal lumen in an attempt to overcome obstruction resulting from mucous plugging. If selective salpingography fails to create tubal patency, proximal tubal cannulation can be performed using a guidewire under direct visualization or using radiologic guidance. Proximal tubal cannulation has a reported a success rate of 85% in establishing tubal patency. Reocclusion occurs in 30% of cases. The risk for tubal perforation with cannulation is reported to be 3% to 11%, but tubal damage is usually mild and heals spontaneously (226).

Until the mid-1970s, tubal implantation was considered the best approach for treating proximal tubal obstruction. Since that time, microsurgical tubocornual anastomosis has become the preferred surgical approach, with postsurgical ongoing pregnancy rates averaging 47.4% in five reported series involving 175 patients (226,235,236,237 and 238). Hysteroscopic cannulation appears to have similar efficacy, with a 48.9% ongoing pregnancy rate among 133 patients treated in four series (226,239,240,241 and 242). Although ongoing pregnancy rates with microsurgical tubocornual anastomosis and hysteroscopic cannulation appear comparable, cannulation is significantly less invasive and has fewer morbid complications. Microsurgery, however, provides access to other pelvic structures, allowing the surgeon to assess the distal fimbriae and to lyse any periadnexal adhesions that may be present. In contrast to both microsurgical anastomosis and hysteroscopic cannulation, the ongoing pregnancy rates for selective salpingography and fluoroscopic tubal cannulation have averaged only 26% (226,243,244,245,246 and 247).

Distal Tubal Occlusion Treatment of distal tubal disease involves surgical correction by fimbrioplasty or neosalpingostomy. By definition, *fimbrioplasty* is the lysis of fimbrial adhesions or the dilation of fimbrial phimosis, whereas *neosalpingostomy* involves the creation of a new tubal opening in an occluded fallopian tube (248). Distal tubal disease can be treated either laparoscopically or by laparotomy using conventional microsurgical techniques. Regardless of the method used, the efficacy of neosalpingostomy or fimbrioplasty as treatment for distal tubal occlusion rests largely on the extent of tubal and peritubal disease, as assessed by HSG and laparoscopy. Poor prognostic factors for a successful pregnancy after neosalpingostomy include hydrosalpinx greater than 30 mm in diameter, absence of visible fimbriae, and dense pelvic or adnexal adhesions (249). The appearance of the tubal mucosa has added prognostic significance for the fertility outcome of laparoscopic tuboplasty for distal tubal occlusion (250). In one study, laparoscopic distal tuboplasty produced an overall pregnancy rate of 27% and an ectopic pregnancy rate of 4.5% among 44 patients (251). Fimbrioplasty appeared to be more successful than neosalpingostomy; however, the choice of surgery might have been influenced by the extent of disease. Similarly, a more recent study on a series of 194 cases of laparoscopic fimbrioplasty and neosalpingostomy resulted in an intrauterine pregnancy rate of 27.3% and an ectopic pregnancy rate of 4.1% (252). Patients with both proximal and distal tubal disease represent the poorest candidates for surgical management of tubal infertility. Studies of surgical treatment for these patients have had small numbers of patients but have consistently yielded poor results (253). This select group of patients should benefit most from IVF.

Sterilization Reversal About 0.2% of women who choose surgical tubal sterilization request reversal procedures (254,255). The success of tubal reanastomosis is dependent on the method of sterilization, the site of anastomosis, and the presence of other infertility factors. Pregnancy rates are lowest (49%) after the reversal of sterilization procedures involving unipolar electrocautery. In contrast, postprocedure pregnancy rates rose to 67% when the sterilization technique involved Fallope rings or spring-loaded clips and 75% when Pomeroy tubal ligation was employed. The prognosis is best when anastomotic sites have no significant differences in tubal diameter (e.g., isthmic–isthmic or cornual–isthmic anastomoses). Tubal length is also an important prognostic consideration: final anastomosed tubal lengths of less than 4 cm are associated with low pregnancy rates (256). Pregnancy rates higher than 40% have been reported after microsurgical fimbriectomy correction (257). Laparoscopy to assess surgical prognostic factors such as potential final tubal length, site of reanastomosis, method of sterilization (if not previously known), and presence of associated pelvic pathology, is often performed before microsurgical fallopian tubal reanastomosis by laparotomy.

Historically, all sterilization reversal procedures have involved laparotomy. More recently, excellent pregnancy rates have been reported after laparoscopic tubal anastomosis. In one study of 186 patients followed after laparoscopic tubal anastomosis with a two-layer closure, cumulative pregnancy postprocedure rates were 60.3%, 79.4%, and 83.3% at 6, 12, and 18 months, respectively (258). In another study, laparoscopic tubal reanastomosis was performed on 102 women, of whom 70% conceived and 65% had ongoing intrauterine pregnancies during the 15-month follow-up period (259). Rates of ectopic pregnancy were similar (3% and 7%) in both series (258,259). The surgical time of laparoscopic tubal reanastomosis most certainly depended on the surgeon's experience as well as the number of layers involved in tubal closure. Reported operative duration ranged from 71.35 minutes to 140.2 minutes, \pm 53.3 minutes (258,259).

Recently, successful robotic-assisted laparoscopic microsurgical tubal anastomosis has been reported in humans. The reported procedures had a mean duration of 159 ± 33.8 minutes and were performed solely using robotic arms that were remotely controlled by surgeons with previous extensive experience with microsurgical tubal anastomosis by laparotomy. The reported postprocedure tubal patency rate was 89% at 6 weeks, and the ongoing pregnancy rate was 50% (260). Despite advances in surgical technology, however, IVF should be considered for patients with prior sterilization and poor prognostic characteristics. Likewise, IVF is indicated

for those patients whose tubal reanastomoses have not yielded a pregnancy by 12 to 18 months after surgery.

Cervical and Immunologic Factors

Postcoital Test Cervical factor is a cause of infertility in no more than 5% of infertile couples. The classic test for evaluation of the potential role of cervical factor in infertility is the postcoital test (PCT). The PCT is designed to assess the quality of cervical mucus, the presence and number of motile sperm in the female reproductive tract after coitus, and the interaction between cervical mucus and sperm. The PCT does not yield sufficient information on sperm count, motility, or morphology to allow assessment of semen quality. The PCT should be performed just before ovulation because its proper interpretation requires the examination of cervical mucus at a time of sufficient estrogen exposure. Serum estrogen levels peak just before ovulation, providing optimal stimulation to the estrogen-sensitive, mucus-producing cervical glands. Therefore, the PCT should be performed 1 or 2 days before the anticipated time of ovulation. For patients with irregular cycles, the patient's urinary LH surge may be helpful in scheduling the test.

Use and interpretation of treatment recommendations based on the PCT are all controversial. Even the appropriate timing of coitus preceding examination of the cervical mucus is unclear. Although an optimal interval may be less than 2 hours from intercourse to PCT, an adequate test can be performed within 24 hours of intercourse. Although the data are not definitive, intercourse after 2 days of abstinence and about 2 to 12 hours before the PCT is performed should yield adequate information. Couples should be reminded not to use lubricants that may contain spermicidal agents.

The PCT is inexpensive and easily performed. A small amount of cervical mucus is withdrawn by means of long oval forceps with small apertures at the tip. Alternatively, an angiocatheter syringe or tuberculin syringe may be used to withdraw mucus from the endocervical canal. The mucus is placed on a glass slide and covered with a cover slip. A small trail of mucus may be left to dry outside the cover slip so that ferning can be assessed. Many infertility specialists also take a "vaginal pool" specimen from the posterior vaginal fornix to document the presence of sperm in the vagina. Cervical mucus is rapidly evaluated for spinnbarkeit (i.e., stretchability), ferning, and clarity. The presence of, number per high-power field, and motility of sperm should be carefully assessed by the examination of several microscopic fields.

Normal estrogen-stimulated mucus should stretch 8 to 10 cm when it is pulled from the cervix with forceps or when the cover slip is lifted off the slide, should demonstrate a highly characteristic ferning pattern similar to that seen on examination of amniotic fluid, and should be clear and watery. The characteristics of cervical mucus change under the influence of progesterone after ovulation. At that time, the cervical mucus appears thick and opaque and lacks ferning. Although the number of motile sperm per high-power field should be documented, normal values have not been established. Some authors suggest that virtually any number of motile sperm seen on the PCT is normal (261), whereas others require greater than 20 sperm per high-power field (262).

There are several potential causes for an abnormal PCT. The most common is incorrect timing of the test within the menstrual cycle, leading to the production of cervical mucus that is suboptimal for sperm penetration. Other causes of poor mucus quality include anovulation, anatomic factors (e.g., prior cervical conization or cryotherapy), infection, and certain medications. Clomiphene citrate may exert detrimental effects on cervical mucus by its antiestrogenic action on cervical glands. This is one reason why clomiphene citrate should be offered to patients with unexplained infertility only when coupled with IUI. Abnormal semen characteristics are often reflected in the PCT and may be responsible for abnormal PCT results. An independent semen analysis is required for proper assessment for male factor infertility. Poor PCT results may, of course, reflect suboptimal mucus-sperm interactions. The observation of shaking or uniformly dead sperm on PCT suggests the presence of antisperm antibodies.

Although there is plausible biologic rationale behind the PCT, this test has been accepted without critical review of its prognostic value or of its impact on the overall management plan of the subfertile couple. The PCT lacks reproducibility, standard methodology, and uniform criteria for assessment. These factors, in conjunction with poor correlation between PCT results and pregnancy outcome, argue against use of the PCT as a standard investigational tool in infertility patients (262,263,264 and 265). For example, one study reported no difference in pregnancy outcomes among women whose cervical mucus contained 0 to 11 motile sperm per high-power field (263), whereas another reported abnormal PCTs in 20% of fertile couples (262). A review of the world's English-language literature challenged the validity of the PCT and found that the sensitivity and specificity of the test ranged from 0.09 to 0.71 and from 0.62 to 1.00, respectively (264).

Couples seeking reproductive medical intervention undergo many tests that are considered necessary, although they are costly from physical, emotional, and financial perspectives. Therefore, any test performed should have proven value in determining the prognosis or the course of treatment. Management decisions based on testing should affect the treatment outcome. This is not the case for the PCT, for which the results seldom alter the management of patients with unexplained infertility because the accepted treatment of superovulation/IUI bypasses the cervical mucus. In a prospective, randomized controlled study, couples who underwent PCT had cumulative pregnancy rates after 24 months of therapy identical to those of a control group not using PCT (266). Therefore, PCT testing has no effect on treatment outcome. Finally, although the PCT may screen for the presence of antisperm antibodies, no proven treatment is accepted for this diagnosis. PCT is therefore not indicated for this application.

Antisperm Antibodies Injection of sperm from one animal into another can elicit an antibody response (267). Spermatozoa can also be autoantigenic. Thus, both males and females have the capacity to produce humoral response to sperm. Either allogenic or autoimmune response could, in turn, adversely affect fertility. Antisperm antibodies are most commonly limited to immunoglobulin G (IgG), IgM, and IgA isotypes, and each subclass has characteristic anatomic localization. Systemically produced IgG molecules may be found in serum as well as in cervical mucus and semen. Agglutinating antibodies of the IgA class are typically found in cervical mucus and seminal plasma. The larger IgM antibodies have difficulty traversing the genital tract mucosa and therefore are found exclusively in serum. In addition to subclassification by isotype, antisperm antibodies can be free, agglutinating, bound to sperm that is motile, or bound to sperm that is immobilized. Further complexity arises in that sperm-bound antisperm antibodies can bind to different parts of the outer sperm plasma membrane, including the head, body, or tail. One major challenge in understanding antisperm antibodies is to determine the relative importance of each of these factors with respect to disease pathogenesis, impact on fertility, and prognosis.

Many etiologies have been proposed to explain the formation of antisperm antibodies (268). In women, coital trauma that disrupts the vaginal epithelium could theoretically expose immune effector cells to sperm antigens, thereby leading to antisperm antibody formation. However, it remains unclear why most women, who are repeatedly exposed to billions of spermatozoa, do not exhibit this immune response. In men, the blood-testis barrier normally shields the serum from exposure to sperm and their antigens. Conditions that cause breaks in this barrier could activate autoimmunity. Testicular trauma or torsion, occlusion of the vas deferens secondary to childhood inguinal herniorrhaphy or cystic fibrosis, vasectomy reversal, and genital tract infections have all been suggested to elicit antisperm antibody formation.

The mechanisms by which antisperm antibodies might adversely affect fertility continue to be contested. Many mechanisms have been proposed. One or more of these could be involved in a particular infertile couple. Distinct mechanisms might be operative under specific circumstances. Adverse antibody-mediated effects on semen quality (either before ejaculation or upon contact of ejaculate with the female reproductive tract) present obvious potential for subfertility. Other, more specific, proposed mechanisms include antisperm antibody-mediated interference with capacitation, with the acrosome reaction, with sperm-egg recognition and fusion, and with cleavage of the early embryo (268). Although some investigators have demonstrated that the presence and amount of antisperm antibodies is associated with fertilization failure during IVF or subzonal sperm insemination (269,270 and 271), others have failed to identify a link between reduced fertility and antibody positivity (272,273).

Myriad tests presently are available for the detection of antisperm antibodies, making the appropriate evaluation of immunologic infertility even more bewildering. Sperm agglutination tests (Kibrick's or Franklin-Dukes) and sperm complement-dependent immobilization tests (Isojoma's) have largely been replaced by the immunobead or mixed agglutination tests (Fig. 27.8). The immunobead test uses commercially available anti-IgG-, anti-IgA-, or anti-IgM-coated polyacrylamide beads. Washed spermatozoa are exposed to the labeled beads, and sperm binding is assessed. The test yields specific information on both the immunoglobulin class of the antisperm antibody and the site of binding to the involved sperm (274). In the mixed agglutination reaction, human red blood cells sensitized with human IgG are mixed with "patient" semen. The presence of antibody-coated spermatozoa results in the formation of mixed agglutinates with the red blood cells (275). A comparison of these two methods demonstrates good correlation of results; however, the latter test is easier to perform (276).

Figure 27.8 The mixed agglutination reaction (MAR) to evaluate immunologic infertility by assessment of antispermantibodies. (Redrawn and adapted from Garenne ML, Frisch RE. Natural fertility. *hapa Infertil Reprod Med Clin North Am* 1994;259–282, with permission.)

Despite recent improvements in techniques for the identification of antisperm antibodies, the clinical utility of these tests should be limited to very special cases until their prognostic value, impact on infertility management, or effectiveness in treatment can be demonstrated in prospective trials. Corticosteroid therapy for men with antisperm antibodies has been studied in a prospective, double-blind, placebo-controlled trial. This trial did demonstrate decreased antisperm IgG in response to corticosteroid therapy; however, no improvement in sperm-bound IgA or pregnancy outcomes could be documented (277). In fact, there is currently no support for the use of corticosteroid therapy in antisperm antibody–positive patients because IUI alone has been shown to result in higher pregnancy rates than the combination of corticosteroids and timed intercourse (272). In summary, in a couple with no identifiable cause of infertility, a positive or negative antisperm antibody test will not alter their proposed therapeutic plan: superovulation and IUI followed by IVF or ICSI (278). One potential use of antisperm antibody testing that warrants investigation is the identification of those couples predicted to have high fertilization failure rates with IVF who might benefit more from immediate use of ICSI.

Uterine Factors

Uterine anatomy and function are both critical determinants governing implantation of the embryo and subsequent fetal growth and development. Of course, these two elements are not distinct entities. They are intimately related; thus, most of the uterine factors implicated in infertility have defects in both structure and function. For example, the endometrial lining of uteri with congenital anatomic abnormalities exhibits functional aberrations. Endometrial molecular mechanisms of implantation and gestation are exquisitely controlled and remarkably complex; thus, even subtle defects in endometrial progression from the periimplantation, luteal phase to the mature decidua supporting a placenta and fetus can result in infertility or early pregnancy loss.

Diagnostic Imaging for Uterine Pathology

Uterine abnormalities that have been implicated in infertility include congenital malformations, luteal-phase defects, and other acquired conditions such as leiomyomas, endometrial polyps, and intrauterine synechiae. For infertility patients who have had no recent imaging tests, it is reasonable to begin the workup with HSG because it has an 85% to 100% sensitivity for detecting tubal pathology among infertility patients (224,225). However, HSG has only 44% and 75% sensitivity rates in documenting uterine malformations and intrauterine adhesions, respectively (279).

Sonohysterography appears to be superior to HSG in the detection of uterine malformations, correctly identifying 90% of abnormalities among infertile patients (280). These data are consistent with those observed in patients with abnormal uterine bleeding in the general gynecologic setting, where sonohysterography has sensitivities of 87% and 93% in detecting any intrauterine pathology and endometrial polyps, respectively (281,282). In women with abnormal bleeding, compared with conventional transvaginal ultrasound, sonohysterography has both higher sensitivity (93% versus 65%) and specificity (94% versus 76%) for the detection of endometrial polyps. Sonohysterography also decreases the false-positive and false-negative rates from 25% to 5.4% and from 36% to 8%, respectively (282).

In most practices, diagnostic hysteroscopy is the preferred procedure for the diagnosis of uterine pathology in infertility patients. However, the ideal imaging test employed during an infertility workup would be one that is relatively noninvasive and has high sensitivity and specificity in the detection of uterine abnormalities as well as tubal blockage. The use of contrast media (i.e., Echovist) instead of saline during sonohysterography has been reported to have sensitivity comparable to that of HSG and laparoscopic chromotubation in the detection of tubal blockage (225). This test has great potential for generalized use in infertility investigations but presently lacks prospective comparison with the combined use of HSG and diagnostic hysteroscopy in the infertile population.

Congenital Anomalies of the Uterus

Congenital uterine anomalies may be associated with infertility, spontaneous pregnancy loss in the first or second trimester, or late-trimester pregnancy complications. In women with didelphic, unicornuate, and septate uteri, the rates of spontaneous abortion and preterm delivery are highly increased at 25% to 38% and 25% to 47%, respectively (283). Endometrial dysfunction during the luteal phase may result in infertility, whereas dysfunction occurring after implantation results in pregnancy loss. Further, pregnancy outcome in the presence of a uterine anomaly may depend on the location of blastocyst implantation in a particular cycle. This may explain why a woman with a septate uterus might encounter recurrent pregnancy loss even after having delivered a term infant.

With the exception of a septate uterus, infertility associated with most congenital uterine anomalies is not amenable to surgical treatment (284,285). Hysteroscopic septoplasty has been demonstrated to decrease significantly the risk for spontaneous abortion in women with septate uteri, and surgical therapy is indicated in patients with known uterine septi and who have recurrent spontaneous abortion (286). Indications for surgical correction of congenital uterine anomalies when the presenting complaint is infertility are less obvious. Among seven series of hysteroscopic metroplasties performed for infertility, the overall pregnancy rate after treatment was 48% (286). It is still reasonable to consider surgical options in some infertile patients with uterine septi because septoplasty may maximize the chance of having a live birth by decreasing the associated risks for spontaneous abortion and preterm labor.

In Utero Exposure to Diethylstilbestrol

Exposure to *DES in utero* increases a woman's risk for congenital reproductive tract malformations and obstetric complications, including preterm labor and cervical incompetence (287). In one study, almost 70% of women exposed to *DES in utero* were noted to have uterine malformations on HSG. The most common malformation was the T-shaped uterus (288). Whether *DES*-exposed women also have higher rates of infertility remains unclear (289,290). One investigator reported that decreased fertility in these women was particularly prevalent when constriction of the upper segment of the reproductive tract was present (291). This question is difficult to study; however, since there is great variation in the degree of congenital uterine, tubal, and cervical anomalies associated with exposure (287). Furthermore, some abnormalities may promote other infertility factors. For instance, cervical anomalies may promote production of suboptimal cervical mucus, or cervical stenosis may promote retrograde menstruation and the subsequent development of endometriosis. Finally, some *DES*-exposed infertile patients will also have unrelated but additional reasons for their infertile state. Overall, when a *DES*-exposed woman has uterine anomalies on HSG and greater than 1 to 2 years of primary infertility, her prognosis for future pregnancy is extremely poor (292). Metroplasty for correction of T-shaped and hypoplastic *DES*-exposed uteri has unproven value and is not recommended. Results of IVF treatment are generally poor in infertile, *DES*-exposed women. Although ovarian response rates to COH are comparable in *DES*-exposed women and nonexposed women with unexplained infertility, *DES* exposure is associated with significantly lower implantation rates in IVF (293).

Acquired Abnormalities of the Uterus

Leiomyomas Among women with infertility and uterine leiomyomas, many variables may affect pregnancy rates, including leiomyoma size, location, and number (solitary versus multiple) as well as the presence of symptoms associated with these tumors. **Leiomyomas have never been shown to be a direct cause of infertility.** It has been suggested, however, that uterine leiomyomas might alter uterine contractility and thereby disrupt normal sperm migration. Alternatively, the presence of leiomyomas might adversely affect vascular and molecular profiles of sites of implantation (294). No prospective, randomized trial comparing expectant management with myomectomy in infertile patients with uterine leiomyomas has yet been conducted. However, one recent case-control study compared pregnancy

outcomes among 106 women who had laparoscopic myomectomy for fibroids, 106 women with uterine fibroids who did not have surgery, and 106 women who had unexplained infertility but no fibroids. Reported live birth rates were significantly different among the study populations: 42% for the laparoscopic surgery group, 11% for the group with myomas but no surgery, and 25% for the unexplained infertility group (295). A metaanalysis of 12 prospective series involving a total of 138 women who underwent abdominal myomectomy for infertility showed that cumulative postprocedure pregnancy rates at 1 year were 57% to 67%. Not surprisingly, pregnancy rates for those women who had no other factor contributing to their infertility were higher than for women with additional causes of infertility (61% versus 38%). Women who had treatment for submucous fibroids had a postoperative pregnancy rate of 70% at 1 year (296). Vercellini and colleagues reported 24-month cumulative conception rates of 87%, 66%, and 47% in patients younger than 30 years of age, 30 to 35 years of age, and older than 35 years, respectively, after abdominal myomectomy in 138 infertile women (297). The presence of other causes of infertility and duration of infertility were associated with worse prognosis, whereas the size, number, or site of fibroids did not affect pregnancy outcomes. Others have reported success rates after abdominal myomectomy that are comparable to the 65% pregnancy rate and 50% live delivery rate reported for laparoscopic myomectomy (298). Successful laparoscopic myomectomy, however, is contingent on a number of factors, including stringent criteria for patient selection and the surgeon's experience with the procedure. In addition, appropriate closure of the created uterine defect is essential to minimize the complication of uterine rupture during subsequent pregnancy (299,300). In short, both myomectomy and superovulation/IUI are reasonable treatment options for women with uterine fibroids and otherwise unexplained infertility, particularly if the leiomyomas are large, submucous, solitary, or distorting the uterine cavity.

Endometrial Polyps Even in the absence of symptomatic uterine bleeding abnormalities, endometrial polyps may be discovered in women with infertility. The incidence of asymptomatic endometrial polyps in women with infertility has been reported to be about 10% (301). The value of routine hysteroscopic removal of endometrial polyps before infertility treatment and the rate of polyp recurrence during therapy are not known. It is intriguing that of 83 patients who were diagnosed with an endometrial polyp during COH for IVF and who underwent hysteroscopy immediately after oocyte retrieval, only 58% had histopathologic confirmation of the diagnosis (302). Although pregnancy rates in these women were similar to those of other IVF patients, spontaneous abortion rates appeared higher in those patients with polyps (302).

Intrauterine Synechiae or Asherman's Syndrome About 13% of 78 infertile women scheduled for IVF treatment were found to have intrauterine adhesions when evaluated with diagnostic hysteroscopy (301). Causes of intrauterine adhesions are often iatrogenic, with typical patient histories involving intraoperative or postoperative complications of uterine evacuations for menorrhagia or pregnancy termination. Other cases of Asherman's syndrome have been associated with intrauterine infection with pathogens including schistosoma and mycobacteria. In some Third World countries, tuberculous endometritis may be an important cause of uterine factor infertility (303). Tuberculous endometritis differs from most other types of chronic bacterial or viral endometritis in that its treatment is followed by significant uterine scarring and low pregnancy rates (304). In its severe forms, Asherman's syndrome has been associated with amenorrhea, menstrual irregularities, and spontaneous abortion. As with submucous myomas and uterine septi, intrauterine adhesions may interfere with embryo implantation.

Intrauterine synechiae can be treated with lysis of adhesions by either dilation and curettage or hysteroscopic resection. In many cases, it is important that postsurgical management include efforts to avoid reformation of adhesive disease. Regimens addressing this problem include intraoperative placement of an intrauterine pediatric Foley catheter or an intrauterine device. These mechanical solutions are typically left in place for about 1 week postoperatively. Postsurgical estrogen therapy may be administered in addition to or in lieu of mechanical devices. It is thought that estrogens will rapidly rebuild the endometrial lining after surgery and thereby prevent the reformation of scar tissue. A typical regimen consists of conjugated estrogen at a dosage of 2.5 mg/d for 1 to 2 months. Surgical treatment of intrauterine synechiae can yield very satisfying results; pregnancy rates above 80% have been reported among patients with mild to moderate disease (305).

Disorders of Endometrial Function and Luteal-phase Defect

There are probably few areas of greater controversy in the field of infertility than those surrounding the existence, diagnosis, and treatment of inadequate luteal phase or luteal-phase defect. The controversy has been fueled by disagreements about both the definition of this entity and the efficacy of its treatment. Although variously defined, **most agree that luteal-phase defect is present when two endometrial biopsies demonstrate a delay in the histologic development of the endometrium of more than 2 days beyond the actual cycle day** (306). Thus, if a luteal-phase lag is found on an initial endometrial biopsy, it must be confirmed on a subsequent biopsy to meet criteria for the diagnosis. The actual cycle day has conventionally been calculated by assigning the onset of the menses following biopsy as day 28 and counting backward to the day of biopsy. However, the use of the day of ovulation as a reference point may be more meaningful physiologically.

In addition to delayed endometrial maturation, luteal-phase defect can also be characterized by histologic asynchrony between endometrial epithelial and stromal compartments. A variety of factors could be responsible for such histologic alterations, including inadequate follicular development, inadequate FSH or LH secretion, hyperprolactinemia, and an inappropriate progesterone production by the corpus luteum (307). Regardless of its primary cause, LPD probably is marked by an aberrant molecular profile within the endometrium, which, in turn, can adversely affect endometrial receptivity to blastocyst implantation (308,309). Using murine gene knockout models, the genes *Hoxa-10*, *Hoxa-11*, *leukemia-inhibiting factor (Lif)*, *Lif receptor*, and *cyclooxygenase-2 (Cox 2)* have each been determined to have a critical functional role in implantation in mice (310,311,312,313 and 314). The cycle-dependent expression patterns of these genes in the human endometrium and their high degree of conservation between mouse and human both serve to support their potential importance in human implantation (315). Thus, these mouse models serve as valuable tools in the dissection of molecular genetic pathways that are potentially relevant in human implantation.

In recent years, a temporal and functional "implantation window" has been proposed to occur during the midluteal phase of the human menstrual cycle. This concept has been offered to help synthesize a growing body of data suggesting a defined period of optimal receptivity of the uterus for the implanting blastocyst. That an implantation window exists is supported by the finding that embryos implanting on postovulation days 8 to 10 have maximal viability, whereas the risk for early pregnancy loss increases with later implantation. Using a ratio of urinary estrogen metabolites to progesterone metabolites to time ovulation, the percentage of pregnancy losses associated with implantation on postovulation days 9, 10, 11, and beyond day 11 were 13%, 26%, 52%, and 82%, respectively (316). Although the implantation window has been defined by the temporal expression pattern of endometrial β_3 , α_1 , and α_2 integrins, there is controversy over length of this proposed window—between days 20 and 24 or much narrower, between days 22 and 23 of a 28-day cycle (317,318). At present, the diagnosis of luteal-phase defect based on testing for the expression of these integrins has not become standard clinical practice because endometrial integrin expression may be characterized by significant intercycle variability. Further, the value of assessing integrin expression levels in predicting pregnancy outcome is not yet known (319).

Perhaps the most crucial question is whether luteal-phase defect exists at all. In a collection of serial luteal-phase endometrial biopsy specimens from normally fertile women, investigators documented isolated out-of-phase specimens in 31.4% of normally cycling participants and sequential out-of-phase specimens in 6.6%, suggesting that normal women often have out-of-phase endometria (320). Other authors have reported that the frequency of out-of-phase endometrial specimens among infertile patients is no greater than the rate that would occur by chance alone (321,322).

Because of the discomfort and inconvenience associated with the multiple endometrial biopsies needed to confirm the diagnosis of luteal-phase defect, several investigators have attempted to identify alternative luteal-phase markers for this diagnosis. One possibility would involve definition of a luteal-phase serum progesterone level that would correlate sufficiently with endometrial biopsy results to allow its use as a screening tool for luteal-phase defect. Although some studies have advocated such testing, data that convincingly associate single midluteal phase serum progesterone levels with proposed luteal-phase abnormalities are lacking. The characteristic pulsatile secretion of progesterone further reduces the utility of such testing (323). Given the current uncertainties about the diagnosis and treatment of luteal-phase defect, attempts to diagnose this disorder should be confined to infertile patients who lack other identifiable diagnoses and to those in whom treatment specifically directed at luteal-phase defect is being contemplated.

Current treatments for presumed luteal-phase defect among infertile patients are empiric and reflect the hypothesis that progesterone insufficiency is causal. Treatment, therefore, involves the administration of vaginal or intramuscular progesterone (50 to 100 mg/d) beginning 3 days after documentation of an LH surge. Progesterone supplementation is typically continued until the first day of the next menstrual cycle or until documentation of a negative serum quantitative hCG value. If a patient becomes pregnant while on therapy, progesterone is continued until 8 to 10 weeks of gestation.

If one accepts both that luteal-phase defect does exist and that it is a reflection of luteal progesterone insufficiency, then it would seem prudent to begin therapeutic progesterone supplementation soon after ovulation and before implantation. Initiating therapy only after pregnancy is confirmed may be misguided. In fact, among patients with proposed luteal-phase defect, those pregnancies that survive to the point of confirmation by hCG may not require any treatment because they have already persisted beyond the periimplantation period. Studies supporting progesterone supplementation for luteal-phase defect have reported pregnancy rates after intervention of 50% to 80%. All of these studies have been small and poorly controlled (324). A prospective, randomized trial studying the impact of progesterone supplementation on pregnancy rates and outcomes in infertility patients diagnosed with luteal-phase defect is warranted.

Infectious Factors

The relationship between subclinical infection and fertility has received considerable attention. Particular interest has focused on two potential pathogens: *Chlamydia trachomatis* and *Mycoplasma* species. The association of chlamydia with PID has been well established. Chlamydia is the predominant pathogen detected in about 20% of cases of acute salpingitis in the United States. Chlamydia may produce asymptomatic infection in the female genital tract, and it is likely that some women experience silent tubal infection. Despite few if any symptoms, these infections may result in tubal damage. A possible link between infection and infertility is suggested by evidence that the prevalence of positive chlamydial cultures may be higher among infertile patients than among controls (325). In a study of 286 women undergoing 344 oocyte retrievals, seropositivity for chlamydia and the presence of bacterial vaginosis were highly associated with tubal disease. Reproductive outcomes of IVF, however, were no different than those of controls (326).

In another recent study, the incidence of bacterial vaginosis among 771 current IVF patients was 25%. Although their pregnancy rates were not affected, those IVF patients with bacterial vaginosis had a significantly higher risk for spontaneous abortion than matched controls, even after adjusting for smoking history, maternal age, the presence of polycystic ovaries, history of recurrent miscarriage, and history of previous live birth (327). It remains to be determined which factors directly caused this increased rate of spontaneous pregnancy loss. Likewise, it is not known whether treatment of bacterial vaginosis before or during IVF treatment would alter the rate of spontaneous abortion.

Mycoplasma species are pleuropneumonia-like organisms. Both *Mycoplasma hominis* and *Ureaplasma urealyticum* have been recovered from the cervical mucus and semen of infertile couples. There also appear to be higher rates of mycoplasma infection among infertile couples than among fertile controls. The effect of the presence of these organisms on fertility, however, remains unclear. For example, mycoplasma organisms have been isolated from the cervix of the female partner in 47% of previously infertile couples who conceived and 53% of couples who remained infertile (328). The role of treating these infections in an infertile population also is controversial. In one study, 60% of infertile men who were culture positive for ureaplasma and whose infection was subsequently cleared by antibiotic treatment impregnated their partners; the rate was only 5% among men whose infection was not cleared (329). In contrast, a double-blind study of doxycycline treatment for mycoplasma infection failed to show an effect on conception rates (328). Until a clear association has been established between mycoplasma infection or its treatment and fertility, testing for these organisms during an infertility evaluation remains controversial.

Systemic Illness

In general, any severe systemic illness, such as renal failure, liver failure, or metastatic cancer, can lead to disruption of the hypothalamic–pituitary–ovarian axis and cause infertility. However, because sporadic ovulation is always possible, even after a period of anovulation, use of contraception should be advised if pregnancy is not desired. If a patient with such severe systemic illness wishes to conceive, careful preconceptional assessment and counseling must be performed before any infertility treatment is undertaken because the risks to the mother and fetus may be tremendous.

The presence of antiphospholipid antibodies has been suspected to be associated with infertility and lower pregnancy outcomes. However, the high prevalence of antiphospholipid antibodies has not been found to be a prognostic factor in IVF in a prospective study and a metaanalysis of seven studies (330,331). Therefore, infertility is currently not an indication for antiphospholipid antibody testing.

Unexplained Infertility

The laboratory assessment of an infertile couple is relatively simple and should be performed rapidly in order to establish a diagnosis and initiate appropriate therapy (Fig. 27.1, Fig. 27.2, Fig. 27.3, Fig. 27.4 and Fig. 27.5). Evaluation of the male by semen analysis in an accredited laboratory skilled in andrology testing is essential. Ovulation should be documented in the woman using over-the-counter ovulation detection kits. If uncertainty surrounding the interpretation of such tests exists, then midluteal serum progesterone levels can be used to confirm ovulation. Unless laparoscopic surgery is already planned for some other indication, tubal obstruction should be excluded using HSG. If laparoscopy is indicated, laparoscopic chromotubation can be performed at the time of surgery. Any previous infertility investigations should be reviewed and repeated if the results are in doubt. This is particularly the case for previous semen analyses. If the cause of infertility remains enigmatic after the aforementioned investigations, further endocrine evaluation should be undertaken, including measurements of serum TSH, day 3 FSH, and prolactin levels.

Role of Diagnostic Laparoscopy

One controversial issue in the management of unexplained infertility is whether diagnostic laparoscopy should be performed and, if so, when. Previously unsuspected conditions that may be detected during laparoscopy include uterine leiomyomas (especially intramural, subserosal, and pedunculated fibroids), peritubal adhesions, and endometriosis. Those uterine fibroids detected by laparoscopy, but not by physical examination, tend to be small, pedunculated, or subserosal and are seldom clinically significant. However, it is possible that clinically important submucosal and intramural fibroids that are too small to be detected on bimanual pelvic examination may distort the uterine cavity. Diagnostic laparoscopy is not sensitive in detecting these tumors, however. In the absence of data on the incidence of pelvic disorders in women with unexplained infertility and normal HSG findings, the value of diagnostic laparoscopy during their initial workup remains controversial. In a retrospective series of 100 such patients, 68 women had laparoscopic diagnoses relevant to their fertility, including 24 with intrinsic tubal disease, 34 with peritubal adhesive disease, and 43 with endometriosis (332). In another retrospective series, among 265 women who had a laparoscopic procedure after normal HSG findings, laparoscopy revealed the following diagnoses: normal pelvises (51%), minimal to mild endometriosis (32%), moderate to severe endometriosis (4.2%), adnexal adhesions (10.2%), subserosal myomas (6.4%), ovarian neoplasms (1.9%), distal phimosis (<0.5%), and salpingitis isthmica nodosa (<0.5%). Because prospective studies have already shown HSG to be highly sensitive in identifying tubal obstruction, diagnostic laparoscopy is not generally thought to be required to confirm tubal patency in the presence of normal HSG findings. It is debatable whether lysis of mild adnexal adhesions found at the time of diagnostic laparoscopy significantly affects fertility. **Therefore, the main argument for performing diagnostic laparoscopy in women with unexplained infertility and normal HSG findings would be the possibility of identifying and treating endometriosis.**

Endometriosis

The value of diagnosing endometriosis in the absence of tubal obstruction and of its treatment in women with unexplained infertility has constituted another area of significant controversy. It is generally thought that there is a higher prevalence of endometriosis in women with infertility (333). In theory, endometriosis could alter fertility by its known association with elevations in a variety of cytokines, including tumor necrosis factor. These soluble mediators of inflammation may alter the peritoneal, intratubal or intrauterine environment and adversely affect fertilization, early embryo development, or implantation (334,335 and 336). Clinical evidence linking the presence of endometriosis to infertility exists, but the mechanism remains unclear. Data on the effect of endometriosis on ART pregnancy rates demonstrate either no significant changes or lower pregnancy rates (337,338 and 339). The fact that pregnancy rates do not appear to correlate with disease stage (according to the Revised American Society for Reproductive Medicine's classification of endometriosis) further clouds arguments about the importance of endometriosis diagnosis and treatment among infertile couples (340).

Medical therapies for endometriosis that involve hormonal suppression (e.g., combination oral contraceptive pills, GnRH agonists, or danazol) are generally reserved for the treatment of pelvic pain because these treatments all prevent pregnancy. Subfertility associated with endometriosis requires alternative, nonsuppressive approaches. In a prospective cohort trial involving 168 infertile women with minimal or mild endometriosis on diagnostic laparoscopy and 263 women with unexplained infertility, the Canadian Collaborative Group on Endometriosis found that fecundity rates were similar in both populations (18.2% versus 23.7%) during 36 weeks of expectant postoperative follow-up (341). The same group performed a randomized trial comparing 172 women who had ablation or resection of minimal or mild endometriosis with 169 women who were not laparoscopically treated for similar operative diagnoses at diagnostic laparoscopy. Cumulative pregnancy rates were significantly different between treated and control groups at 30.7% and 17.7%, respectively. By 36 weeks of follow-up, fecundity rates were 4.7 and 2.4 per 100 person-months, respectively. The rates of spontaneous abortion (20.6% and 21.6%) were nearly identical (342). In contrast, the Gruppo Italiano per lo Studio dell'Endometriosi reported that, after 1 year of follow-up, 54 women with otherwise unexplained infertility who had resection or ablation of minimal to mild endometriosis had pregnancy rates similar to 47 women whose endometriosis was not treated (24% versus 29%, respectively) (343). Of course, it is possible that any improvement in pregnancy rates resulting from ablation or resection of endometriosis has been so small that a very large trial would be required to document differences in posttreatment pregnancy rates. In fact, based on the Canadian prospective randomized trial, it has been calculated that laparoscopic treatment of 6.7 patients with minimal to mild endometriosis would yield one pregnancy (344). Assuming that 20% of couples with unexplained infertility by an otherwise negative workup have mild to minimal endometriosis, 33.5 patients would need to undergo laparoscopy to yield one pregnancy that can be attributed to the treatment of

endometriosis (344).

In light of the continuing controversies, it is reasonable to start fertility treatment empirically in women with unexplained infertility and normal HSG without assessment of the pelvis by diagnostic laparoscopy. This recommendation takes into consideration a number of issues, including the questionable value of diagnostic laparoscopy, minimal efficacy of treating minimal to mild endometriosis in these patients, known surgical risks of laparoscopy, and proven efficacy of empirical treatment. Diagnostic laparoscopy can always be reserved for later use if initial treatments fail. If the patient proceeds to IVF treatment, laparoscopy might be omitted altogether. The performance of diagnostic laparoscopy as part of an initial workup of unexplained infertility is neither correct nor incorrect. However, if laparoscopy is performed, visible endometriotic lesions should either be ablated or resected. One retrospective study has reported electrocoagulation and resection of endometriosis to be indistinguishable with respect to postprocedure pregnancy outcome (345). The best overall approach to patients with unexplained infertility involves offering both interventional options—empiric therapy or diagnostic laparoscopy—to patients, who can then participate more actively in their own management.

Treatment of Unexplained Infertility

As the requirements for both diagnostic laparoscopy and prior exclusion of endometriosis have become less stringent in the diagnosis of unexplained infertility, one must consider the potential impact of this broader definition of the disease on treatment efficacy. In a retrospective analysis, 131 women with more than 2 years of unexplained infertility were managed expectantly while waiting for IVF. Their pregnancy rate was only 0.9% per exposure cycle, whereas a similar group of 119 women receiving IVF treatment had a 17% pregnancy rate per cycle (346). Thus, the low spontaneous pregnancy rates in these patients promote the abandonment of expectant management and the rapid initiation of empiric therapies. These therapies are all aimed at increasing the chances of conception by increasing the available numbers and proximity of healthy gametes. More specifically, this typically involves superovulation (more female gametes); collection of, washing, and concentrating the semen (more healthy sperm); and bypassing a potential cervical factor using IUI. Superovulation with clomiphene citrate and IUI is usually the initial treatment regimen employed. This therapy is fairly efficacious in many couples with unexplained infertility and is less invasive, less expensive, and associated with fewer complications than other forms of treatment. However, if clomiphene citrate with IUI is unsuccessful after 3 months of treatment, then COH using gonadotropins should be undertaken in conjunction with IUI (COH/IUI). If both these approaches fail to result in pregnancy, IVF or ICSI can be performed.

Clomiphene Citrate and IUI The rationale for using *clomiphene citrate* to increase the fecundity rate in ovulatory women with unexplained infertility is that of superovulation. IUI has become a standard part of the *clomiphene citrate* regimen in treating these women. The degree of superovulation using *clomiphene citrate* is mild and most commonly results in the release of two eggs in ovulatory women. This low degree of superovulation limits complications such as multiple gestation, but it also limits efficacy. In fact, multiple pregnancy occurs in only 10% of patients treated with *clomiphene citrate*, and most of these are twin pregnancies. A recent metaanalysis of six randomized controlled trials has shown the use of *clomiphene citrate* in women with unexplained infertility to be superior to placebo in increasing the clinical pregnancy rates per patient (OR, 2.37, CI, 1.22 to 4.62) and per treatment cycle (OR, 2.5, CI, 1.35 to 4.62) (347). *Clomiphene citrate* use, however, is not without drawbacks. By its action as an antiestrogen within the endometrium and cervix, *clomiphene citrate* may cause thinning of the endometrium and thickening of the cervical mucus in a small group of women. However, these complications of *clomiphene* therapy may be treated. In a randomized, double-blind study involving 64 patients with unexplained infertility undergoing superovulation with *clomiphene citrate*, the addition of *ethinyl estradiol* (0.05 mg daily for 5 days starting on day 8) resulted in a thicker endometrium and a higher ongoing pregnancy rate (37.5% versus 6.25%). Therefore, it is reasonable to add *ethinyl estradiol* to *clomiphene citrate*/IUI, if a patient has a history of a thin endometrium. The benefits and effects of this regimen need to be confirmed. The rates of multiple pregnancy when estrogen is added to *clomiphene citrate*/IUI should be assessed before this regimen is accepted as standard practice (348).

COH and IUI IUI has now evolved to become a standard adjunct to any superovulation treatment in unexplained infertility. A metaanalysis of prospective, randomized trials comparing IUI and timed intercourse in women with unexplained infertility has determined that the pregnancy rate is higher with IUI (20% versus 11.4%; OR, 1.84; 95% CI, 1.30 to 2.62) (349). For optimal pregnancy rates, IUI should be performed twice. A prospective, randomized trial demonstrated that IUI performed 12 and 34 hours after the triggering of ovulation with hCG resulted in significantly higher pregnancy rates per patient (30.4%) and per cycle (19.4%) than use of a single IUI at 12 hours or double IUI at 34 and 60 hours (350).

In a multicenter, prospective, randomized trial involving 932 couples with unexplained infertility, the combination of COH with gonadotropins and IUI has proved superior to IUI alone, intracervical insemination (IC) alone, or COH/IC (53). The National Cooperative Reproductive Medicine Network reported that the pregnancy rate was significantly higher in couples who were treated with COH/IUI (33%) than those treated with IUI alone (18%), COH/IC (19%), or IC alone (10%) (53). However, the multiple pregnancy rates were concomitantly increased.

Pregnancy rates using IVF have been reported to be higher than those using COH/IUI in the treatment of unexplained infertility (351,352). However, the risks and costs associated with IVF treatment are appreciably higher, making it standard practice to treat these couples with COH/IUI before attempting IVF (351). The question of how many COH/IUI cycles should be attempted before conversion to IVF can be a challenging one, especially because this decision is affected by financial as well as medical factors. The relatively low degree of invasiveness and low costs of COH/IUI must be balanced against the potential decrease in ovarian reserve that can compromise IVF success if treatment is delayed. This is a particularly important consideration for the older, infertile couple. Therefore, it is good practice to recommend, *a priori*, a maximum number of COH/IUI cycles that will be attempted. This definition of treatment expectations may help to temper reactions to unsuccessful therapeutic interventions and foster a sense of control among patients.

It has been recommended that patients with unexplained infertility experience no more than three to six COH/IUI cycles before therapy is discontinued or changed (353,354 and 355). One study recommended a maximum of three trials of COH/IUI, based on the cycle fecundity and cumulative pregnancy rates observed in historical controls involving 594 patients with unexplained infertility. In this study, the investigators reported a mean fecundity rate per cycle of 16.4% and a cumulative pregnancy rate of 39.2% during the first three COH/IUI cycles. Cycles four to six yielded a mean fecundity rate of 5.6% and a cumulative pregnancy rate of 48.5%, a value only 9.3% higher than the rate achieved with three cycles. In contrast, a historical control group consisting of 131 patients who failed three cycles of COH/IUI had a cycle fecundity rate of 36.6% in their first attempt of IVF/ICSI treatment (356). Thus, the benefit of continuing COH/IUI treatment beyond three cycles appears to be minimal among patients with unexplained infertility, unless financial hindrance to IVF/ICSI treatment is insurmountable.

The low rates of pregnancy in patients with unexplained infertility using COH/IUI beyond three cycles might be an indication that two (or more) populations of unexplained infertility patients exist. The fact that a significant proportion of these patients will exhibit complete failure of *in vitro* fertilization of oocytes (352) suggests that some of the “unexplained” infertility patients who do poorly using COH/IUI actually have significant defects in fertilization. The rates of complete failure of fertilization for conventional IVF have been reported to be 11.4% and 17.6% in two studies of couples with unexplained infertility (352,357). The overall pregnancy rate, however, was not increased with the use of ICSI, compared with IVF, in patients with unexplained infertility in a prospective, randomized trial (357). Nevertheless, IVF treatment might be considered diagnostic in identifying those patients with fertilization defects. Because of their high risk for complete failure to fertilize in conventional IVF protocols, it is reasonable to offer combined IVF and ICSI on sibling oocytes within a single cycle for couples with unexplained infertility. This approach would prevent the disappointment and loss of potential pregnancy faced by couples with total fertilization failure discovered in the first IVF cycle (357).

Treatment Options

Gonadotropin Therapy

Medical preparations of gonadotropins (LH, FSH) can be used to stimulate ovarian follicular development and induce ovulation. Gonadotropin therapy can be used in the treatment of several conditions:

1. Ovulation induction in anovulatory PCOS that is resistant to ovulation induction by *metformin* and *clomiphene citrate*
2. Ovulation induction in hypogonadotropic hypogonadism or pituitary dysfunction
3. COH or superovulation combined with IUI in the treatment of unexplained infertility
4. COH in IVF/ICSI

The first gonadotropin preparation to become widely used in infertility treatment was human menopausal gonadotropins (hMG). A mixture of FSH and LH, hMG is purified from the urine of postmenopausal women (358) and supplied for intramuscular injection with 75 IU of FSH and 75 IU of LH per ampule. The mechanism of action of hMG is much less controversial than that of clomiphene citrate. It supplements or replaces the woman's own gonadotropins. Functional ovarian tissue is necessary for successful treatment because the major activities of gonadotropins are directed at the ovary itself. Recapitulating spontaneous ovulatory cycles, FSH and LH are presumed to act in concert to stimulate folliculogenesis; FSH acts primarily on the granulosa cells, and LH acts on the thecal lutein cells. Treatment with

hCG is typically added to hMG-stimulated cycles to promote oocyte maturation, induce ovulation, and allow appropriate corpus luteum formation and function.

Table 27.6 lists the different types of gonadotropins and their composition, and Table 27.7 lists the contraindications of gonadotropin treatment. The key differences among various preparations lie in the methods of extraction or synthesis of FSH and LH, the proportion of each hormone in the preparation, and the route of administration. The response to gonadotropins varies from one person to another. Even the same person may respond differently to the same gonadotropin regimen in different cycles. Therefore, one of the advantages of using recombinant FSH is an improved batch-to-batch consistency, allowing a more consistent response to the same gonadotropin dosage. An additional benefit of recombinant FSH is its subcutaneous route of administration, which is preferred over intramuscular injections by most patients.

Trade Name (Manufacturer)	Name of Compound	Source	Amount of FSH per Ampule	Amount of LH per Ampule	Route of Administration
Humagen (Organon Inc.)	Humanenon	Extracted urinary hMG	75 IU	75 IU	IM
Reproval Series Laboratories, Inc.)	Humanenon	Extracted urinary hMG	75 IU	75 IU	IM
Agonon (Living Pharmaceuticals, Inc.)	Humanenon	Extracted urinary hMG	75 IU	75 IU	IM or SC
Atretein	Purified uriboltingon	Purified urinary FSH (pFSH)	75 IU	<1 IU	IM
Anton Series Laboratories, Inc.)	Highly purified uriboltingon	Highly purified urinary FSH (hPFSH)	75 IU	<1 IU	SC
Follitropin Papan (Organon Inc.)	Follitropin beta	Recombinant FSH (rFSH)	75 IU	None	SC
Coreal (Organon Laboratories, Inc.)	Follitropin alpha	Recombinant FSH (rFSH)	75 IU or 150 IU	None	SC

FSH, follicle-stimulating hormone; LH, luteinizing hormone; hMG, human menopausal gonadotropin; IM, intramuscular; SC, subcutaneous. From Physicians Desk Reference, Micromedex (R) Healthcare Series Vol. 107, Micromedex Inc, 1994-2001, with permission.

Table 27.6. Different Types of Gonadotropin Preparations

- In women:**
1. Primary ovarian failure with elevated follicle-stimulating hormone levels
 2. Uncontrolled thyroid and adrenal dysfunction
 3. An organic intracranial lesion such as a pituitary tumor
 4. Undiagnosed abnormal uterine bleeding
 5. Ovarian cysts or enlargement not due to polycystic ovary syndrome
 6. Prior hypersensitivity to the particular gonadotropin
 7. Pregnancy

- In men:**
1. Normal gonadotropin levels indicating normal pituitary function
 2. Elevated gonadotropin levels indicating primary testicular failure
 3. Infertility disorders other than hypogonadotropic hypogonadism

From Physicians Desk Reference, Micromedex (R) Healthcare Series Vol. 107, Micromedex Inc, 1994-2001, with permission.

Table 27.7. Contraindications of Gonadotropin for the Treatment of Infertility

The absence of LH in recombinant FSH preparations may minimize the amount of androgen production within the theca cells of the follicles, which presumably results in improved follicular quality. This property may be particularly desirable in the subset of PCOS patients who have an elevated LH-to-FSH ratio. A metaanalysis of prospective, randomized trials comparing purified FSH and hMG in the induction of ovulation among clomiphene citrate-resistant women with PCOS showed no difference in clinical pregnancy rates. However, a lower rate of moderate to severe OHSS appeared to be associated with the use of purified FSH (OR, 0.2; 95% CI, 0.09 to 0.46). Therefore, both purified FSH and recombinant FSH may be especially beneficial in the induction of ovulation in women with PCOS (359).

The relative efficacies of hMG, purified FSH, highly purified FSH, and recombinant FSH have been studied predominantly in ART cycles and are discussed in greater detail in the ART section. To summarize, one metaanalysis of randomized, controlled trials found that use of purified FSH or highly purified FSH was associated with significantly higher clinical pregnancy rates when compared with hMG use in IVF cycles not involving GnRH agonist downregulation (360). However, the same study found that there was no difference in clinical outcomes between the two types of gonadotropins in IVF protocols using GnRH agonist downregulation. Because GnRH agonist downregulation is not included in most COH/IUI cycles, FSH preparations may be particularly beneficial in these regimens.

Another metaanalysis of 12 randomized, controlled trials comparing urinary FSH (purified FSH and highly purified FSH) and recombinant FSH in ART cycles concluded that higher pregnancy rates resulted from recombinant FSH use (OR, 1.20; 95% CI, 1.02 to 1.42) (361). However, there is no evidence to suggest a difference in clinical outcomes between the two available recombinant FSH preparations. Overall, recombinant FSH appears to be superior to other gonadotropin preparations and is preferred in COH cycles, with or without ART. Nonetheless, there may be subsets of patients who respond better to hMG, perhaps because they need the LH component. Alternatively, the recombinant forms may not elicit optimal response in patients with particular FSH receptor variants. Therefore, if the ovarian response is poor with recombinant FSH, a trial of hMG should be considered.

Regardless of the indication, regimens involving gonadotropin therapy for ovulation induction or COH follow fairly similar protocols. All include close monitoring of folliculogenesis using transvaginal ultrasonography and serum estradiol levels. Such monitoring allows informed adjustment of gonadotropin dosages, timed hCG injection and IUI, and most importantly, limitation of complications such as OHSS and multiple gestation. Patient age, ovarian reserve, and infertility diagnosis help to individualize the initial gonadotropin dose, the maximum allowable number of follicles, and the speed of ovarian stimulation (or cycle length). Of the many protocols that have been proposed, the following sections illustrate the key points for gonadotropin stimulation in non-IVF/ICSI cycles.

Baseline Transvaginal Ultrasound Scan

Patients begin therapy on day 2 or 3 after the onset of a spontaneous or induced menses. (Day 1 is the first day of menses.) A baseline transvaginal ultrasound is performed on day 1 or 2, before the start of therapy, to identify uterine abnormalities such as endometrial polyps, submucosal fibroids, or congenital defects. Hormonally responsive pathology, including endometrial polyps and submucosal fibroids, may not be apparent at this point in the menstrual cycle, when tissues are in a hypoestrogenic state. Therefore, a systematic survey should be repeated in subsequent ultrasound examinations throughout the course of the stimulation protocol (363). The two-hand transvaginal ultrasound technique often allows better visualization over the one-hand technique. This technique combines current technology with the traditional bimanual pelvic examination. The nondominant hand of the ultrasonographer can be used to apply gentle abdominal pressure to improve the definition of pelvic structures (363). The findings of a thin endometrium (<4 mm) and quiescent ovaries on the baseline scan reflect the hypoestrogenic state of the early follicular phase, which provide the optimal conditions with which to commence treatment. Conversely, a thick endometrium represents endogenous hormonal stimulation above normal basal levels and indicates that the patient should not initiate the cycle.

Unilocular, clear cysts may represent functional cysts or unruptured luteinized cysts. Complex ovarian cysts detected at baseline usually reflect old hemorrhagic corpus luteae and are commonly seen if the patient has been treated with gonadotropins in the previous cycle. Nevertheless, the differential diagnoses, including endometrioma, benign ovarian tumor, or malignancy, must be considered. The management of ovarian cysts present at baseline is controversial. In 174 prospective, non-IVF, COH cycles, a significantly lower cycle fecundity rate was observed with a baseline ovarian cyst larger than 10 mm (364). Confusion may have arisen because several IVF studies have reported no adverse effect on pregnancy outcomes associated with presence of a baseline ovarian cyst (365,366 and 367). Extrapolation of results from IVF studies to non-IVF, COH cycles is not appropriate; this issue is debatable even among IVF studies (368). More importantly, these ovarian cysts tend to resolve spontaneously within 1 to 2 months. Low-dose oral contraceptive has a lower efficacy than older, high-dose oral contraceptive in preventing the formation of new cysts (369,370). Since oral contraceptives do not affect the speed of resolution of old cysts, they are not necessary in this scenario.

Starting Dose of Gonadotropin

Gonadotropin dosages can be administered each day in the evening, allowing morning measurements of serum estradiol to reflect the steady state. If the patient has

had previous gonadotropin treatment, the starting dose should be based on review of ovarian response in previous cycles. The following guidelines can be used for determining the starting dose of gonadotropins in the first COH or ovulation induction cycle:

- In unexplained infertility, the patient's ovarian response is usually dependent on her age, and it may be difficult to predict. There are no strict guidelines; however, one should always start at lower doses and increase the dose on day 6, if necessary. For example, a maximum of 1 to 1.5 ampules of gonadotropin per day should be used for women younger than 30 years of age, whereas women older than 40 years of age can be started at a maximum of 2 to 3 ampules per day.
- Anovulatory PCOS patients should start at 1 ampule of gonadotropin per day. A smaller dose of 0.5 ampule per day is sometimes necessary to minimize the risk for OHSS.
- Patients with hypogonadotropic hypogonadism usually begin with 1 ampule per day.

Monitoring and Adjustment of Dosage

The chosen initial daily dosage of gonadotropins is maintained until day 6 or 7, when the serum estradiol level is first measured to document ovarian response. Transvaginal ultrasound also is done at this time to determine follicular response.

- If no response has occurred by these measurements, the gonadotropin dosage is increased by 1 or 2 ampules per day every 3 or 4 days until a response is evident by rising estradiol levels (or until the maximal dosage is reached). The maximal dosage is usually 6 to 8 ampules per day because an increase in ovarian response is not seen with higher dosages ([371](#)).
- Once an ovarian response is obtained, treatment typically is continued without further increase in dose.

Cycle Progression and Monitoring

Transvaginal ultrasound and serum estradiol measurements are performed every 1 to 3 days to evaluate follicular size, number, and quality. Follicles can be predicted to grow 1 to 2 mm per day, and follicular development is believed to be adequate when maximal follicular diameter exceeds 18 to 19 mm. When hMG is used, the serum estradiol level roughly corresponds to 150 to 250 pg/mL per mature follicle. However, serum estradiol levels may not be as closely correlated with the number of mature follicles when recombinant FSH is used. In general, the serum estradiol level can be expected to double every 24 hours if the same dosage of gonadotropins is maintained. Therefore, the main reasons for following the estradiol levels are as follows:

1. To detect missed spontaneous ovulation or premature luteinization, which may be reflected by a drop in serum estradiol levels
2. To identify patients at risk for OHSS:
 - Estradiol levels approaching 800 to 1000 pg/mL indicate increased risk for OHSS. A decrease in gonadotropin dosage should be considered, and monitoring is mandated in 24 hours. Withholding gonadotropin in this situation is referred to as “coasting” and is usually followed by a more than 25% decrease in serum estradiol while the follicle numbers and diameters increase. If follicle numbers increase and are excessive, the cycle should be cancelled ([372,373](#) and [374](#)).
 - Estradiol levels in the range of 1,500 to 2,000 pg/mL indicate that treatment should absolutely be stopped because of the high risk for OHSS. All medications should be discontinued, and hCG should not be administered. The patient should be asked to abstain from intercourse until menses occurs because she may spontaneously ovulate. Under these conditions, ovulation and intercourse may lead to increased risk for multiple gestation.

Human Chorionic Gonadotropin Administration

When the largest measured follicle reaches a maximum diameter of 18 to 19 mm or more, 10,000 IU of hCG is administered intramuscularly. Recombinant hCG is also available now for subcutaneous injection. Optimal pregnancy rates are achieved with IUI performed at 12 and 34 to 36 hours after the hCG injection. If the plan is to have natural intercourse, it can be timed within 12 to 36 hours of hCG administration as well.

Pregnancy Test or Plans for Next Cycle

If menses does not ensue after a treatment cycle, testing for pregnancy should be performed about 15 or 16 days after hCG administration. Testing for serum or urinary levels of b-hCG should not be affected by prior administration of exogenous hCG at this point, and b-hCG should be detectable by either method. If pregnancy does not occur, the cycle should be reviewed. If appropriate follicle size, number, and estradiol levels have been reached, then there is no need to change the gonadotropin dosage. The dosage should be changed if COH was inadequate or excessive. If the length of the stimulated cycle was too short (i.e., the follicular stimulation was too fast), endometrial maturation could have been suboptimal, and gonadotropin dosage should be decreased in a subsequent cycle.

Special Issues of COH and IUI in PCOS PCOS patients represent one of the most challenging subpopulations to treat safely and successfully using COH/IUI. The multiple small ovarian antral follicles characteristic of these patients may be very resistant to stimulation, but they are equally likely to respond and grow with minimal increases in gonadotropin dosage. The incidence of multiple pregnancy and OHSS is increased in these patients ([375](#)). Up to 30% or more of COH cycles may be cancelled as a result of excessive follicular development. Several approaches that have been proposed to avoid complications of COH and cycle cancellation include downregulation with gonadotropin-releasing hormone GnRH agonists, dual suppression with oral contraceptives and GnRH agonists, pretreatment with metformin, and surgical ovarian diathermy ([205,376,377,378](#) and [379](#)).

A dual suppression protocol described for PCOS hyperresponders in IVF treatment could also be used to lower ovarian response in COH/IUI cycles. In this protocol, low-dose oral contraceptives were taken for 25 days, the last 5 of which utilized concurrent administration of the GnRH agonist leuprolide acetate (1 mg/d by subcutaneous injection). Low-dose gonadotropin was then started on day 3 of GnRH agonist treatment. This protocol resulted in significant improvements in clinical pregnancy rates, a decrease in cancellation as a result of excessive ovarian response, and a decrease in the incidence of OHSS ([378](#)).

Alternatively, PCOS patients can be pretreated for at least 1 month with metformin at the full dose of 1,500 mg/d, before COH/IUI with gonadotropins. In a randomized, prospective trial, pretreatment with metformin resulted in fewer ovarian follicles, lower serum estradiol levels, and no cycle cancellations due to excessive ovarian response during gonadotropin COH ([378](#)).

Hypogonadotropic Hypogonadism Therapy with hMG is most successful in patients with hypogonadotropic hypogonadism, yielding cumulative pregnancy rates of 91.2% after six treatment cycles using hMG alone ([380](#)). In this particular group of patients, hMG is recommended over purified FSH for ovulation induction because purified FSH has been associated with a significantly higher total dosage requirement, lower estradiol, and decreased number of lead follicles ([381](#)). Prior to ovulation induction in these patients, one must first determine on baseline transvaginal ultrasound whether the ovaries appear PCO-like, with multiple small antral follicles, thick stroma, or enlarged ovarian volume. A subset of patients with isolated hypogonadotropic hypogonadism has been described to have PCO-like ovaries and respond to gonadotropins much like PCOS patients, exhibiting higher serum estradiol levels and a greater number of follicles ([382](#)). This finding, in conjunction with the fact that patients with hypogonadotropic hypogonadism typically are younger and have better ovarian reserve than patients with unexplained infertility, make it prudent to start with small doses of hMG in this population. This practice should help to avoid complications of OHSS and multiple gestation.

Hypothalamic Failure Most patients with acquired hypogonadotropic hypogonadism secondary to cranial surgery, or radiotherapy for various cranial tumors have hypothalamic failure as the source of their dysfunctional hypothalamic–pituitary axis ([383](#)). In these patients, GnRH stimulation testing and the assessment of endogenous pulsatile LH secretion often can confirm whether the hypothalamic–pituitary axis is intact. Patients with hypothalamic failure and subsequent ovulatory factor infertility represent the best candidates for ovulation induction with GnRH agonists. To mimic physiologic hypothalamic–pituitary interactions, GnRH agonists must be administered in a pulsatile fashion, thereby avoiding the downregulation of the GnRH receptors that accompanies continuous GnRH agonist stimulation. Coexistent growth hormone deficiency or prolactin abnormalities do not affect the efficacy of pulsatile GnRH agonist therapy ([383](#)). Because GnRH agonists are rapidly degraded by gastric enzymes (and thus ineffective when administered orally), pulsatile GnRH agonists are administered either intravenously or subcutaneously with a minipump delivery system. Adverse effects of pulsatile GnRH agonist therapy are mainly related to pump function and route of delivery (i.e., phlebitis at the needle site). The intravenous route is superior ([384](#)), but it is recommended that women with a history of bacterial endocarditis be offered only subcutaneous therapy.

In hypothalamic hypogonadotropic hypogonadism, normal pituitary negative and positive feedback mechanisms are functional upon treatment with pulsatile GnRH

agonists. In this situation, pulsatile GnRH agonist therapy simulates normal physiology and offers some advantages over hMG as a treatment for ovulatory infertility. More than two dominant follicles are seen in only 18.9% of patients with hypogonadotropic infertility who are treated with pulsatile GnRH, and more than three follicles are seen in only 5.4% of patients (385). Because OHSS is a rare occurrence, less intensive monitoring is required during GnRH agonist treatment cycles. Moreover, the risk for multiple gestation approximates that associated with *clomiphene citrate* therapy—only 8% (385). These are important advantages when compared with gonadotropin therapies. Cumulative pregnancy rates among women with hypothalamic hypogonadism approach 80% after 6 treatment cycles and 93% after 12 GnRH agonist treatment cycles (386), with no documented increase in the rates of spontaneous abortion (387).

The optimal dosing interval for pulsatile GnRH agonist therapy is 60 to 90 minutes, and the usual recommended dosage is 75 to 100 ng/kg/pulse (381,382). Increased dosage of up to 250 ng/kg/pulse has been reported to be required in the successful treatment of a patient with known GnRH receptor mutation (388). With typical regimens of pulsatile GnRH, ovulation occurs on day 14 and can be documented by standard LH testing. Patients treated with pulsatile GnRH usually benefit from luteal-phase support through continuation of the GnRH pump, administration of hCG, or progesterone supplementation.

Assisted Reproductive Technologies

All methods of ART, by definition, involve interventions to retrieve oocytes. These techniques include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. A typical ART cycle has the following main components:

- Downregulation using GnRH agonist
- COH using gonadotropins with folliculogenesis monitoring using transvaginal ultrasound and assessment of serum estradiol levels
- Oocyte maturation using hCG
- Oocyte retrieval
- Fertilization by IVF, ICSI, or GIFT
- *In vitro* embryo culture (except in GIFT)
- Luteal support or endometrial preparation using progesterone supplementation
- Transfer of fresh embryos with possible cryopreservation of excess embryos
- First-trimester pregnancy monitoring

Folliculogenesis in the Spontaneous Cycle In unassisted ovulation, the cohort of follicles destined to begin folliculogenesis in any particular menstrual cycle are recruited in the previous cycle's luteal phase. By about the middle of the next follicular phase, one of these follicles will become dominant, and further development of this dominant follicle suppresses maturation of other follicles within the selected cohort of that particular cycle. Follicular-phase growth of a single dominant follicle in nonstimulated cycles induces an intricate series of hormonally regulated feedback loops, resulting in the midcycle LH surge, which is critical for maturation of the oocyte and ovulation. Progesterone production commences just before ovulation and becomes significantly increased after ovulation. Estradiol production during the follicular phase causes proliferation of the endometrial epithelium. However, progesterone is critical in the final maturation of the endometrial glands and stroma required for implantation of the blastocyst. In the presence of successful implantation, the hCG-stimulated corpus luteum will continue to be the critical source of progesterone until the placenta independently produces sufficient amounts of progesterone at 8 to 10 weeks of gestation.

Downregulation Using GnRH Agonist The use of GnRH agonist has become standard in ART protocols. It prevents spontaneous ovulation, decreases treatment complications, and allows the control of ovulation to rest exclusively on administration of exogenous medications. Commercial preparations of GnRH agonist consist of decapeptides that differ from the endogenous GnRH agonist at 2 amino acid residues. This modification increases both the half-life and the receptor binding affinities of GnRH agonist. When used in a nonpulsatile fashion, GnRH agonist causes an initial agonist effect that is accompanied by upregulation of GnRH receptors within the pituitary gland. This initial activity may be manifested as increased gonadotropin effects, which are referred to as the *flare response*. However, continued administration of GnRH agonist downregulates GnRH receptors, resulting in minimal basal production of LH and FSH and no stimulation of the ovarian follicles. Therefore, GnRH agonist induces a quiescent hypothalamic–pituitary–ovarian axis and a menopause-like state characterized by low estradiol levels. Consequently, in addition to rash or skin irritation at the subcutaneous injection site, it is not uncommon for patients using GnRH agonist to experience side effects such as hot flashes and moodiness.

The most commonly used regimen for superovulation in ART is called the *long, or luteal, downregulation protocol*. In this protocol, GnRH agonist is started in the luteal phase (day 21) of the previous cycle, which minimizes its flare effect and prevents the follicular recruitment that is thought to begin in the luteal phase. The couple undergoing treatment is advised to abstain from intercourse during the cycle before the start of COH; however, concomitant use of GnRH agonist in the presence of an unsuspected pregnancy has not been reported to be associated with increased spontaneous abortion, congenital abnormalities, or pregnancy complications.

Before the adoption of GnRH agonist as a standard part of ART cycles, premature luteinization and spontaneous ovulation presented significant challenges to the success of ART. Prospective, randomized trials indicate that use of GnRH agonist under the long protocol offers many benefits when compared with either no GnRH agonist use or use commencing in the follicular phase of the ART cycle (called the *short, or flare, protocol*). GnRH agonist in the long protocol significantly lowered the incidence of premature luteinization and spontaneous ovulation, resulting in reduced cycle cancellation rates (389,390 and 391). Significantly more oocytes and embryos were yielded using the long protocol, whereas the rate of OHSS decreased (389,391,391). For logistical reasons, patients preferred the convenience of the long protocol because it requires less frequent monitoring (393). Most importantly, clinical pregnancy rates (389) and live birth rates per retrieval (394) were significantly higher using the long protocol. The benefits of using the long protocol GnRH agonist greatly outweigh its disadvantages: daily administration (for most preparations, e.g., leuprolide acetate), increased requirement for gonadotropins, and an overall increase in the costs of medication. A metaanalysis reviewing the efficacy of various GnRH agonist regimens concluded that the addition of GnRH agonist downregulation to ovulation induction regimens for ART was advantageous (395). They noted an improvement in pregnancy rates and a decrease in cancellation rates with no associated increase in spontaneous abortion rates.

The controversy over the choice of long or short GnRH agonist protocols was put to rest by a large, prospective, observational, multicenter study involving 1,244 couples receiving their first IVF or GIFT treatment. Although serum estradiol levels were higher in patients on short protocols, these patients had 11% fewer oocytes retrieved. Further, the clinical pregnancy rate was 35% lower using the short protocol when compared with the long protocol, even after adjusting for factors such as age, infertility diagnosis, IVF or GIFT therapy, and year of treatment (396). Currently, the long GnRH agonist protocol is generally recommended for most patients, and use of the short protocol in ART patients with poor ovarian response has not been proven beneficial (396).

Many other regimens have been suggested for the administration of GnRH agonists in gonadotropin-stimulated cycles. Some of the more commonly used ones are summarized in Fig. 27.9 and Table 27.8. Recently, GnRH antagonists (*Cetrorelix* by Asta Medica and *Ganirelix* by Organon) have been proposed to have advantages over traditional GnRH agonists. GnRH antagonists bind to gonadotropin receptors and cause immediate downregulation of gonadotropin release by the pituitary gland. Because they avoid the flare effect associated with the use of GnRH agonists, they can be started concurrently with gonadotropins and do not require additional time for downregulation. GnRH antagonists also have the theoretic potential to decrease the risk for OHSS. However, more studies need to be conducted to identify the optimal dosage and the effects of GnRH antagonists on IVF pregnancy outcomes (397).

Figure 27.9 Protocols for using gonadotropin-releasing hormone (GnRH) agonist with gonadotropins in controlled ovarian hyperstimulation.

Protocol	Time of GnRH Start	Time of GnRH Administration	Comments
Long follicular (downregulation) COH	Luteal phase of previous cycle or earlier	Day of hCG injection	Theoretical benefit for patients at high risk for OHSS due to increased suppression
Long luteal (downregulation)	Luteal phase of previous cycle (day 21)	Day of hCG injection	More common protocol (see text)
Short (flare)	Luteal phase of ART cycle (started concurrently with or just before, or immediately after)	Day of hCG injection	Flare effect is hypothesized to cause additional stimulatory effects on follicles. Theoretical enhancement of ovarian response in poor responders
Urofollitropin (Urofollin)	Day 2 of ART cycle	GnRH is given for 3 days only	
Discontinuation (hCG)	Luteal phase of previous cycle (day 21)	Start day of paranealogen injection	Theoretically decreased suppression, which may be desired in poor responders
OCTherapy (343,348)	Low-dose DCP started on day 1 of previous cycle (beginning around day 10) and continued in luteal phase of previous cycle or concurrently with paranealogen	Day of hCG injection	Reported to enhance ovarian response in poor responders

Table 27.8. Protocols for Using Gonadotropin-Releasing Hormone (GnRH) Agonist with Gonadotropins in Controlled Ovarian Hyperstimulation

Controlled Ovarian Hyperstimulation Typical use of gonadotropins for COH in ART is similar to the superovulation protocol used in COH/IUI for unexplained infertility. There are several key differences:

- When the GnRH agonist luteal downregulation protocol is used, ovarian suppression should be confirmed by a baseline transvaginal ultrasound showing no ovarian cysts larger than 5 cm (365), a thin endometrium, serum estradiol level of less than 50 pg/mL, and serum progesterone level of less than 1.0 ng/mL. Ovarian suppression is usually achieved after about 10 days of GnRH agonist therapy. Once ovarian suppression is confirmed, COH using gonadotropins can be initiated.
- The aim of COH in ART is to recruit more follicles than in COH/IUI. Unlike COH/IUI, the risk for multiple gestation under ART regimens is strictly dependent on the number of embryos that are transferred and not on the number of follicles.
- In general, the monitoring during COH for ART is slightly less frequent than in COH/IUI. Spontaneous ovulation is prevented by the routine use of GnRH agonist, and slightly greater flexibility can be exercised on the day of hCG administration without affecting the pregnancy outcomes (398).
- The removal of granulosa cells during aspiration of each developing follicle with ART is believed to decrease the risk for subsequent OHSS (399). Thus, higher serum estradiol levels and larger follicular sizes are typically allowed before hCG administration in ART protocols. OHSS does, however, remain a major concern (400).

Choice of Gonadotropins In recent years, improved clinical pregnancy rates have been accompanied by progress in all facets of ART. Concurrent with improvements in embryo culture and embryo transfer techniques has been the introduction of several generations of gonadotropin formulations. The main theme of this pharmaceutical progress has been that of increasing the purity of the FSH component in novel preparations. As a result, current recombinant FSH preparations contain absolutely no LH and no other protein contaminants.

Although no difference in pregnancy rates can be shown between use of urinary FSH and hMG in downregulated ART cycles, urinary FSH has been linked to higher pregnancy rates in nondownregulated ART cycles (360). Further, purified FSH appears to be superior to hMG in the COH of clomiphene citrate-resistant PCOS patients in that it reduces the incidence of moderate to severe OHSS without affecting pregnancy rates (359).

In contrast to the comparisons between purified FSH and hMG, the efficacy of recombinant FSH relative to purified FSH or highly purified FSH has not been as certain. In addition to the benefits discussed under the section on COH and IUI, the impact on clinical outcomes of recombinant FSH relative to purified FSH or highly purified FSH has been studied in many prospective, randomized trials involving predominantly IVF or ICSI treatment or both. The data are conflicting. Some studies have reported no differences among preparations with regard to number of follicles, eggs, embryos, fertilization rate, or total dosage requirement (401,402). Others have found recombinant FSH to be associated with shorter duration of stimulation (403,404 and 405), decreased total dosage requirements (403,405,406), greater numbers of follicles and oocytes (403,404), and greater number of embryos (405,406). Importantly, pregnancy rates per cycle have not increased significantly with use of recombinant FSH (401,402,403,404,405,406,407 and 408). Of course, this lack of demonstrable difference could be attributed to inadequate power in each individual study. A recent metaanalysis reported that recombinant FSH improved pregnancy rates when compared with studies using purified FSH or highly purified FSH with OR, 1.20 (95% CI, 1.02 to 1.42)(361).

Whether recombinant FSH affects the incidence of therapeutic complications in women undergoing ART deserves attention as well. Several randomized, controlled trials have reported a trend toward an elevated incidence of OHSS with the use of recombinant FSH, although this effect has not reached statistical significance (403,404 and 405). Taken together, results suggest an important role for recombinant FSH in ART regimens. This is based on its characteristic batch-to-batch consistency and subcutaneous route of administration, its possible superiority in outcomes over other gonadotropin preparations used in typical COH, its documented benefits over hMG in PCOS patients, and the small increase in ART pregnancy rates as determined by metaanalysis. Whether new metaanalyses that include recently published studies (401,402,403 and 404,406) will change current recommendations remains to be seen.

Role of Low-Dose Aspirin in ART A recent prospective, randomized trial demonstrated that the use of *aspirin* at a dose of 100 mg/d, initiated at the time of GnRH agonist luteal downregulation and continued throughout COH, resulted in an improvement in ovarian response, implantation, and pregnancy rates in IVF (409). Although low-dose *aspirin* has not become a standard part of the ART protocol, many patients are now taking it with or without recommendation. Significant complications have yet to be reported with the use of low-dose *aspirin* in ART. Still, the safety of this adjunctive therapy warrants close examination before its wide acceptance in ART.

Recombinant Human Luteinizing Hormone According to the two-cell theory of ovarian hormone production, stimulation of the theca lutein cells by LH is critical to the overall development of the ovarian follicle. Highly purified FSH contains minimal amounts of LH (<0.1%), and GnRH agonist suppresses endogenous pituitary LH and FSH production. Therefore, it has been suggested that supplemental LH might improve folliculogenesis and pregnancy rates when highly purified or recombinant FSH is used for COH in ART. A prospective, randomized trial comparing highly purified FSH and highly purified FSH combined with supplemental rhLH has reported a trend toward lower implantation and pregnancy rates when rhLH was added to GnRH agonist-downregulated ovulation induction cycles (410). Although it is possible that some yet-to-be determined subset of infertility patients might benefit from rhLH supplementation, the generalized use of this hormone in ART currently appears to be limited.

hCG Injection The injection of hCG serves to induce oocyte maturation before oocyte retrieval. The dosage of hCG is typically 10,000 IU given intramuscularly. Different criteria for hCG injection during COH for ART have been described, but all usually include the presence of one or two leading follicles with mean diameters larger than 16 to 18 mm, at least two other follicles with mean diameters larger than 14 mm, and serum estradiol levels above defined threshold levels of 300 to 500 pg/mL. Each IVF center sets site-specific criteria based on its own experience and pregnancy outcomes. The overall goal, however, is to avoid performing surgery (oocyte retrieval) on patients who have zero to minimal chance of conceiving because of poor ovarian response. In the past, serial hCG injections were given for induction of luteal support; however, that approach can lead to an increased incidence and severity of OHSS. Luteal-phase support now relies solely on exogenous progesterone supplementation.

Oocyte Retrieval Oocyte retrieval is typically performed 36 hours after the hCG injection. Although historically performed by laparoscopy, laparoscopic oocyte retrieval has now been replaced by the transvaginal ultrasound-guided approach. Transvaginal ultrasound-guided retrieval is markedly less invasive than its laparoscopic counterpart, and the use of ultrasound permits the surgeon to visualize the location of the needle within each ovarian follicle. Intravenous sedation is commonly used for transvaginal ultrasound-guided oocyte retrieval; however, spinal anesthesia may offer an advantage in certain cases, especially when the patient has numerous follicles or the retrieval is anticipated to be anatomically challenging (411,412 and 413).

Because the vaginal canal and wall are traversed using transvaginal ultrasound-guided oocyte aspiration, the possibility of iatrogenically infecting the patient or her oocytes deserves particular consideration. Sterile normal saline typically is used for surgical preparation during oocyte retrieval. In one prospective, randomized trial comparing sterile normal saline to 1% *povidone-iodine* for this application, the former had higher associated pregnancy rates while maintaining low infection rates (414). Although the exact mechanism for this finding is unclear, it is hypothesized that contact with *povidone-iodine* could potentially harm oocytes. Therefore, if *povidone-iodine* is used, it is recommended that the vagina be lavaged with normal saline after preparation. In addition, routine antibiotic prophylaxis is recommended

for transvaginal ultrasound procedures. Such prophylaxis reduces the incidence of postprocedure positive microbiology cultures of embryo catheter tips in 78% of patients undergoing embryo transfer. The importance of this effect is suggested by the fact that lower implantation and pregnancy rates are associated with positive microbial catheter-tip cultures (415).

Performance of the retrieval itself often is fairly simple. A long, 16-gauge needle, secured by a guide onto the transvaginal ultrasound probe, is used to traverse the upper vaginal wall and enter into a follicle under direct, real-time transvaginal ultrasound guidance. Follicular fluid is then aspirated using about 100 mm Hg of vacuum. Higher pressures may traumatize the oocyte. When the entire follicular fluid content has been aspirated into sterile, prewarmed culture tubes, the inner wall of the follicle is gently curetted with the needle. This process is repeated until all the follicles are aspirated. At the end of the procedure, a speculum is inserted into the vagina, and the cervix and vaginal walls are inspected for bleeding. Although transvaginal ultrasound-guided oocyte retrieval is both rapid and minimally invasive, all potential risks, albeit rare, should be clearly explained to the patient before IVF treatment begins. These risks include the following:

- Excessive bleeding, possibly requiring blood transfusion
- Potential needle-induced injury to structures in proximity to the ovaries, including bowel, bladder, and major blood vessels, may require repair by emergency laparotomy, resulting in an abdominal surgical scar.
- Late infectious complications, such as abscesses in the peritoneum, bowel, ovary, or uterus, may require hospitalization for intravenous antibiotics or surgical interventions. In the specific case of iatrogenic tuboovarian abscess, failure of medical treatment may necessitate surgical removal of the tubes and ovaries.
- Risks associated with intravenous sedation or general anesthesia
- A remote risk that no oocytes will be obtained or fertilized

IVF, ICSI, GIFT, and ZIFT Fertilization of the human oocyte by human sperm *in vivo* requires the interaction of capacitated spermatozoa with ovulated oocytes, most often within the ampullary portion of the fallopian tube. Capacitation of sperm takes place in the female reproductive tract and involves both changes in sperm motility and changes in the sperm cell membrane that allow the acrosome reaction. Acrosome-reacted sperm are able to penetrate the oocyte's cumulus oophorus and zona pellucida, binding to the oocyte cell membrane and promoting fertilization. The interaction of spermatozoa and oocyte is not a chance occurrence as Complex oocyte–sperm intercommunications appear to play an important role in this process (416).

The mandate of the ART team is to attempt to re-create precisely those processes known to occur in unassisted conception. In all ART procedures, male gametes are initially collected directly by ejaculation into a sterile cup. They are then processed, concentrated, and incubated in protein-supplemented media for 3 to 4 hours before being used for fertilization. This final incubation allows for sperm capacitation. Before fertilization, retrieved oocytes are also cultured in protein-supplemented media for about 6 to 8 hours. For IVF purposes, 50,000 to 100,000 capacitated sperm are placed in culture with a single oocyte; 16 to 18 hours later, fertilization is documented by the presence of two pronuclei within the developing embryo.

Indications for ICSI are discussed under Male Factor Infertility. The procedure itself begins by stripping all granulosa cells from the aspirated cumulus complex (oocyte and surrounding cells). This is followed by micromanipulation of egg and sperm under magnification. More specifically, a holding pipette is used to stabilize the egg while an injection pipette is used to insert a viable sperm into the ooplasm of the egg.

Techniques such as GIFT and ZIFT use the tubal microenvironment as the initial point of germ cell contact after transfer. As in standard IVF, all regimens typically involve GnRH agonist downregulation followed by COH with gonadotropins. GIFT and ZIFT differ both in the duration that the gametes remain *in vitro* and their time of transfer. In the GIFT procedure, oocyte retrieval can be performed transvaginally or laparoscopically. Aspirated oocytes and freshly processed sperm are then resuspended in a small amount of media and rapidly transferred into the fallopian tube by laparoscopy. Historically, GIFT was initially preferred over IVF for two reasons. The limited quality of transvaginal ultrasound at the time precluded reliable transvaginal ultrasound-guided oocyte retrieval and required laparoscopic approaches. At the same time, *in vitro* embryo culture techniques had significant limitations, and it was felt that minimization of the duration of *in vitro* gamete exposure was desirable. Today, however, transvaginal ultrasound quality is excellent, and dramatic improvements have been made in gamete and embryo culture techniques. To its detriment, GIFT requires normally functioning fallopian tubes and precludes the assessment of fertilization. Taken together, there remain very few primary medical indications for GIFT; nearly all are social or religious. ZIFT also requires normally functioning fallopian tubes; unlike GIFT, however, the ZIFT procedure involves *in vitro* fertilization of retrieved oocytes and overnight culture. Zygote-stage embryos are then laparoscopically transferred to the fallopian tubes about 24 hours after oocyte retrieval. Fertilization can be assessed with ZIFT.

Luteal Support Because the act of retrieving oocytes and associated granulosa cells may adversely affect subsequent corpus luteal function, retrieval poses the possible risk of subsequent progesterone insufficiency. Therefore, the requirement for luteal support represents yet another way in which ART cycles differ from COH/IUI protocols. Luteal support is usually initiated on the day after oocyte retrieval for ART. Commonly used regimens include the following:

- Progesterone in oil 50 mg, once a day, intramuscularly
- Vaginal progesterone suppositories, 200 mg twice a day.
- Oral micronized progesterone, 200 mg twice a day

Despite similar levels of circulating progesterone, the last regimen is associated with decreased per-embryo implantation rates when compared with use of intramuscular progesterone (417).

Embryo Transfer In unassisted conception, the fertilized oocyte traverses through the fallopian tube for 2 to 3 days before entry into the uterus for implantation. This transport is largely dependent on directional ciliary movement within the fallopian tube, although tubal muscular contractions may be involved (418). The embryo is normally at the morular or early blastocyst stage of development when it reaches the uterine cavity. By this time, and under the influence of luteal-phase levels of progesterone, the endometrium has undergone the decidual changes that prepare it for implantation. The embryo resides in the intrauterine cavity for 2 to 3 days before implantation. During this period, the zona pellucida detaches, allowing implantation to occur 5 to 7 days after fertilization.

ART protocols for *in vitro* embryo culture and development attempt to recapitulate the timing and conditions of these events, albeit in an incredibly simplified fashion. The development of sequential media has allowed embryos to be grown *in vitro* until about 72 hours (or day 3 after oocyte retrieval), when they are transferred back into the cavity of the uterus. Embryo morphologic criteria—including such parameters as cell number, symmetry, fragmentation, and granularity—are used in most centers to judge the quality of a particular embryo; however, these methods of assessment do not correlate well with embryonic developmental potential (419).

In an effort to better assess and select for transfer those embryos that will result in successful pregnancy, investigators have recently evaluated the advantages of extending the *in vitro* embryo culture period before transfer. *In vitro* culture to day 5 postretrieval allows the evaluation and selection of embryos at the blastocyst stage. It is possible that this extended culture does, in fact, increase the ability to judge appropriately the quality of an embryo. For instance, grading of the blastocyst according to the morphology of the inner cell mass and trophectoderm has been correlated with implantation and pregnancy rates (420). Because of its increased implantation rate, extended embryo culture may offer the advantage of limiting the number of transferred embryos while maintaining clinical pregnancy rates. The true value of blastocyst transfer may therefore lie in its potential to decrease the rates of high-order multiple gestation resulting from ART. However, for reasons that are unclear, there appears to be an increased risk for monozygotic twinning of embryos cultured to the blastocyst stage, which can lead to increased obstetric complications (421).

Pregnancy rates resulting from blastocyst transfer range between 44% for low-scoring blastocysts and 87% for top-scoring ones. Another predictor of the success rate of day 5 transfer is the number of eight-cell embryos on day 3 (421). Extended culture to the blastocyst stage (day 5) has been advocated by some to be beneficial for all IVF patients, with overall pregnancy rates of up to 43.8% (420,422). Others recommend it only if there are three or more eight-cell embryos on day 3 of *in vitro* culture (422). Still others do not recommend it at all (423). The true application of extended embryo culture and blastocyst transfer remains to be determined.

Technical Aspects of Embryo Transfer Despite its theoretic simplicity, transcervical embryo transfer into the intrauterine cavity is a procedure that requires a significant amount of skill. Correct performance of the procedure is thought to exert significant impact on clinical outcome. Apart from the skill and experience of the operator, variables such as aspiration of cervical mucus (424), visualization by ultrasound guidance (425), duration of supine position immediately after embryo transfer (426), and type of bacteria cultured from the transfer catheter-tip postprocedure (427) have all been suggested to affect clinical pregnancy outcomes. Microbial contamination of the embryo transfer is especially relevant because it may be prevented by antibiotic prophylaxis at the time of oocyte retrieval and careful handling of the catheter. Clinical pregnancy rates are reduced by half in women with positive catheter-tip cultures (428).

Many different types of catheters have been used to perform embryo transfers, including hard catheters (Erlangen, Tefcat, Tom Cat, Norfolk) and soft catheters

(Frydman, Wallace). The Frydman and Wallace catheters are currently the most popular because they are thought to be the least traumatic to the endometrium; however, no catheter has been demonstrated to be definitively superior (429,430).

In women with a history of tubal disease, the difficulty of embryo transfer has been associated with an increased risk for ectopic pregnancy (431). The number of transfer attempts, the time required for embryo transfer procedures, and the presence of blood inside the transfer catheter after the procedure do not affect clinical outcomes (432). In a series of more than 800 consecutive embryo transfer procedures, 85.9% were easy, 8.4% were difficult, 3.2% needed to be repeated, and 2.5% required cervical dilation. Technical difficulties, repeated embryo transfers due to retained embryos, and cervical dilation for stenosis did not affect the pregnancy rates in this study (433). The timing of the correction of cervical hindrances to embryo transfers may be crucial. Specifically, although it markedly facilitated the embryo transfers itself, cervical dilation at the time of oocyte retrieval in patients with a history of very difficult embryo transfer was associated with poor pregnancy outcome (1 in 41 cycles) (434). In contrast, if performed before commencement of IVF/embryo transfer, surgical treatments for anticipated problems with embryo transfer yield good pregnancy rates. For example, hysteroscopic examination of the cervical canal may reveal a ridge, which can be resected (435). Alternatively, transcervical placement of a Malecot catheter at the time of hysteroscopy has been successful in allowing facile entry into the uterine cavity during subsequent embryo transfer or IUI. The Malecot catheter can be left in place for several weeks after hysteroscopy, as long as *doxycycline* 100 mg twice daily is taken; it is easily removed using gentle traction in the office as the day of embryo transfer approaches (436). Good clinical pregnancy outcomes have been reported for both techniques.

Cryopreservation of Embryos The success of modern ovulation induction and fertilization regimens often results in embryos in excess of the number appropriate for transfer in a single cycle. Cryopreservation of these embryos permits embryo transfer to the same patient in nonstimulated cycles in the future. Some patients receive cryopreserved embryos during “natural” cycles; others undergo endometrial preparation with sequential exogenous estrogen and progesterone. Either regimen is significantly less expensive than a gonadotropin-stimulated cycle. More importantly, the risks of surgical complications and OHSS are nonexistent in cycles using cryopreserved embryos. Therefore, pregnancies resulting from transfer of cryopreserved embryos effectively reduce both the financial and medical costs of pregnancy per ovulation stimulation. There is, of course, a perceived downside to cryopreserved cycles because not all embryos survive thawing and pregnancy rates are lower than those using fresh embryos. In transfers of cryopreserved embryos using nondonor eggs (eggs from the intended recipient), 90% of thawing procedures resulted in viable embryos for transfer. The rates of clinical pregnancy and delivery were 23.8% and 18.8%, respectively, for cryopreserved embryo transfer procedures (437). These are only perceived disadvantages, however, because the risk for cryocycles is minimal and excess embryos would otherwise not be used.

Pregnancy Testing and Follow-up of Early Pregnancy The uncertainties surrounding ART treatment and its outcomes can be highly stressful and treated couples are understandably anxious to obtain a pregnancy test as early as possible (438). Serial quantitative hCG levels can be done starting on day 16 after oocyte retrieval. Serum hCG levels taken earlier than this day may give false-negative or false-positive results. The latter may reflect the use of intramuscular hCG to trigger ovulation because this exogenous hCG can be detected for up to 14 days after injection (439). Day 16 serum quantitative hCG levels lower than 50 IU/L are associated with a 35% chance of an ongoing intrauterine pregnancy; levels greater than 500 IU/L are predictive of successful outcome in more than 95% of cases (440). In this same study, a single serum progesterone level on day 16 did not provide further prognostic value and is therefore not recommended (440).

Patients are usually followed with serial serum hCG levels early in pregnancy, followed by transvaginal ultrasound at 5 to 6 weeks of gestation to document intrauterine location of the pregnancy and the number of gestational sacs. This is especially important for patients with risk factors for ectopic pregnancy, those who are experiencing vaginal bleeding, and those at high risk for higher-order multiple gestation. In addition, such close follow-up in early pregnancy is both indicated and necessary among ART patients because an ongoing pregnancy requires patients to continue daily self-administration of supplemental progesterone (until the luteal-placental shift at about 9 to 10 weeks of gestation). Transvaginal ultrasound at 7 to 8 weeks for identification of fetal cardiac activity can provide further reassurance.

Success Rates Success rates of IVF vary from program to program; within a program, the rates of success vary with the patient's diagnosis and age. The most comprehensive assessment of the efficacy of ART in North American programs comes from the database of the Society for Assisted Reproductive Technology (SART) (437). The society's data collection began in 1985, and its annual summary is published in an effort to improve the quality of statistical reporting on ART. The database attempts to eliminate the effects of interprogram variation. The most recently published report of the society summarizes the results of ART in the United States and Canada for 1997, which are shown in Table 27.9 (437). **Information on SART and registered ART clinics are accessible by the public at <http://www.sart.org/>.** Significant improvements in the overall ART outcomes have been made when compared with the last published results. In 1997, a 28.4% (16.8% in 1992) rate of delivered pregnancies was reported per oocyte retrieval for standard IVF, with a cancellation rate of 21.7% (15.4% in 1992), a pregnancy loss rate of 18.1% (20% in 1992), and an ectopic pregnancy rate of 0.9% (1.2% in 1992) per transfer. The delivered-pregnancy rate for cryopreserved embryo transfer was 18.8% in 1997 (11.6% in 1992). Although the rates of birth defects did not appear to be different from that of the general population, the SART reporting system was not designed to specifically address this issue.

Table 27.9. Reported Outcomes for Assisted Reproductive Technology Procedures Performed in 1997 in the United States^a

The age of the woman was a significant determinant of success in ART (437) (Table 27.10). Women aged 41 years and older had a delivery rate per retrieval of only 9.4%. The increase in cancellation rates with age—most likely the result of poor ovarian response—was consistent with significantly decreased ovarian reserve in older women. With the high efficacy of ICSI as a treatment for male factor infertility, the delivery rates per retrieval among couples with male factor infertility were comparable to those achieved in couples without male factor for a given female age group.

Patient Category	No. of Attempts	Cancelled (%)	Transfer per Attempt (%)	No. of Pregnancies	No. of Deliveries	Delivered per Retrieval (%)	Multiple Births per Delivery (%)
1987-97 procedures without ICSI							
Women < 34 years of age, no male factor infertility	24,725	18.2	35.9	5,882	4,981	33.5	44.7
Women 35-37 years of age, no male factor infertility	7,511	14.8	36.4	2,716	2,226	28.1	28.4
Women 38-40 years of age, no male factor infertility	4,257	19.3	31.8	1,761	1,321	21.2	28.6
Women > 41 years of age, no male factor infertility	2,682	24.4	26.9	291	241	9.4	28.8

^a Data are for standard IVF, intracytoplasmic sperm injection (ICSI), and micromanipulated zona manipulation (MZO). From Meltzer et al. (437).

Table 27.10. In Vitro Fertilization (IVF) Procedures^a by Maternal Age Group and Infertility Diagnosis

Treatment with Donor Oocytes Women with premature ovarian failure have very few reproductive options. The use of donor oocytes may represent the only proven

method by which most of these patients can become pregnant. Other patients to be considered for donor oocyte technology may include those with poor oocyte quality (including some patients with failed fertilization), those with poor ovarian response to stimulation, and those with a history of multiple failed ART cycles. Using embryos fertilized from donor eggs in 418 fresh embryo transfer involving 276 recipients, clinical pregnancy and delivery rates were 36.2% and 29.3%, respectively. The cumulative pregnancy rate after four cycles reached 87.9% (441).

Treatment with donor oocytes is available in most ART programs. The method of donor selection is an important consideration. Some patients may wish to find their own donor in a sister or friend; others may choose to use a matching service to identify a donor, who can remain anonymous. Although some ART programs may choose to be excluded from the matching process, most will assume the responsibility of screening the donor for medical, reproductive, and psychological fitness. Like semen donors, potential oocyte donors must be stringently assessed, including screening for transmittable infectious or genetic diseases. Unlike semen, however, oocytes cannot presently be cryopreserved and quarantined; hence, the risk for transmission of infectious agents cannot be completely averted. Moreover, because oocyte donation involves COH, a donor is exposed to the same intensive monitoring and significant potential complications inherent to this intervention. Potential donors must be provided with detailed educational information and meticulous informed consent is mandatory. In addition to undergoing medical screening, oocyte donors are subjected to a comprehensive psychosocial evaluation before being accepted as program participants. Even with such extensive screening and preparation, there is a significant dropout rate for both anonymous and directed oocyte donors (442). It is advisable to obtain legal counsel in the development of any ovum donation center because many potentially litigious issues arise in the administration of such a program.

Oocyte cryopreservation is not generally available or successful and embryo cryopreservation reduces subsequent pregnancy rates. Considerable coordination is required to ensure that the recipient's endometrium is appropriately prepared when embryos freshly fertilized from the donor oocytes are ready to be transferred (443). Regimens for ovulation induction and oocyte retrieval for the oocyte donor follow those of standard IVF protocols (Fig. 27.10). Although the oocyte donor is exposed to many of the adverse effects of COH protocols (OHSS, postoperative pelvic discomfort, surgical and anesthesia risks, and medication side effects), her risk for multiple gestation and ectopic pregnancy can be virtually eliminated if she abstains from intercourse during her stimulation cycle.

Figure 27.10 Regimens of ovarian stimulation and hormone replacement used to synchronize the development of ovarian follicles in the oocyte donor and the endometrial cycle in the recipient. (hMG, human menopausal gonadotropin; hCG, human chorionic gonadotropin; b-hCG, the b subunit of hCG; OHSS, ovarian hyperstimulation syndrome; OCP, oral contraceptive pill; ART, assistive reproductive technology.) *Reproduced with permission from: Chang PL, Sauer MY. Assisted reproductive techniques. Stenchever MA, ed. hape Atlas of Clinical Gynecology, Mishell DR, ed, hape Reproductive Endocrinology. Vol. 3. Philadelphia: Current Sciences Group, 1998.*

To ensure adequate endometrial preparation, most recipients of donor oocytes are taken through a “mock” cycle before their actual treatment cycle. During the mock cycle, all hormonal agents are administered, and endometrial adequacy is documented by timed endometrial biopsies. The impact that the completion of a mock cycle might have on the pregnancy rates of subsequent ART cycles with donor eggs has not been studied in a randomized trial. However, important factors such as patient compliance, histologic evidence of endometrial response to exogenous hormones, and the ease of embryo transfer can be assessed (444). Many regimens for endometrial preparation have been described, although successful pregnancies have also been reported after embryo transfer in natural cycles. The following is a typical regimen for endometrial preparation in recipients of donor oocytes:

- **If the recipient has no baseline ovarian function, no downregulation or baseline testing is required.** However, if the recipient has endogenous ovarian function, GnRH agonist is started on day 21 in the luteal phase of the previous cycle. At onset of menses, downregulation is confirmed with serum estradiol levels of less than 50 pg/mL and progesterone levels of less than 1.0 ng/mL. If confirmed, the dose of GnRH agonist is reduced.
- Start *estradiol*: (*Estraderm* patches 0.2 mg every 48 hours or *Vivelle* patches 0.2 mg every 48 hours or *Estrace*, 1.0 mg orally once per day).
- Monitor serum estradiol levels every 3 to 7 days and adjust dosage to maintain serum estradiol levels of 150 to 300 pg/mL, or continue fixed dose.
- Continue supplementation at dosages that maintain these estrogen levels for at least 21 days.
- The progesterone start day is scheduled according to the day of embryo transfer (in a therapeutic cycle) or the day of endometrial biopsy (in the mock cycle).
- Start *progesterone*, 25–50 mg intramuscularly (day 1), then increase to 50–100 mg/d intramuscularly the following day.
- Discontinue GnRH agonist on day 2 of *progesterone*.
- Mock cycle: perform endometrial biopsy 10 to 12 days after *progesterone* is started. Therapeutic cycle: perform embryo transfer on day 4 of *progesterone*.
- Measure quantitative hCG 16 days or more after the day of donor oocyte retrieval.

Many controversial issues and much ethical debate surround oocyte donation. Donors' expectations regarding the process itself, the quality of their medical care, and their level of involvement in decisions can be addressed by a conscientious ART team (445). Other topics, such as methods of donor recruitment and amounts of financial compensation, are much more challenging issues (446,447). Further effort is warranted to help clarify these issues and provide access to this highly efficacious ART treatment.

Complications of ART

Twins and Higher-order Multiple Gestation

Multiple gestation, especially higher-order multiple gestation, is a serious complication of infertility treatment and has tremendous medical, psychological, social, and financial implications. In recent years, it has been reported that only 20% of higher-order multiple gestations are the result of spontaneous conceptions. The remaining 80% are attributable to reproductive interventions. Of these multiple gestations, half are attributable to ART and half to the use of ovulation drugs in non-ART cycles (448). Because the average age of women attempting pregnancy has risen during recent decades and increased maternal age affects the incidence of multiple gestation, rates of higher-order multiple gestation must be adjusted for maternal age when compared across time (449). For decades before 1971, higher-order multiple gestation occurred at a maternal age-adjusted incidence of about 30 per 100,000 live births from spontaneous conceptions (449,450). This incidence rose to 173.6 per 100,000 live births in 1997 (449) (Table 27.11). Because higher-order multiple gestations are predominantly triplets (91.2% were triplets in 1997) (448), this rate represents 6,737 triplets born in the United States in 1997 alone (Table 27.12).

Age group (yr)	Triplet and Higher-order Multiple Births	
	1980	1997

Table 27.12. Contribution of Assisted Reproductive Technology (ART) to Triplet and Higher-order Multiple Births (³ Triplets)—United States, 1989–1997

Significant medical risks accompany higher-order multiple gestation. There is an increased incidence of potentially life-threatening obstetric conditions such as acute fatty liver (452) and severe preeclampsia (452). The rate of fetal death during the third trimester is also unacceptably high at almost 17% (454). Obstetrically, triplets are at increased risk for preterm birth, low birth weight (<2,500 g), and very low birth weight (<1,500 g) compared with singletons or twins (451,455). When adjusted for gestational age at birth, triplets have the same rates of neonatal morbidity and mortality as twins and singletons (456,457), but triplets typically deliver much earlier. One exception to this equalization is that premature triplets are at significantly greater risk for severe retinopathy of prematurity even when delivered at the same gestational age as a matched singleton or twin (457). Because of the extensive obstetric and neonatal intensive care required in higher-order multiple gestation pregnancies, enormous expenditures are required to provide medical care to these families (458). Finally, although not fully described, the immediate and long-term emotional and psychological impact on the mother, her partner, and the family unit, including other siblings, is likely to be daunting.

To rectify this trend in higher-order multiple gestations, a number of medical and nonmedical causes are being identified. Non-ART COH with gonadotropins is a highly efficacious and commonly used treatment modality for infertile couples. It is significantly less expensive than ART and thereby more accessible to many patients. Unfortunately, it is associated with a 20% incidence of twin gestations and 10% incidence of higher-order multiple gestation (459). Current monitoring protocols for non-ART COH, based on serum estradiol levels and the number of large follicles on ultrasound cannot entirely predict the risk for higher-order multiple gestation (460). The risk for higher-order multiple gestation is significantly increased with younger age, peak serum estradiol levels greater than 1,385 pg/mL, and a total number of follicles of seven or more (460). It is difficult to glean the significance of this latter measurement, however, because total follicle number depends on which follicles are measured, and it is unclear what should be the smallest reportable size. Further, a high total number of follicles may result from overstimulation of a patient with normal ovaries but unexpectedly high ovarian response or from treatment of a patient with PCO-like ovaries. Because the prevention and management strategies would differ for these two conditions, further stratification of patients and characterization of the COH cycles may clarify relative risks and direct more efficacious prevention of multiple gestation and OHSS.

Suggestions to address non-ART COH as a cause of higher-order multiple gestation are being explored. None is without cost. One option would promote lowering the dosage of gonadotropins used in COH to aim at a lesser degree of ovarian response. This approach will almost certainly lower pregnancy rates. An alternative would be fewer interventions with non-ART COH and substitution with ART. In ART, the rate of higher-order multiple gestation is determined by the number of embryos transferred, not the ovarian response, so that there is a greater control of the higher-order multiple gestation rate by physicians. This approach, however, would require a dramatic change in the guidelines for insurance company reimbursement of infertility treatments or would necessitate the financing of such treatment by the couple. Currently, there are no accepted criteria guiding when a non-ART cycle should be cancelled in an attempt to reduce the risk for higher-order multiple gestation. Informed recommendations for such standardization might be helpful.

More progress is being made toward reduction of higher-order multiple gestation in the area of ART. One approach, discussed under Embryo Transfer, would involve greater use of extended embryo culture, in which embryos are allowed to grow to the blastocyst stage *in vitro*. Blastocysts have been shown to have greater developmental potential and higher implantation rates than day 3 embryos, so that even if fewer (a maximum of one to two) blastocysts are transferred, pregnancy rates remain high (420). Another approach would follow the lead of countries outside the United States that have defined set limits for the maximum number of embryos transferred in a given ART cycle. The American Society of Reproductive Medicine has recently addressed this issue by publishing guidelines for embryo transfer during ART. Briefly, a maximum of three, four, and five embryos can be transferred to women with above-average prognosis (age < 35 years), average prognosis (age between 30 and 40 years), and below-average prognosis (age > 40 years or multiple failed ART cycles), respectively (461). In donor oocyte cycles, the age of the donor (not the recipient) should be used to determine the number of embryos to be transferred (461). Data on the efficacy of this protocol is expected to be available in a few years. Meanwhile, Templeton and Morris advocated even more stringent guidelines, promoting the transfer of a maximum of two embryos in ART cycles to minimize the risk for higher-order multiple gestation (462). Cryopreservation of excess embryos should certainly be encouraged further in order to promote more cycles involving transfer of cryopreserved embryos. Universal application of such changes will force patients and doctors to emphasize cumulative birth rates rather than pregnancy rate per cycle. By focusing on cumulative birth rates, patients can have more realistic expectations, and the demand to have an excessive number of embryos transferred would decrease (463,464). As discussed for non-ART COH, these changes will involve alterations in the entire financial reimbursement structure for ART services. There is no doubt that this approach will present many challenges.

Other factors contributing to the increased rates of higher-order multiple gestation have been identified. It has been suggested that government-mandated annual reporting of clinic-specific pregnancy rates places undue emphasis on pregnancy rate per cycle. This may encourage the promotion of higher pregnancy rates at the expense of higher multiple pregnancy rates. If our goal in infertility therapy is the delivery of a healthy baby, both pregnancy rates and incidence of multiple gestation must be considered in determining treatment efficacy. Financial reimbursement schedules by insurance companies, lack of federal support for IVF research, and insufficient patient education regarding the true risk for higher-order multiple gestation are all being examined (465,466,467 and 468).

On the scientific front, new technologies, such as preimplantation genetic diagnosis, may ultimately eliminate the risk for higher-order multiple gestation. Preimplantation genetic diagnosis is a clinical diagnostic procedure that can be performed on the embryo itself in order to determine whether a particular genetic abnormality is present before its transfer into the uterus (469). Preimplantation genetic diagnosis has been developed in an effort to improve the chances of having healthy infants among families at high risk for a particular genetic disease. It is most frequently performed using blastomere (a cell from a day 3 embryo containing six to eight cells) biopsy, followed by genetic testing on the cell obtained. The technique chosen for diagnostic testing depends on the type of genetic defect being investigated. For example, fluorescence *in situ* hybridization (FISH) can be used to assess aneuploidy, translocation, and other chromosomal structural defects (470). FISH can also be used to exclude transmittal of X-linked diseases by identification X and Y chromosomes, thus allowing transfer of female embryos only (471). Alternatively, familial single gene mutations can be identified by extracting blastomere DNA, followed by polymerase chain reaction, restriction enzyme digest, or sequencing. In a recent study involving 262 ART cycles, the embryos obtained from women with a poor prognosis (characterized by age older than 35 years with previous IVF failures and karyotypic defects) were randomized to preimplantation genetic diagnosis for aneuploidy or a control procedure. Those chromosomes commonly involved in aneuploidies (X, Y, 13, 14, 15, 16, 18, 21, and 22) were assessed using FISH in the study group. Although fewer embryos were transferred in the preimplantation genetic diagnosis group, higher clinical pregnancy rates (37% versus 27%) and implantation rates (22.5% versus 10.2%) were reported when compared with controls (472). Therefore, preimplantation genetic diagnosis may assist in the selection of euploidic embryos, relegating to this technique a tremendous potential in lowering the risk of higher-order multiple gestation.

As progress is being made to eradicate the complication of higher-order multiple gestation, others have suggested ways to reduce subsequent risks once higher-order multiple gestation has occurred. One option for preventing some of the maternal and fetal complications of higher-order multiple gestation involves the judicious use of selective pregnancy termination or multifetal reduction. Although any high-order multiple gestation is a candidate for this procedure, the reduction of triplet to twin pregnancies is most common and best studied. Overall, about 14% of triplet pregnancies reduce spontaneously to twin pregnancies after fetal heart activity is documented on transvaginal ultrasound at 8 to 9 weeks (473,474). Although some studies have not found multifetal reduction to result in significant improvement in gestational length or intrauterine growth restriction (474,475), many centers have reported improved outcomes after reductions to twin gestations. Twin gestations

after reduction have similar outcomes when compared with spontaneous twin gestations (476,477). Reduction of triplet to twin gestation has been reported to decrease the risk for preterm birth (478), low birth weight (478), preeclampsia (477), and delivery before 36 weeks (477). Specifically, preterm birth before 28, 32, and 34 weeks of gestation, as well as birth weights of less than 1,000, 1,500, and 2,000 g were significantly lower in twins after reduction from triplet pregnancy compared with triplets who did not undergo reduction (479). However, any benefits achieved for newborn health often incur tremendous emotional, psychological, and physical costs. The major complications of fetal reduction include a 13% risk for premature rupture of the membranes for triplet to twin reduction (480). There is a 5% to 10% risk for losing the entire pregnancy (481) after reduction has occurred. Further, major depression occurs in 80% of women who lose the pregnancy as a complication of fetal reduction and in one third of women who have live twins after fetal reduction (482).

Ovarian Hyperstimulation Syndrome

OHSS is a medical complication that is both completely iatrogenic and unique to the treatment of infertility. Although the pathophysiology of OHSS is not well understood, the signs and symptoms of this disease can be attributed to local and systemic increase in capillary permeability. These changes, in turn, result in the depletion of intravascular volume at the expense of third-space fluid accumulation.

OHSS has been directly associated with increasing numbers of stimulated follicles and retrieved oocytes (483,484), the presence of PCOS (485,486 and 487) and high serum estradiol levels (483,488,489). Despite these associations, however, hyperestrogenemia is not currently thought to be the main cause of OHSS (490,491,492 and 493). Rather, the increased production of vasoactive substances, such as prorenin, renin, angiotensin-converting enzyme, angiotensin I, angiotensin II, and angiotensinogen, by the hyperstimulated ovaries has been implicated in this disease (494,495,496,497,498,499,500,501 and 502). Still, it remains possible that hyperestrogenemia, especially in the presence of hemoconcentration, has important effects on the thromboembolic risks demonstrated with OHSS.

Inflammatory responses are certainly present in OHSS patients, with possible roles for cytokines, histamine, and prostaglandins in the disease pathogenesis (503,504,505,506,507,508 and 509). In particular, the link between vascular endothelial growth factor (VEGF) and OHSS has been extensively studied. VEGF has been shown to exhibit a dose-related expression in human granulosa cells upon stimulation by hCG (510). Further, serum VEGF levels correlate with OHSS severity (511,512) demonstrating a sensitivity and specificity of 100% and 60%, respectively (512). The central role of an inflammatory response is supported by a number of other findings. For instance, mast cells are abundant in ovulatory follicles (513), and histamine blockade has been reported to ameliorate and, in some cases, even prevent OHSS in animal models (505,506 and 507,514). Further, it is clinically well recognized that allergy or hypersensitivity act as risk factors for the development of OHSS (483). However, to date, scientific evidence for these factors is still considered preliminary, and further investigation is warranted to clarify their true role in OHSS (493).

Recently, a distinction between early- and late-onset OHSS has been described (515). Early OHSS, with onset arbitrarily set within 9 days of oocyte retrieval, is associated with higher serum estradiol levels and follicle numbers during COH. In contrast, late OHSS has onset more than 9 days after oocyte retrieval. Late-onset OHSS has been associated, not with measures of follicular response, but rather with multiple gestation. Early and late OHSS may even reflect somewhat distinct pathophysiologic mechanisms. It has been proposed that early OHSS may result from ovarian stimulation by the exogenous hCG given to trigger ovulation, whereas late OHSS may be more closely linked to the endogenous hCG produced when pregnancy ensues (515).

OHSS has a varied spectrum of clinical presentation. An attempt to better understand this heterogeneity led to the development of a staging system for OHSS that would reflect symptom severity. This classification categorizes patients into mild, moderate, and severe disease (516). In mild OHSS, patients often complain of mild abdominal distention and soreness, nausea, and vomiting. Ovarian enlargement can be 5 to 12 cm. Moderate disease is marked by the presence of abdominal ascites on ultrasound examination. Severe disease is diagnosed when there are clinical signs of tense ascites, hydrothorax, shortness of breath, hemoconcentration, hypercoagulability, or any complications of OHSS such as renal failure, thromboembolism, or acute respiratory distress syndrome (ARDS).

This classification may serve as a useful guide; however, its application may sometimes be misleading. For example, ovarian enlargement is common after COH and, by itself, is not informative. Further, many patients experience mild pelvic soreness and abdominal bloating after COH, and their ovaries may be enlarged when viewed on transvaginal ultrasound. Whether these patients reflect an abnormal response to COH or merely represent a subset of normal responders is debatable. The fact that reported incidence of OHSS after COH has ranged from 7.3% (mild or moderate disease) and 4.2% (severe disease) to 33% overall may suggest that the staging system is itself open to interpretation (483,516).

Management of OHSS Patients undergoing COH with or without ART should be educated about the signs and symptoms of OHSS. They should be instructed to contact their health care provider if they experience abdominal bloating, abdominal discomfort or pain, early satiety, nausea, vomiting, decreased urine output, or weight gain of more than 2 lb per day. Patients with these initial symptoms should be fully assessed to establish their baseline condition for future comparisons, if that should become that necessary. Following are those points most pertinent in the assessment of patients with OHSS potential:

History

- Age, history of OHSS in previous infertility treatment, history of PCOS
- Characteristics of COH (dose of gonadotropins, number of follicles, number of eggs for an ART cycle, peak serum estradiol level, date of hCG administration, date of oocyte retrieval, date of embryo transfer, number of embryos transferred at embryo transfer)
- Onset of symptoms, their progression (stable versus rapidly worsening), and their severity

Specific questions should address the presence of the following symptoms:

- Abdominal discomfort, pain, bloating; increased abdominal girth; early satiety
- Shortness of breath, chest pain
- Nausea, vomiting
- Weight gain (total amount gained since start of COH and pounds gained per day)
- Decreased urine output

A complete physical examination should be performed, with specific attention to the following areas:

- Signs of hypotension, hemodynamic instability, and dehydration
- Chest: evidence of pleural effusion, congestive heart failure, limited chest expansion because of ascites
- Abdomen: ascites (mild, moderate, tense), peritoneal signs
- Peripheral exam: pitting edema
- Pelvic exam is **contraindicated** because enlarged ovaries can be fragile

Investigations

- Complete blood count, prothrombin time, partial thromboplastin time, serum electrolytes, liver function tests, creatinine, blood urea nitrogen
- Chest x-ray if there is significant shortness of breath or abnormalities on chest exam (shielding the pelvis can protect potential pregnancy from irradiation)
- Transvaginal ultrasound to document the baseline amount of ascites and size of ovaries
- Documentation of oxygen saturation is indicated if there is evidence of respiratory compromise
- Serum hCG on day 16 after oocyte retrieval if embryo transfer has occurred

This initial assessment should enable the clinician to decide whether the OHSS patient needs to be admitted to the hospital for observation and supportive care. Accepted indications for hospitalization include inability to tolerate oral hydration, hemodynamic instability, respiratory compromise, tense ascites, hemoconcentration, leukocytosis, hyponatremia, hyperkalemia, abnormal renal or liver function, and decreased oxygen saturation. If the diagnosis and its severity remain in doubt after initial assessment, it is reasonable to observe patients overnight while further assessing fluid balance and the presence of oliguria. The need for more prolonged hospitalization often becomes rapidly evident. The presence of peritoneal signs, such as abdominal rebound tenderness or guarding, in a patient with possible OHSS may indicate ovarian torsion, hemorrhage, or rupture of enlarged ovarian cysts. These signs may also represent those rare cases of post-oocyte retrieval tuboovarian abscess. Further, admission to hospital is mandatory, and admission to an intensive care setting should be seriously considered if the patient has complications of

OHSS such as renal failure, ARDS, thromboembolic disease, or severe hydrothorax.

The onset of OHSS soon after hCG administration or oocyte retrieval is associated with an increased risk for progression to severe disease. Pregnancy is also known to cause worsening of OHSS, most likely due to ovarian stimulation by endogenous hCG. Therefore, in cases of very-early-onset OHSS, the benefits of withholding embryo transfer, cryopreserving these embryos, and performing ET in a future unstimulated cycle should be considered and discussed.

Outpatient Management If hospitalization is not indicated by initial assessment and the patient can be managed as an outpatient, she should be instructed to limit her activity, to weigh herself daily, and to monitor her fluid intake (at least 1 L/d of mostly electrolyte-balanced fluid) and output. Daily follow-up by telephone or visit is important because the severity of OHSS may change any time. The patient should contact her health care provider if she notes worsening of the symptoms or if her weight gain increases to more than 2 lb per day. Reassessment is indicated in these situations.

Inpatient Management Inpatient management of patients with OHSS is composed of meticulous vital sign and fluid balance monitoring as well as supportive care. This typically involves use of intravenous hydration and prevention of complications such as thromboembolic prophylaxis, although more invasive interventions, such as paracentesis, may become necessary. The following is a typical inpatient protocol used for management of the patient with moderate to severe OHSS:

Perform the initial assessment as outlined previously.

- Vital signs (including oxygen saturation monitoring if respiratory compromise is present) every 4 hours initially
- Fluid intake and output measurements
- Daily weights and abdominal girth
- Daily hematocrit, leukocyte count, serum electrolytes, renal function tests
- Liver function tests, prothrombin time, partial thromboplastin time on admission and then repeated only as necessary

Supportive Care

- If there is hypotension or oliguria, give a bolus of 1 L of normal saline (NS) over 1 hour, then maintain with D5NS (or D5 _{1/2}NS) at 150 mL/h. If there is no hypotension or oliguria, but the hematocrit is greater than 45%, start maintenance at D5NS at 150 mL/h. The maintenance rate for intravenous fluids can be lowered if the hematocrit is normal. Although administration of intravenous fluids will certainly lead to an increase in third spacing, it is important to maintain adequate intravascular volume and urine output. The hematocrit may need to be monitored twice a day initially; the intravenous fluid maintenance can be titrated downward as the hematocrit normalizes. This should help to minimize third-spacing side effects. Lactated Ringer's solution should not be used for intravenous hydration in patients with OHSS.
- If oliguria persists, a small bolus of 250 to 500 mL of NS can be given to increase urine output. The efficacy of albumin (or other plasma expanders) in the treatment or resolution of OHSS has not been studied in a prospective, randomized fashion. However, it is reasonable to attempt gentle diuresis in a patient who has normal blood pressure and hematocrit but in whom oliguria or weight gain persists. This may be accomplished using sequential administration of 50 mL of 25% albumin followed by *furosemide*, 10 mg given intravenously. This combination can be repeated 3 to 4 times per 24 hours as necessary. Serum sodium, potassium, and creatinine must be monitored closely when employing albumin or furosemide diuresis.
- Small amounts of fluid can be taken orally. As the OHSS improves, amount of intake can be increased as the intravenous fluid maintenance decreases. During the resolution of OHSS, a maximum total input of 1 L/d has been recommended to prevent increases in third spacing (493).
- Paracentesis is indicated if the patient has severe abdominal discomfort and respiratory compromise due to large volumes of ascites. Hydrothoraces have also been reported to resolve after paracentesis. Presence of massive ascites combined with persistent oliguria or hypotension despite medical therapy is also an indication for paracentesis because diuresis often results after the severe abdominal pressure is relieved. Both abdominal paracentesis under ultrasound guidance and transvaginal ultrasound-guided transvaginal paracentesis are described and acceptable practices (517,518).
- If embryo transfer has already been performed or is scheduled, progesterone supplementation should be given as indicated by the ART protocol. Administration of progesterone is not thought to affect OHSS adversely. However, pregnancy may cause worsening of OHSS as a result of the stimulation of the ovaries by increasing levels of endogenous hCG.
- Antiemetics and analgesics (i.e., *acetaminophen*) can be given symptomatically.
- Complications of OHSS, such as ARDS, thromboembolism, and renal failure, should be treated in the intensive care setting when indicated.

Preventative Measures

- Hemoconcentration and severe leukocytosis are considered risk factors for thromboembolic disease among OHSS patients (493). Therefore, *heparin*, 5,000 IU subcutaneously twice a day, should be given to all OHSS inpatients to prevent thromboembolism. In addition, high-high vascular support stockings should be used in ambulatory patients. Intermittent compression stockings should be used for patients who are not ambulating.

Prevention of OHSS Because OHSS has the potential to cause severe and sometimes life-threatening complications, it is prudent to aim toward disease prevention. It is usually not possible to identify patients who are at risk for OHSS during COH. However, when high estradiol levels ($\geq 3,000$ pg/mL) are noted before hCG administration, prevention of OHSS can be attempted using a technique called coasting. Coasting involves withholding gonadotropin and delaying hCG until serum estradiol levels decrease or follicular diameter of greater than or equal to 18 mm is seen on transvaginal ultrasound (372,373 and 374). Coasting does not completely prevent the risk for severe OHSS or cycle cancellation, but it does minimize the risk for severe OHSS while maintaining high pregnancy rates. An alternative strategy to minimize OHSS risk would cryopreserve embryos (or prezygotes) at the pronucleate stage and transfer thawed embryos to the uterus in a subsequent cycle using endometrial preparation without COH. The strategy of prezygote cryopreservation results in excellent pregnancy and live birth rates comparable to similar cycles with fresh embryo transfer. The incidence of severe OHSS appears to be decreased, but more importantly, the duration of severe OHSS may be shortened when cryopreservation strategies are used (519,520 and 521).

Unfortunately, even with close monitoring and use of the lowest possible doses of gonadotropins during COH, it is still often difficult to prevent OHSS. One novel strategy that may address these difficulties involves the *in vitro* maturation (IVM) of oocytes. IVM has been performed with success in some centers. Using IVM, immature follicles are aspirated and the retrieved oocytes are grown *in vitro* until mature. This is potentially advantageous because IVM completely obviates the need to stimulate the ovaries with gonadotropins. ICSI is performed on IVM oocytes, and embryos are transferred to a uterus that has been hormonally prepared. This technology is especially promising and appropriate in women with PCOS. IVM is particularly applicable to women with PCOS, who have a known increased risk for OHSS; further, their ovaries are characterized by multiple small follicles that can be aspirated in the absence of stimulation. IVM has been reported to yield pregnancy rates of 27.1% to 38% in women with PCOS (522,523 and 524).

Ectopic and Heterotopic Pregnancies

The incidence of ectopic pregnancy is 2% in the general population (525). However, its incidence is increased in IVF and can be as high as 4% (526). The main risk factors for ectopic pregnancy in IVF treatment are tubal factor infertility and possibly, previous myomectomy (526). The incidence of heterotopic pregnancy, which is normally rare, is particularly high (1%) after IVF treatment. Multiple gestation and high hormonal levels during COH and early pregnancy have been suggested to be possible causes. It is important to have a high index of suspicion for the occurrence of heterotopic pregnancies because only 40% to 84% of cases can be diagnosed on transvaginal ultrasound at the initial presentation (527,528). After treatment of the heterotopic gestation with laparoscopy, laparotomy, or ultrasound-guided KCl injection into the extrauterine pregnancy, the overall delivery rate for the intrauterine pregnancy is 66% (527).

Risk for Cancer after Fertility Therapy

The possibility that ovulation-inducing medications might promote the development of cancers of the reproductive tract was first introduced in the early 1990s by Whittenmore and colleagues, specifically with regard to ovarian cancer (529). One theory behind this proposed risk is that ovarian cancer may arise, in some cases, as the result of damage to the ovarian epithelium during ovulation. Lactation, oral contraceptives, late onset of menarche, early menopause, and multiparity are known to protect against ovarian cancer. Moreover, each is associated with a reduction in the total lifetime number of ovulatory cycles. The decreased risk for ovarian cancer noted among women with increased length of anovulation begged the question of whether dramatic increase in the number of eggs ovulated during superovulation therapy would, in turn, increase the risk for ovarian cancer. Alternatively, some believe that because gonadotropins (FSH and LH) increase cellular proliferation and division within ovarian follicles, their use might create a predisposition toward the occurrence of cancer cells. Both of the most common hormonal therapies used for induction of ovulation—clomiphene citrate and exogenous gonadotropins—result in increased gonadotropin stimulation to the ovary. These therapies might therefore

increase the incidence of ovarian cancer in treated infertility patients. Concern about this potential risk for cancer after fertility therapy has also been extended to other organs, including the uterus and breast.

Currently, several factors prevent an accurate calculation of the true risk for developing cancer of the breast, uterus, or ovary after treatment with ovulation-inducing agents. First, contemporary fertility treatments and their dosages remain relatively new and are usually used in women younger than 40 to 45 years of age. Because ovarian, uterine, and some breast cancers typically occur in older women, the number of patients who were treated with fertility drugs and are now in their middle to late 60s may still be too small to allow us to detect elevations in cancer risk. Second, it is hard to differentiate the effect of fertility treatment from the effect that being infertile might itself have on future development of malignancies of the breast, uterus, or ovary. Finally, most of the studies addressing these risks are clouded by small numbers, intake of a variety of medications, and recall bias. All these factors make the interpretation of data difficult (530).

Two of the most recent studies failed to attribute an increased risk for breast, uterine, or ovarian cancer to medications used for superovulation in the treatment of infertility (531,532). One study evaluated more than 20,000 women with exposure to fertility drugs used for IVF and compared them to nearly 10,000 infertile controls. The authors reported no overall increased incidence of uterine, breast, or ovarian cancers in women exposed to medications used for IVF (532). Two other interesting findings represent some of the limitations to these types of studies. The authors reported that the risk for ovarian and uterine cancer was higher in women with unexplained infertility, regardless of whether they had received ovulation induction medications. This may suggest risks associated with the unexplained infertility itself, or the possibility of undiagnosed cancers causing infertility. In addition, the authors reported an increase in the risk for breast and uterine cancer only within the first year after receiving infertility medications for IVF. Again this result is confusing. Patients undergoing IVF are followed closely and may therefore be more likely to report early signs or symptoms of these cancers to their physicians. Alternatively, rather than causing these cancers, fertility medications may only stimulate the growth and subsequent diagnosis of preexisting tumors.

Psychological Support

Stress, as manifested by anxiety or depression, is thought to be increased in women experiencing infertility. The relationship between stress and infertility is complex and may represent a vicious cycle in which infertility results in stress, which results in further difficulty in conceiving (533,534 and 535). Results from a recent prospective, randomized trial support the value of group cognitive-behavioral therapy among infertile couples (536). This therapy uses a variety of approaches, including relaxation training such as yoga, cognitive restructuring, methods for emotional expression, and information on nutrition and exercise with respect to infertility. Although the mechanism by which relaxation therapies aid fertility is unknown and issues such as high dropout rates need to be addressed by further research, the option of psychological support and counseling, on an individual or group basis, should be offered to patients experiencing infertility (537).

Other Considerations

One of the most important aspects of the treatment of patients with subfertility or infertility is the process of deciding when no further treatment will be pursued. This crucial topic must be addressed early in infertility therapy. Patients must be accurately informed of estimated success rates and reasonable expectations for all therapeutic interventions. It is equally important to identify an end point to medical intervention at the outset of treatment. This end point offers patients a mental time frame in which they can make both medical and personal decisions. One viable alternative for many couples is adoption, although the process of adoption has recently become increasingly complex. Many patients may want to explore simultaneously infertility therapy and adoption. The choice of which course to pursue is a very difficult decision that may be facilitated by both physician input and strong psychosocial counseling and support.

Preservation of Fertility in Cancer Patients

Aside from helping subfertile couples build families, technologic advances in tissue and gamete cryopreservation, in combination with ART, have made future fertility possible for some men and women who are faced with surgery, radiotherapy, or chemotherapy for cancer treatment. Sperm cryopreservation has become a widely available option to allow fertility preservation in young men whose cancer treatment may render them infertile. The wide range of neoplastic disorders for which sperm cryopreservation have been successful include leukemia, lymphoma, Hodgkin's lymphoma, non-Hodgkin's lymphoma, and testicular cancer (538). Although most patients with these disorders are systemically ill and therefore exhibit decreased total motile sperm counts when compared with patients who do not have cancer, less than 20% have azoospermia, and cryopreservation is possible in most patients (538). Further, cryopreserved sperm from cancer patients tolerate thawing as well as samples obtained from patients without cancer (539).

Unfortunately, the efficacy of oocyte cryopreservation lags far behind that of sperm preservation. Married women who are scheduled to undergo sterility-inducing cancer treatments may take the option of completing an IVF cycle so that oocytes can be fertilized and the resulting embryos can be cryopreserved for transfer later in life. However, an IVF cycle may require 2 weeks to complete, rendering this option unrealistic for patients in whom a delay in cancer treatment would compromise their prognosis. Even patients who are able to undergo IVF treatment usually do not have the time necessary for use of a downregulation protocol. Consequently, these women are usually prescribed the shorter, flare protocol, which may give suboptimal response (396). GnRH antagonists may have a special advantage in this situation. GnRH antagonists can induce hypothalamic-pituitary downregulation after being started on day 6 of gonadotropin treatment, which obviates the need for the more time-consuming use of GnRH agonists (540).

Patients who are single or who have medical contraindications to IVF treatment may be candidates for ovarian tissue cryopreservation. Ovarian cortical biopsy specimens containing numerous primordial follicles have been successfully retrieved by a laparoscopic approach in healthy volunteers and in cancer patients (541,542 and 543). It remains to be determined whether this promising technology creates a risk for reintroduction of malignant cells after autotransplantation of ovarian tissue and whether thawed immature oocytes should be used in *in vitro* maturation protocols.

Advances in the ability to document and diagnose early pregnancy have revealed that spontaneous pregnancy loss is a common event. Spontaneous pregnancy loss is, in fact, the most common complication of pregnancy. About 70% of human conceptions fail to achieve viability, and an estimated 50% are lost before the first missed menstrual period (1). Most of these pregnancy losses are unrecognized. Studies using sensitive assays for human chorionic gonadotropin (hCG) indicate that the actual rate of pregnancy loss after implantation is 31% (2). Of pregnancies that are clinically recognized, loss occurs in 15% before 20 weeks of gestation (from last menstrual period) (3,4).

Traditionally, recurrent abortion has been defined as the occurrence of three or more clinically recognized pregnancy losses before 20 weeks from the last menstrual period. Using this definition, recurrent pregnancy loss occurs in about 1 in 300 pregnancies (2). Clinical investigation of pregnancy loss, however, should be initiated after two consecutive spontaneous abortions, especially when fetal heart activity is identified before any of the pregnancy losses, when the woman is older than 35 years of age, or when the couple has had difficulty conceiving. If clinical intervention is undertaken in the form of investigation after two spontaneous abortions, about 1% of pregnant women require evaluation (3). Even with a history of recurrent pregnancy loss, a patient is more likely to carry her next pregnancy to term than to miscarry. For patients with a history of recurrent pregnancy loss, the risk for subsequent pregnancy loss is estimated to be 24% after two clinically recognized losses, 30% after three losses, and 40% to 50% after four losses (5). These data make clinical study of recurrent pregnancy loss and its treatment difficult because very large groups of patients must be studied to demonstrate the effects of any proposed therapeutic intervention.

Etiology

Parental chromosomal abnormalities and thrombotic complications of the antiphospholipid antibody syndrome (APAS) are the only undisputed causes of recurrent abortion. However, collectively these abnormalities account for less than 10% to 15% of recurrent pregnancy losses. Although the exact proportion of patients diagnosed with a particular abnormality may vary among the populations studied, other associations have been made with anatomic abnormalities (12% to 16%), endocrine problems (17% to 20%), infections (0.5% to 5%), and immunologic factors, including those associated with APAS (20% to 50%). Other miscellaneous factors have been implicated and account for about 10% of cases. Even after a thorough evaluation, however, the potential cause remains unexplained in about half of cases (6) (Table 28.1).

Category	Proposed Etiologies for Recurrent Spontaneous Abortion
Genetic Factors	Parental chromosomal abnormalities, including balanced translocations, reciprocal translocations, and Robertsonian translocations.
Anatomic Abnormalities	Uterine anomalies (septate uterus, bicornuate uterus, unicornuate uterus, and congenitally absent uterus), cervical anomalies (cervical incompetence and cervical stenosis), and placental anomalies (placental abruption and placental insufficiency).
Endocrine Abnormalities	Hypothyroidism, hyperthyroidism, and diabetes mellitus.
Maternal Infection	Chlamydia, gonorrhea, and toxoplasmosis.
Immunologic Phenomena	Antiphospholipid antibody syndrome (APAS), autoimmune thyroid disease, and systemic lupus erythematosus.
Cellular Immune Mechanisms	Chromosomal abnormalities and immunologic factors.
Humoral Immune Mechanisms	Antiphospholipid antibody syndrome (APAS).
Other Factors	Maternal age, environmental factors, and psychological stress.

Table 28.1. Proposed Etiologies for Recurrent Spontaneous Abortion

Genetic Factors

The most common inborn parental chromosomal abnormalities contributing to recurrent abortion are balanced translocations (7,8 and 9), in which one

parent carries an overall normal gene content but has a piece of one chromosome inappropriately attached to another. Depending on the nature of the translocation (reciprocal or robertsonian), the gametes produced by the translocation carrier are either normal (reciprocal only), balanced, or unbalanced for the translocated DNA. Once fertilized by a chromosomally normal gamete, the resulting embryos may be either chromosomally normal (reciprocal only) or balanced or unbalanced carriers of the translocation. Most gametes and their resulting embryos with abnormal chromosomal status do not survive. Of those that do, live offspring are either carriers of a balanced translocation or, for robertsonian translocations, monosomic or trisomic for the translocated chromosomal DNA.

Among the possible chromosomal monosomies, only that of the X chromosome typically permits viable offspring. On careful examination, however, many of these offspring may, in fact, exhibit mosaicism. Recent evidence also suggests that embryonic chromosomal monosomy may be particularly prevalent among patients with a history of recurrent pregnancy loss who are undergoing *in vitro* fertilization (10). Compared with monosomies, chromosomal trisomies (e.g., trisomies 13, 18, and 21) appear to be tolerated a bit more readily, although mosaicism may be implicated with these abnormalities as well.

Neither family history alone nor a history of prior term births is sufficient to rule out a potential parental chromosomal abnormality. Whereas the frequency of detecting a parental chromosomal abnormality is inversely related to the number of previous spontaneous losses (9), the chance of detecting a parental chromosomal abnormality also is increased among couples who have never experienced a live birth. Of course, abnormalities may be detected upon parental karyotype analysis of some couples with a history of spontaneous abortions interspersed with stillbirths and live births (with or without congenital anomalies) as well. Unfortunately, the use of parental karyotyping in evaluating structural chromosomal etiologies of recurrent pregnancy loss may soon become an insufficient screening modality. Evidence now suggests that, in some cases, paternal chromosomal abnormalities may be isolated within a particular fertilizing spermatozoa (11). Further, aneuploid spermatozoa may be particularly motile (12).

Other structural chromosome anomalies, such as inversions and insertions, also may contribute to recurrent abortion, as can chromosomal mosaicism and single gene defects. X-linked disorders uncommonly may result in recurrent abortion of male but not female offspring (13). Single gene defects and their resulting disorders (e.g., the delta f 508 mutation and cystic fibrosis) typically are recognized through either analysis of detailed family histories or the identification of some pattern of anomalies characteristic of a known heritable syndrome.

Recently, there has been a great deal of interest in the role of inherited thrombophilias in recurrent pregnancy loss (14,15). This heterogeneous group of disorders results in increased venous or arterial thrombosis. Their associations with pregnancy loss rest on both proven (16) and hypothetical alterations in placental growth and development, particularly placental vascular development. Abnormal placental vascularization and inappropriate placental thrombosis would link these thrombophilic states to pregnancy loss. Although some thrombophilic states may be acquired, most are heritable. Those heritable thrombophilias most often linked with reference to recurrent pregnancy loss include hyperhomocysteinemia, activated protein C resistance associated with mutations in factor V Leiden deficiencies in proteins C and S, mutations in prothrombin, and mutations in antithrombin III.

Circulating homocysteine is derived from dietary methionine. Homocysteine, in turn, is metabolized either into cystathionine or back into methionine (Fig. 28.1). The latter process involves the enzyme *methylene tetrahydrofolate reductase* (MTHFR) (15). The nutritional supplements folic acid, vitamin B₆, and vitamin B₁₂ are all required for proper metabolism of homocysteine; therefore, their deficiency is associated with acquired elevations in circulating homocysteine levels (17,18). Although heritable deficiencies in the enzymes required for metabolism of homocysteine have been described for the pathways leading to cystathionine formation and to reconversion to methionine (14,15), the latter has received considerable attention. Point mutations in MTHFR are surprisingly common (19,20), are associated with hyperhomocysteinemia, and are linked to thrombosis (15). Data directly linking hyperhomocysteinemia, folic acid, vitamin B₁₂, and MTHFR mutations to recurrent pregnancy loss have been contradictory (21,22,23,24 and 25). However, two recent studies have evaluated pooled data from previous investigations (one using metaanalysis), and both studies show these disorders to be linked to risk for recurrent pregnancy loss (15,26).

Figure 28.1 Homocysteine metabolism. Dietary methionine is metabolized either to cystathionine or back into methionine. Conversion of homocysteine to methionine requires transfer of a methyl group from methyltetrahydrofolate. The conversion of folate to methyltetrahydrofolate is a multistep process requiring vitamin B₁₂ and a functional enzyme, methylene tetrahydrofolate reductase (MTHFR). Vitamin B₆ is also required for metabolism of sulfur-containing amino acids such as methionine.

The final steps in the clotting cascade involve the conversion of factor X to factor Xa, a process catalyzed by activated factor IX (in the presence of factor VIII) (Fig. 28.2). Activated factor X (Xa), in turn, catalyzes the conversion of prothrombin (factor II) to thrombin (factor IIa). This conversion involves factor V. Thrombin, in turn, converts fibrinogen to fibrin, an essential building block for stable clot formation. A number of thrombotic control mechanisms have evolved to limit inappropriate clotting. These involve antithrombin III, protein C, and protein S. Fibrinolytic mechanisms, including plasmin-mediated clot dissolution, help limit downstream thrombotic effects.

Figure 28.2 Final pathways involved in clot formation and dissolution. Pathways in *black* are part of the clotting cascade and are prothrombotic. Pathways in *red* limit or inhibit clot formation and aid in clot dissolution. FSP, fibrin split products; TPA, tissue plasminogen activator.

Antithrombin III is a serine protease that inhibits the activity of thrombin as well as factors Xa, XIa, and XIIa. Although antithrombin III mutations are fairly uncommon, their association with thrombotic complications during pregnancy is quite dramatic (15). Some have demonstrated antithrombin III deficiency to represent the worst prognostic factor of all heritable thrombophilias in terms of pregnancy outcome (27). Protein C and protein S both exert their antithrombotic effects at those steps in the clotting cascade that involve conversion of factor X to Xa and conversion of prothrombin to thrombin. Heritable deficiencies in factors C and S have been demonstrated, and each is associated with thrombophilia and pregnancy complications (27). Most recently, genetic mutations in factor V have been described that disallow appropriate interactions with protein C. All mutations may be linked to recurrent fetal loss (27,28 and 29). One of the multiple mutations causing this resistance to activated protein C has been called factor V Leiden. Factor V Leiden results from a heritable point mutation at the cleavage site for factor V (30), and

among white populations, it represents the most common of the genetic causes of thrombophilia (31). Although the available data are limited by studies with small patient numbers, most large studies have noted association between factor V Leiden and recurrent pregnancy loss (19,22,24,27,28 and 29,32,33,34 and 35).

Heritable point mutations in prothrombin (factor II) have been linked to thrombosis and, more specifically, to pregnancy loss (35,36). Factor XII deficiencies have also been reported and appear to be particularly prevalent among Japanese women with recurrent pregnancy loss (37). Associations between fibrinogen and factor XIII defects and fetal loss suggest that interactions between the clotting cascade and pregnancy maintenance involve mechanisms more complex than simple placental thrombosis and infarction (38,39).

In light of the recent completion of the human genome project and the rapid development of novel and improved molecular cytogenetic techniques (40), many advances and additional insight into the contribution of parental genetic abnormalities to recurrent pregnancy loss can be anticipated in the coming years.

Anatomic Abnormalities

Anatomic abnormalities of both the uterine cervix and the uterine body have been associated with recurrent pregnancy loss. These anatomic causes may be either congenital or acquired. During development, the uterus forms by the apposition of a portion of bilateral hollow tubes called the *müllerian ducts*. The dissolution of the walls of these ducts along their site of apposition allows formation of the intrauterine cavity, the intracervical canal, and the upper vagina. Congenital uterine anomalies may, therefore, include incomplete müllerian duct fusion, incomplete septum resorption, and uterine cervical anomalies. Although the causes underlying many of the congenital anomalies of the female reproductive tract are unclear, it has been well documented that prenatal exposure to maternally ingested *diethylstilbestrol* (DES) results in complex congenital uterine, cervical, and vaginal changes.

Historically, all congenital reproductive tract abnormalities have been linked to both isolated spontaneous pregnancy loss and recurrent pregnancy loss (41,42), although the presence of an intrauterine septum and prenatal exposure to DES demonstrate the strongest associations. In fact, women with an intrauterine septum may have as high as a 60% risk for spontaneous abortion (43). Uterine septum-related losses most frequently occur during the second trimester. However, if an embryo implants into the poorly developed endometrium overlying the uterine septum, abnormal placentation and resultant first-trimester losses may occur as well (44). The most common uterine congenital anomaly associated with *in utero* DES exposure is hypoplasia, which may contribute to first- or second-trimester spontaneous abortions, incompetent cervix, and premature labor (45,46). Congenital anomalies of the uterine arteries also may contribute to pregnancy loss through adverse alterations in blood flow to the implanted blastocyst and developing placenta (47).

Acquired anatomic anomalies have likewise been linked to both isolated and recurrent pregnancy losses. These abnormalities include such disparate conditions as intrauterine adhesions, uterine fibroids, and endometriosis. Endometrium that develops over an intrauterine synechiae or over a fibroid that impinges in the intrauterine cavity (submucous) may be inadequately vascularized (48). This may promote abnormal placentation for any embryo attempting to implant over such lesions. Although data supporting these concepts are a bit tenuous, this abnormal placentation may lead to spontaneous pregnancy loss.

Endocrine Abnormalities

The endocrinology of normal pregnancy is complex. Because spontaneous pregnancy is critically dependent on appropriately timed endocrinologic changes of the menstrual cycle, it is not surprising that those endocrine abnormalities that ultimately alter pregnancy maintenance may mediate their effects during the follicular phase of the cycle in which conception occurs, or even earlier. Modifications in follicular development and ovulation, in turn, may be reflected in abnormalities of blastocyst transport and development, alterations in uterine receptivity to the implanting blastocyst, and improper functioning of the corpus luteum. Beginning with ovulation and lasting until about 7 to 9 weeks of gestation, maintenance of early pregnancy depends on the production of progesterone by the corpus luteum. Normal pregnancies are characterized by a luteal-placental shift at about 7 to 9 weeks of gestation, during which the developing placental trophoblast cells take over progesterone production and pregnancy maintenance (49). Spontaneous pregnancy losses occurring before 10 weeks of gestation may result from a number of alterations in normal progesterone production or use. These include failure of the corpus luteum to produce sufficient quantities of progesterone, impaired delivery of progesterone to the uterus, or inappropriate use of progesterone by the uterine decidua. Pregnancy failures may also occur near the time of the expected luteal-placental shift if the trophoblast is unable to produce biologically active progesterone after demise of the corpus luteum.

Endocrinologic factors associated with recurrent abortion include luteal-phase insufficiency, diabetes mellitus thyroid disease, and potentially, hyperprolactinemia and decreased ovarian reserve. Luteal-phase insufficiency or luteal-phase defects (LPDs) are characterized by inadequate luteal milestones and most likely relate to adverse pregnancy outcome through inadequate or improperly timed endometrial development at potential implantation sites. LPD has many causes, some of which are associated with hypersecretion of luteinizing hormone. Although the mechanism underlying the association of elevated luteinizing hormone (LH) levels with recurrent pregnancy loss remains incompletely understood, abnormal LH secretion may have direct effects on the developing oocyte (premature aging), on the endometrium (dyssynchronous maturation), or both. Many patients with elevated LH levels also display physical, endocrinologic, and metabolic characteristics of polycystic ovarian syndrome (PCOS). In fact, some studies report ovarian radiologic evidence of PCOS in as many as 80% of recurrent pregnancy loss patients (50). In addition to inappropriately elevated LH levels, PCOS patients are frequently obese and often have elevated circulating androgen levels. Although not undisputed (51), both changes have been linked to recurrent pregnancy loss (50,52), and elevated androgen levels have been shown to effect markers of uterine receptivity adversely in women with a history of recurrent pregnancy loss (53).

Many women with PCOS have metabolic alterations in glycemic control characterized by insulin resistance. This too may be directly or indirectly related to adverse pregnancy outcome, and it may be related to the mechanisms for spontaneous pregnancy loss among women with type II diabetes mellitus (54). Women with overt insulin-dependent diabetes mellitus (IDDM) appear to exhibit a threshold of pregestational glycemic control above which spontaneous pregnancy loss is increased (55,56). In fact, hyperglycemia has now been directly linked to embryonic damage (57). In cases of advanced IDDM with accompanying vascular complications, compromised blood flow to the uterus may be mechanistically involved in subsequent pregnancy loss.

Patients with thyroid disease often have concomitant reproductive abnormalities, including ovulatory dysfunction and LPDs. In addition, the metabolic demands of early pregnancy mandate an increased requirement for thyroid hormones. It is therefore not surprising that hypothyroidism has been associated with spontaneous pregnancy loss and with recurrent pregnancy loss (58). Although it continues to be debated, evidence suggests that, even in clinically euthyroid patients, the presence of antithyroid antibodies might be associated with recurrent pregnancy loss (59,60,61 and 62). The mechanism for this association remains unclear; however, these antibodies could be markers of more generalized autoimmunity or may predict an impaired ability of the thyroid gland to respond to the demands of pregnancy.

Two additional endocrinologic abnormalities have been linked to recurrent pregnancy loss, although support for these associations and their mechanistic pathways remains shrouded in controversy. The relationship of hyperprolactinemia with recurrent pregnancy loss continues to be debated. Animal models suggest that elevated prolactin levels may adversely affect corpus luteal function; however, this concept is not well supported in humans (63,64). Some have suggested that elevated prolactin levels may promote pregnancy wastage by direct effects on the endometrium or indirect immunomodulatory mechanisms (65). Most recently, attempts have been made to correlate markers of ovarian reserve (day 3 follicle-stimulating hormone, day 3 estradiol, response to the clomiphene challenge test) with recurrent pregnancy loss (51,66,67). At present, no consensus exists concerning this potential association.

Maternal Infection

The association of infection with recurrent abortion is among the most controversial and poorly explored of the potential causes of pregnancy loss. Reproductive tract infections with bacterial, viral, parasitic, zoonotic, and fungal organisms have all been linked theoretically to pregnancy loss; however, mycoplasma, ureaplasma, chlamydia, and b-streptococcus are the most commonly studied pathogens (68,69). More recent data have directly addressed the roles of some of these proposed organisms in recurrent pregnancy loss. One prospective comparison trial involving 70 recurrent pregnancy loss patients reported no elevations in any markers for present or past infection with *Chlamydia trachomatis* when compared with controls (70). In contrast, a very large, prospective trial demonstrated a link between the detection of bacterial vaginosis and history of second-trimester pregnancy loss among 500 recurrent pregnancy loss patients (71). The risk for bacterial vaginosis detection was also positively correlated with cigarette smoking in this study.

The etiologic mechanism linking specific organisms to either isolated or recurrent pregnancy loss remains unclear and must certainly differ among infectious organisms. Certain viral organisms, such as herpes simplex virus (72) and human cytomegalovirus (73), can directly infect the placenta and fetus (72,73). The resulting villitis and related tissue destruction may lead to pregnancy disruption. Another theoretical possibility warranting study is that infection-associated early pregnancy loss may result from immunologic activation in response to pathologic organisms. A large body of evidence supports the role of this mechanism in adverse

events later in gestation, such as intrauterine growth restriction (74), premature rupture of membranes, and preterm birth (75). Alternatively, mechanisms that protect the fetus from autoimmune rejection also may protect virally infected placental cells from recognition and clearance. This could potentially promote periods of unfettered infectious growth for some of the pathogenic organisms gaining entry to the reproductive tract (76).

Immunologic Phenomena

In recent years, there has been extensive information published concerning the possible immunologic causes and treatments of recurrent pregnancy loss. However, there is a lack of consensus regarding the mechanisms and the impact of therapeutic intervention because the detection of a therapeutic effect is difficult in the absence of very large studies. This situation reflects the fact that many recurrent pregnancy loss patients present after their index pregnancy has expired but before being expelled. In these cases, the physiologic immune reaction to the presence of nonviable tissue may mask any alternative, underlying immune causes of the demise itself. Finally, it is very likely that there are a wide variety of immune alterations that may result in the same end point—isolated or recurrent pregnancy loss. This latter theory is certainly supported by a recent review article that lists 10 well-supported immune mechanisms that are each potentially important in pregnancy maintenance (77).

Before launching into the most commonly accepted causes of immune-mediated pregnancy loss, a brief review of some of the important concepts in basic immunology is warranted (Table 28.2). Although these descriptions are presented in general terms and are further defined in Chapter 6, they should serve as useful reference for the ensuing information.

Table 28.2. Concepts in Reproductive Immunology

Immune responses classically are divided into innate and acquired responses. *Innate responses* represent the body's first line of defense against pathogenic invasion. They are rapid and are not antigen specific. Cell types and mechanisms typically considered vital to innate immunity include complement activation, phagocytosis by macrophage, and lysis by natural killer (NK) cells and possibly by T-cell receptor-gd-positive (TCR-gd⁺) T cells (see later). *Acquired immune responses*, in contrast, are antigen specific and are largely mediated by T cells and B cells. Acquired responses can be further divided into *primary* (response associated with initial antigen contact) and *secondary* (rapid and powerful amnestic response associated with subsequent contact to the same antigen).

Antigen specificity is generally regulated by two sets of genes in the major histocompatibility complex (MHC), located on chromosome 6 in humans. Class I MHC molecules [human leukocyte antigens (HLA) A, B, and C] are present on the surface of nearly every cell in the human body and are important in defense against intracellular pathogens, such as viral infection and oncogenic transformation. Class I MHC molecules act as important ligands for both the TCR on CD8⁺ cytotoxic and suppressor T cells and for a variety of receptors on NK cells (78). Class II MHC molecules (HLA-DR, HLA-DP, and HLA-DQ), in contrast, are present on the surface of a limited number of antigen-presenting cells, including dendritic cells, macrophage-monocytes, B cells, and tissue-specific cells, such as the Langerhans cells in the skin. These molecules are important in defense against extracellular pathogens, such as bacterial invaders. The major ligand for class II MHC is the TCR on CD4⁺ T-helper cells.

One very important concept in immunology that has particular application to pregnancy is that of immune tolerance. It has been well described that bone marrow-derived T cells pass through the fetal thymus during early development. During this developmental interval, the T cells encounter a process termed *thymic education*. During thymic education, T cells are chosen that express either the CD4 or the CD8 co-receptor, and autoreactive cells are effectively eliminated. In short, this education promotes T-cell tolerance, allowing selection and survival only of those T cells that can recognize nonself but will not react against self.

These immunologic characteristics have all been thoroughly described and investigated for the immune effector cells populating the peripheral immune system. The peripheral immune system consists of the spleen and peripheral blood, and it is generally responsible for protection against blood-borne pathogens. Pathogens that enter through the extensive surface areas of the lacrimal ducts, respiratory system, gastrointestinal tract, mammary ducts, and genitourinary tract encounter a very distinct and important immune environment—that of the mucosal immune system. Although the mucosal immune system may be primarily responsible for the initial protection against most exogenous pathogens, an understanding of its immune characteristics has lagged far behind that of the peripheral immune system. Insight into the specific characteristics of immunity within the reproductive tract is even further limited.

Cellular Immune Mechanisms

Many of the immune theories surrounding the causes of isolated and recurrent spontaneous pregnancy losses have stemmed from attempts to define immunologic rules as they apply specifically to the mucosal reproductive tract. Four main questions summarize much of the theoretical thinking surrounding pregnancy maintenance and reproductive immunology:

1. Which immune cells populate the reproductive tract, particularly at implantation sites?
2. How do these cells arrive at this mucosal immune site, and are they educated in the same way as those populating the periphery?
3. How do the characteristics of antigen presentation differ at the maternal–fetal interface?
4. What regulatory mechanisms specifically affect reproductive tract immune cells?

Resident Cells Immune cells populating the reproductive tract exhibit many characteristics that distinguish them from their peripheral counterparts. In particular, the human endometrium is populated by T cells, macrophage, and NK-like cells, but very few B cells are present (79,80). The relative proportions of these resident cells vary with the menstrual cycle and change dramatically during early pregnancy. In fact, surrounding the time of implantation, one particular cell type composes between 70% to 80% of the total endometrial lymphocyte populations (79,80). This cell type is called a variety of names, including *decidual granular lymphocytes*, *large granular lymphocytes*, and *decidual NK cells*. This heterogeneity of names reflects the fact that this particular cell type differs from similar cells isolated from the periphery, although most believe it to be an NK cell variant. If we do consider them to be NK cells, the implantation site represents the largest accumulation of NK cells in any state of human health or disease. The true function of these cells remains unclear, but their remarkable abundance at the maternal–fetal interface makes their further study compelling (81,82). Other immune cells have been described in the periphery that have characteristics of both NK cells and T cells. These NKT cells have recently been demonstrated to play a role in pregnancy loss in animal models (83), and their presence in the decidua in humans is now being investigated.

In the peripheral immune compartment, most T cells express a TCR composed of an ab heterodimer (TCR-ab⁺). In addition to TCR-ab⁺ T cells, the human reproductive tract also is populated by a subset of T cells with a distinctive TCR composed of the gd heterodimer (TCR-gd⁺), and the numbers of these cells increases in early pregnancy (84,85 and 86). TCR-gd⁺ T cells appear to fulfill functions quite distinct from their TCR-ab⁺ counterparts; functions that may include direct, non-MHC-restricted recognition of antigens within tissues (87). In fact, TCR-gd⁺ T cells may fill a protective niche missed or poorly covered by B cells and TCR-ab⁺ T cells. The role and importance of TCR-gd⁺ cells in the reproductive tract and, more particularly, in pregnancy maintenance deserves further attention.

Finally, it has been suggested that a subset of macrophage, termed *suppressor macrophage*, may be implicated in pregnancy maintenance. These specific cells differ from typical macrophage in their promotion of antiinflammatory effects, and they have been detected in normal murine placenta (88). Their presence in human

decidual specimens requires further investigation.

The human decidua is populated by characteristic immune effector cells. To date, investigations into whether alterations in these cells (including T cells, decidual NK cells, and NKT cells) determine pregnancy outcome have been hampered by insufficient patient numbers to allow meaningful conclusions. Still, these immune cell populations have been repeatedly reported to be altered in recurrent pregnancy loss patients ([89,90,91,92](#) and [93](#)) but not in patients experiencing isolated spontaneous pregnancy losses ([86](#)).

Immune Cell Education and Homing to the Reproductive Tract The implanting fetus represents the most common model of allograft acceptance. How the maternal immune system avoids rejection of the implanting fetus in an uncomplicated pregnancy invokes the presence of some manifestation of immune tolerance. This, in turn, begs the questions of how the resident decidual immune effector cells are selected and educated, how they home to reproductive sites, and how they are maintained once they reach this destination. Animal studies have suggested that the rules for selection and maintenance of these cells, in terms of their requirement for MHC and their education within the thymus, may be distinct from those governing either peripheral immune cells or cells within other mucosal sites, including the intestine ([94](#)). Although the results of most studies are preliminary, it appears that the human reproductive tract displays similar characteristics—the immunophenotypes of immune cells populating the human reproductive tract are distinct from both the periphery and from other mucosal sites ([95](#)). The education of TCR-gd⁺ cells populating epithelial sites may occur outside the thymus and might involve mechanisms that substitute for or modify interaction with MHC ([86,96](#)). The development of MHC specificity among NK cells is presently being carefully dissected in animal models ([97,98](#)) with the hope that these investigations will shed light on similar processes in humans and, more specifically, on the selection and maintenance characteristics of decidual NK cells.

It is now becoming increasingly evident that the cells populating mucosal immune tissues select these sites through interactions between cell surface molecules on the immune cell (integrins) and cell surface molecules on the endothelial cells of blood vessels within the mucosal tissues (e.g., selectins, vascular adhesion molecule VCAM). This cellular recruitment process, called homing, has been most thoroughly described for the intestine ([99,100](#)). However, both murine ([99,101](#)) and human ([102](#)) reproductive tract tissues do express these integrin–vascular ligand pairs. The extension of these findings to pregnancy maintenance will surely prove fruitful. Solving the mechanisms of selection, education, and maintenance of reproductive tract immune effector cells is of paramount importance. Until we understand these vital processes in the normal state, we cannot define the effects that alterations will have on human disease, nor can we develop therapeutic interventions.

Antigen Presentation at the Maternal–Fetal Interface Historically, it was proposed that one method by which the implanting trophoblastic allograft could potentially avoid immune detection by the maternal host would be by making itself antigenically invisible. It could downregulate its expression of the MHC-encoded transplantation antigens (some of which would be of paternal origin) and thereby avoid recognition as nonself. Although current knowledge of immunology now makes this theory somewhat obsolete ([103](#)), the implanting fetus does, in fact, use this strategy to some extent. It is certainly true that placental trophoblast cells do not express class II MHC molecules ([104,105](#)).

Unlike nearly every other cell in the human body, trophoblast cells do not express the classic class I MHC transplantation antigens HLA-A and -B. Rather, a subpopulation of placental cells, specifically the extravillous cytotrophoblast cells, express the classic class MHC I HLA-C products and the nonclassic HLA-E and -G products ([76,106,107,108,109,110](#) and [111](#)). These extravillous cytotrophoblast cells are of particular interest because they are characterized by remarkable invasive potential ([112](#)). In fact, these cells move from the tips of the anchoring villi of the human placenta and invade deeply into the maternal decidua. Further, they can replace cells within the walls of decidual arterial vessels ([112,113](#)). Although the invasive characteristics of extravillous cytotrophoblast may reflect non–MHC-related mechanisms, including well-described integrin switching ([114](#)), the intimate contact of these fetal-derived cells with maternal immune effector cells certainly exposes the fetus to recognition as nonself.

It is not known why all placental cells downregulate expression of HLA-A and -B, whereas invasive extravillous cytotrophoblast cells express HLA-C, -E, and -G. However, this area of investigation is ripe with hypotheses and study. Because NK cells of the innate immune system recognize and kill cells that express no MHC ([103](#)), the complete downregulation of MHC would cause trophoblast cells to act as targets for those NK cells that are pervasive at sites of implantation. In addition to possible protection from direct NK cell–mediated killing, the expression of HLA-C, -E, and -G by trophoblast cells may serve a variety of alternative roles. NK cell receptor–mediated interactions with extravillous cytotrophoblast MHC could modulate cytokine expression profiles at the maternal–fetal interface ([81,82](#)). MHC expression may aid in decidual and vascular invasion by the trophoblast, an activity essential for proper placental development ([115](#)). Whereas definitive correlations between placental class I MHC expression patterns and recurrent pregnancy loss have yet to be reported, trophoblast expression of HLA-G has been linked to other disorders of placental invasion, such as preeclampsia ([115,116](#)). Finally, soluble or secreted trophoblast MHC products may aid in the development of maternal immune tolerance toward the placenta ([117](#)).

To date, the study of newly described trophoblast class I MHC products in recurrent pregnancy loss remains limited. However, the results of two small studies investigating the possible association between polymorphisms in these MHC products and recurrent pregnancy loss have been negative ([118,119](#)). Aberrant expression of class II MHC determinants, or enhanced expression of class I MHC on syncytiotrophoblasts occurring in response to interferon-g (IFN-g), could mediate abortion by enhancing cytotoxic T-cell attack ([120,121](#)). This theory appears unlikely, however, because the expression of classic MHC antigens does not appear to be induced on aborted tissues from women experiencing one or more pregnancy losses ([122](#)). Finally, class II MHC genotypes appear to affect susceptibility to a variety of diseases, including diabetes and other autoimmune diseases. A similar link between MHC class II typing and adverse pregnancy outcome has been reported for recurrent pregnancy loss ([123,124](#)).

Regulation of Decidual Immune Cells The characteristics of the interactions between decidual immune effector cells and the implanting fetus may be determined by factors other than those already mentioned. Local regulation of the cells that populate the human decidua will further modify the effects of selection, maintenance, and homing as well as the distinctive characteristics of antigen presentation at the maternal–fetal interface. As might be predicted, these regulatory effects are often targets for investigative efforts because they may offer more direct insight into potential therapies for immune-mediated disorders of pregnancy maintenance. Three such regulatory mechanisms are discussed here: (a) alterations in T-helper cell phenotypes, (b) reproductive hormones and immunosuppression, and (c) tryptophan metabolism.

As discussed in [Chapter 6](#), antigen-stimulated immune responses involving CD4⁺ T cells can be divided into two major classes: T-helper cell subset 1 (T_H1) responses and T-helper cell subset 2 (T_H2) responses. This subclassification is based on the characteristics of the CD4⁺ cells present as well as on their associated cytokines. The production of these responses rests on the environment in which relatively undifferentiated CD4⁺ T_H0 cells become differentiated. Thus, T_H0 cells exposed to IFN-g become T_H1-type cells, and those exposed to interleukin-4 (IL-4) become T_H2-type cells ([125](#)). T_H1 responses are associated with inflammation and primarily involve IFN-g and IL-12 but also involve IL-2 and tumor necrosis factor- β (TNF- β). T_H2 cell responses are associated with antibody production and the cytokines IL-10, IL-4, IL-5, and IL-6 ([126,127](#) and [128](#)). Although TNF- α can be secreted by both T_H1 and T_H2 cells, it is most often characteristic of a T_H1 response ([129,130](#)). A reciprocal regulating relationship exists between T_H1 and T_H2 cells and cytokines ([131,132,133](#) and [134](#)), with one response supporting its own persistence while averting conversion to the other.

Extending these immune regulatory phenomena to pregnancy, the type of CD4⁺ cellular response to the implanting fetus is controlled not only by the types of cells (e.g., T-helper cells) in the decidua but also by the cytokine environment at the maternal–fetal interface. As mentioned previously, the human endometrium and decidua are replete with immune and inflammatory cells capable of cytokine secretion ([135,136,137,138](#) and [139](#)). Cytokines may affect reproductive events either directly or indirectly, depending on the specific cytokines secreted, their concentrations, and the differentiation stage of potential reproductive target tissues. It is now well documented that T_H1-type cytokines can be harmful to an implanting embryo ([140,141](#) and [142](#)). Further, most agree that some patients with recurrent pregnancy loss exhibit a dysregulation of their T-helper cellular immune response to antigens at the site of implantation, with typical shifts toward T_H1 inflammatory responses ([143,144,145](#) and [146](#)). Depending on the individual series, 60% to 80% of nonpregnant women with a history of otherwise unexplained recurrent spontaneous abortion have been found to have evidence of abnormal *in vitro* T_H1 cellular immune responses. Fewer than 3% of women with normal reproductive histories demonstrate these responses ([143,145,146](#) and [147](#)). Rather, most women with normal pregnancies have a T_H2 immune response to trophoblast antigens ([146](#)).

Methods for the documentation of cytokine dysregulation among recurrent pregnancy loss patients also vary among investigators, but groups have recently confirmed this abnormality within the endometrium ([148,149](#) and [150](#)) or among immune cells isolated from the decidua ([151](#)) of these patients. Others use peripheral lymphocytes from women with a history of recurrent pregnancy loss and stimulate them *in vitro* with trophoblast antigens ([146,152,153](#)). One study documented aberrant cytokine secretion when peripheral blood lymphocytes (PBLs) from recurrent pregnancy loss patients were stimulated *in vitro* by HLA-G bearing cells ([154](#)), whereas another study demonstrated that decidual and peripheral immune cells exhibit a shift toward the T_H2 phenotype when exposed to HLA-G ([155](#)). Whether peripheral cytokine levels reflect T-helper cell dysregulation at the maternal–fetal interface or whether this dysregulation affects peripheral as well as local immune response during pregnancy remains controversial ([156,157](#) and [158](#)). Finally, as with all immune theories, there appears to be significant redundancy in the necessity

for particular cytokines and soluble immunoregulatory factors at the site of implantation. To date, animal models with directed gene deletions have shown only one of these factors to be absolutely essential to pregnancy maintenance—leukemia inhibitory factor (LIF) is required for blastocyst implantation (159), but not for subsequent embryogenesis (160). Interestingly, LIF induces the transcription of HLA-G *in vitro* in human placental cells (161).

Although many mechanisms are aimed at avoiding maternal immune recognition of the implanting fetus, research in both humans and animals indicates that immune responses to fetal antigens can be detected (162,163 and 164). Thus, the regulation of this response at the maternal–fetal interface may be critical. The concept that successful pregnancy requires some form of generalized suppression of maternal immune response is supported by reports that failure to downregulate maternal responses to recall antigens, such as tetanus toxoid and influenza, is associated with poor pregnancy outcome among recurrent pregnancy loss patients (165). Reproductive hormones have dramatic effects on peripheral cell-mediated immunity, as demonstrated by well-documented and notable gender differences in immune responsiveness (166). The levels of these potentially immunosuppressive hormones are quite elevated in pregnant women. The fact that the levels of these hormones at the maternal–fetal interface may be far above those in the maternal circulation during pregnancy (167) may explain an apparent inconsistency: overall immune responsiveness during pregnancy appears to change little, whereas local suppression at the maternal–fetal interface may be vital.

It has been suggested for some time that the immunosuppressive effects of progesterone within the reproductive tract are at least partially responsible for the maintenance of the semiallogeneic implanting fetus (168). *In vitro* studies have shown that the progesterone mediates its suppression of T-cell effector function by alterations in membrane-resident potassium channels and cell membrane depolarization. This action, in turn, affects intracellular calcium signaling cascades and gene expression (169) and may be non-receptor mediated (170). Progesterone-mediated changes in T-cell gene expression have been associated with the development of T_H2-type responses and with increased LIF expression (151,171). Because a shift in the intrauterine immune environment from T_H2 to T_H1 has been linked to early spontaneous pregnancy loss (146,151), the elevated intrauterine concentrations of progesterone characteristic of early pregnancy may promote an immune environment favoring pregnancy maintenance. To this point, recent *in vitro* evidence indicates that progesterone can inhibit both mitogen-induced proliferation of and cytokine secretion by CD8⁺ T cells (172).

Levels of estrogen also rise dramatically during pregnancy, and attention has focused on the role of estrogen in immune modulation. A group of animal studies has shown that estrogens improve immune responses in males after significant trauma and hemorrhage (173), suppress cell-mediated immunity after thermal injury (174), and protect against chronic renal allograft rejection (175). *In vitro*, estrogens appear to downregulate delayed-type hypersensitivity reactions and promote the development of T_H2-type immune responses, particularly at the elevated estrogen concentrations typical of pregnancy (176,177).

One additional regulatory mechanism proposed for the induction of maternal tolerance to the fetal allograft involves the amino acid tryptophan and its catabolizing enzyme indoleamine 2,3-dioxygenase (IDO). The IDO hypothesis of tolerance in pregnancy rests on data that T cells need tryptophan for activation and proliferation (178) and that local alterations in tryptophan metabolism at the maternal–fetal interface could either activate or fail to suppress maternal antifetal immunoreactivity (179). Recent studies in mice have shown that the inhibition of IDO leads to loss of allogeneic, but not syngeneic, fetuses and that this effect is mediated by lymphocytes (180). Further support lies in studies demonstrating that hamsters fed diets high in tryptophan have increased rates of fetal wastage (181). Extending this theory to humans requires further investigation. However, the demonstration of IDO expression in human uterine decidua (182) and the documentation of alterations in serum tryptophan levels with increasing gestational age during human pregnancy (183) both support further interest in this potential local immunoregulatory mechanism.

Endometriosis is the growth of both endometrial glands and stroma outside of the intrauterine cavity. Although associations between the development of endometriosis and immunologic abnormalities are now being defined (184), the link between endometriosis and recurrent pregnancy loss remains contentious. Recurrent pregnancy loss in the presence of endometriosis certainly would involve the interaction of complex mechanisms, some of which may involve cellular or humoral dysfunction (185,186).

Humoral Immune Mechanisms

Humoral responses to pregnancy-specific antigens exist, and patients with recurrent pregnancy loss can display altered humoral responses to endometrial antigens (187) (Table 28.2). Nevertheless, most of literature surrounding humoral immune responses and recurrent pregnancy loss focus on organ-nonspecific autoantibodies associated with APAS. Historically, these immunoglobulin G (IgG) and IgM antibodies were thought to be directed against negatively charged phospholipids. Those phospholipids most often implicated in recurrent pregnancy loss are cardiolipin and phosphatidylserine. Most recently, however, it has been shown that antiphospholipid antibodies often are directed against a protein cofactor, called b₂ glycoprotein 1, that assists antibody association with the phospholipid (188,189). Antiphospholipid antibodies were originally characterized by prolonged phospholipid-dependent coagulation tests *in vitro* [activated partial thromboplastin time (aPTT), Russell viper venom time] and by thrombosis *in vivo*. The association of these antiphospholipid antibodies with thrombotic complications has been termed the *antiphospholipid syndrome*, and although many of these complications are systemic, some are pregnancy specific—spontaneous abortion, preterm labor, premature rupture of membranes, stillbirth, intrauterine growth retardation, and preeclampsia (190). A recent reassessment of the criteria used to diagnose APAS was undertaken during a postconference workshop after the Eighth International Symposium on Antiphospholipid Antibodies held in 1998 in Sapporo, Japan (191). This reassessment resulted in the Sapporo criteria for diagnosis of APAS, which include adverse pregnancy outcomes. These criteria, which have been validated clinically (192), are as follows:

For a patient to be diagnosed with antiphospholipid antibody syndrome, one or more clinical and one or more laboratory criteria must be present:

Clinical

1. One or more confirmed episodes of vascular thrombosis of any type
 - Venous
 - Arterial
 - Small vessel
2. Pregnancy complications
 - Three or more consecutive spontaneous pregnancy losses at less than 10 weeks of gestation
 - One or more fetal deaths at greater than 10 weeks of gestation
 - One or more preterm births at less than 34 weeks of gestation secondary to severe preeclampsia or placental insufficiency

Laboratory (testing must be positive on two or more occasions, 6 weeks or more apart)

1. Positive plasma levels of anticardiolipin antibodies of the IgG or IgM isotype at medium to high levels
2. Positive plasma levels of lupus anticoagulant

The presence of antiphospholipid antibodies (anticardiolipin or lupus anticoagulant) during pregnancy is a major risk factor for adverse pregnancy outcome (193). In large series of couples with recurrent abortion, the incidence of the antiphospholipid syndrome was between 3% and 5% (68). The presence of anticardiolipin antibodies among patients with known systemic lupus erythematosus portends less favorable pregnancy outcome (194).

A number of mechanisms have been proposed by which antiphospholipid antibodies might mediate pregnancy loss. Antibodies against phospholipids could increase thromboxane and decrease prostacyclin synthesis within placental vessels. The resultant prothrombotic environment could promote vascular constriction, platelet adhesion, and placental infarction (195,196 and 197). Alternatively, *in vitro* evidence from trophoblast cell lines indicates that IgM action against phosphatidylserine inhibits formation of syncytial trophoblast (198). Syncytialization is, of course, required for proper placental function. One study demonstrated that both extravillous cytotrophoblast and syncytiotrophoblast cells synthesize b₂ glycoprotein 1, the essential cofactor for antiphospholipid antibody binding (199). Although it has been investigated, data surrounding the prognostic value of serum levels of specific antibodies against b₂ glycoprotein 1 with respect to pregnancy outcome among recurrent pregnancy loss patients remain inconsistent (200,201). Some have proposed that sera from antibody-positive recurrent pregnancy loss patients is particularly adept at inhibiting trophoblast adhesion to endothelial cells *in vitro* (202). Others have noted rapid development of atherosclerosis in the decidual spiral arteries of patients who test positive for antiphospholipid antibodies (203). Finally, still others have suggested that levels of the placental antithrombotic molecule—annexin V—are reduced within the placental villa from those women with recurrent pregnancy loss who are antiphospholipid antibody positive (204). It must be mentioned, however, that placental pathologic evidence supporting causal involvement of the antiphospholipid antibody syndrome in pregnancy loss is often equivocal. The characteristic lesions for this syndrome (placental infarction, abruption, and hemorrhage) are often missing in women with antiphospholipid antibodies

(205), and these same pathologic lesions can be found in placentas from women with recurrent abortion who do not have biochemical evidence of antiphospholipid antibodies (206).

One additional group of autoantibodies that have been linked to recurrent pregnancy loss is the antithyroid antibodies (ATAs). Although the data remain somewhat controversial (207,208), one large retrospective study has demonstrated an increased prevalence of these antibodies among women with a history of recurrent pregnancy loss, even in the absence of thyroid endocrinologic abnormalities (62). The overall significance of ATAs, however, is unclear. In fact, one study recently reported that the presence of serum ATA had no effect on pregnancy outcome in euthyroid pregnant patients with a history of recurrent pregnancy loss (60).

Other antibody-mediated mechanisms for recurrent abortion have been proposed, including antisperm and antitrophoblast antibodies, as well as blocking antibody deficiency. Although each hypothesis has been shown to have minimal relevance to recurrent pregnancy loss (68,121), their discussion is warranted because therapies aimed at these disorders persist. Historically, the blocking antibody deficiency hypothesis has received the most attention. This hypothesis is based on a supposition that blocking factors (presumably antibodies) were required to prevent a maternal, cell-mediated, antifetal immune response that was believed to occur in all pregnancies. It was therefore proposed that, in the absence of these blocking antibodies, abortion occurred (209,210). This supposition has never been consistently substantiated (211,212). For instance, maternal hyporesponsiveness in mixed lymphocyte culture with paternal stimulator cells was originally proposed to identify women with deficient blocking activity (210). Investigations based on this type of testing were continued by others (213,214), who proposed that parental HLA sharing resulted in a predisposition to blocking antibody deficiency. These reports were of limited sample size, were retrospective in nature, and lacked population-based controls. One prospective, population-based control study conclusively demonstrated that HLA heterogeneity was not essential for successful pregnancy (215). However, follow-up studies have now shown that, in the exceedingly rare case of complete sharing of the entire HLA region, spontaneous pregnancy losses do increase (216). This particular 10-year prospective trial concluded, however, that HLA typing is of no use in outbred populations because only isolated and significantly inbred populations have such HLA homogeneity. Further evidence refuting the blocking antibody hypothesis for recurrent abortion comes from reports of successful pregnancies both among women who do not produce serum factors capable of mixed lymphocyte culture inhibition (210) and among women who do not produce antipaternal cytotoxic antibodies (211). Those mixed lymphocyte culture results that demonstrate hyporesponsiveness in some recurrent pregnancy loss patients are now believed to represent the effect of the pregnancy loss rather than the cause of recurrent abortion (164,210,211 and 212).

One last theory that arose out of the blocking antibody investigations involved a novel HLA-linked alloantigen system. The finding that polyclonal rabbit antisera could recognize both lymphocytes and trophoblast cells suggested to some the presence of trophoblast–lymphocyte cross-reactive alloantigens (called TLXes) (217). These TLXes were, in turn, linked to maternal blocking antibody deficiency and recurrent pregnancy loss. The TLX hypothesis is now of historical relevance only because this theory was invalidated when TLX was found to be identical to CD46, a complement receptor that is thought to protect the placenta from complement-mediated attack (218). CD46 was not a novel alloantigen. It can be found on a wide variety of cells, thus explaining the cross-reactive nature of the original rabbit antisera.

It is important to conclude this in-depth discussion of the immune-mediated mechanisms of isolated and recurrent pregnancy loss by suggesting that pregnancy may not require an intact maternal immune system. Supporting this concept are data showing that agammaglobulinemic animals and women can successfully reproduce (219). Further, viable births also occur among women with severe immune deficiencies and in murine models that lack T and B cells (SCID mice) and those that display a congenital absence of their thymus (nude mice). Still, immune factors may play important roles in a significant proportion of patients with recurrent pregnancy loss, and their presence is the subject of immense amounts of research. Until this role is better defined, an understanding of the contemporary immunologic hypotheses allows for the informed consideration of novel findings.

Other Factors

It is now becoming increasingly evident that the implantation of the blastocyst within the uterine decidua represents an exquisitely scripted cross-talk between embryo and mother. Alterations in this dialogue often result in improper implantation and placental development. For instance, recurrent pregnancy loss has been linked to a dysregulation in the expression patterns of vascular endothelial growth factors on the developing placenta and their requisite receptors within the maternal decidua (220). Cellular and extracellular matrix adhesion properties may also be involved in this dialogue. Lessey recently reviewed the concept of uterine receptivity, with particular emphasis on the importance of integrins and the timing of integrin switching in implantation (221). Others have reported decreased levels of endometrial mucin secretion (222) and reductions in the endometrial release of soluble intercellular adhesion molecule I (223) among women with a history of recurrent pregnancy loss. Programmed cell death (apoptosis) may also play an essential role in normal placental development. Alterations in two important apoptotic pathways—Fas-Fas ligand and bcl2—have both been linked to recurrent pregnancy loss and poor pregnancy outcome (77,224).

A variety of environmental factors have been linked to sporadic and recurrent early spontaneous pregnancy loss. These are difficult studies to perform because, in humans, they must all be retrospective and are all confounded by alternative or additional environmental exposures. Nevertheless, the following factors have been linked to pregnancy loss: exposure to medications (e.g., antiprogesterones, antineoplastic agents, and inhalation anesthetics), exposure to ionizing radiation, prolonged exposure to organic solvents, and exposure to environmental toxins, especially heavy metals (225,226,227 and 228). The latter has recently been demonstrated to have both endocrine and immune effects that could lead to poor placentation and subsequent pregnancy loss (229). Associations between spontaneous pregnancy loss and exposures to video display terminals, microwave ovens, high-energy electric power lines, and high altitudes (e.g., flight attendants) have not been substantiated (230,231). There is no compelling evidence that moderate exercise during pregnancy is associated with spontaneous abortion. In the absence of cervical anatomic abnormalities or incompetent cervix, coitus does not appear to increase the risk for spontaneous pregnancy loss (232,233). Exposure to three particular substances—alcohol, cigarettes, and caffeine—deserves specific attention. Although some conflicting data exist (234,235), one very large epidemiologic study has shown that alcohol consumption during the first trimester of pregnancy, at levels as low as three drinks per week, is associated with an increased incidence of spontaneous pregnancy loss (236). Cigarette smoking has also been linked to early spontaneous pregnancy loss (237,238); however, this is also not without controversy (239). Interestingly, alcohol and tobacco intake in the male partner correlates with the incidence of domestic violence, which in turn is associated with early pregnancy loss (240). Finally, recent evidence adds to a growing body of literature that consumption of coffee and other caffeinated beverages during early pregnancy is linked to adverse pregnancy outcome (238,241). In fact, this most recent report casts doubt on the definition of a lower limit for safe use of caffeine in the first trimester of pregnancy (238).

Preconception Evaluation

Investigative measures that are potentially useful in the evaluation of recurrent spontaneous abortion include obtaining a thorough history from both partners and performing a physical assessment of the woman with attention to the pelvic examination and laboratory testing (Table 28.3).

History
1. History of previous and characteristics of prior pregnancy losses
2. History of uterine or tubal surgery
3. History of chronic gynecologic or obstetric infections
4. Signs or symptoms of diabetes, proteinuria, glucose intolerance, and hyperandrogenism (including PCOS)
5. History of thyroid disease
6. History of autoimmune disease
7. Factors associated with the antiphospholipid syndrome (thrombosis, fetal demise, and venous thromboses)
8. Other autoimmune disorders
9. Medications
10. Environmental exposures, stress, and consumption of alcohol, caffeine, alcohol, and tobacco
11. Family history of recurrent spontaneous abortion, obstetric complications, or any chronic medical conditions
12. Previous diagnostic tests and treatments
Physical Examination
1. General physical examination with particular attention to:
a. Weight and height
b. Blood pressure and pulse rate
c. Thyroid gland and goiter
d. Pelvic examination
e. Anemia
f. Venous thromboses
g. Uterine cavity
Laboratory
1. Fetal and placental blood sampling
2. Chromosomal karyotype, followed by cytogenetics or fluorescence in situ hybridization, if indicated
3. Uterine and tubal patency
4. Hematologic studies, including hemoglobin, hematocrit, serum ferritin level if indicated
5. Autoantibody studies
6. Uterine and tubal patency
7. Complete blood count with platelets

Table 28.3. Investigative Measures Useful in the Evaluation of Recurrent Early Pregnancy Loss

History

Descriptions of all prior pregnancies and their sequence, as well as whether histologic assessment and karyotype determinations were performed on previously aborted tissues, are important aspects of the history. About 60% of abortuses lost before 8 weeks of gestation have been reported to be chromosomally abnormal (242); most of these pregnancies are affected by some type of trisomy, particularly trisomy 16 (243). The most common single chromosomal abnormality is monosomy

X (45X), especially among anembryonic conceptuses (244). Although somewhat controversial, the detection of aneuploidy in miscarriage specimens may be less when the couple experiencing recurrent abortions is euploidic. Alternatively, some investigators have suggested that, because aneuploidy is common among miscarriage specimens from patients experiencing both isolated and recurrent spontaneous pregnancy losses, the documentation of aneuploidy among tissues from recurrent pregnancy loss patients does not affect their prognosis for future pregnancy maintenance (9).

Most women with recurrent pregnancy losses tend to experience spontaneous abortion at about the same gestational age in sequential pregnancies. Unfortunately, the gestational age when pregnancy loss occurred, as determined by last menstrual period, may not be informative, because there is often a 2- to 3-week delay between fetal demise and signs of pregnancy expulsion (245). The designation of couples experiencing recurrent abortion into either primary or secondary categories is also not helpful in either the diagnosis or management of women with recurrent abortion. About 10% to 15% of couples cannot even be classified into either the primary or secondary categories because, although their first pregnancy resulted in a loss, this was followed by a term delivery before subsequent losses.

It is important to evoke any history of subfertility or infertility among couples with recurrent pregnancy loss. This is defined by the inability to conceive after 12 months of unprotected intercourse. By definition, 15% of all couples meet this criteria; this number increases to 33% among couples with recurrent pregnancy losses. In fact, because many pregnancies are lost before or near the time of missed menses, subfertility among recurrent pregnancy loss patients may in some cases reflect preclinical losses. Menstrual cycle history also may provide information about the possibility of oligoovulation or other relevant endocrine abnormalities in recurrent pregnancy loss patients. An assessment of the timing of intercourse relative to ovulation should be reviewed with couples in an effort to detect dyssynchronous fertilization that could contribute to pregnancy loss (246). A personal and family history of thrombotic events or renal abnormalities may provide vital information. A family history of pregnancy losses and obstetric complications should be addressed specifically. Detailed information about drug and environmental exposure should also be obtained.

Physical Examination

A general physical examination should be performed to detect signs of metabolic illness, including PCOS, diabetes, hyperandrogenism, and thyroid or prolactin disorders. During the pelvic examination, signs of infection, DES exposure, and previous trauma should be ascertained. Estrogenization of mucosal tissues, cervical and vaginal anatomy, and the size and shape of the uterus should also be determined.

Laboratory Assessment

Laboratory assessment of couples with recurrent pregnancy losses should include the following:

1. Parental peripheral blood karyotyping with banding techniques
2. Assessment of the intrauterine cavity with either office hysteroscopy or hysterosalpingography, followed by operative hysteroscopy if a potentially correctable anomaly is found
3. A well-timed luteal-phase endometrial biopsy, ideally 10 days after the LH surge or after cycle day 24 of an idealized 28-day cycle. If the cycle is abnormal by 3 or more days, the assessment should be repeated in a subsequent cycle. If endometrial histology is out of phase, the biopsy should be repeated in the subsequent cycle. Confirmed out-of-phase biopsies warrant further testing with serum prolactin and androgen profiles.
4. Thyroid function testing, including serum thyroid-stimulating hormone levels
5. Platelet assessment
6. Anticardiolipin and a lupus anticoagulant testing (aPTT or Russell viper venom testing)

A number of laboratory assessment tools are under investigation for use in patients with a history of recurrent pregnancy loss. At present, results are either too preliminary to warrant recommendation or studies of their use have been too contradictory to allow final determination of their value. Tests with unproven or unknown utility include the following:

1. Evaluation of ovarian reserve using day 3 serum follicle-stimulating hormone levels or the clomiphene challenge test. It appears that decreased ovarian reserve may portend poor outcome in all patients, including those with recurrent pregnancy loss (247,248).
2. Testing for serologic evidence of PCOS using LH or androgen values may be useful (50,51,52 and 53,249).
3. Testing for peripheral evidence of T_H1 and T_H2 cytokine dysregulation. Although large studies have failed to demonstrate an association between peripheral cytokine alterations and pregnancy outcome among patients with recurrent pregnancy loss (156), smaller studies have reported peripheral shifts toward T_H1 profiles only in those recurrent pregnancy loss patients who subsequently lose their pregnancy (158). One study documented a shift toward T_H1 profiles at the time of fetal demise in these patients; however, it is particularly difficult to determine cause and effect in this situation (157).
4. Testing for hypercoagulability using the aPTT (14) or for the presence of a hereditary thrombophilia (250) in patients with otherwise unexplained recurrent pregnancy loss has been suggested.
5. Preconceptional testing for the prevalence and activity of peripheral NK cells has been reported in small studies to reflect prognosis and to assist in patient counseling (251,252).
6. Testing for antithyroid antibodies, even among women with recurrent pregnancy loss who are euthyroid, remains controversial. Although some have shown no association between their presence and recurrent loss (207), others have demonstrated an increased prevalence among patients with a history of recurrent pregnancy loss (62,208). However, even if the prevalence of antithyroid antibodies is increased among these patients, the significance of their presence has been questioned (209).
7. Testing for the presence of a variety of autoantibodies (other than lupus anticoagulant and anticardiolipin antibody) has been hotly debated, but without consensus (253,254). Testing for some antiphospholipid antibodies, such as antiphosphatidylserine and anti- b_2 glycoprotein 1 (anti- b_2 G1), are particularly attractive because mechanistic connections between their presence and placental pathology have been made (198,199,200 and 201). One recent, large series has demonstrated anti- b_2 G1 to be associated with risk for recurrent pregnancy loss (255). Among patients with known autoimmune diseases and recurrent pregnancy loss, additional antiphospholipid testing may be warranted (256).
8. Testing for congenital or acquired defects in homocysteine metabolism may play a role in the evaluation of some patients with recurrent pregnancy loss. The most common methods involve the measurement of blood levels of homocysteine, either fasting or after methionine loading (15). Methionine loading may increase the usefulness of results; however, it has been associated with acute endothelial dysfunction (257), which could pose potential problems if testing is performed during early pregnancy.
9. Cervical cultures for mycoplasma, ureaplasma, and chlamydia may be considered.

The following investigations have no place in modern clinical care of patients with recurrent spontaneous pregnancy loss:

1. Evaluations that involve extensive testing for serum or site-specific autoantibodies or alloantibodies (including antinuclear antibodies and antipaternal cytotoxic antibodies) are both expensive and unproven. Their use often serves only to verify the statistical tenet that if the number of tests performed reaches a critical limit, the results of at least one will be positive in every patient.
2. Testing for parental HLA profiles is never indicated in outbred populations. Findings that HLA sharing is associated with poor pregnancy outcomes are strictly limited to those specific populations studied, which have very high and sustained levels of marriage within a limited community (214).
3. Mixed lymphocyte cultures have not proved useful. Use of other immunologic tests also is unnecessary unless these studies are performed, with informed consent, under a specific study protocol in which the costs of these experimental tests are not borne by the couple or their third-party payers.
4. Further work is necessary before suppressor cell and factor determinations; cytokine, oncogene, and growth factor measurements; or embryotoxic factor assessment can be clinically justified.

Postconception Evaluation

After conception, close monitoring of patients with a history of recurrent pregnancy loss is advised to provide psychological support and to confirm intrauterine pregnancy and its viability. The incidence of ectopic pregnancy (258,259) and complete molar gestation (259,260) is increased in women with a history of recurrent spontaneous pregnancy loss. Although somewhat controversial (259), some data suggest that the risk for pregnancy complications other than spontaneous abortion are not significantly different between women with and without a history of recurrent losses (261,262). Two exceptions to this observation are those women who have

antiphospholipid antibodies and those who have an intrauterine infection.

Determining serum levels of b-hCG may be helpful in monitoring early pregnancy until an ultrasonographic examination can be performed; however, not all investigators have found inadequate b-hCG levels in pregnancies that ultimately abort ([263](#)). Other hormonal determinations are rarely of benefit because levels are often normal until fetal death or abortion occurs ([264](#)).

The best method for monitoring in early pregnancy is ultrasonography. If used, serum b-hCG levels should be serially monitored from the time of a missed menstrual period until the level is about 1,500 mIU/mL, at which time an ultrasonographic scan is performed and blood sampling is discontinued. Ultrasonographic assessment is then performed every 2 weeks until the gestational age at which previous pregnancies were aborted. The prognostic value of serial ultrasonography and a variety of hormonal and biochemical measurements during early pregnancy in women with a history of recurrent losses has been recently investigated ([265](#)).

If a pregnancy has been confirmed, but fetal cardiac activity cannot be documented by about 6 to 7 weeks of gestation (by sure menstrual or ultrasonographic dating), intervention is recommended to expedite pregnancy termination and to obtain tissue for karyotype analysis. Maternal serum is obtained for a-fetoprotein assessment at 16 to 18 weeks of gestation. Amniocentesis is recommended to assess the fetal karyotype after the pregnancy has progressed past the time of prior losses.

The importance of obtaining karyotypic analysis from tissues obtained after pregnancy demise in a woman experiencing recurrent losses cannot be overemphasized. Results may suggest karyotypic anomalies in the parents. The documentation of aneuploidy may have important prognostic implications and may direct future interventions. A cost analysis has even demonstrated that karyotypic analysis is financially prudent among patients with histories of recurrent pregnancy loss ([266](#)). Of course, obtaining karyotypic data from aborted specimens has many hindrances, including difficulties in culturing cells from tissues that may have significant inflammation or necrosis and contamination of specimens with maternal cells. Efforts to develop methods that avoid such difficulties include the application of comparative genomic hybridization technology to recurrent pregnancy loss ([267](#)). This technology has even been used successfully on archived and paraffin-embedded pregnancy tissues ([268](#)). In the future, fetal karyotype assessment may also be performed using DNA isolated from nucleated fetal erythrocytes in maternal blood ([269](#)).

Therapy

Advances in the treatment of patients with recurrent pregnancy loss have been regrettably slow. Although we have experienced a rapid expansion in our understanding of the molecular and subcellular mechanisms involved in implantation and early pregnancy maintenance, extension of these concepts to prevention of recurrent early pregnancy loss has lagged. In addition to these limitations, progress toward treatment of most causes of recurrent pregnancy loss has been hampered by a variety of factors. The condition itself has been inconsistently defined. The results of clinical trials involving recurrent pregnancy loss patients are therefore often nearly impossible to compare and evaluate. Trial design is frequently substandard, with lack of rationale, lack of appropriate controls, and poor statistical analysis, limiting the ability to draw rational conclusions from reported results. Finally, epidemiologic data indicate that most patients with a history of recurrent pregnancy loss will, in fact, have a successful pregnancy the next time they conceive ([5](#)). For these reasons, with few exceptions, most therapies for recurrent pregnancy loss must be considered experimental. Until further study is completed, these treatment protocols should be undertaken only with informed consent and in the setting of a well-designed, double-blind, placebo-controlled clinical trial.

Common therapeutic options that currently exist for patients with recurrent pregnancy loss include the use of donor oocytes or sperm, the use of preimplantation genetic diagnosis (PGD), the use of antithrombotic interventions, the repair of anatomic anomalies, the correction of any endocrine abnormalities, the treatment of infections, and a variety of immunologic interventions and drug treatments. Psychological counseling and support should be recommended for all patients.

Genetic Abnormalities

No therapies are presently available to address directly those parental chromosomal anomalies that potentially contribute to recurrent abortion. Three alternative approaches exist when genetic factors are linked to recurrent pregnancy loss. Some, such as antithrombotic therapy for patients with inherited thrombophilias, address the effects of the genetic abnormality. Others attempt to identify those particular embryos that are affected by chromosomal disorders and select against them. This approach involves the technique of PGD. Recent evidence suggests that, in women with a history of two or more spontaneous pregnancy losses, a subsequent pregnancy loss has a 60% chance of chromosomal abnormality. This raises the genetic etiology of recurrent pregnancy loss to new prominence. If the incidence of chromosomal abnormalities among the conceptuses of recurrent pregnancy loss patients is indeed this high, it could be argued that the use of assisted reproductive technologies, including PGD, might be indicated for all patients with unexplained recurrent pregnancy loss.

PGD involves the removal of a single cell from an *in vitro*-matured embryo. Genetic testing can be performed on this cell to rule out gross chromosomal abnormalities or the presence of specific genetic diseases (e.g., cystic fibrosis). Embryos that are diagnosed with genetic abnormalities would not be chosen for replacement into the uterine cavity. Those demonstrated to be genetically normal would be considered appropriate for transfer into the uterus. Use of preimplantation genetic diagnosis, therefore, has the potential to reduce dramatically the incidence of pregnancy loss arising from a genetic etiology. Use of PGD in patients with known heritable genetic disorders (e.g., cystic fibrosis, X-linked disorders) is presently in widespread use in internationally recognized assisted reproductive technology centers. Efficacy of PGD in the treatment of patients with recurrent pregnancy loss is now under investigation ([270,271](#) and [272](#)). The third approach to patients with genetic factors and recurrent pregnancy loss is particularly relevant to those with robertsonian translocations involving homologous chromosomes. In these patients, their genetic anomaly always results in embryonic aneuploidy. Therefore, use of either donor oocyte or donor sperm, depending on the affected partner, is recommended. Use of donor gametes among patients with a history of recurrent pregnancy loss has been demonstrated to be as effective as its use in matched patients without such a history ([273](#)). Synchronization of intercourse with ovulation may benefit some patients with genetic factor recurrent pregnancy loss ([246](#)). In all cases, genetic counseling is warranted.

Anatomic Anomalies

Hysteroscopic resection represents state-of-the-art therapy for submucous leiomyomas, intrauterine adhesions, and intrauterine septa. This approach appears to limit postoperative sequelae while maintaining efficacy in terms of reproductive outcome ([43](#)). Use may even be safely extended to patients with *DES* exposure, hypoplastic uteri, and complicating septal anomalies ([274](#)). Attempts to improve on standard hysteroscopic metroplasty, which is typically performed in the operating room using general anesthesia, often with laparoscopic guidance, are presently under investigation. Ultrasonographically guided transcervical metroplasty has been reported to be safe and effective ([275](#)). Ambulatory, office-based procedures ([276](#)), including septum resection under fluoroscopic guidance ([277](#)), are also becoming attractive options.

For patients with a history of loss secondary to cervical incompetence, placement of a cervical cerclage is indicated. This is usually performed early in the second trimester, and certainly after documentation of fetal viability. Cervical cerclage should be considered as a primary intervention for women with *DES*-associated uterine anomalies. If endometriosis is encountered during a diagnostic evaluation, it should be resected laparoscopically.

Endocrine Abnormalities

Some investigators have proposed the use of ovulation induction for the treatment of recurrent pregnancy loss ([278,279](#)). The theory behind its use in these patients rests on hypotheses that ovulation induction is associated with healthier oocytes. Healthier oocytes, in turn, may decrease the incidence of luteal-phase insufficiency, which should result in improved pregnancy maintenance. This approach grossly oversimplifies the mechanisms involved in implantation and early pregnancy maintenance. Until appropriately studied, use of empiric ovulation induction for treatment of unexplained recurrent pregnancy loss should be viewed with caution. Recent evidence from small studies indicates that such use is not effective ([279](#)). Use of ovulation induction in some subsets of patients with recurrent pregnancy loss could be of benefit. For instance, stimulating folliculogenesis with ovulation induction or luteal-phase support with progesterone should be considered for women with luteal-phase insufficiency. The efficacy of these therapies, however, has never been substantiated ([280](#)). Ovulation induction might also be beneficial for women with hyperandrogen and LH hypersecretion disorders, especially following pituitary desensitization with gonadotropin-releasing hormone agonist therapy ([68](#)). This treatment also remains controversial because the only large, prospective, randomized controlled trial to date reports no therapeutic efficacy, either for prepregnancy pituitary suppression or for luteal-phase progesterone supplementation ([281](#)).

Recent links between PCOS, hyperandrogenism, hyperinsulinemia, and recurrent pregnancy loss ([50,51,52](#) and [53](#)) make use of insulin-sensitizing agents in the

treatment of recurrent pregnancy loss associated with PCOS attractive. At present, their use for this application is limited to case reports ([282](#)). Prepregnancy glycemic control may be particularly important for women with overt diabetes mellitus ([54,55](#)). Thyroid hormone replacement with synthroid may be helpful in cases of hypothyroidism. There is no place in the medical management of recurrent abortion for either thyroid medication or bromocriptine for women who do not have a thyroid or prolactin disorder.

Infections

Empiric antibiotic treatment has been used for couples with recurrent abortion. Its efficacy is unproven. Thus, elaborate testing for infectious factors among recurrent pregnancy loss patients and use of therapeutic interventions are not justified unless a patient is immunocompromised or a specific infection has been documented ([69](#)). For cases in which an infectious organism has been identified, appropriate antibiotics should be administered to both partners, followed by posttreatment culture to verify eradication of the infectious agent before attempting conception.

Immunologic Factors

Immune-mediated recurrent pregnancy loss has received more attention than any other single etiologic classification of recurrent pregnancy loss. Nevertheless, the diagnosis and subsequent treatment of most cases remain unclear ([121,283,284](#) and [285](#)). Most therapies for proposed immune-related recurrent pregnancy loss must be considered experimental. As stated earlier, it is known that the developing conceptus contains paternally inherited gene products and tissue-specific differentiation antigens and that there is maternal recognition of these antigens ([162,163](#) and [164](#)). Historically, it has been speculated that both inappropriately weak immune responses to these antigens and unusually strong responses could result in early pregnancy loss. As a consequence, both immunostimulating and immunosuppressive therapies have been proposed.

Immunostimulating Therapies—Leukocyte Immunization

Stimulation of the maternal immune system using alloantigens on either paternal or pooled donor leukocytes has been promoted for patients with immune recurrent pregnancy loss, and a number of reports support possible mechanisms for potential therapeutic value ([286,287,288](#) and [289](#)). Both individual clinical trials and metaanalyses, however, continue to report conflicting results concerning the efficacy of leukocyte alloimmunization in patients with recurrent pregnancy loss ([290,291,292,293](#) and [294](#)). This most certainly reflects the remarkable heterogeneity in study design, patient selection, and therapeutic protocols, as well as the typically small numbers of enrolled subjects in these investigations. One published analysis reported that about 11 women with unexplained recurrent abortion would need to be immunized with alloantigenic lymphocytes before one additional live birth was achieved ([292](#)). About 92% of successful pregnancy outcomes in this study were not attributable to leukocyte immunization. Whether the 8% successful pregnancy rate achieved in leukocyte-immunized women is clinically relevant remains uncertain. One of the most recent and largest trials evaluating the efficacy of leukocyte immunization in patients with unexplained recurrent pregnancy loss is a part of the Recurrent Miscarriage (REMIS) study ([294](#)). This investigation was large (more 90 patients per treatment arm), prospective, placebo controlled, randomized, and double blinded. It demonstrated no efficacy for paternal leukocyte immunization in couples with unexplained recurrent pregnancy loss. Despite the unsubstantiated rationale for this therapy and the controversial reports concerning its efficacy, paternal leukocyte transfusion has been widely used, often in response to patient demand that some form of therapy be initiated. Unfortunately, entrepreneurial interests have also clouded the rational assessment of couples experiencing recurrent abortion, resulting in a growing number of financially lucrative leukocyte immunization clinics. However, there is no credible clinical or laboratory method to identify a specific individual who may benefit from such therapy. Further, leukocyte immunization also poses significant risk to both the mother and her fetus ([295,296](#)). Several cases of graft-versus-host disease, severe intrauterine growth retardation, and autoimmune and isoimmune complications have been reported ([68,291,292,295,296,297](#) and [298](#)). In addition, alloimmunization to platelets contained in the paternal leukocyte preparation has been associated with cases of potentially fatal fetal thrombocytopenia. The routine use of this therapy for recurrent abortion (that, at best, will only be efficacious in 1 of 11 women treated) cannot be clinically justified.

Other immunostimulating therapies have been proposed and abandoned. Intravenous preparations consisting of syncytiotrophoblast microvillous plasma membrane vesicles have been used to mimic the fetal cell contact with maternal blood that normally occurs in pregnancy ([299](#)). The efficacy of this therapy has not been established ([299](#)). The use of third-party seminal plasma suppositories has also been attempted ([300](#)), based on the misconception that TLX was part of an idio-anti-idio control system ([301](#)). Third-party seminal plasma suppositories for recurrent abortion have no scientifically credible rationale and should not be used.

Immunosuppressive Therapies

Immunosuppressive and other immunoregulating therapies have been advocated for cases in which abortion was believed to be due to antiphospholipid antibodies or to inappropriate cellular immunity toward the implanting fetus. Again, study design problems, including small numbers of recruited patients, lack of prestratification by maternal age and number of prior losses before randomization, and other methodologic and statistical inaccuracies preclude definitive statements regarding therapeutic efficacy for most of the proposed immunosuppressive approaches.

Intravenous Immunoglobulin Intravenous immunoglobulins (IVIgs) are composed of pooled samples of immunoglobulins harvested from a large number of blood donors. Studies on the use of IVIg therapy in the treatment of recurrent pregnancy loss are based on the theory that some recurrent pregnancy loss patients have an overzealous immune reactivity to their implanting fetus. IVIGs do have immunosuppressive effects, but the mechanisms underlying this immune modulation are only partially understood. These mechanisms may include decreased autoantibody production and increased autoantibody clearance, T-cell and Fc receptor regulation ([302](#)), complement inactivation ([303](#)), enhanced T-cell suppressor function, decreased T-cell adhesion to the extracellular matrix ([304](#)), and downregulation of T_H1 cytokine synthesis ([305](#)). Based on a large number of relatively small studies using a variety of treatment protocols, there remains no conclusive evidence to suggest that use of IVIg in the treatment of patients with unexplained (and presumed immunologic) recurrent pregnancy loss has any benefit ([306,307,308,309,310,311,312](#) and [313](#)). However, improved posttreatment pregnancy rates may be seen when IVIg is used in those specific patients with autoimmune-mediated pregnancy loss associated with antiphospholipid syndrome (APS) ([314,315](#)). Therapy with IVIGs for recurrent pregnancy loss is expensive, invasive, and time-consuming, requiring multiple intravenous infusions over the course of pregnancy. Side effects of IVIg therapy include nausea, headache, myalgias, and hypotension. More serious adverse effects include anaphylaxis (particularly in patients with IgA deficiency) ([316](#)).

Progesterone As mentioned earlier, progesterone also has known immunosuppressive effects ([166,167](#) and [168](#)). A number of studies using *in vitro* cellular systems relevant to the maternal–fetal interface have now demonstrated that progesterone either inhibits T_H1 immunity or causes a shift from T_H1- to T_H2-type responses ([151,171,172,317,318](#)). Progesterone has been administered both intramuscularly and intravaginally for the treatment of recurrent pregnancy loss. It is thought that vaginal administration may increase local, intrauterine concentrations of progesterone better than systemic administration. Vaginal formulations may therefore provide a better method of attaining local immunosuppressive levels of progesterone while averting any adverse systemic side effects. Although both vaginal and intramuscular progesterone therapy are associated with few minor side effects, their efficacy in the treatment of either unexplained recurrent pregnancy loss or recurrent pregnancy loss associated with T-helper cell dysregulation has never been appropriately investigated.

Other immunoregulating therapies theoretically useful in treating recurrent pregnancy loss include the use of *cyclosporine*, *pentoxifylline*, and *nifedipine*, although maternal and fetal risks with these agents preclude their clinical use. Plasmapheresis has also been used to treat women with recurrent abortion suspected to be caused by antiphospholipid antibodies ([319](#)). Generalized immunosuppression with corticosteroids, such as *prednisone*, has been advocated during pregnancy for women with recurrent losses and APAS. Although corticosteroids have shown some treatment promise in these patients ([320](#)), maternal and fetal side effects and the availability of alternative therapies have limited their use. The efficacy and side effects of *prednisone* plus low-dose *aspirin* were examined in a recent, large, randomized, placebo-controlled trial treating patients with autoantibodies and recurrent pregnancy losses. Pregnancy outcomes for treated and control patients were similar; however, the incidence of maternal diabetes and hypertension and the risk for premature delivery were all increased among those treated with *prednisone* and *aspirin* ([321](#)).

Antithrombotic Therapy

Therapy for patients with recurrent pregnancy losses associated with either the APAS or other thrombophilic disorders has now shifted toward the use of antithrombotic medications. Unlike immunosuppressive treatments, this approach mainly addresses the effect (hypercoagulability), but not the underlying cause (e.g., genetic, APAS), of recurrent pregnancy loss. However, there are reports that *heparin*, one typical anticoagulant, may exert direct immunomodulatory effects by binding

to antiphospholipid antibodies (322). The combined use of low-dose aspirin (75 to 80 mg/d) and subcutaneous unfractionated heparin (5,000 units twice daily) during pregnancy has been best studied among women with APAS and appears to be efficacious (323,324 and 325). A typical regimen for women with antiphospholipid antibody syndrome would include use of aspirin (80 mg every day) beginning with any attempts to conceive. After pregnancy has been confirmed, 5,000 IU unfractionated sodium heparin is administered subcutaneously twice daily, throughout gestation. An aPTT should be obtained weekly, and dosages of heparin should be adjusted until anticoagulation is achieved. Patients using this therapy should be treated in conjunction with a perinatologist because of their increased risk for preterm labor, premature rupture of the membranes, intrauterine growth restriction, intrauterine fetal demise, and preeclampsia. Other potential risks include gastric bleeding, osteopenia, and abruptio placentae.

Attempts have recently been made to extend the finding that antithrombotic therapy is efficacious when used to treat patients with APAS and recurrent pregnancy loss in a number of directions. These directions include the use of low-molecular weight heparin (LMWH) and the use of antithrombotic therapy in non-APAS patients with thrombophilia and recurrent pregnancy loss and even among recurrent pregnancy loss patients without thrombophilia (unexplained recurrent losses).

New formulations of heparin (LMWH) have been demonstrated to be superior to unfractionated heparin in the treatment of many clotting disorders (326,327). LMWH has the advantage of an increased antithrombotic ratio when compared with unfractionated heparin. This results in improved treatment of inappropriate clotting but fewer bleeding side effects. In addition, LMWH has been associated with a decreased incidence of thrombocytopenia and osteoporosis when compared with its unfractionated counterpart. Finally, LMWH has a long half-life and requires less frequent dosing and monitoring, thereby improving patient compliance. Although its safe use in pregnancy is only now being fully evaluated, LMWH has shown promise when combined with low-dose aspirin in the treatment of recurrent pregnancy loss associated with APAS (324). Efficacy has also been suggested for similar treatment of recurrent pregnancy loss associated with other thrombophilias, including activated protein C resistance associated with factor V Leiden (328,329 and 330).

The prophylactic use of daily low-dose aspirin has become common practice within the lay public based on its perceived cardiovascular effects combined with its low incidence of side effects. Its sole use in the treatment of recurrent pregnancy loss has likewise gained momentum, and many patients with a history of recurrent loss will either be self-prescribing this therapy or will inquire about its usefulness. At present, there are no good data supporting its use either in patients with thrombophilia or in the general recurrent pregnancy loss population. In fact, although studies are small, the use of low-dose aspirin alone has not been shown to be effective in the treatment of recurrent pregnancy loss associated with APAS (323,331). One large study recently addressed the therapeutic efficacy of empiric low-dose aspirin among 805 patients with unexplained recurrent pregnancy losses. The authors conclude that such therapy cannot be justified (332).

More directed antithrombotic therapies have also been described for the treatment of recurrent pregnancy loss among patients with thrombophilias. For instance, the use of protein C concentrates has been reported to be associated with favorable pregnancy outcome in a patient with a history of thrombosis, recurrent fetal losses, and protein C deficiency (333).

As mentioned previously, vitamins B₆, B₁₂, and folate are important in homocysteine metabolism (17,18), and hyperhomocysteinemia is linked to recurrent pregnancy loss (15,16,26). Use of folate or B vitamin supplementation in patients with heritable or acquired disorders in homocysteine metabolism has been suggested (14).

Psychological Support

Despite commonly held biases that anxiety, stress, depression, and other psychological variables might be related to the occurrence of miscarriage, a number of recent studies have reported no causal association (334,335). It is important to discuss this misconception, which may otherwise promote inappropriate feelings of guilt among patients with recurrent losses. There is no doubt, however, that experiencing both isolated and recurrent losses can be emotionally devastating. The risk for major depression is increased greater than twofold among women with spontaneous pregnancy loss; in most women, it arises in the first weeks after delivery (336).

A caring and empathetic attitude is prerequisite to all healing. The acknowledgment of the pain and suffering couples have experienced as a result of recurrent abortion can be a cathartic catalyst enabling them to incorporate their experience of loss into their lives rather than their lives into their experience of loss (68). Referrals to support groups and counselors should be offered. Self-help measures, such as meditation, yoga, exercise, and biofeedback, may also be useful.

Prognosis

The prognosis for successful pregnancy depends both on the potential underlying cause of pregnancy loss and (epidemiologically) on the number of prior losses (Table 28.4). As previously discussed, epidemiologic surveys indicate that the chance of a viable birth even after four prior losses may be as high as 60%. Depending on the study, the prognosis for successful pregnancy in couples with a cytogenetic etiology for reproductive loss varies from 20% to 80% (337,338 and 339). Women with corrected anatomic anomalies may expect a successful pregnancy in 60% to 90% of cases (337,338,340,341). A success rate higher than 90% has been reported for women with corrected endocrinologic abnormalities (337). Between 70% and 90% of pregnancies reported among women receiving therapy for antiphospholipid antibodies have been viable (342,343).

Following:	
One spontaneous loss	75%
Two spontaneous losses	70%
Three spontaneous losses	65%
Four spontaneous losses	60%
With:	
Genetic factors	20%–80%
Anatomic factors	60%–90%
Endocrine factors	>90%
Infectious factors	70%–90%
Antiphospholipid antibodies	70%–90%
T _H 1 cellular immunity	70%–80%
Unknown factors	40%–90%
Following Detection of Fetal Cardiac Activity:	
Unexplained RPL	77%–80%
APAS and RPL	30%–70%

RPL, recurrent pregnancy loss; APAS, antiphospholipid antibody syndrome.

Table 28.4. Prognosis for a Viable Birth

Many forms of preconceptional and postconceptional tests have been proposed to help predict pregnancy outcome (147,165,250,252,344); none has been fully substantiated in large, prospective trials. The documentation of fetal cardiac activity on ultrasound may offer prognostic value; however, it appears that its predictions may be greatly affected by any underlying diagnosis. In one study, the live birth rate following documentation of fetal cardiac activity between 5 and 6 weeks from the last menstrual period was about 77% in women with two or more unexplained spontaneous abortions (345). It may be important to note that most of the patients in this study had evidence of inappropriate antitrophoblast cellular immunity. Others have shown that 86% of patients with antiphospholipid antibodies and recurrent pregnancy loss had fetal cardiac activity detected before subsequent demise (346). Most recently, however, a prospective, longitudinal, observational study of 325 patients with unexplained recurrent pregnancy losses demonstrated that only 3% of 55 miscarriages occurred after the detection of fetal cardiac activity using transvaginal ultrasonography (347).

More than 30% of the female population of the United States is postmenopausal, and this percentage is increasing ([1](#)). Despite the universality of “the change of life,” the importance of its medical and psychological implications has only recently been appreciated. Each woman’s response to menopause may be different; as a result, management must be individualized to each woman’s needs.

Menopause is defined as the permanent cessation of menses for 1 year and is physiologically correlated with the decline in estrogen secretion resulting from the loss of follicular function. It is the most identifiable event of the perimenopausal period. The years immediately preceding and the decades afterward, however, are of far greater clinical significance. The perimenopausal period encompasses the time before, during, and after menopause. This period of hormonal transition is sometimes known as the menopausal transition period. Perimenopause usually begins in the mid- to late 40s; it often is insidious and uneventful but may be abrupt and symptomatic. Symptoms that begin with the menopausal transition usually continue into the postmenopausal period.

The postmenopausal period is associated with a significant increase in the incidence of age-related medical conditions. Some of these conditions, specifically osteoporosis and cardiovascular disease, are related to estrogen deficiency as well. For this reason, hormone replacement therapy should be a part of gynecologic care of postmenopausal women.

Perimenopausal Phases

The perimenopause is the period surrounding the menopause—before, during, and after. The length of this period varies, but it is usually considered to last approximately 7 years, beginning with the decline in ovarian function in a woman’s 40s, and continuing until she has not had a menstrual period for 1 year.

Menopausal Transition

The period that precedes menopause is characterized by a varying degree of somatic changes that reflect alterations in the normal functioning of the ovary. Early recognition of the symptoms and the use of appropriate screening tests can minimize the impact of this potentially disruptive period. In many cases, however, it is difficult to differentiate stress-related symptoms from those associated with decreasing levels of estrogen. For this reason, both stress and relative estrogen deficiency should be considered when managing problems associated with the menopausal transition.

In some women, menstrual irregularity is the most significant symptom of the menopausal transition ([2](#)). Because abnormal bleeding is one of the most common symptoms of uterine problems, menstrual irregularity during the perimenopause should be evaluated carefully. Often uterine bleeding associated with this transition period is secondary to normal physiologic estrogen fluctuations rather than underlying pathology and may be treated medically ([3](#)).

Menopause

The cessation of menses resulting from the loss of ovarian function is a natural event, a part of the normal process of aging. Menopause is associated with the cessation of menses resulting from the loss of ovarian follicular function, and should be characterized as an event rather than a period of time. **The time of menopause is determined genetically and occurs at a median age of 51 years ([2,3](#) and [4](#)).** It is related neither to race nor nutritional status. However, menopause occurs earlier in nulliparous women, in those who smoke tobacco, and in some women who have had hysterectomies ([4,5](#)).

With the depletion of ovarian follicles that are able to respond to gonadotropins, follicular development and cyclic estrogen production cease. The ovaries, however, continue indefinitely to produce small amounts of androgens postmenopausally. Traditionally, menopause has been diagnosed retrospectively based on the lack of menstrual periods. With the advent of modern laboratory testing, menopause may now be more precisely defined as amenorrhea, with signs of hypoestrogenemia,

and an elevated serum follicle-stimulating hormone (FSH) level of greater than 40 IU/L. Menopause can also be diagnosed on the basis of subjective symptoms, such as hot flashes, or on the basis of provocative studies such as the progesterone withdrawal test. Hot flashes and other acute symptoms associated with the perimenopausal period often become more intense near menopause when the levels of circulating estrogen suddenly drop. These symptoms are especially intense in patients who experience premature ovarian failure or surgical menopause, which are accompanied by gradual drops in circulating estrogens.

Postmenopausal Period

The postmenopausal period is one of relative ovarian quiescence following menopause. Given the current lifespan of women in the United States, this period can comprise more than one-third of the average woman's life. During this prolonged period, women are vulnerable to conditions caused by estrogen deficiency. Even though the long-term health impact of estrogen deficiency may be similar to that of thyroid or adrenal disorders, relatively little attention has been paid to this problem until recently. For this reason hormone replacement therapy is one of the primary concerns of many postmenopausal women's health care.

Reasons for this lack of attention are many. Health problems associated with estrogen deficiency tend to be chronic rather than acute. For example, osteoporosis is not clinically apparent until decades after menopause, when unfortunately it becomes harder to treat. Second, the impact of estrogen deficiency on cardiovascular disease is often confused with age-related changes. Third, because of the peripheral conversion of both ovarian and adrenal androgens to estrogen, the loss of ovarian function does not result in an absolute estrogen deficiency. As a result, some women are less affected by estrogen deficiency than others.

Premature Ovarian Failure

As previously stated, loss of ovarian function is usually a gradual process that occurs over a number of years and culminates in menopause. Ovarian function is lost earlier and more suddenly than expected in some women as a result of natural causes, chemotherapy, or surgery.

Premature ovarian failure is defined as menopause occurring spontaneously before 40 years of age (6). Because of the relatively young age and the unexpected nature of the event, both psychological and hormonal support may be necessary. Although most practitioners are not adequately prepared to offer comprehensive psychological support, asking appropriate questions and making support services available can be helpful. The possibility of associated endocrine abnormalities should also be considered in women who develop premature ovarian failure. This is further addressed in Chapter 25.

In more than 40% of women who have hysterectomies, both ovaries are removed (3). As a result, many of these women undergo surgical menopause at a significantly younger age than do their counterparts who undergo natural menopause. The relatively young age of these women and the abrupt onset of associated symptoms create special problems (7).

The most obvious problem with surgical menopause is the acute onset of hot flashes (8). After several months, these hot flashes may be followed by signs of vaginal atrophy. In addition, long-term surgical menopause has been associated with significantly higher risk for both osteoporosis and cardiovascular disease than has natural menopause (9,10). The risk of osteoporosis can be decreased with estrogen replacement therapy. Because long-term hormone replacement may expose women to other types of risks, the relative risks and benefits of oophorectomy in conjunction with estrogen replacement therapy should be thoroughly discussed with any woman considering bilateral oophorectomy at the time of hysterectomy.

Hormonal Changes

Changes in hormone production and metabolism occur gradually during the menopausal transition. After almost 4 decades of cyclic production of estrogen and progesterone, the ovaries decrease their production of estrogen and will eventually cease any cyclic activity.

Menopausal Transition

During the menopausal transition, ovarian follicles become increasingly resistant to FSH stimulation even though levels of estradiol remain relatively constant. This process is most clearly demonstrated even before the onset of clinically apparent perimenopause by the relative resistance to gonadotropins in women undergoing ovulation stimulation for *in vitro* fertilization. In the average woman younger than 30 years, levels of estradiol higher than 1,000 pg/ml are easily attainable using stimulation of approximately 225 IU of FSH per day. In contrast, most women older than 40 years rarely attain estradiol levels this high, despite stimulation with up to 3 times as much gonadotropin per day. This degree of ovarian resistance to stimulation may explain the hot flashes experienced by some women, despite what appear to be normal levels of estradiol. It suggests that hot flashes may be the result of gonadotropin surges related to fluctuating estradiol levels or low levels of other ovarian hormones such as inhibin.

Progesterone is produced almost exclusively by granulosa cells and is highest in the midluteal phase. During the menopausal transition, ovulation becomes less frequent, with a decrease in overall progesterone production (11). In some women ovulation continues to occur, but the luteal levels of progesterone are lower than those observed in younger women (12).

Menopause

Near the time of the menopause, the levels of hormones, the way they are produced, and their roles change. Hormones most affected are those produced by the ovaries and include estrogen, progesterone, and androgens.

Estrogen

Even though the amount of estrogen secreted by the postmenopausal ovary is negligible, postmenopausal women continue to have measurable amounts of both estrone and estradiol (13). Prior to menopause, estradiol levels range from 50 to 300 pg/ml. However, even with cessation of ovarian function levels of estradiol may remain as high as 100 pg/ml (14). The answer to this apparent paradox lies in the ability of peripheral tissue to aromatize adrenal and ovarian androgens.

Androstenedione is produced by the adrenal and ovary and is aromatized to estrogen primarily by muscle and adipose tissue (15,16). Obese women have an increased level of circulating estrogens, and the unopposed estrogen places them at an increased risk for endometrial cancer (17). In contrast, thin women have a decreased level of circulating estrogens and are at an increased risk for developing osteoporosis (18). Surprisingly, the increased levels of estrogen often seen in obese women do not appear to protect them from acute menopausal symptoms; however, the higher levels do provide some skeletal protection (19).

Progesterone

After menopause, progesterone production ceases (20). The absence of cyclic changes in progesterone is usually associated with the absence of premenstrual symptoms (21). Decreased progesterone levels affect organs that are responsive to gonadal hormones, such as endometrium and breasts. During the reproductive years, progesterone protects the endometrium from excess estrogen stimulation by directly regulating estrogen receptors. It also exerts a direct intranuclear effect by inhibiting the trophic effects of estrogen on the endometrium (22).

Because circulating levels of estrogen can remain high enough to stimulate the endometrium both pre- and postmenopausally, unopposed stimulation of the endometrium may be a relatively common problem just prior to and after menopause (12). This probably explains the higher risk of endometrial hyperplasia and cancer found during this time (23).

Breast tissue also is known to be extremely sensitive to gonadal hormones. Although the relationship is less clear with breast than with endometrial tissue, unopposed stimulation of the breast ductal epithelium by estrogen in the absence of progesterone may play a role in the development of breast cancer (24). There are data that suggest that the use of combined estrogen and progestin replacement therapy may decrease the risk of breast cancer; however, a more recent large study does not

support this conclusion (25).

Androgens

The third class of steroids produced by the ovaries is androgens, most notably testosterone and androstenedione. The role of ovaries in androgen production, especially postmenopausally, has only recently been appreciated (11).

Prior to menopause, the ovaries produce approximately 50% of the circulating androstenedione and 25% of the testosterone produced by a woman's body.

Circulating concentration of testosterone in women is less than one-tenth that in men (0.50 ng/ml versus 6 ng/ml) and the amount of biologically active testosterone in women is only one-third that in men. In part, this is accounted for by the amount of sex hormone-binding globulin, which is relatively higher in women (30 to 90 nmol/L) than men (10 to 50 nmol/L) (26).

After menopause, total androgen production decreases, mainly because ovarian production decreases but also because adrenal production decreases (11). The circulating levels of androstenedione and testosterone after menopause are approximately 0.53 and 0.23 ng/ml, respectively (27). After ovulation has ceased, the ovaries are responsible for 20% of the androstenedione and 40% of the testosterone as a result of continued gonadotropin stimulation of ovarian stromal cells (28). Although oophorectomy also results in a marked reduction in androgen production, the significance of these decreases will remain uncertain until the physiologic role of these hormones becomes more fully elucidated (12).

Patient Concerns about Menopause

A broad spectrum of emotions often is associated with hormonal and bodily changes characteristic of this period (29,30). A patient's response to menopause may be affected by factors such as lifestyle and regulation of the aging process. The loss of fertility and menstrual function that accompany natural or surgical menopause may have an impact on a woman's sense of well-being. The physician should be sensitive to the potentially significant emotional distress faced by women entering menopause and be prepared to offer psychological support. Subtle signs of the menopausal transition may be overlooked, because a woman may be hesitant to report unusual and potential hormonally related symptoms. Unless asked about directly, these symptoms often go undetected and result in a delay in diagnosis and treatment.

Loss of Childbearing Capacity

The effect of the loss of the ability to have children may depend on many factors, including the role childbearing has played in a woman's life. For some women in whom childbearing and childrearing have been a major source of status and self-esteem, the loss of fertility may cause great distress (30). For other women who have delayed childbearing for various reasons and are now unable to become pregnant, menopausal symptoms may represent tangible evidence of their inability to have children. One study suggests, however, that single and childless women are less likely to be depressed than their parous counterparts (31).

Loss of Youth

Regardless of the effect of the loss of childbearing capacity, the distress produced by the loss of youth symbolized by menopause may be subtle yet disturbing (29). In our society, youth is highly prized whereas maturity often is not; thus, tangible evidence of aging may be traumatic. The degree to which this may affect a woman may be related to the value she places on personal appearance. Aging may not be important to many women, but the possibility that this may cause anxiety or depression should be considered.

Skin Changes

The apparent acceleration of the skin changes associated with aging, especially after menopause, is a concern for many women. Evidence suggests that estrogen deficiency may play a role in these changes and that estrogen therapy may help to maintain skin thickness (32). Mechanisms underlying this effect are not completely understood but appear related to the ability of estrogen to both prevent and restore age-related skin collagen (33,34). Certainly, estrogen therapy cannot completely prevent the effects of aging on skin, nor can it counteract the effects of environmental stresses on skin, such as sun exposure and cigarette smoking.

Changes in Mood and Behavior

Depression

Depression is a particularly common problem for women and older patients. It accounts for more than 20% of visits of those who seek medical care (35). Although it is a widely held belief that depression is increased during the perimenopausal period, studies have failed to show a relationship between clinical depression and hormonal status (36). This finding would suggest that many psychiatric symptoms occurring during this period may be more related to psychosocial events such as changes in relationships with children, marital status, and other life events than to changes in hormonal status (37).

Anxiety and Irritability

Many women report an increased level of anxiety and irritability during the perimenopausal period; thus, these symptoms have become a prominent part of what is sometimes termed the *climacteric syndrome* (38). These feelings can be exacerbated by sleep deprivation as a result of vasomotor symptoms. Although the incidence of overt psychiatric disorders may not be increased, these complaints become more frequent following menopause. A popular notion is that anxiety and irritability associated with menopause are the result of estrogen deficiency (30). Multiple studies, however, have found no evidence to suggest that psychological symptoms experienced during the menopausal transition are related to estrogen changes (39,40). Increased anxiety and irritability associated with the perimenopausal period are more clearly associated with psychosocial factors than with estrogen status (41). It is important not only to investigate and treat the constellation of symptoms associated with the menopausal transition, but also to realize that psychological intervention may be helpful for some women.

Decreased Libido

A major concern for some women is a decrease in libido or sexual satisfaction that may occur with natural or surgical menopause. Sexual activity, however, remains relatively stable in menopausal women (42). However, only one-half of menopausal women report being sexually active (43). This may be related to a decrease in the number of available male partners in an aging population (1).

Vaginal changes associated with menopause may also contribute to decreased sexual satisfaction. Approximately one-third of postmenopausal woman not taking estrogen supplements will experience vaginal atrophy (44). Discomforts resulting from a lack of vaginal lubrication can also lead to dyspareunia. Atrophy can be treated easily with oral or vaginal estrogen therapy. Vaginal lubricants, especially those that are water soluble, are specifically useful for vaginal dryness.

The role androgens play in libido before and after menopause is uncertain. Although testosterone levels have been reported to be lower in postmenopausal than in premenopausal women, circulating concentrations do not change at menopause, and free testosterone levels might actually increase for several months before they decrease to levels lower than those of premenopausal women (45). In contrast, there is a marked drop in androgen levels following oophorectomy (11). In men, the relationship of androgens to libido is well established. For this reason, some clinicians have advocated androgen therapy in women experiencing decreased libido (46). In women, however, the decrease in circulating androgens following menopause has not been shown to consistently alter libido. Available evidence suggests that sexual satisfaction among postmenopausal women is not decreased over time, making treatment with androgens controversial (47).

Menopausal Transition

Beginning at the age of 40 years, routine health maintenance should include screening for problems related to hormonal changes. Questions concerning changes in menstrual function, abnormal bleeding, hot flashes, sleep disturbances, and sexual function should be asked routinely.

Abnormal Bleeding

Menstrual irregularity occurs in more than one-half of all women during the menopausal transition (48). Uterine bleeding can be irregular, heavy, or prolonged. In most cases, this bleeding is related to anovulatory cycles. This disruption of normal menstrual flow has been attributed to a gradual decrease in the number of normally functioning follicles and is reflected by a gradual increase in early follicular-phase FSH levels (49).

Although anovulation is one of the more common causes of abnormal uterine bleeding, pregnancy must always be considered. There are numerous reports of pregnancies in women in their late 40s who did not consider themselves fertile. In these women, abnormal bleeding may be the first indicator of an unexpected pregnancy.

Endometrial cancer should be suspected in any perimenopausal women with abnormal uterine bleeding. After menopause, the overall incidence of endometrial cancer is approximately 0.1% of women per year, but in women with abnormal uterine bleeding, it is about 10% (50,51,52 and 53). This risk is increased at least fivefold in women with a history of unopposed estrogen use (52,53) and decreased by more than two-thirds in women taking a combination of estrogen and a progestin (50).

Malignant precursors such as complex endometrial hyperplasia become more common during the menopausal transition. Because early diagnosis is the most effective way to improve a woman's prognosis, perimenopausal women with abnormal uterine bleeding should undergo an endometrial biopsy to exclude a malignant condition. Other causes that should be considered when a woman experiences abnormal uterine bleeding include cervical cancer, polyps, or leiomyomata.

Evaluation

The goal of evaluation of abnormal uterine bleeding is to achieve the greatest accuracy with the least risk and expense for the patient. In the past, when few diagnostic options were available, this condition was routinely managed with inpatient uterine curettage (54). However, with the development of less invasive office procedures and more accurate outpatient surgical approaches, uterine curettage without hysteroscopy is seldom done (Fig. 29.1).

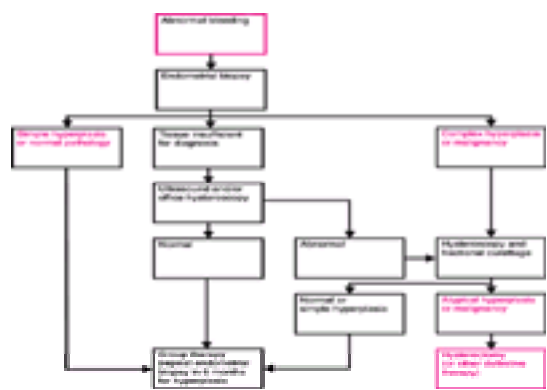

Figure 29.1 Management of postmenopausal abnormal uterine bleeding.

Vaginal Ultrasonography

With the advent of newer diagnostic modalities, vaginal ultrasonography has become an established first step in the evaluation of perimenopausal bleeding. In premenopausal women, vaginal ultrasonography is extremely useful for identifying leiomyomata and endometrial asymmetry suggestive of endometrial polyps. When combined with saline injection, sonohysterography can accurately visualize polyps and other focal intrauterine lesions (55).

In postmenopausal women, vaginal ultrasonography, with or without saline injection, is even more helpful than in premenopausal women. An endometrial stripe <5 mm thick has been shown to be associated with an extremely low risk of endometrial hyperplasia or cancer (55,56 and 57). A thickened or asymmetric endometrial lining or an obvious intrauterine lesion is an indication for more thorough evaluation (Fig. 29.1) (55). Likewise, refractory abnormal uterine bleeding in a high-risk patient is an indication for endometrial biopsy even in the presence of reassuring ultrasonographic findings.

Endometrial Sampling

The importance of the endometrial biopsy cannot be overemphasized for the pre- or postmenopausal woman with abnormal uterine bleeding. It is well accepted that endometrial biopsy performed in the office is just as accurate as dilation and curettage and certainly more economical (54). Although vaginal ultrasonography has changed the way patients with abnormal uterine bleeding are evaluated, endometrial biopsy continues to be the most accurate screening method available for these patients. **Dilation and curettage in the operating room with adequate anesthesia should be reserved for patients with abnormal endometrial biopsies or for conditions that preclude performing an office biopsy, such as cervical stenosis.**

Hysteroscopy with Uterine Curettage

The addition of hysteroscopy to uterine curettage has greatly improved diagnostic accuracy in the evaluation of focal intrauterine lesions (58,59). It allows for visual inspection of the endometrial cavity and gives the physician the opportunity to perform directed biopsies (59). Endometrial polyps or submucosal leiomyomas can easily be identified by hysteroscopy. As with many high-technology approaches, however, hysteroscopy requires appropriate training and equipment to ensure patient safety. If hysteroscopy is unavailable, dilation and curettage remains an accepted method for evaluation of the endometrium (54) (see Chapter 13).

Treatment

Treatment of perimenopausal abnormal uterine bleeding may be either hormonal or surgical, depending on the patient's symptoms and diagnosis. Because anovulation is one of the most common causes of abnormal uterine bleeding during menopause, hormonal therapy is the first approach after the presence of intrauterine pathology has been excluded.

Hormonal Therapy

Oral Contraceptives In low-risk premenopausal women with hormone-related symptoms, modern low-dose (0.35 mg ethinyl estradiol) oral contraceptives offer many advantages with minimal risk (60). New formulations contain as little as 20 mg of ethinyl estradiol and 1 mg of desogestrel. In addition to preventing undesired pregnancies, these formulations are associated with a high degree of menstrual regularity and can be used to treat symptoms associated with relative estrogen deficiency. The use of oral contraceptives until menopause has been found to be safe in women with no risk factors for cardiovascular disease (61).

Before starting the administration of oral contraceptives in this age group, patients should be free of the following risk factors: hypertension, hypercholesterolemia, cigarette smoking, previous thromboembolic disorders, cerebral vascular disease, or coronary artery disease. Because the estrogen dose in these pills is approximately 4 times the dose used after the menopause, women taking this therapy should be switched to traditional estrogen therapy by 50 years of age or sooner if symptoms occur. If the estradiol level is <20 pg/ml on day 7 of the pill-free interval, it may be appropriate to

switch from oral contraceptives to estrogen replacement therapy (62).

Cyclic Progestins Some women may not be candidates for oral contraceptives, because their use is contraindicated or unacceptable based on the presence of other symptoms or because of fear of complications. In these patients, alternative methods of hormonal therapy can be used. A standard approach is cyclic progestin therapy (*medroxyprogesterone* 10 mg daily for 10 days each month) to induce withdrawal bleeding and to decrease the risk of endometrial hyperplasia. It may be difficult to control abnormal uterine bleeding with cyclic progestin during the menopausal transition, because the ovaries continue to cycle intermittently. Progestin administration may be difficult to synchronize with spontaneous ovulation.

Surgical Therapy

During the menopausal transition, surgery may be required for treatment of conditions causing abnormal uterine bleeding.

Dilation and Curettage When endometrial polyps are determined to be the cause of abnormal uterine bleeding, curettage can be both therapeutic and diagnostic. Because polyps can be missed by curettage alone, it has been recommended that diagnostic hysteroscopy be performed prior to uterine curettage for abnormal uterine bleeding (58). With the exception of endometrial polyps, uterine curettage has not been shown to have any long-term benefit in the treatment of abnormal uterine bleeding.

Hysterectomy Although removal of the uterus is the most common and effective surgical treatment for abnormal uterine bleeding (63), hysterectomy is associated with a certain degree of morbidity and cost. Prior to recommending hysterectomy, an adequate preoperative evaluation must include endometrial sampling and an adequate trial of hormonal therapy to control the bleeding.

A special consideration is whether normal ovaries should be removed (see Chapter 22). It is now standard practice for postmenopausal women undergoing hysterectomy to have their ovaries removed to avoid the subsequent risk of ovarian cancer (64). Oophorectomy has been recommended in women older than 40 to 45 years for the same reason. In premenopausal women, however, there are some disadvantages to oophorectomy. First, immediate hormone replacement is necessary and may be somewhat more difficult to manage because of the sudden and precipitous drop in estrogen levels. In addition, oophorectomy results in a decrease in androgen production, which may have as yet unknown long-term effects (11). After 40 years of age, the decision to remove normal ovaries during hysterectomy should be discussed carefully and the patient should be made aware of the potential known advantages and disadvantages.

Endometrial Ablation A relatively new and potentially advantageous approach to dysfunctional uterine bleeding during the menopausal transition is endometrial ablation. This relatively minor surgical procedure involves destroying the functioning endometrium with electrical energy using a hysteroscopic resectoscope, as discussed in Chapter 21. The risks of uterine perforation, bowel injury, and fluid overload related to the nonconducting distention media are low if the technique is used correctly (65).

In response to these problems, a nonsurgical thermal balloon endometrial ablation technique has been developed that requires a substantially lower level of technical skill (65). First reported in 1994, this method is performed by blind placement in the uterus of a single-use saline-filled balloon catheter that is warmed rapidly to cause thermal damage to the endometrium. Most patients report either decreased bleeding or amenorrhea, and both intraoperative and postoperative complications are uncommon.

The risk of uterine malignancy after any type of endometrial ablation procedure remains uncertain. The concern is that as the injured endometrial lining remodels, glandular tissue may be buried under scar tissue. Theoretically, this situation could delay uterine bleeding, which is the earliest sign of endometrial cancer. However, subsequent endometrial cancer after endometrial ablation has been reported only in women who had preexisting endometrial hyperplasia (66). For this reason, a thorough fractional curettage should be performed prior to the procedure. Monthly progestin therapy could be used thereafter in an attempt to decrease the risk in these potentially anovulatory women. Until long-term data become available, women considering this therapy should be informed about the potential risk of endometrial ablation.

Menopause

Most women experience some effects of estrogen deficiency during menopause. Other symptoms often associated with menopause may not be directly related to estrogen deficiency but rather are multifactorial or the results of aging. Effects can range from short-term discomfort to long-term changes that can have a profound effect on a woman's health. Both short-term and chronic effects respond to hormone replacement therapy.

Diagnosis of Estrogen Deficiency

The determination of ovarian function is based primarily on clinical criteria. If a woman's body is producing enough hormones to sustain regular menstruation, her estrogen level is presumed to be sufficient to protect against osteoporosis and heart disease. In the years prior to menopause, many women experience symptoms of estrogen deficiency due to declining ovarian function even while they are having relatively regular menses. These symptoms typically begin with a break in the regular pattern of ovulatory cycles and often include irregular vaginal bleeding, hot flashes, night sweats, mood swings, vaginal dryness, insomnia, heart palpitations, headache, and fatigue. Even though measurable levels of circulating hormones are still present, hormone replacement therapy in these women can be extremely helpful in controlling symptoms (67). If a woman who is almost 50 years old stops menstruating completely, a presumptive diagnosis of estrogen insufficiency can be made. However, because chronic anovulation is common during this time and can also cause amenorrhea, a progestin challenge test is frequently used as a bioassay of estrogen status (68). If a nonpregnant woman has amenorrhea but no other symptom of estrogen deficiency, administration of *medroxyprogesterone* (10 mg orally for 10 days) will produce withdrawal bleeding in women who have levels of circulating estrogen adequate to produce endometrial proliferation.

Estradiol

In women who have amenorrhea along with other symptoms of estrogen deficiency or in whom progestin withdrawal bleeding does not occur, measurement of serum estradiol levels can be helpful. In a menstruating woman, normal estradiol levels range from 40 to 300 pg/ml. In an oligoovulatory woman, an estradiol level of 30 pg/ml usually indicates some degree of residual ovarian function. Women over 70 years of age occasionally have levels this high, presumably as a result of peripheral conversion (30). For this reason, **the absolute estradiol level should not be the deciding factor when considering hormone replacement therapy.**

During the menopausal transition, relative ovarian resistance with fluctuating estrogen secretion may result in hot flashes and related symptoms despite relatively normal serum estradiol levels. Because many of the symptoms of the menopausal transition are central nervous system in origin, treatment is sometimes indicated for symptoms alone and should not be withheld simply because the serum estradiol levels are in the normal range.

Follicle-stimulating Hormone

The most consistent finding in the menopausal transition is an elevation of serum FSH levels. In fertile menstruating women, FSH on cycle day 3 should be 5 to 10 IU/L with normally functioning ovaries (69). Elevated FSH levels (10 to 25 IU/L) suggest relative ovarian resistance consistent with the menopausal transition, even if estradiol levels are in the normal range. Physiologically, this is believed to be the result of decreased inhibin production by the ovarian follicles during the last decade of menstrual function. FSH levels >40 IU/L are consistent with complete cessation of ovarian function. However, ovarian function can wax and wane over several years, and levels can fluctuate accordingly. Therefore, women with amenorrhea and FSH >40 IU/L may resume menstruating for a short time in the future and occasionally may achieve pregnancy (70).

Luteinizing Hormone

Evaluation of luteinizing hormone (LH) levels appears to be of somewhat less value than other hormone assessments during the menopausal transition. Prior to menopause, LH levels are usually in the range of 5 to 20 IU/L. Although LH levels increase during the menopausal transition in a manner similar to those of FSH, LH is also significantly elevated during the midcycle surge and in cases of chronic anovulation. Because individuals rarely may have amenorrhea as a result of

gonadotropin-secreting pituitary adenomas, it is reasonable to check both LH and FSH in women, especially young patients, with apparent loss of ovarian function (71).

Symptoms

Amenorrhea

The most obvious symptom of cessation of cyclic ovarian function is prolonged amenorrhea. The cessation of menstruation indicates that the amount of estrogen produced by the ovaries is no longer enough to promote endometrial proliferation, and the absence of cyclic progesterone production is accompanied by the absence of withdrawal bleeding.

This is an advantageous situation for several reasons. First, the sometimes-disabling discomfort and anemia suffered by many women as a result of cyclic bleeding is no longer a problem. Second, any abnormal bleeding that may occur later serves as a warning for potential malignancy and is obvious to both the patient and her physician.

Unfortunately, hormone replacement therapy results in vaginal bleeding in most women (72). Not only is this effect a common reason for discontinuing hormone replacement therapy, but bleeding that would normally be interpreted as a warning sign is attributed to the hormone therapy, potentially delaying diagnosis of a malignancy.

Hot Flashes

The classic symptom associated with estrogen deficiency is the hot flash, also known as a *hot flush*. This symptom is described as "recurrent, transient periods of flushing, sweating, and a sensation of heat, often accompanied by palpitations, feelings of anxiety, and sometimes followed by chills" (73). The entire episode usually lasts no more than 1 to 3 minutes and may recur as many as 30 times per day, although 5 to 10 times per day is probably more common (8). Hot flashes are experienced by at least one-half of all women during natural menopause and by even more women after surgical menopause (73,74).

Although most women do not report these events as particularly disturbing, as many as 25% complain of severe or frequent hot flashes, especially after surgical menopause. In these cases, hot flashes may be accompanied by fatigue, nervousness, anxiety, irritability, depression, and memory loss (75). These sensations may result in part from hot flashes that occur at night, referred to as *night sweats*, which are believed to exert their effect by the interruption of sleep patterns. Early in the menopausal transition, vasomotor instability may manifest as an intermittent sleep disturbance in the absence of obvious hot flashes.

Physiologically, hot flashes correspond to marked, episodic increases in the frequency and intensity of gonadotropin-releasing hormone (GnRH) pulses from the hypothalamus. Although it has not been firmly established, it is believed that these symptoms are not the result of increased GnRH secretion. Instead, the increased pulsatile activity is a marker for the same central disturbance of the body temperature regulation center that is responsible for the hot flashes (76).

Estrogen replacement therapy results in the resolution of hot flashes in most women in a matter of days. In some women, especially after oophorectomy, a higher dose of estrogen is commonly needed. In the case of women without risk factors for cardiovascular disease, low-dose oral contraceptives can be used with excellent results. Alternatively, the daily estrogen dose can be increased stepwise to as high as the equivalent of 2.5 mg of *conjugated estrogens* to resolve persistent hot flashes. The estrogen dose should be tapered slowly over a period of months to no more than 1.25 mg of *conjugated estrogen* per day, because the risk of cardiovascular disease actually may be increased in women taking larger doses (77).

In women for whom hormone replacement is contraindicated, multiple alternative treatments for hot flashes have been developed. Somewhat effective alternatives may be progestins such as *medroxyprogesterone* (10 to 30 mg daily orally) (78) or *megestrol acetate* (20 to 40 mg daily orally) (79). If either of these progestins results in intolerable side effects, the use of alternative progestins may be considered, although few data exist regarding their efficacy.

In addition to the progestins, other nonsteroidal treatments for hot flashes have been developed. One of the best studied is the β_2 -adrenergic agonist, *clonidine*. This drug probably works through both central and peripheral mechanisms and can be given either orally (0.05 mg twice daily) or by transdermal patch (0.1 mg weekly) (80).

In the past, night sweats were treated with a formulation that contained a combination of *phenobarbital*, *ergotamine*, and *belladonna*. However, this combination has a marked sedative effect and potentially can be habit forming. In addition, controlled studies show little long-term effectiveness of this treatment (81). For these reasons, this formulation is not currently recommended as a treatment for hot flashes.

Many women have mild hot flashes that they do not feel require therapy. The patients can be advised that, without treatment, the symptoms usually subside slowly over 3 to 5 years (73).

Sleep Disturbances

Changes in sleep patterns occur in both sexes with age. However, during the menopausal transition, many women experience increasing sleep difficulties and insomnia that appear to be related to estrogen deficiency (38). Hot flashes may disrupt sleep and sleep patterns, a problem that may be markedly improved by hormone therapy (82).

Long-term Health Problems Associated with the Menopause

Low estrogen levels have a cumulative effect on many tissues. Prolonged estrogen deficiency may contribute to the development of potentially reversible conditions, such as genitourinary atrophy, or more life-threatening and irreversible conditions, such as cardiovascular disease and osteoporosis. Prevention and early detection remain the cornerstones of health maintenance in this age group.

Vaginal and Urinary Tract Changes

Vaginal tissue and the tissues of the urethra and bladder base are known to be estrogen sensitive. Within 4 to 5 years of menopause, approximately one-third of women who are not taking hormone therapy develop symptomatic atrophy (83). Vaginal symptoms include dryness, dyspareunia, and recurrent vaginal infections. Fortunately, these symptoms are reversible with estrogen therapy (84).

Urinary symptoms may include dysuria, urgency, and recurrent urinary tract infections (44). In addition, genuine stress urinary incontinence may be related to estrogen deficiency. Urethral shortening associated with postmenopausal atrophic changes may result in urinary incontinence. Estrogen therapy may improve or cure stress urinary incontinence in more than 50% of treated women, presumably by exerting a direct effect on urethral mucosa (85). A trial of hormone therapy should be undertaken prior to a surgical approach in any woman with vaginal atrophy.

Central Nervous System

Estrogen deficiency appears to have effects on the central nervous system that have only recently been appreciated. Perimenopausal women often experience difficulty concentrating and loss of short-term memory. These symptoms have been attributed to either the effects of aging alone or subtle sleep deprivation associated with hot flashes (86). Estrogen appears to have direct effects on mental function, and replacement therapy has been shown to improve both short-term and long-term memory in postmenopausal women (87,88).

One of the most intriguing areas of research is the potential role of estrogen therapy in the prevention or treatment of Alzheimer's disease. Evidence suggests that the risk of developing Alzheimer's disease can be decreased by estrogen therapy (89,90), but prospective trials to verify this are lacking. Although the precise role of

estrogen deficiency in Alzheimer's disease has yet to be defined, the implications of this finding for the aging population are readily apparent.

Cardiovascular Disease

Cardiovascular disease, including coronary artery disease and cerebrovascular disease, continues to be the leading public health problem in this country. Combined, these diseases account for more than 50% of all deaths in women over 50 years of age (91).

Cardiovascular disease has been associated with multiple causes, the most important of which may be age. The risk of cardiovascular disease increases for men and women throughout their lifetimes (91). Although the risk of death from coronary artery disease is at least 3 times as great for men as for women before menopause, the relative risk for women increases significantly after menopause. It is essential to be aware of preventable risk factors for cardiovascular disease and to encourage women to minimize these risk factors.

One of the most pervasive and treatable risk factors after the menopause is hypoestrogenemia. In the past, it was believed that age alone explained the increased risk of cardiovascular disease observed after menopause (92). Recent data have indicated that estrogen deficiency significantly increases the risk of cardiovascular disease and that this risk may be reduced by hormone replacement therapy (93). Postmenopausal women taking estrogen replacement therapy have less than one-half the risk of either myocardial infarction or stroke as women who are not taking estrogen therapy (77,91,94). However, long-term prospective trials of the cardiovascular benefits and risks of estrogen replacement therapy are lacking. This potentially substantial but controversial benefit of estrogen therapy should be made known to patients, especially those who may be reluctant to take estrogens for other reasons. On the other hand, a short-term trial suggested no overall decrease in mortality and an increase in early venous thrombotic events in women with preexisting cardiovascular disease (95).

Although hypoestrogenemia is apparently a major contributing factor to cardiovascular disease in women, other risk factors that are amenable to change may be equally important. Probably the most significant risk factors are hypertension and cigarette smoking (55). Studies suggest that hypertension increases the risk of cardiovascular disease by 10-fold and cigarette smoking increases the risk by at least threefold (96). Other risk factors include diabetes mellitus, hypercholesterolemia, and a sedentary lifestyle. To decrease cardiovascular disease in postmenopausal women, screening for these risk factors must be performed and lifestyle changes must be recommended.

Osteoporosis

The association between both natural and surgical menopause and osteoporosis has been clearly established. By definition, osteoporosis is the reduction in the quantity of bone. Because this definition may be too broad to be clinically useful, some authors have narrowed the definition to include only bone loss that has progressed to a point that specific parts of the skeleton are so thin that they have an enhanced susceptibility to fractures or that fractures are actually present (97). The degree of cortical and trabecular bone loss necessary to meet this criterion is uncertain in those who have not yet had a bone fracture. The numbers of elderly women who have osteoporosis-related crush fractures of spinal vertebrae or fractures of either the radius or the neck of the femur have reached epidemic proportions (98). With the aging of the population, the problem is likely to increase.

Although the rate of bone loss significantly increases at the time of menopause, the maximal incidence of osteoporosis-related fractures appears to occur several decades later. It is estimated that more than 30% of all women older than 90 years will experience hip fractures (99), and approximately 20% of these women will die within 3 months, most commonly from complications related to prolonged immobilization (100). By the time signs of osteoporosis become apparent, treatment is difficult.

Pathophysiology

The cause of osteoporosis is multifactorial. The primary factors associated with osteoporosis include heredity, age, estrogen status, and dietary calcium intake.

Age is the most important factor associated with bone loss (101). All women begin losing bone mass in their early 30s, and this loss continues throughout their lives. Before menopause, the rate of loss is less than 1% of total bone tissue per year. After menopause, the rate of bone loss increases to as high as 5% per year in estrogen-deficient women. Evidence suggests that this may be related to the gradual decrease in growth hormone levels associated with age (102).

Heredity plays a role primarily by determining the peak bone mass that a woman will attain during her life and the subsequent rate of bone loss. On average, African American women have a higher bone mass than white women, and this may explain the low risk of osteoporosis-related fractures observed in African Americans (103). A family history of osteoporosis is a strong risk factor (104).

A third factor associated with bone loss is estrogen status. For women not taking hormone replacement, bone loss after menopause is accelerated to a rate of 3% to 5% per year (105). This loss is most rapid during the first 5 years after menopause, when up to 20% of the expected lifetime loss from the femoral neck may occur (106). Depending on the age at surgery, surgical menopause poses a higher risk than natural menopause because a woman experiences a longer period with low estrogen levels (107). Hypoestrogenemia has a direct effect on osteoblast function and appears to exert its adverse effects by altering calcium balance (108,109).

A fourth factor affecting bone loss is dietary calcium. Dietary intake of calcium, primarily in the form of dairy products, has been shown to be associated with decreased bone loss in premenopausal women (110). In postmenopausal women taking estrogen therapy, calcium supplementation of 1,000 mg/day appears to be sufficient to decrease bone loss (111). Combined with the average dietary intake of calcium in the United States of only 500 mg/day for adults (110), the total requirement of 1,500 mg/day is provided by diet plus supplementation. Calcium therapy can be given as calcium carbonate (oyster shell) tablets or as calcium citrate. Fortunately, this amount of calcium supplementation does not appear to increase the risk of kidney stones (112). However, it may be associated with gastrointestinal complaints such as constipation or increased flatus.

Other factors that preserve bone density and decrease the risk of osteoporosis include physical activity (113) and avoidance of cigarette smoking (114). There have been no controlled studies of these factors to determine their impact on osteoporosis-related fractures in later life.

Methods for Detection

After a prolonged period of hypoestrogenemia, bone loss is only partially reversible. For these reasons, it is more practical and effective in most women to implement therapy to prevent bone loss at the time of menopause than to screen for early signs of osteoporosis.

In some women, hormone replacement therapy may be contraindicated or not desired by the patient. In these women, an alternative approach would be to screen for bone loss at set intervals and institute therapy if a defined threshold of osteopenia is reached (Table 29.1). No standard guideline for significant osteopenia has been established, but recommendations for screening have been published (115).

Test	Advantages	Disadvantages
Standard radiograph	Lowest total radiation exposure	Detects only bone losses of >30–40%
Single-photon absorptiometry, hand	Does not closely correlate with vertebral bone density	—
Dual-energy x-ray absorptiometry	Measures radius, hip, and spine	—
Quantitative computed tomography	—	Highest total radiation exposure

Table 29.1. Radiographic Techniques to Screen for Osteoporosis

Hormone Replacement Therapy

Estrogen deficiency has been considered by many to be a physiologic rather than a pathologic condition, probably because ovarian failure is genetically programmed. With the increased life expectancy of women, however, the negative impact of prolonged estrogen deficiency becomes more significant. Although estrogen deficiency is treatable, fewer than 20% of postmenopausal women take estrogen (116). Although hormone replacement therapy is not completely risk free, the health benefits appear to outweigh the risks for most women.

Benefits

Hormone replacement therapy is indicated for any woman with signs or symptoms of hypoestrogenemia (Table 29.2). Because of the health risks associated with estrogen deficiency, replacement therapy should be offered to all postmenopausal women who have no contraindications. Women with known risk factors for osteoporosis should be encouraged to consider taking estrogen to minimize their risks. Some of the benefits of estrogen are felt immediately, but the long-term benefits may not be apparent for several decades.

Indications	Contraindications
Menopause	Absolute
Hot flashes	Pregnancy
Vaginal atrophy	Undiagnosed uterine bleeding
Urinary tract symptoms	Active thrombophlebitis
High risk for osteoporosis	Current gallbladder disease
Family history	Liver disease
Cigarette smoker	Relative
Low body weight	History of breast cancer
Radiographic evidence	History of recurrent thrombophlebitis or thromboembolic disease
High risk for cardiovascular disease	
Previous myocardial infarction or angina	
Hypertension	
Family history	
Cigarette smoker	

Table 29.2. Indications and Contraindications for Estrogen Replacement Therapy

Hot Flashes

Relief of hot flashes is the most common reason motivating women to start and continue hormone replacement. Hot flashes may interfere with the normal sleep cycle resulting in insomnia (86) and, in severe cases, they may also interfere with concentration (73). Although oral estrogen therapy usually is effective in reducing the severity and frequency of hot flashes within a few days, patients should be advised that it might be several weeks before maximal relief is achieved.

Osteoporosis

Hormone replacement therapy helps maintain bone mass and skeletal integrity, thereby protecting against osteoporosis (117). Estrogen conserves calcium by both enhancing the efficiency of intestinal absorption and by improving renal calcium conservation (108). In addition, estrogen appears to have a direct effect on osteoclast function (109). Estrogen can effectively slow bone loss and, to a limited degree, it can reverse the bone loss associated with osteoporosis (118). For this reason, hormone replacement therapy should be initiated at menopause and should be given for a long term, although the optimal duration is unclear.

Recent evidence has suggested that progesterone also has a role in maintaining bone density (119). Progesterone appears to promote bone formation by increasing osteoblast activity, either directly or indirectly, by inhibiting the corticosteroid effect on osteoblasts. This finding supports the use of a progestin alone in women who are unable to take estrogen therapy.

Cardiovascular Disease

Estrogen replacement therapy may protect against cardiovascular disease, including coronary artery disease and stroke, although the issue has not been settled. Multiple cohort and case-control studies have suggested that estrogen decreases the risk of both myocardial infarction and stroke by 50% (76,90,93). Even when there is angiographic evidence of coronary artery disease, estrogen enhances survival (120). However, carefully controlled prospective trials to rule out the possibility of selection bias and other confounding factors must be completed to fully understand the cardiovascular benefits and risks of hormone replacement therapy.

There are several mechanisms by which estrogen could protect the heart. The most important mechanism appears to be the effect of estrogen on serum lipids and lipoproteins. Estrogen decreases circulating levels of low-density lipoproteins (121,122) and increases levels of high-density lipoproteins. Both the absolute decrease in total cholesterol and the increase in the high-density to low-density lipoprotein ratio appear to retard progression of coronary artery disease. Although these effects are attenuated by concomitant progestin use, this effect appears to decrease over time (123). It has been estimated that estrogen accounts for 20% to 50% of the total protective effect for cardiovascular disease. The degree to which progestins may diminish this effect, if any, is unknown.

Estrogen also exerts an antiarteriosclerotic effect on blood vessels (124). This appears to result, in part, from a direct effect on blood vessels that is not reversed by progestin. Estrogen appears to be an antioxidant that decreases the formation of lipid peroxidases, which may prevent arteriosclerosis by minimizing the oxidation of low-density lipoprotein cholesterol, a potent inducer of plaque formation in vessels (125).

A third beneficial effect is that of vasodilation (126). There appears to be a direct effect on blood vessel endothelial cells that results in immediate vasodilation, perhaps mediated by estrogen receptors (127).

A final beneficial effect is on coagulation. Low-dose estrogen therapy (i.e., 0.625 mg daily of *conjugated estrogens*) results in a subclinical decrease in coagulability by decreasing platelet aggregation and fibrinogen and by inhibiting plasminogen formation (128). This effect appears to be lost with higher doses of estrogen (i.e., 1.25 mg of *conjugated estrogens*). At even higher doses, equivalent to those used in oral contraceptives, there is an increase in coagulability. Therefore, doses of estrogen equivalent to 0.625 mg of *conjugated estrogens* should be used for long-term therapy.

Potential Health Risks

The risks of estrogen therapy appear to be dose related. Many of the side effects of high-dose oral contraceptives have not occurred with the lower doses of estrogen used for hormone replacement therapy. Because of the sensitivity of some tissues to estrogen, the potential risks of estrogen for postmenopausal women must be considered.

Breast Cancer

Numerous retrospective and prospective observational studies have evaluated whether exogenous estrogens in the form of either oral contraceptives or estrogen replacement therapy have an impact on the incidence of breast cancer. Although some recent meta-analyses have concluded that there is no increased risk of this malignancy among women who receive hormone replacement (129,130), others have demonstrated a significant increase in breast cancer risk that may be related to the duration of estrogen use (24,131,132). One of these studies showed a relative risk for the development of breast cancer of 1.46 in women who took postmenopausal estrogens for 5 years or longer (24). However, large prospective clinical trials are incomplete and the benefits of hormone replacement may outweigh

this potential risk in some patients.

Endometrial Cancer

A well-established risk of estrogen replacement therapy is endometrial hyperplasia and endometrial cancer. Early observational studies found that women who used estrogen alone were 4 to 7 times more likely to develop endometrial cancer than women who did not (53). The simultaneous use of progestins effectively prevents this problem in most cases (133,134). However, it should be kept in mind that even women taking progestin therapy can develop endometrial cancer, especially if they have used unopposed estrogens in the past (135). Therefore, endometrial evaluation remains an important part of management for all women with irregular vaginal bleeding.

Gallbladder Disease

The risk of symptomatic gallbladder disease is increased by the use of oral contraceptives (135). In a recent questionnaire study of postmenopausal women, hormone replacement therapy doubled the risk of gallbladder disease compared with women taking no hormones (136). However, in two case-control studies, no increased risk could be appreciated (135,137).

Thrombophlebitis

There is no increased risk of thrombophlebitis associated with hormone replacement therapy, despite the well-established association with the use of oral contraceptives. With the standard doses of conjugated estrogens normally used, there is no increased risk of either venous thrombosis or pulmonary embolism in healthy women (138), although there appears to be some increased risk in women with preexisting cardiovascular disease (95). Hormone replacement therapy does not significantly alter clotting factors (139).

No study has specifically addressed the risk of recurrent thrombophlebitis for women taking estrogen. Therefore, women who have a history of thrombophlebitis should be offered hormone replacement therapy with the understanding that it is unlikely, but uncertain, that this therapy alters the risk of recurrent thrombophlebitis (140).

Hypertension

Hypertension has been one of the relative contraindications to oral contraceptives because the higher-dose formulations were found to further increase blood pressure (141). In contrast, at the dosages used for hormone replacement therapy, conjugated estrogens appear to have little effect on blood pressure (142). Because chronic hypertension is a well-established risk factor for myocardial infarction and stroke, women with this disorder should be encouraged to maintain low blood pressure levels and to consider the potential protective effect of hormone replacement therapy for cardiovascular disease.

Side Effects

Vaginal Bleeding

Any vaginal bleeding may be distressing; therefore, hormone replacement regimens associated with amenorrhea are preferable. Daily use of estrogen and cyclic use of progestin produces cyclic bleeding in most women. In an effort to avoid cyclic bleeding, the daily use of estrogen and progestin has been advocated. After several months, daily progestin therapy will result in amenorrhea in more than one-half of women with minimal risk of hyperplasia (72).

Irregular bleeding may be an early warning sign of endometrial hyperplasia or malignancy. More commonly, it is a sign of endometrial atrophy or asynchronous shedding. Because of the known association of estrogen replacement therapy with endometrial cancer, endometrial biopsy is indicated when irregular uterine bleeding occurs postmenopausally.

Breast Tenderness

Breast tenderness can occur with hormone replacement therapy (143). This effect may be related to both estrogen and progesterone stimulation of breast tissue. The symptoms of fibrocystic breast changes may be increased (143,144). The initial approach to relieving breast symptoms is to decrease the daily estrogen dose to the equivalent of 0.625 mg of *conjugated equine estrogen*, and reduce progestin to the equivalent of 2.5 mg of *medroxyprogesterone*. If this is ineffective, the type of estrogen may be changed.

Mood Changes

Progestins are known to cause mood disturbances similar to those of premenstrual syndrome, including anxiety, irritability, or depression (145,146). Because of the significant protective effect of progestins against endometrial cancer, a dose or formulation of progestin that has the fewest side effects should be sought.

Weight Gain and Water Retention

Some women are extremely sensitive to exogenous estrogens and experience symptoms such as weight gain or water retention (147). Although few data are available regarding these problems, alternative doses and formulations of both estrogen and progestins should be used to find the combination with the fewest side effects.

Special Cases

In some women, the standard approach to hormone replacement therapy may not be appropriate or sufficient. Despite the benefits of estrogen administration after menopause, for some this therapy is contraindicated ([Table 29.2](#)).

History of Breast Cancer

One of the most controversial subjects concerning hormone replacement therapy is whether a woman with a history of successfully treated breast cancer can receive estrogen. Because it appears that estrogen replacement therapy may increase the risk of breast cancer, there has been a fear that estrogen may increase the risk of recurrent breast cancer. The limited data available suggest no increased risk of recurrent breast cancer among postmenopausal estrogen users (148,149). Until more long-term data are available, estrogen should be used with caution in women with a history of breast cancer. In a woman with nonmetastatic (node-negative) estrogen receptor–negative breast cancer, particularly one who has a strong family history of osteoporosis and heart disease, the benefits of estrogen may outweigh the low theoretic risk that the hormone will predispose her to the development of recurrent cancer.

History of Endometrial Cancer

Although, theoretically, estrogen and progestin therapy should not increase the risk of recurrent endometrial cancer, there are few data regarding estrogen or progestin therapy in women who have been treated for endometrial cancer (150). Progestins have been used to treat recurrent endometrial cancer (151). One study of women successfully treated for stage I endometrial cancer revealed that a combination of estrogen and progestin therapy does not increase the risk of recurrence (152). Because of the limited information available, any woman with a history of endometrial cancer should be informed of the unknown risk of recurrence with hormone therapy.

Endometriosis

There have been anecdotal reports of recurrent endometriosis (153,154) or malignant transformation of endometriosis in women with endometriosis who take hormone replacement therapy following bilateral oophorectomy (155). Therefore, such women should be treated with continuous estrogen and progestin. In women with severe endometriosis, especially when the bowel, bladder, or ureter is involved, a hormone-free period for up to 6 months immediately after surgery may also be advisable prior to instituting combined estrogen and progestin therapy.

Liver Disease

Hormone replacement therapy has not been associated with the development of liver disease. However, estrogens are metabolized in the liver, and women with normal ovarian function and chronic liver disease are known to have significantly elevated levels of circulating estrogens (156). Likewise, normal doses of conjugated estrogens could lead to a substantially higher level of circulating estrogens than expected in these women. Therefore, hormone replacement therapy should be avoided in women with active or chronic liver disease.

Replacement Hormones and Regimens

The mainstay of hormone replacement in the absence of ovarian function is estrogen, usually with the addition of a progestin. Standard replacement therapy has consisted of concurrent estrogen and progestin in anyone with an intact uterus. Estrogen only was given to women who had had hysterectomies. Better understanding of the effects hormones have on the body has altered these classic approaches to therapy.

Types of Estrogen and Progesterone

Estrogens are available in oral and parenteral forms (Table 29.3). The most commonly prescribed oral estrogen preparation is *conjugated equine estrogen*, a combination of estrone (50%), equilin (23%), 17 α -dihydroequilin (13%), and various other estrogens extracted from the urine of pregnant mares (157). This formulation has been available in the United States for more than 50 years; thus, most of the data regarding the safety and efficacy of estrogen replacement therapy have been gathered from women taking *conjugated estrogens*. Several other estrogen preparations have been developed, and data are accumulating regarding their comparable effectiveness. There is, at present, no compelling reason to recommend one preparation over others based on risks or side effects. If side effects become a problem with one formulation, a woman should be encouraged to try a different dose or estrogen formulation rather than abandon estrogen replacement altogether.

Preparation	Standard Dosage
Conjugated equine estrogen	0.625 mg daily

postmenopausal osteoporosis. Calcium can slow bone loss but does not increase bone mass (182), and calcium intake of 1,500 mg daily is considered a mainstay of both prevention and treatment of osteoporosis in postmenopausal women. Fluoride is the only known agent that can stimulate bone formation and substantially increase bone density (183), but the bone formed is actually more fracture prone, and fluoride is not recommended therapy. *Calcitonin* is probably as effective as estrogen in reducing fracture risk and is a consideration for women who cannot take oral medication (184). *Calcitriol*, a vitamin D analog, can increase lumbar bone mass and decrease the rate of vertebral fractures (185) in women with low vitamin D levels despite adequate daily intake of 400 IU vitamin D. Although *raloxifene* does not appear to slow bone loss as effectively as conventional hormone replacement therapy, it does appear to be effective in reducing fracture risk (186).

Of the bisphosphonates, *alendronate* is approximately 1,000 times more potent than *etidronate* in terms of the inhibition of bone resorption. Newer bisphosphonates, *pamidronate* and *risedronate*, are being evaluated and appear to be equally effective in increasing bone mineral density and reducing fracture risk with fewer side effects. In a randomized study, *alendronate* was given orally 5 to 20 mg/day for 3 years, or 20 mg/day for 2 years followed by 5 mg/day for the third year, along with 500 mg/day of calcium (187). Compared with placebo, the rate of vertebral fracture was approximately one-half: 3.2% for those receiving *alendronate* versus 6.2% for the placebo group.

In general, all women with documented osteoporosis, either by densitometry or previous fracture, are candidates for aggressive antiresorptive therapy in addition to calcium and vitamin D replacement.

Endometrial carcinoma is the most common malignancy of the female genital tract, accounting for almost half of all gynecologic cancers in the United States. About 39,300 new cases are diagnosed annually, resulting in more than 6,600 deaths. Endometrial carcinoma is the fourth most common cancer, ranking behind breast, lung, and bowel cancers, and the seventh leading cause of death from malignancy in women. Overall, about 2% to 3% of women develop endometrial cancer during their lifetime (1).

In recent years, certain factors have led to an increasing awareness of and emphasis on diagnosis and treatment of endometrial cancer. These factors include the declining incidence of cervical cancer and related deaths in the United States, prolonged life expectancy, postmenopausal use of hormone replacement therapy, and earlier diagnosis. The availability of easily applied diagnostic tools and a clearer understanding of premalignant lesions of the endometrium have led to an increase in the number of women diagnosed with endometrial cancer. Although endometrial carcinoma usually presents as early-stage disease and can generally be managed without radical surgery or radiotherapy, deaths from endometrial carcinoma now exceed those from cervical carcinoma in the United States. **Endometrial cancer is a disease that occurs primarily in postmenopausal women and is increasingly virulent with advancing age. The role of estrogen in the development of most endometrial cancers has clearly been established; any factor that increases exposure to unopposed estrogen increases the risk for endometrial cancer.**

During the past several decades, the histopathology, spread patterns, and prognostic factors that affect the prognosis of endometrial cancers have been better defined. Management of endometrial cancer has evolved from a program of preoperative intrauterine radium packing or external pelvic irradiation followed in 6 weeks by hysterectomy, to a single brachytherapy session using an intrauterine tandem and colpostats followed immediately by hysterectomy, to an individualized approach using hysterectomy as primary therapy and employing additional postoperative treatment depending on surgical and pathologic findings. Further analysis and investigation are needed to determine whether this initial operative approach to treatment and staging, followed by targeted postoperative therapy, will translate into improved survival rates and lower morbidity.

Epidemiology and Risk Factors

There appear to be two different pathogenetic types of endometrial cancer (2). The most common type occurs in younger, perimenopausal women with a history of exposure to unopposed estrogen, either endogenous or exogenous. In these women, tumors begin as hyperplastic endometrium and progress to carcinoma. These “estrogen-dependent” tumors tend to be better differentiated and have a more favorable prognosis than tumors that are not associated with hyperestrogenism. The other type of endometrial carcinoma occurs in women with no source of estrogen stimulation of the endometrium. These spontaneously occurring cancers are not associated pathologically with endometrial hyperplasia, but may arise in a background of atrophic endometrium. They are less differentiated and associated with a poorer prognosis than estrogen-dependent tumors. These “estrogen-independent” tumors tend to occur in older, postmenopausal, thin women and are present disproportionately in African American and Asian women.

Several risk factors for the development of endometrial cancer have been identified (3,4,5,6,7 and 8) (Table 30.1). Most of these risk factors are related to prolonged, unopposed estrogen stimulation of the endometrium. Nulliparous women have 2 to 3 times the risk of parous women. Infertility and a history of irregular menses as a result of anovulatory cycles (prolonged exposure to estrogen without sufficient progesterone) increase the risk. Natural menopause occurring after 52 increases the risk for endometrial cancer 2.4 times compared with that in women whose menopause occurred before 49 years of age, probably as a result of prolonged exposure of the uterus to progesterone-deficient menstrual cycles. The risk for endometrial cancer is increased 3 times in women who are 21 to 50 pounds overweight and 10 times in those more than 50 pounds overweight (excess estrone as a result of peripheral conversion of adrenally derived androstenedione by aromatization in fat).

Characteristic	Relative Risk
Nulliparity	2-3
Late menopause	2.4
Obesity	
21-50 lb overweight	3
>50 lb overweight	10
Diabetes mellitus	2.8
Unopposed estrogen therapy	4-8
Tamoxifen therapy	2-3
Atypical endometrial hyperplasia	8-29

Table 30.1. Risk Factors for Endometrial Cancer

Other factors leading to long-term estrogen exposure, such as polycystic ovary syndrome and functioning ovarian tumors, also are associated with an increased risk for endometrial cancer. Menopausal estrogen replacement therapy without progestins increases the risk for endometrial cancer 4 to 8 times. This risk is greater with higher doses and with more prolonged use and can be reduced to essentially baseline levels by the addition of progestin (7). It has been noted that the use of the antiestrogen *tamoxifen* for treatment of breast cancer is associated with a twofold to threefold increased risk for the development of endometrial cancer (8,9). Diabetes mellitus increases a woman's risk for endometrial cancer by 1.3 to 2.8 times. Other medical conditions, such as hypertension and hypothyroidism, have been associated with endometrial cancer, but a causal relationship has not been confirmed.

Endometrial Hyperplasia

Endometrial hyperplasia represents a spectrum of morphologic and biologic alterations of the endometrial glands and stroma, ranging from an exaggerated physiologic state to carcinoma *in situ*. Clinically significant hyperplasias usually evolve within a background of proliferative endometrium as a result of protracted estrogen stimulation in the absence of progestin influence. Endometrial hyperplasias are important clinically because they may cause abnormal bleeding, be associated with estrogen-producing ovarian tumors, result from hormonal therapy, and precede or occur simultaneously with endometrial cancer.

The most recent classification scheme endorsed by the International Society of Gynecological Pathologists is based on architectural and cytologic features as well as long-term studies that reflect the natural history of the lesions (10) (Table 30.2). Architecturally, hyperplasias are either simple or complex; the major differing features are complexity and crowding of the glandular elements. Simple hyperplasia is characterized by dilated or cystic glands with round to slightly irregular shapes, an increased glandular-to-stromal ratio without glandular crowding, and no cytologic atypia. Complex hyperplasia has architecturally complex (budding and infolding), crowded glands with less intervening stroma without atypia. Atypical hyperplasia refers to cytologic atypia and can be categorized as simple or complex, depending on the corresponding glandular architecture. Criteria for cytologic atypia include large nuclei of variable size and shape that have lost polarity, increased nuclear-to-cytoplasmic ratios, prominent nucleoli, and irregularly clumped chromatin with parachromatin clearing (Fig. 30.1).

Type of Hyperplasia	Progression to Cancer (%)
Simple (cystic without atypia)	1
Complex (adenomatous without atypia)	3
Atypical	
Simple (cystic with atypia)	8
Complex (adenomatous with atypia)	29

Table 30.2. Classification of Endometrial Hyperplasias

Figure 30.1 Atypical hyperplasia (complex hyperplasia with severe nuclear atypia) of endometrium. A: The proliferative endometrial glands reveal considerable crowding and papillary infoldings. The endometrial stroma, although markedly diminished, can still be recognized between the glands. **B:** Higher magnification demonstrates disorderly nuclear arrangement and nuclear enlargement and irregularity. Some contain small nucleoli. (Reproduced or modified from **Berek JS, Hacker NF. Practical gynecologic oncology.** 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

The risk of endometrial hyperplasia progressing to carcinoma is related to the presence and severity of cytologic atypia. Kurman and colleagues retrospectively studied endometrial curettings from 170 patients with untreated endometrial hyperplasia followed a mean of 13.4 years (11). They found that **progression to carcinoma occurred in 1% of patients with simple hyperplasia, 3% of patients with complex hyperplasia, 8% of patients with atypical simple hyperplasia, and 29% of patients with atypical complex hyperplasia.** Most of the hyperplasias seemed to remain stable (18%) or regress (74%). The premalignant potential of hyperplasia is influenced by age, underlying ovarian disease, endocrinopathy, obesity, and exogenous hormone exposure (12,13).

Of patients with atypical hyperplasia detected in an endometrial biopsy or curettage specimen, about 25% have an associated, usually well-differentiated, endometrial carcinoma seen at hysterectomy. Marked cytologic atypia, a high mitotic rate, and marked cellular stratification are features of atypical endometrial hyperplasia most often associated with the finding of an undiagnosed carcinoma at hysterectomy.

In a report of 85 menopausal women with endometrial hyperplasia treated with *medroxyprogesterone acetate* (10 to 20 mg per day), 84% of 65 who did not have cytologic atypia had complete reversal of the lesions, 6% developed recurrent hyperplasia, but none developed cancer, at a mean follow-up of 7 years (14). By contrast, of 20 patients with cytologic atypia, only 50% responded to progestin, 25% developed recurrent hyperplasia, and 25% developed adenocarcinoma. In another study, hyperplasia resolved in 94% of 32 patients with atypical endometrial hyperplasia who were treated with *megestrol acetate* (20 to 40 mg/d); however, relapse occurred in all 7 patients who discontinued progestin therapy (15).

Progestin therapy is very effective in reversing endometrial hyperplasia without atypia but is less effective for endometrial hyperplasia with atypia. For

women with endometrial hyperplasia without atypia, ovulation induction, cyclical progestin therapy (e.g., *medroxyprogesterone acetate*, 10 to 20 mg/d for 14 days per month), or continuous progestin therapy (e.g., *megestrol acetate*, 20 to 40 mg/d) all appear to be effective. Continuous progestin therapy with *megestrol acetate* (40 mg/d) is probably the most reliable treatment for reversing complex or atypical hyperplasia. Therapy should be continued for 2 to 3 months, and endometrial biopsy should be performed 3 to 4 weeks after completion of therapy to assess response.

Periodic endometrial biopsy or transvaginal ultrasound is advisable in patients being followed after progestin therapy for atypical hyperplasia, because of the presence of undiagnosed cancer in 25% of cases, the 29% progression rate to cancer, and the high recurrence rate after treatment with progestins.

Endometrial Cancer Screening

Screening for endometrial cancer should currently not be undertaken because of the lack of an appropriate, cost-effective, and acceptable test that reduces mortality (16,17 and 18). **Routine Papanicolaou's (Pap) test is inadequate and endometrial cytology is too insensitive and nonspecific to be useful in screening for endometrial cancer even in a high-risk population.** A progesterone challenge test reveals whether the endometrium has been primed by estrogen, but it does not identify abnormal endometrial pathology. Transvaginal ultrasound examination of the uterus and endometrial biopsy are too expensive to be employed as screening tests.

Although many risk factors for endometrial cancer have been identified, screening of high-risk individuals could at best detect only half of all cases of endometrial cancer. Furthermore, no controlled trials have been carried out to evaluate the effectiveness of screening for endometrial cancer. Screening for endometrial cancer or its precursors may be justified for certain high-risk women, such as those receiving postmenopausal estrogen replacement therapy without progestins and members of families with hereditary nonpolyposis colorectal cancer. Conversely, women taking *tamoxifen* receive no benefit from routine screening with transvaginal ultrasound or endometrial biopsy (19,20).

Fortunately, most patients who have endometrial cancer present with abnormal perimenopausal or postmenopausal uterine bleeding early in the development of the disease, when the tumor is still confined to the uterus. Application of an appropriate and accurate diagnostic test in this situation usually results in early diagnosis, timely treatment, and a high cure rate.

Endometrial Cancer

Clinical Features

Symptoms

Endometrial carcinoma most often occurs in women in the sixth and seventh decades of life, at an average age of 60 years; 75% of cases occur in women older than 50 years of age. **About 90% of women with endometrial carcinoma have vaginal bleeding or discharge as their only presenting complaint.** Most women recognize the importance of this symptom and seek medical consultation within 3 months. Some women experience pelvic pressure or discomfort indicative of uterine enlargement or extrauterine disease spread. Bleeding may not have occurred because of cervical stenosis, especially in older patients, and may be associated with hematometra or pyometra, causing a purulent vaginal discharge. This finding is often associated with a poor prognosis (21). **Less than 5% of women diagnosed with endometrial cancer are asymptomatic.** In the absence of symptoms, endometrial cancer is usually detected as the result of investigation of abnormal Pap test results, discovery of cancer in a uterus removed for some other reason, or evaluation of an abnormal finding on a pelvic ultrasound or computed tomography (CT) scan obtained for an unrelated reason. Women who are found to have malignant cells on Pap test are more likely to have a more advanced stage of disease (22).

Abnormal perimenopausal and postmenopausal bleeding should always be taken seriously and be properly investigated, no matter how minimal or nonpersistent. Causes may be nongenital, genital extrauterine, or uterine (23). Nongenital tract sites should be considered based on the history or examination, including testing for blood in the urine and stool.

Invasive tumors of the cervix, vagina, and vulva are usually evident on examination, and any tumors discovered should be biopsied. Traumatic bleeding from an atrophic vagina may account for up to 15% of all causes of postmenopausal vaginal bleeding. This diagnosis can be considered if inspection reveals a thin, friable vaginal wall, but the possibility of a uterine source of bleeding must first be eliminated.

Possible uterine causes of perimenopausal or postmenopausal bleeding include endometrial atrophy, endometrial polyps, estrogen replacement therapy, hyperplasia, and cancer or sarcoma (24,25,26 and 27) (Table 30.3). Uterine leiomyomas should never be accepted as a cause of postmenopausal bleeding. **Endometrial atrophy is the most common endometrial finding in women with postmenopausal bleeding, accounting for 60% to 80% of such bleeding.** Women with endometrial atrophy have usually been menopausal for about 10 years, endometrial biopsy often yields insufficient tissue or only blood and mucus, and there is usually no additional bleeding after biopsy. Endometrial polyps account for 2% to 12% of postmenopausal bleeding. Polyps are often difficult to identify with office endometrial biopsy or curettage. Hysteroscopy, transvaginal ultrasonography, or both may be useful adjuncts in identifying endometrial polyps. Unrecognized and untreated polyps may be a source of continued or recurrent bleeding, leading eventually to unnecessary hysterectomy.

Cause of Bleeding Frequency	Percentage
Endometrial atrophy	60-80
Estrogen replacement therapy	15-25
Endometrial polyps	2-12
Endometrial hyperplasia	5-10
Endometrial cancer	10

Table 30.3. Causes of Postmenopausal Uterine Bleeding

Estrogen therapy is an established risk factor for endometrial hyperplasia and cancer. The risk for endometrial cancer is 4 to 8 times greater in postmenopausal women receiving unopposed estrogen replacement, and the risk increases with time and higher estrogen doses. This risk can be decreased by the addition of a progestin to the estrogen, either cyclically or continuously. Endometrial biopsy should be performed as indicated to assess unscheduled bleeding or annually in women not taking a progestin. **Endometrial hyperplasia occurs in 5% to 10% of patients with postmenopausal uterine bleeding.**

The source of excess estrogen should be considered, including obesity, exogenous estrogen, or an estrogen-secreting ovarian tumor. **Only about 10% of patients with postmenopausal bleeding have endometrial cancer.**

Premenopausal women with endometrial cancer invariably have abnormal uterine bleeding, which is often characterized as menometrorrhagia or oligomenorrhea, or cyclical bleeding that continues past the usual age of menopause. The diagnosis of endometrial cancer must be considered in premenopausal women when abnormal bleeding is persistent or recurrent or if obesity or chronic anovulation is present.

Signs

Physical examination seldom reveals any evidence of endometrial carcinoma, although obesity and hypertension are commonly associated constitutional factors. Special attention should be given to the more common sites of metastasis. Peripheral lymph nodes and breasts should be assessed carefully. Abdominal examination

is usually unremarkable except in advanced cases in which ascites or hepatic or omental metastases may be palpable. On gynecologic examination, the vaginal introitus and suburethral area, as well as the entire vagina and cervix, should be carefully inspected and palpated. Bimanual rectovaginal examination should be performed specifically to evaluate the uterus for size and mobility, the adnexa for masses, the parametria for induration, and the cul-de-sac for nodularity.

Diagnosis

Office endometrial aspiration biopsy is the accepted first step in evaluating a patient with abnormal uterine bleeding or suspected endometrial pathology (28). The diagnostic accuracy of office-based endometrial biopsy is 90% to 98% when compared with subsequent findings at dilation and curettage (D & C) or hysterectomy (29,30 and 31).

The narrow plastic cannulas are relatively inexpensive, can often be used without a tenaculum, cause less uterine cramping, resulting in increased patient acceptance, and are successful in obtaining adequate tissue samples in more than 95% of cases. If cervical stenosis is encountered, a paracervical block can be performed, and the cervix can be dilated. Premedication with an antiprostaglandin agent can reduce uterine cramping. Complications following endometrial biopsy are exceedingly rare; uterine perforation occurs in only 1 to 2 cases per 1,000. Endocervical curettage may also be performed at the time of endometrial biopsy if cervical pathology is suspected. **A Pap test is an unreliable diagnostic test because only 30% to 50% of patients with endometrial cancer have abnormal Pap test results (32).**

Hysteroscopy and D & C should be reserved for situations in which cervical stenosis or patient tolerance does not permit adequate evaluation by aspiration biopsy, bleeding recurs after a negative endometrial biopsy, or the specimen obtained is inadequate to explain the abnormal bleeding. Hysteroscopy is more accurate in identifying polyps and submucous myomas than endometrial biopsy or D & C alone (33,34).

Transvaginal ultrasound may be a useful adjunct to endometrial biopsy for evaluating abnormal uterine bleeding and selecting patients for additional testing (35,36 and 37). Transvaginal ultrasound, with or without endometrial fluid instillation (ultrasonohysterography), may be helpful in distinguishing between patients with minimal endometrial tissue whose bleeding is due to perimenopausal anovulation or postmenopausal atrophy and patients with significant amounts of endometrial tissue or polyps who are in need of further evaluation. The finding of an endometrial thickness greater than 4 mm, a polypoid endometrial mass, or a collection of fluid within the uterus requires further evaluation. Although most studies agree that an endometrial thickness of 5 mm or less in a postmenopausal woman is consistent with atrophy, more data are needed before ultrasound findings can be considered to eliminate the need for endometrial biopsy in a patient who has symptoms.

Pathology

The histologic classification of carcinoma arising in the endometrium is shown in [Table 30.4 \(10,38\)](#).

Endometrioid adenocarcinoma
Usual type
Variants
Villoglandular or papillary
Secretory
With squamous differentiation
Mucinous carcinoma
Papillary serous carcinoma
Clear cell carcinoma
Squamous carcinoma
Undifferentiated carcinoma
Mixed carcinoma

Table 30.4. Classification of Endometrial Carcinomas

Endometrioid Adenocarcinoma

The endometrioid type accounts for about 80% of endometrial carcinomas. These tumors are composed of glands that resemble normal endometrial glands; they have columnar cells with basally oriented nuclei, little or no intracytoplasmic mucin, and smooth intraluminal surfaces (Fig. 30.2). As tumors become less differentiated, they contain vadjust solid areas, less glandular formation, and more cytologic atypia. The well-differentiated lesions may be difficult to separate from atypical hyperplasia.

Figure 30.2 Well-differentiated adenocarcinoma of endometrium. The glands and complex papillae are in direct contact with no intervening endometrial stroma, the so-called back-to-back pattern. (Reproduced or modified from **Berek JS, Hacker NF. Practical gynecologic oncology.** 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Criteria that indicate the presence of invasion and are used to diagnose carcinoma are desmoplastic stroma, glands back-to-back without intervening stroma, extensive papillary pattern, and squamous epithelial differentiation. These changes, with the exception of the infiltrating pattern with desmoplastic reaction, require an area of involvement equal to or exceeding half of a low-power microscopic field (LPF) (>1 LPF; 4.2 mm in diameter) (39,40).

The differentiation of a carcinoma, expressed as its grade, is determined by architectural growth pattern and nuclear features (Table 30.5). In the International Federation of Gynecology and Obstetrics (FIGO) grading system proposed in 1989, tumors are grouped into three grades: grade 1, 5% or less of the tumor shows a solid growth pattern; grade 2, 6% to 50% of the tumor shows a solid growth pattern; and grade 3, more than 50% of the tumor shows a solid growth pattern. In addition, notable nuclear atypia that is inappropriate for the architectural grade increases the tumor grade by one.

Histopathologic degree of differentiation:
 G1: >5% nonsquamous or nonmonolayer growth pattern
 G2: 6%–50% nonsquamous or nonmonolayer growth pattern
 G3: >50% nonsquamous or nonmonolayer growth pattern
Notes on pathologic grading:
 Notable nuclear atypia, inappropriate for the architectural grade, raises a grade 1 (G1) or grade 2 (G2) tumor by one grade.
 In serous adenocarcinoma, clear cell adenocarcinoma, and squamous cell carcinoma, nuclear grading takes precedence.
 Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

FIGO, International Federation of Gynecology and Obstetrics

Table 30.5. FIGO Definition for Grading of Endometrial Carcinoma

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component. This FIGO system is applicable to all endometrioid carcinomas, including its variants, and to mucinous carcinomas. In serous and clear cell carcinomas, nuclear grading takes precedence; however, most investigators believe that these two carcinomas should always be considered high-grade lesions, making grading unnecessary.

About 15% to 25% of endometrioid carcinomas have areas of squamous differentiation (Fig. 30.3). In the past, tumors with benign-appearing squamous areas were called *adenocanthomas*, and tumors with malignant-looking squamous elements were called *adenosquamous carcinomas*. It is now recommended that the term *endometrial carcinoma with squamous differentiation* be used to replace these two designations because the degree of differentiation of the squamous component parallels that of the glandular component and the behavior of the tumor is largely dependent on the grade of the glandular component (41,42).

Figure 30.3 Adenocarcinoma with squamous differentiation of endometrium. This lesion is also classified as adenoacanthoma. Squamous cells with eosinophilic cytoplasm and distinct cell borders form solid clusters in the lumina of neoplastic glands. (Reproduced or modified from **Berek JS, Hacker NF. Practical gynecologic oncology.** 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

A villoglandular configuration is present in about 2% of endometrioid carcinomas (43,44). In these tumors, the cells are arranged along fibrovascular stalks, giving a papillary appearance but maintaining the characteristics of endometrioid cells. The villoglandular variants of endometrioid carcinomas are always well-differentiated lesions that behave like the regular endometrioid carcinomas, and they should be distinguished from papillary serous carcinomas.

Secretory carcinoma is a rare variant of endometrioid carcinoma that accounts for about 1% of cases (45,46). It occurs mostly in women in their early postmenopausal years. The tumors are composed of well-differentiated glands with intracytoplasmic vacuoles similar to early secretory endometrium. These tumors behave as regular well-differentiated endometrioid carcinomas and generally have an excellent prognosis. Secretory carcinoma may be an endometrioid carcinoma that exhibits progesterational changes, but a history of progesterational therapy is rarely elicited. Secretory carcinoma must be differentiated from clear cell carcinoma because both tumors have predominately clear cells. These two tumors can be distinguished by their structure: secretory carcinomas have uniform glandular architecture, uniform cytology, and low nuclear grade, whereas clear cell carcinomas have more than one architectural pattern and a high nuclear grade.

Mucinous Carcinoma

About 5% of endometrial carcinomas have a predominant mucinous pattern in which more than half of the tumor is composed of cells with intracytoplasmic mucin (47,48). Most of these tumors have a well-differentiated glandular architecture; their behavior is similar to that of common endometrioid carcinomas, and the prognosis is good. It is important to recognize mucinous carcinoma of the endometrium as an entity and to differentiate it from endocervical adenocarcinoma. Features that favor a primary endometrial carcinoma are the merging of the tumor with areas of normal endometrial tissue, presence of foamy endometrial stromal cells, presence of squamous metaplasia, or presence of areas of typical endometrioid carcinoma. Positive perinuclear immunohistochemical staining with vimentin suggests an endometrial origin (49).

Papillary Serous Carcinoma

About 3% to 4% of endometrial carcinomas resemble serous carcinoma of the ovary and fallopian tube (50,51,52 and 53). Most often, these tumors are composed of fibrovascular stalks lined by highly atypical cells with tufted stratification (Fig. 30.4). Psammoma bodies are frequently observed.

Figure 30.4 Papillary serous carcinoma of endometrium. Branching papillae are supported by delicate fibrovascular cores and lined with columnar cells with moderate nuclear atypism, multiple nucleoli, and mitotic figures. (Reproduced or modified from **Berek JS, Hacker NF. Practical gynecologic oncology.** 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Uterine papillary serous carcinomas (UPSCs) are all considered high-grade lesions. They are commonly admixed with other histologic patterns, but mixed tumors behave as aggressively as pure serous carcinomas. Serous carcinomas are often associated with lymph-vascular space and deep myometrial invasion. Even when

these tumors appear to be confined to the endometrium or endometrial polyps without myometrial or vascular invasion, they behave more aggressively than endometrioid carcinomas and have a propensity for intraabdominal spread, simulating the behavior of ovarian carcinoma. Of patients with clinical stage I disease, more than half are found to have deep myometrial invasion, three fourths manifest lymph–vascular space invasion (LVSI), and about half have extrauterine disease detected at surgery.

The first description of UPSC, in 1982, noted that this entity usually occurred in elderly, hypoestrogenic women who presented with advanced-stage disease and accounted for up to half of deaths from endometrial carcinoma (50). Since then, several reports have documented the aggressive nature and poor prognosis of UPSC. Even when the disease was confined to an endometrioid polyp without other evidence of spread, recurrence developed in more than half of patients (51,52). More recently, in a report on 50 surgically staged patients with UPSC, extrauterine disease was found in 72% (53). Presence of lymph node metastases, positive peritoneal cytology, and intraperitoneal tumor did not correlate with increasing myometrial invasion (53).

Clear Cell Carcinoma

Clear cell carcinoma accounts for less than 5% of all endometrial carcinomas (45,54). Clear cell carcinoma usually has a mixed histologic pattern, including papillary, tubulocystic, glandular, and solid types.

The cells have highly atypical nuclei and abundant clear or eosinophilic cytoplasm. Often, the cells have a hobnail configuration arranged in papillae with hyalinized stalks (Fig. 30.5). Clear cell carcinoma characteristically occurs in older women and is a very aggressive type of endometrial cancer; the prognosis is similar to or worse than that of papillary serous carcinoma. Overall survival rates of 33% to 64% have been reported. Myometrial invasion and LVSI are important prognostic indicators.

Figure 30.5 Clear cell adenocarcinoma of the endometrium. Back-to-back glands lined by polygonal to columnar cells with distinct cell membrane, abundant granular to clear cytoplasm, and variably sized nuclei (including binucleated and multinucleated forms) with prominent nucleoli (magnification × 400).

Squamous Carcinoma

Squamous carcinoma of the endometrium is rare. Some tumors are pure, but most have a few glands. To establish primary origin within the endometrium, there must be no connection with or spread from cervical squamous epithelium. Squamous carcinoma often is associated with cervical stenosis, chronic inflammation, and pyometra at the time of diagnosis. This tumor has a poor prognosis, with an estimated 36% survival rate in patients with clinical stage I disease (55).

Simultaneous Tumors of the Endometrium and Ovary

Synchronous endometrial and ovarian cancers are the most frequent simultaneously occurring genital malignancies, with a reported incidence of 1.4% to 3.8% (56,57,58,59 and 60). Most commonly, both the ovarian and endometrial tumor are well-differentiated endometrioid adenocarcinomas of low stage, resulting in an excellent prognosis. Patients often are premenopausal and present with abnormal uterine bleeding. The ovarian cancer usually is discovered as an incidental finding and is diagnosed at an earlier stage because of the symptomatic endometrial tumor, leading to a more favorable outcome. As many as 29% of patients with endometrioid ovarian adenocarcinomas have associated endometrial cancer. If more poorly differentiated, nonendometrioid histologic subtypes are present or if the uterine and ovarian tumors are histologically dissimilar, the prognosis is less favorable. Immunohistochemical studies, flow cytometry, and assessment of molecular DNA patterns to detect loss of heterozygosity may be helpful in distinguishing between metastatic and independent tumors, but the differential diagnosis can usually be determined by conventional clinical and pathologic criteria.

Pretreatment Evaluation

After establishing the diagnosis of endometrial carcinoma, the next step is to evaluate the patient thoroughly in order to determine the best and safest approach to management of the disease. A complete history and physical examination is of utmost importance. Patients with endometrial carcinoma are often elderly and obese and have a variety of medical problems, such as diabetes mellitus and hypertension, that affect surgical management. Any abnormal symptoms, such as bladder or intestinal complaints, should be evaluated.

On physical examination, attention should be directed to enlarged or suspicious-feeling lymph nodes, abdominal masses, and possible areas of cancer spread within the pelvis. Evidence of distant metastasis or locally advanced disease in the pelvis, such as gross cervical involvement or parametrial spread, may alter the treatment approach. Stool should be tested for occult blood.

A chest x-ray should be performed to exclude pulmonary metastasis and to evaluate the cardiorespiratory status of the patient. Other routine preoperative studies should include electrocardiography, complete blood and platelet counts, serum chemistries (including renal and liver function tests), blood type and screen, and urinalysis. Other preoperative or staging studies are neither required nor necessary for most patients with endometrial cancer. **Studies such as cystoscopy, colonoscopy, intravenous pyelography, barium enema, and CT scanning of the abdomen and pelvis are not indicated unless dictated by patient symptoms, physical findings, or other laboratory tests (61).** Ultrasonography and magnetic resonance imaging (MRI) can be used to assess myometrial invasion preoperatively with a fairly high degree of accuracy (62). This information may be of use in planning the surgical procedure with regard to whether lymph node sampling should be undertaken.

Serum CA125, an antigenic determinant that is elevated in 80% of patients with advanced epithelial ovarian cancers, also is elevated in most patients with advanced or metastatic endometrial cancer (63). In one study, 23 of 81 patients with apparently localized disease preoperatively had elevated CA125 levels (64). At surgery, 20 (87%) of these 23 patients with an elevated CA125 were found to have extrauterine disease, whereas only 1 of 58 patients with a normal CA125 had disease spread outside the uterus (64). Preoperative measurement of serum CA125 may, therefore, help determine the extent of surgical staging and, if elevated, may be useful as a tumor marker in assessing response to subsequent therapy (65).

Clinical Staging

Clinical staging, according to the 1971 FIGO system (Table 30.6), should be performed in patients who are deemed not to be surgical candidates, because of their poor medical condition or the spread of their disease (66). With improvements in preoperative and postoperative care, anesthesia administration, and surgical techniques, almost all patients are medically suitable for operative therapy. One study reported an operability rate of 87% in a series of 595 consecutive patients with clinical early-stage endometrial cancer (67). A small percentage of patients will not be candidates for surgical staging because of gross cervical involvement, parametrial spread, invasion of the bladder or rectum, or distant metastasis.

Stage	Characteristic
I	Confined to the corpus
Ia G123	Uterine cavity <8 cm
Ib G123	Uterine cavity >8 cm
II	Involves the corpus and cervix but has not extended outside the uterus
III	Extends outside the uterus but not outside the true pelvis
IV	Extends outside the true pelvis or obviously involves the mucosa of the bladder or rectum
IVa	Spread to adjacent organs
IVb	Spread to distant organs

FIGO, International Federation of Gynecology and Obstetrics.

Table 30.6. FIGO Clinical Staging of Endometrial Carcinoma (1971)

Surgical Staging

Most patients with endometrial cancer should undergo surgical staging based on the 1988 FIGO system (68,69 and 70) (Table 30.7). At a minimum, the surgical procedure should include sampling of peritoneal fluid for cytologic evaluation, exploration of the abdomen and pelvis with biopsy or excision of any extrauterine lesions suggestive of metastatic cancer, extrafascial hysterectomy, and bilateral salpingo-oophorectomy. The uterine specimen should be opened and tumor size (71), depth of myometrial involvement (72,73 and 74), and cervical extension assessed. Any suspicious pelvic and paraaortic lymph nodes should be removed for pathologic examination.

Stage	Finding
Ia G123	No myometrial invasion
Ib G123	< 1/2 Myometrial invasion
Ic G123	> 1/2 Myometrial invasion
Iia G123	Extension to endocervical glands
Iib G123	Cervical stromal invasion
Iia G123	Positive uterine serosa, adnexa, and/or peritoneal cytology
Iib G123	Vaginal metastasis
Iic G123	Metastasis to pelvic and/or paraaortic lymph nodes
Iva G123	Tumor invasion of bladder and/or bowel mucosa
Ivb	Distant metastasis including intraabdominal and/or inguinal lymph nodes

FIGO, International Federation of Gynecology and Obstetrics.

Table 30.7. FIGO Surgical Staging for Endometrial Carcinoma (1988)

Additionally, clinically negative retroperitoneal lymph nodes should be sampled in all patients with one or more of the risk factors noted in Table 30.8. Tumor histology and depth of myometrial invasion appear to be the two most important factors in determining the risk for lymph node metastasis (69,70). The overall incidence of lymph node metastasis in clinical stage I endometrial cancer is about 3% in grade 1, 9% in grade 2, and 18% in grade 3 tumors (Table 30.9). Less than 5% of patients with no myometrial invasion or with superficial (<50%) myometrial invasion have lymph node metastasis, compared with about 20% of patients with deep (>50%) myometrial invasion (Table 30.10). Pelvic lymph node metastases are present in less than 5% of grade 1 and 2 tumors with superficial myometrial invasion, in about 15% of grade 1 and 2 tumors with deep myometrial invasion or grade 3 tumors with superficial invasion, and in more than 40% of grade 3 tumors with deep myometrial invasion (Fig. 30.6). About one half to two thirds of patients with positive pelvic lymph nodes also have paraaortic lymph node metastases, but the aortic nodes are seldom involved in the absence of pelvic nodal disease. Cervical involvement is associated with about a 15% risk for pelvic or paraaortic node metastasis (70). The incidence of lymph node metastasis also correlates with tumor size (<2 cm, 4%; >2 cm, 15%; entire cavity, 35%) (71). Extrauterine spread of disease increases the risk for pelvic and paraaortic nodal metastasis. Adnexal metastasis increases the risk for pelvic and paraaortic nodal metastasis to 32% and 20%, respectively. Of patients with positive peritoneal cytology, 25% have positive pelvic nodes, and 19% have positive paraaortic nodes (70).

Table 30.10. Relationship of Myometrial Invasion to Lymph Node Metastasis in Clinical Stage I Endometrial Carcinoma

Figure 30.6 The risk for pelvic lymph node metastasis with grade and depth of myometrial penetration in clinical stage I endometrial cancer. Adjuvant pelvic irradiation is recommended for the high-risk group but not for the low-risk group. (From DiSaia PJ, Creasman WT. Management of endometrial adenocarcinoma, stage I with surgical staging followed by tailored adjuvant radiation therapy. *Clin Obstet Gynecol* 1986;13:751, with permission.)

At a minimum, high common iliac and paraaortic lymph node dissections should be performed in the presence of adnexal or cervical involvement, a large tumor (>2 cm), deep (>50%) myometrial invasion, or a moderate to poorly differentiated endometrioid, papillary serous, or clear cell tumor. Pelvic lymph node biopsy may not be as important in patients with these risk factors because most of these patients are treated postoperatively with whole pelvis irradiation. Because fewer than 10% of patients with lymphatic metastasis have grossly enlarged nodes, palpation is not an acceptable alternative to biopsy. Conversely, because almost all patients with lymph node metastases have one or more of the aforementioned risk factors, lymph node biopsies are not required in patients at very low risk for lymphatic metastasis [i.e., patients with small (<2 cm) grade 1 and grade 2 endometrial cancers with only superficial myometrial invasion]. In addition, partial omentectomy should be considered in some high-risk patients, especially those with papillary serous and mixed müllerian tumors, which have a propensity for intraabdominal spread and upper abdominal recurrence.

Extended surgical staging, including selective pelvic and paraaortic lymphadenectomy, in patients with endometrial cancer does not significantly add to the morbidity from hysterectomy, which is primarily related to other factors, such as patient weight, age and race, operating time, and surgical technique. The complication rate with this type of surgery is about 20%; about 6% of these complications are serious. The most common complications are wound infection, embolic phenomena, excess blood loss, gastrointestinal injury or obstruction, and lymphocyst formation (75,76,77,78 and 79).

In addition, selective pelvic and paraaortic lymphadenectomy may have a therapeutic effect (80,81). One study noted that patients who underwent pelvic lymph node sampling had a significant survival advantage overall, as well as in both low-risk and high-risk groups (80). Likewise, paraaortic lymphadenectomy has been found to be a significant positive predictor for recurrence-free survival in patients with high-risk endometrial cancer. Among 137 high-risk patients, the 5-year progression-free survival rate was 77% for patients undergoing paraaortic lymph node dissection, compared with 62% for patients not having paraaortic lymphadenectomy (81).

Surgical staging is extremely important when one considers the poor correlation of preoperative evaluation and clinical staging with surgical and pathologic findings. In a comparison of preoperative findings with surgical pathology, tumor histology was changed in 27% of patients, tumor grade was changed in 34% of patients, and stage was changed in 51% of patients (82). In the Gynecologic Oncology Group (GOG) series, 22% of 621 patients with clinical stage I endometrial cancer had evidence of extrauterine spread, including lymph node metastasis, adnexal spread, peritoneal implants, and positive peritoneal cytology, discovered at staging laparotomy (70) (Table 30.11). In two other studies, extrauterine spread was found in clinical stages I (19%) and II (40%), with an overall incidence of 23.4% (83), and in 19 (12.3%) of 154 clinical stage I and II patients (84). In a retrospective comparison of clinical and surgical stage with respect to survival in 156 patients with endometrial cancer, surgery resulted in an increase in the stage in 12.4% and 27.3% of clinical stage I and II patients, respectively (85). Surgical stage was found to be the most important factor affecting prognosis.

Table 30.11. Surgical-Pathologic Findings in Clinical Stage I Endometrial Cancer

All patients with endometrial cancer who are taken to the operating room for primary therapy should, therefore, be prepared to undergo surgical staging. Such staging may include selective pelvic and paraaortic lymph node dissection in addition to hysterectomy and salpingo-oophorectomy, based on the intraoperative assessment of risk for lymph node metastasis or other extrauterine spread.

Surgical staging identifies most patients with extrauterine disease and has a significant impact on treatment decisions. Surgical staging also identifies patients with uterine risk factors, including deep myometrial invasion, cervical extension, and LVSI. The identification of these factors allows for a more informed approach to the use of postoperative adjuvant radiotherapy, and it is hoped that this approach will improve survival and spare many patients unnecessary exposure to radiation (86,87,88,89,90,91,92 and 93).

Prognostic Variables

Although stage of disease is the most significant variable affecting survival, a number of other individual prognostic factors for disease recurrence or survival have

been identified, including tumor grade, histopathology, depth of myometrial invasion, patient age, and surgical-pathologic evidence of extrauterine disease spread (Table 30.12). Other factors, such as tumor size, peritoneal cytology, hormone receptor status, flow cytometric analysis, and oncogene perturbations, have also been implicated as having prognostic importance.

Age
Histologic type

Genetic/molecular tumor markers

Table 30.12. Prognostic Variables in Endometrial Carcinoma

Age

In general, younger women with endometrial cancer have a better prognosis than older women. Two authors observed no deaths related to disease in patients with endometrial cancer diagnosed before 50 years of age (86,94). Others have demonstrated a 60.9% 5-year survival rate for patients older than 70 years of age, compared with 92.1% survival rate for patients younger than 50 years of age (95). Decreased survival was associated with an increased risk for extrauterine spread (38% versus 21%) and deep myometrial invasion (57% versus 24%) for these two groups. The GOG reported 5-year survival rates of 96.3% for patients 50 years of age or younger, 87.3% for patients 51 to 60 years, 78% for patients 61 to 70 years, 70.7% for patients 71 to 80 years, and 53.6% for patients older than 80 years of age (96).

Increased risk for recurrence in older patients has also been related to a higher incidence of grade 3 tumors or unfavorable histologic subtypes; however, age appears to be an independent prognostic variable. Increasing patient age is independently associated with disease recurrence in endometrial cancer (91). The mean age at diagnosis of patients who had recurrence or died of disease was 68.6 years, compared with 60.3 years for patients without recurrence. For every 1-year increase in age, the estimated rate of recurrence increased 7%. None of the patients younger than 50 years of age developed recurrent cancer, compared with 12% of patients aged 50 to 75 years and 33% of patients older than 75 years of age.

Histologic Type

Nonendometrioid histologic subtypes account for about 10% of endometrial cancers and carry an increased risk for recurrence and distant spread (97,98). In a retrospective review of 388 patients treated at the Mayo Clinic for endometrial cancer, 52 (13%) had an uncommon histologic subtype, including 20 adenocarcinomas, 14 papillary serous, 11 clear cell, and 7 undifferentiated carcinomas. In contrast to the 92% survival rate among patients with endometrioid tumors, the overall survival for patients with one of these more aggressive subtypes was only 33%. At the time of surgical staging, 62% of the patients with an unfavorable histologic subtype had extrauterine spread of disease (97).

Histologic Grade

Histologic grade of the endometrial tumor is strongly associated with prognosis (70,76,88,89,90,91,92 and 93). In one study, recurrences developed in 7.7% of grade 1 tumors, 10.5% of grade 2 tumors, and 36.1% of grade 3 tumors. Patients with grade 3 tumors were more than 5 times more likely to have a recurrence than were patients with grade 1 and 2 tumors. The 5-year disease-free survival rates for patients with grades 1 and 2 tumors were 92% and 86%, respectively, compared with 64% for patients with grade 3 tumors (91). Another study reported similar results, noting recurrences in 9% of patients with grade 1 and 2 tumors compared with 39% of patients with grade 3 lesions (89). Increasing tumor anaplasia is associated with deep myometrial invasion, cervical extension, lymph node metastasis, and both local recurrence and distant metastasis.

Myometrial Invasion

Because access to the lymphatic system increases as cancer invades into the outer one half of the myometrium, increasing depth of invasion has been associated with increasing likelihood of extrauterine spread and recurrence (69,90,93). The association of depth of myometrial invasion with extrauterine disease and lymph node metastases has been confirmed (69). Of patients without demonstrable myometrial invasion, only 1% had pelvic lymph node metastasis, compared with patients with outer one-third myometrial invasion who had 25% pelvic and 17% aortic lymph node metastases. Survival also decreases with increasing depth of myometrial invasion. In general, patients with noninvasive or superficially invasive tumors have an 80% to 90% 5-year survival rate, whereas those with deeply invasive tumors have a 60% survival rate. The most sensitive indicator of the effect of myometrial invasion on survival is distance from the tumor-myometrial junction to the uterine serosa. Patients with tumors that are less than 5 mm from the serosal surface are at much higher risk for recurrence and death than those with tumors greater than 5 mm from the serosal surface (99,100).

Lymph-Vascular Space Invasion

LVSI appears to be an independent risk factor for recurrence and death from all types of endometrial cancer (93,101,102 and 103). The overall incidence of LVSI in early endometrial cancer is about 15%, although it increases with increasing tumor grade and depth of myometrial invasion. One author reported LVSI in 2% of grade 1 tumors and 5% of superficially invasive tumors, compared with 42% of grade 3 tumors and 70% of deeply invasive tumors (101). Another reported deaths in 26.7% of patients with clinical stage I disease who had LVSI, compared with 9.1% of those without LVSI (93). Likewise, an 83% 5-year survival rate has been reported for patients without demonstrable LVSI, compared with a 64.5% survival rate for those in whom LVSI was present (102). Using multivariate analysis, only depth of myometrial invasion, DNA ploidy, and vascular invasion-associated changes correlated significantly with survival of patients with stage I endometrial adenocarcinomas (103).

Isthmus and Cervix Extension

The location of the tumor within the uterus is important. Involvement of the uterine isthmus, cervix, or both is associated with an increased risk for extrauterine disease and lymph node metastasis as well as recurrence. One study reported that if the fundus of the uterus alone was involved with tumor, there was a 13% recurrence rate, whereas if the lower uterine segment or cervix was involved with occult tumor, there was a 44% recurrence rate (88). A subsequent GOG study found that tumor involvement of the isthmus or cervix without evidence of extrauterine disease was associated with a 16% recurrence rate and a relative risk of 1.6 (76). Patients with cervical involvement also tended to have higher-grade, larger, and more deeply invasive tumors, undoubtedly contributing to the increased risk for recurrence.

Adnexal Involvement

Most patients with adnexal spread have other poor prognostic factors that place them at high risk for recurrence. For the 20% of patients with adnexal spread as their only high-risk factor, however, the survival rate has been reported to be as high as 85% (76).

Peritoneal Cytology

The significance of malignant peritoneal cytology in endometrial cancer is a controversial issue ([104](#)). Several reports in the literature have noted increased recurrence rates and decreased survival rates and, on this basis, have recommended treatment for positive cytology. In an early report, positive peritoneal cytology was noted in 26 (16%) of 167 patients with clinical stage I adenocarcinoma of the endometrium ([105](#)). Recurrent cancer developed in 10 (38%) of these 26 patients, compared with 14 (10%) of 141 patients with negative cytology. Positive peritoneal cytology was found to be associated with deep myometrial invasion, cervical involvement, adnexal spread, and lymph node metastasis as well as a propensity for intraabdominal disease recurrence. Several subsequent reports supported the observation that positive peritoneal cytology was associated with an increased risk for cancer recurrence. Most of the studies included patients with other evidence of extrauterine disease spread and were performed without appropriate multivariate analysis and with patients who were incompletely staged. The GOG study, however, critically analyzed 1,180 clinical stage I and II endometrial cancer patients in whom appropriate surgical and pathologic staging was performed ([76](#)). Considering only the 697 patients for whom peritoneal cytology status and adequate follow-up were available, 25 (29%) of 86 patients with positive cytology developed recurrence, compared with 64 (10.5%) of 611 patients with negative cytology. They noted, however, that 17 of the 25 recurrences in the positive cytology group were outside the peritoneal cavity.

In contrast to these reports, an equal number of studies have found no significant relationship between malignant peritoneal cytology and an increased incidence of disease recurrence in early endometrial cancer. In a prospective evaluation of peritoneal cytology in 157 patients with clinical stage I endometrial cancer who underwent primary surgical therapy ([106](#)), no treatment was directed specifically to positive cytology. Positive cytology was not significantly associated with disease recurrence. Recurrence developed in 5 (17%) of 30 patients with positive cytology and in 11 (9%) of 127 patients with negative cytology. Of the 5 patients with positive peritoneal cytology who had disease recurrence, only one recurrence arose within the peritoneal cavity. Patients with malignant washings often had other poor prognostic factors: 37%, deep myometrial invasion; 37%, grade 3 tumors; 17%, positive lymph nodes. Disease recurred in none of the patients with positive cytology but no other poor prognostic factors. A subsequent study confirmed by multivariate analysis that positive peritoneal cytology was not an independent prognostic factor for endometrial cancer recurrence. Only 6 (22%) of the 27 patients with positive cytology as their only evidence of extrauterine disease spread suffered a recurrence despite no therapy directed toward this finding ([91](#)). Positive peritoneal cytology seems to have an adverse effect on survival only if the endometrial cancer has spread to the adnexa, peritoneum, or lymph nodes—not if the disease is otherwise confined to the uterus ([107](#)). More grade 3 tumors (41% versus 19%), vascular invasion (18% versus 6%), adnexal spread (18% versus 4%), lymph node metastasis (29% versus 8%), and intraperitoneal spread (18% versus 2%) occurred in patients with positive peritoneal cytology, which contributed to the overall recurrence rate of 47% in these patients ([107](#)). The 5-year survival rate for patients with positive peritoneal cytology with disease otherwise confined to the uterus exceeded 90%.

The following conclusions may be reached regarding the prognostic implications of positive peritoneal cytology:

1. Positive peritoneal cytology is associated with other known poor prognostic factors.
2. Positive peritoneal cytology in the absence of other evidence of extrauterine disease or poor prognostic factors probably has no significant effect on recurrence and survival.
3. Positive peritoneal cytology, when associated with other poor prognostic factors or extrauterine disease, increases the likelihood for distant as well as intraabdominal disease recurrence and has a significant adverse effect on survival.
4. Use of several different therapeutic modalities has not resulted in any proven benefit to patients with endometrial cancer and positive peritoneal cytology.

Lymph Node Metastasis

Lymph node metastasis is the most important prognostic factor in clinical early-stage endometrial cancer. Of patients with clinical stage I disease, about 10% will have pelvic and 6% paraaortic lymph node metastases. Patients with lymph node metastases have almost a sixfold higher likelihood of developing recurrent cancer than patients without lymph node metastases. One study reported a recurrence rate of 48% with positive lymph nodes, including 45% with positive pelvic nodes and 64% with positive aortic nodes, compared with 8% with negative nodes. The 5-year disease-free survival rate for patients with lymph node metastases was 54%, compared with 90% for patients without lymph node metastases ([91](#)). The GOG found that the presence or absence of paraaortic lymph node metastases was of paramount importance in determining prognosis. Of 48 paraaortic node–positive patients, 28 (58%) developed progressive or recurrent cancer, and only 36% of these patients were alive at 5 years, compared with 85% of patients without paraaortic node involvement ([76](#)).

Intraperitoneal Tumor

Extrauterine metastasis, excluding peritoneal cytology and lymph node metastasis, occurs in about 4% to 6% of patients with clinical stage I endometrial cancer. Gross intraperitoneal spread has been highly correlated with lymph node metastases; one study noted that 51% of patients with intraperitoneal tumor had positive lymph nodes, whereas only 7% of patients without gross peritoneal spread had positive nodes ([70](#)). Extrauterine spread other than lymph node metastasis is also significantly associated with tumor recurrence. Another study found that 50% of patients with extrauterine disease developed recurrence, compared with 11% of patients without extrauterine disease, making recurrence almost 5 times more likely in patients with extrauterine disease spread. The 5-year disease-free survival rate for patients with nonlymphatic extrauterine disease was 50%, compared with 88% in the other patients ([91](#)).

Tumor Size

Tumor size is a significant prognostic factor for lymph node metastasis and survival in patients with endometrial cancer ([71,108](#)). One report determined tumor size in 142 patients with clinical stage I endometrial cancer and found lymph node metastasis in 4% of patients with tumors 2 cm or smaller, in 15% of patients with tumors larger than 2 cm, and in 35% of patients with tumors involving the entire uterine cavity ([71](#)). Tumor size better defined an intermediate-risk group for lymph nodes metastasis (i.e., patients with grade 2 tumors with less than 50% myometrial invasion). Overall, these patients had a 10% risk for lymph node metastasis, but there was no nodal metastasis associated with tumors 2 cm or smaller, compared with 18% when tumors were larger than 2 cm. Five-year survival rates were 98% for patients with tumors 2 cm or smaller, 84% for patients with tumors larger than 2 cm, and 64% for patients with tumors involving the whole uterine cavity ([108](#)).

Hormone Receptor Status

Estrogen receptor and progesterone receptor levels have been shown to be prognostic indicators for endometrial cancer independent of grade in several studies ([109,110,111,112,113,114](#) and [115](#)). Patients whose tumors are positive for one or both receptors have longer survival times than patients whose carcinomas lack the corresponding receptors. Even patients with metastasis have an improved prognosis with receptor-positive tumors ([112](#)). Progesterone receptor levels appear to be stronger predictors of survival than estrogen receptor levels, and the higher the absolute level of the receptors, the better the prognosis.

DNA Ploidy and Proliferative Index

About two thirds of endometrial adenocarcinomas have a diploid DNA content as determined by flow cytometric analysis ([103,113,116,117,118,119,120,121,122,123](#) and [124](#)). The proportion of nondiploid tumors increases with stage, lack of tumor differentiation, and depth of myometrial invasion. In several studies, DNA content has been related to clinical course of the disease, with death rates generally reported to be higher in women whose tumors contained aneuploid populations of cells. The proliferative index also is related to prognosis.

Genetic and Molecular Markers

Mutations in codons 12 or 13 of the *K-ras* oncogene have been reported in 10% to 20% of endometrial adenocarcinomas ([125](#)). In one study, the presence of mutations of *K-ras* appeared to be an independent unfavorable prognostic factor ([126](#)). Overexpression of the *HER-2/neu* oncogene, which encodes for a cell surface glycoprotein that is similar to the human epidermal growth factor receptor, has been identified in 10% to 15% of endometrial adenocarcinomas. It is more frequently found in women with metastatic disease, and overexpression has been related to diminished progression-free survival ([127,128](#)). Alteration of the tumor suppressor gene *p53* has been demonstrated in about 20% of endometrial carcinomas and has been associated with papillary serous cell type, advanced stage, and poor prognosis ([123,129,130](#)). Expression of *MIB-1 (Ki-67)*, a proliferation marker, has been associated with extrauterine disease spread and decreased survival ([131](#)). Analysis of homozygous deletions on chromosome 10q23 in human cancer has led to the discovery of the *PTEN* tumor-suppressor gene. Mutations and deletions of the *PTEN* gene occur in 30% to 50% of endometrial cancers, which tend to be endometrioid, well differentiated, and minimally invasive ([132](#)). Microsatellite instability, present in about 20% of endometrial cancers, appears to be restricted to endometrioid adenocarcinomas and is associated with other molecular features that predict a

favorable outcome, including *PTEN* mutation and absence of *p53* overexpression ([133,134](#)).

Treatment

An algorithm for the management of patients with clinical stage I and II endometrial cancer is presented in [Fig. 30.7](#).

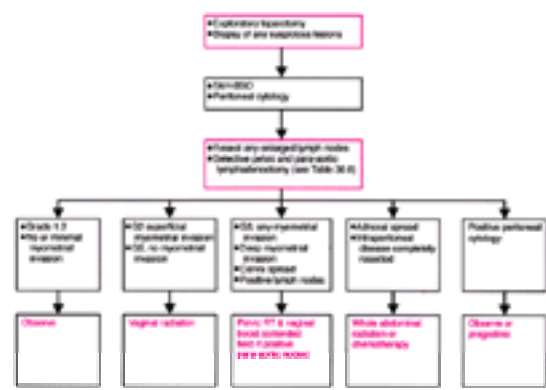

Figure 30.7 Management of patients with clinical Stage I and II endometrial carcinoma.

Surgery

Abdominal Hysterectomy

Total abdominal hysterectomy and bilateral salpingo-oophorectomy are the primary operative procedures for carcinoma of endometrium. The adnexa should be removed because they may be the site of microscopic metastasis, and patients with endometrial carcinoma are at increased risk for ovarian cancer occurring either simultaneously or developing later. Removal a segment of vagina below the cervix is not necessary.

Laparotomy is performed through an abdominal incision that is adequate to allow thorough intraabdominal exploration and retroperitoneal lymph node dissection, if necessary. A lower abdominal midline vertical incision is most commonly employed, although a lower abdominal transverse, muscle-dividing incision (e.g., Maylard incision) or muscle-detaching incision (e.g., Cherney incision) usually provides adequate exposure. After opening the abdomen, peritoneal washings are taken from the subdiaphragmatic area, paracolic gutters, and pelvis using 50 mL of saline for each. These washings are sent to the cytology laboratory for examination. Exploration of the abdomen and pelvis is then performed, noting particularly the diaphragm, liver, omentum, and pelvic and aortic lymph nodes. The uterus should be observed for tumor on the serosal surface. Any suspicious-looking lesions or lymph nodes should be excised for biopsy or removed for histologic examination. The uterus is opened in the operating room, and tumor size, depth of myometrial invasion, and cervical extension are assessed. This information, along with the surgical findings and knowledge of the preoperative histology, influences whether pelvic and aortic lymph node dissection is indicated. The uterus is sent to the pathology laboratory, where tissue can be obtained for measurement of steroid hormone receptors and flow cytometry.

For patients in whom lymph node sampling is indicated, lower paraaortic lymph node resection can be accomplished by extending the pelvic peritoneal incisions over the common iliac arteries and lower aorta. A sample of lymph nodes along the upper common iliac vessels from either side and the fat pad overlying the vena cava are removed. Pelvic lymph node samples are obtained by removing nodes overlying the midportion of the external iliac artery and vein and within the obturator fossa above and along the obturator nerve. An omental biopsy or partial omentectomy may also be performed.

Vaginal Hysterectomy

Vaginal hysterectomy may be considered for selected patients who are extremely obese and have a poor medical status, or for patients with extensive uterovaginal prolapse. The disadvantages to this approach are that bilateral salpingo-oophorectomy often is technically difficult and abdominal exploration and lymph node sampling cannot be performed. Vaginal hysterectomy is, therefore, particularly suitable for patients who are at low risk for extrauterine spread of disease (i.e., those with clinical stage I, well-differentiated tumors). A 94% survival rate has been found in 56 patients with clinical stage I endometrial carcinoma treated vaginal hysterectomy, with or without postoperative radiotherapy (mostly brachytherapy). Three fourths of these patients had grade 1 lesions ([135](#)). Others have reported similar good results ([136,137](#) and [138](#)). Vaginal hysterectomy clearly is preferable to radiation therapy alone, but generally should be reserved for specific patients.

Laparoscopic Management

Recent advances in endoscopic surgery have allowed application of a laparoscopic approach to the management of endometrial cancer. Since 1992, there have been several reports that have documented the feasibility of laparoscopically-assisted vaginal hysterectomy with bilateral salpingo-oophorectomy and laparoscopic retroperitoneal lymph node sampling for staging and treatment of patients with endometrial cancer ([139,140](#) and [141](#)). In an early study of 59 patients with endometrial cancer managed laparoscopically, 29 had retroperitoneal lymph node sampling ([139](#)). In a comparison study of the results of laparoscopic versus traditional laparotomy management of 44 patients with endometrial cancer, 20 patients underwent successful laparoscopic management; 15 had both pelvic and paraaortic lymph node sampling, and 4 had pelvic node sampling only ([140](#)). There was no difference in the number of lymph nodes (19 versus 17) removed in the laparoscopy and laparotomy groups, respectively. Patients undergoing laparoscopic management had shorter hospital stays (2.5 versus 5.0 days) and a lower overall complication rate, although all three patients who had serious complications (one ureteral injury and two small bowel herniations through 12-mm trocar sites) were in the laparoscopy group. A subsequent retrospective analysis compared the clinical outcomes and hospital charges for 69 women with early-stage endometrial cancer who underwent laparoscopically-assisted vaginal hysterectomy, compared with 251 women who had traditional laparotomy. The patients managed laparoscopically had fewer complications, shorter hospital stays, and lower overall hospital charges than those who underwent laparotomy. Furthermore, there was no difference in recurrence rates between the two groups ([141](#)). Although it seems reasonable that many patients with endometrial cancer can undergo successful laparoscopic management, more experience with the technique and prospective studies are necessary to determine the specific indications for and complications of this approach.

Radical Hysterectomy

Radical hysterectomy, with removal of the parametria and upper vagina, as well as bilateral pelvic lymphadenectomy, does not improve survival of patients with clinical stage I disease compared with extrafascial hysterectomy and bilateral salpingo-oophorectomy alone ([142,143,144](#) and [145](#)). Radical hysterectomy also increases both intraoperative and postoperative morbidity and should not, therefore, be performed for treatment of apparent early endometrial cancer.

Radiation Therapy

Primary surgery followed by individualized radiation therapy has become the most widely accepted treatment for early-stage endometrial cancers.

However, about 5% to 15% of endometrial cancer patients have severe medical conditions that render them unsuitable for surgery ([61](#)). These patients tend to be elderly and obese with multiple chronic or acute medical illnesses, such as hypertension, cardiac disease, diabetes mellitus, and pulmonary, renal, and neurologic diseases.

Several series have demonstrated that radiotherapy is effective treatment for patients with inoperable endometrial cancer ([146,147,148,149,150,151,152,153,154](#) and [155](#)) ([Table 30.13](#)). One reported on the treatment of 120 patients with clinical stage I and 17 patients with clinical stage II endometrial cancer with radiation alone, 85% of whom received only intracavitary irradiation. Because of the high incidence of death caused by intercurrent illness in this group of patients, the 5- and 10-year overall survival rates were only 55% and 28%, respectively, compared with disease-specific survival rates of 87% and 85%, respectively. There was no difference in disease-specific survival rates between patients with stage I and II disease. Intrauterine cancer recurred in 14% of patients, and extrauterine pelvic disease recurred in 3%. The authors also treated 15 patients with stage III and IV disease, usually with a combination of external-beam and intracavitary radiation therapy, yielding a

5-year disease-specific survival rate of 49%. Five patients (3%) had serious late complications of radiation therapy (155).

Table 30.13. Review of Recent Series of Endometrial Carcinoma Treated with Radiation Alone

Although it is generally agreed that intracavitary irradiation is necessary to achieve adequate local control, the indications for external-beam radiation therapy in the primary treatment of endometrial cancer are less well defined. Patients with cervical involvement and known or suspected extrauterine pelvic spread undoubtedly would benefit from external-beam radiation therapy. Theoretically, external-beam irradiation could also sterilize microscopic nodal disease and possibly increase the radiation dose to deep myometrial or subserosal uterine disease that may receive an insufficient dose from intracavitary irradiation alone. A correlation between tumor grade and recurrence has been noted by several authors. One found that the 5-year progression-free survival rate for medically inoperable patients with clinical stage I disease treated with radiotherapy alone was 94% for grade 1, 92% for grade 2, and 78% for grade 3 tumors (152). Therefore, patients with grade 3 tumors and a known propensity for deep myometrial invasion and lymph node metastasis also may benefit from external-beam therapy.

The decision to treat a patient who has endometrial cancer with radiation alone must involve a careful analysis of the relative risks and benefits of surgery. Although radiation alone can produce excellent survival and local control, it should be considered for definitive treatment only if the operative risk is estimated to exceed the 10% to 15% risk for uterine recurrence expected with radiation treatment alone.

Postoperative Adjuvant Therapy

Postoperative therapy should be based on prognostic factors determined by surgical and pathologic staging. Patients can generally be classified into three treatment categories: (1) those who show a low incidence of recurrence and a high rate of cure without any postoperative therapy (low risk), (2) those who have a reduced rate of surgical cure but may or may not benefit from additional therapy (intermediate risk), and (3) those who have a high rate of recurrence and a low survival rate without postoperative therapy (high risk) (Table 30.14). Options for postoperative management in these patients include observation, vaginal vault irradiation, external pelvic irradiation, extended-field (pelvic and paraaortic) irradiation, whole-abdomen irradiation, intraperitoneal phosphorus-32 (³²P), progestins, or systemic chemotherapy (Fig. 30.7).

Surgical/Pathologic Findings	Stage	Postoperative Treatment
Low risk G1, G2, no myometrial invasion No cervical/ovarian invasion Negative postoperative cytology No LVN No evidence of metastasis	Ia-G1, 2	None
Intermediate risk G1, G2, <50% myometrial invasion G3, no myometrial invasion G3, <50% myometrial invasion G1, G2, intrauterine extension G1, G2, <50% myometrial invasion G3, intrauterine extension G1, G2, G3, ovarian invasion LVN Positive postoperative cytology	Ib-G1, 2 Ia-G3 Ib-G3 Ia-G1, G2 Ia-G1, G2, G3 Ib-G1, G2, G3	Vaginal cuff irradiation Ia-G3 Pelvic and vaginal cuff irradiation Pelvic irradiation plus vaginal cuff boost Progesterone ¹⁵⁶
High risk Adnexal/ovarian/parametrial spread Vaginal metastasis Lymph node metastasis Bladder/bowel invasion Intraepithelial spread	Ib-G1, G2, G3 Ib-G1, G2, G3 Ib-G1, G2, G3 Ib-G1, G2, G3 Ib-G1, G2, G3	Pelvic and vaginal irradiation Extended-field radiation therapy if positive metastatic disease (see lymph nodes) Pelvic and vaginal irradiation Whole-abdomen irradiation; systemic chemotherapy

Table 30.14. Postoperative Management of Endometrial Carcinoma Based on Surgical-Pathologic Findings and Stage

Observation

Patients with grade 1 and 2 lesions without myometrial invasion (stage Ia, grades 1 and 2) have an excellent prognosis and require no postoperative therapy. In a GOG study, there were no recurrences and a 100% disease-free 5-year survival rate in the 91 patients in this category, 72 of whom had received no additional treatment after hysterectomy (76). Other investigators have reported equally favorable results with only surgical therapy in similar patients.

Vaginal Vault Irradiation

Numerous studies have shown that the incidence of vaginal recurrence in patients with tumors apparently confined to the uterus can be reduced from as high as 15% to 1% or 2% by the administration of vaginal irradiation. This is important because vaginal vault recurrence carries a poor prognosis. Preoperative or postoperative vaginal vault irradiation use has been found to decrease the incidence of vaginal recurrence from 14% to 1.7% and to improve 5-year survival rates from 75% to 90% (87). In a 10-year follow-up of a randomized trial comparing surgery alone (total abdominal hysterectomy and bilateral salpingo-oophorectomy) with preoperative and postoperative radium treatment in patients with clinical stage I endometrial adenocarcinoma, the incidence of vaginal recurrence was 7.5% with hysterectomy alone, 4.5% with preoperative intracavitary radium followed by hysterectomy, and 0% with hysterectomy followed by postoperative vaginal radium (156). In a subsequent study of 92 patients with surgical stage I disease who had grade 1 or 2 tumors with less than 50% myometrial invasion treated with total abdominal hysterectomy and bilateral salpingo-oophorectomy and postoperative vaginal cesium or radium, there were no recurrences, and the 5-year estimated disease-free survival rate was 99% (157). There was only one minor complication, proctitis, which responded to conservative treatment.

In a GOG study of surgical and pathologic risk factors and outcomes, none of the three recurrences in the vaginal radiation implant group was vaginal or pelvic, whereas 7.4% of recurrences in the pelvic radiation therapy group were vaginal, and 18.2% of recurrences were vaginal in the group that did not receive adjuvant radiation. The investigators concluded that postoperative vaginal cuff irradiation reduced local recurrence and had a therapeutic ratio superior to whole pelvis irradiation in patients at risk for isolated vaginal cuff recurrence (76).

Postoperative vaginal irradiation is most commonly administered using colpostats to deliver a surface dose of 6,000 to 7,000 cGy to the upper vagina. More recently, afterloading outpatient techniques using high-dose rate have been employed at some centers (158). Morbidity is low, although vaginal stenosis and dyspareunia may be a problem for postmenopausal patients in the absence of regular vaginal dilation. Patients most likely to benefit from vaginal irradiation are those who have surgical stage I grade 1 and 2 tumors with superficial (<50%) myometrial invasion or grade 3 tumors with no invasion and some patients with stage IIa disease who otherwise meet the aforementioned criteria.

External Pelvic Irradiation

External pelvic irradiation decreases the risk for pelvic recurrence after hysterectomy in certain high-risk groups. Patients found to benefit most from adjuvant postoperative whole pelvis irradiation are those with cervical involvement, pelvic lymph node metastases, or pelvic disease outside the uterus

(adnexa, parametria), and patients with clinical stage I disease who are at significant risk for nodal metastasis [grade 3 tumors with any degree of myometrial invasion, grade 1 and 2 tumors with more than 50% myometrial invasion, large (>2 cm) grade tumors with superficial myometrial invasion, and any grade tumor with lymph-vascular space invasion] (159).

Of 41 endometrial cancer patients treated with postoperative pelvic irradiation (5,000 to 5,040 cGy) who had grade 3 tumors or deep myometrial invasion and histologically negative paraaortic lymph nodes (pelvic lymph nodes not sampled), 4 patients (9.7%) developed recurrences, but only one of the recurrences (2.4%) was within the treatment field, and the 5-year estimated disease-free survival rate was 88% (157). In the GOG study, the pelvic recurrence rate was higher in the surgery-only group of patients (31.8%) than in the patients who received postoperative external beam radiation therapy (16.8%) (76).

In 1980, the first randomized study was performed to evaluate the possible benefit of postoperative pelvic irradiation in clinical stage I endometrial cancer (93). After total abdominal hysterectomy and bilateral salpingo-oophorectomy, all 540 patients received vaginal vault radium and were then randomized to receive either 4,000 cGy of whole-pelvis irradiation or no further therapy. The addition of pelvic irradiation did not affect the overall 5-year survival rate. Patients receiving pelvic irradiation had a lower pelvic failure rate but a higher distant failure rate. Of note, patients with grade 3 tumors and more than 50% myometrial invasion had a lower rate of death from cancer if they received postoperative pelvic irradiation (18.2% versus 27.5%). This study has been criticized for a lack of complete surgical staging (no lymph node biopsies were done) and the relatively low dose of external-beam irradiation (4,000 cGy) used.

The GOG recently completed a prospective, randomized study of surgery alone versus surgery plus adjuvant pelvic irradiation in intermediate-risk endometrial cancer (stages Ib to IIb occult). Of patients accrued to the study, more than 80% were actually low-risk patients (90.6% stage I, 81.6% grade 1 to 2, 82% <50% myometrial invasion). The pelvic failure rate was 13% (22 of 171 patients) in the surgery-alone group, compared with 0.6% (1 of 179 patients) in the postoperative pelvic irradiation group. Disease-free survival was also better in the patients receiving postoperative pelvic irradiation than in those treated only with surgery (93.7% versus 84.7%, respectively) (160).

Another randomized trial of surgery and postoperative pelvic radiotherapy versus surgery alone for 714 patients with stage I endometrial carcinoma was carried out by the Netherlands PORTEC Study Group. Eligibility criteria were stage IC, grade 1 to 2 and stage IB, grade 2 to 3; patients with stage IB, grade 3 made up only 10% of the study population, and lymph node biopsies and peritoneal cytology were not required. Locoregional recurrences developed in 13.7% of the surgery group, compared with 4.2% of the postoperative pelvic irradiation group. Overall, the 5-year survival rate was no different between the two groups (85% versus 81%, respectively) (161).

Postoperative whole-pelvis external-beam radiation usually involves the delivery of 4,500 to 5,040 cGy in 180 cGy daily fractions over 5 to 6 weeks to a field encompassing the upper half of the vagina inferiorly, the lower border of the L4 vertebral body superiorly, and 1 cm lateral to the margins of the bony pelvis. The dose of radiation at the surface of the vaginal apex is usually boosted to 6,000 to 7,000 cGy by a variety of techniques. The most frequently reported side effects are gastrointestinal, usually abdominal cramps and diarrhea, although more serious complications such as bleeding, proctitis, bowel obstruction, and fistula can occur and may require surgical correction. The urinary system may also be affected in the form of hematuria, cystitis, or fistula. The overall complication rate ranges from 25% to 40%; however, the rate of serious complications requiring surgical intervention is about 1.5% to 3%.

Patients at high risk for recurrence may benefit from pelvic irradiation. The pelvic failure rate is reduced and, at least in patients with grade 3 tumors and deep myometrial invasion, survival rates also appear to be improved. Patients with cervical extension and extrauterine pelvic disease, including adnexal spread, parametrial involvement, and pelvic lymph node metastases, in the absence of extrapelvic disease, also should benefit from postoperative pelvic irradiation.

Extended-field Irradiation

Patients with histologically proven paraaortic node metastases who have no other evidence of disease spread outside the pelvis should be treated with extended-field irradiation. The entire pelvis, common iliac lymph nodes, and paraaortic lymph nodes are included within the radiation field. The paraaortic radiation dose is limited to 4,500 to 5,000 cGy. **Extended-field radiotherapy appears to improve survival in patients with endometrial cancer who have positive paraaortic lymph nodes (76,162,163,164 and 165).**

Five-year survival rates of 47% and 43% have been reported for patients with surgically confirmed paraaortic lymph node metastases only and for those with paraaortic as well as pelvic lymph node metastases, respectively, using postoperative extended-field irradiation. Only one case of severe enteric morbidity occurred in 48 patients, a complication rate of 2% (162). In a GOG study, 37 of 48 patients with positive paraaortic nodes received postoperative paraaortic irradiation, 36% of whom remained tumor free at 5 years (76). A comparison of patients with positive paraaortic nodes treated with megestrol acetate alone versus megestrol acetate and extended-field irradiation showed that the survival rate in the patients receiving extended-field irradiation was significantly better: 53% versus 12.5%, respectively (163). In another study of 18 patients with positive paraaortic nodes, 5-year survival rates were 67% for microscopic nodal disease and 17% for gross nodal disease (164).

Whole-abdomen Irradiation

Whole-abdomen radiation therapy usually is reserved for patients with stage III and IV endometrial cancer. It may also be considered for patients who have papillary serous or mixed müllerian tumors, which have a propensity for upper abdominal recurrence (166,167,168,169,170 and 171). The recommended dose to the whole abdomen is 3,000 cGy in 20 daily fractions of 150 cGy with kidney shielding at 1,500 to 2,000 cGy, along with an additional 1,500 cGy to the paraaortic lymph nodes and 2,000 cGy to the pelvis. Gastrointestinal side effects, including nausea, vomiting and diarrhea, sometimes make it necessary to interrupt therapy, but it is rare for patients not to finish treatment because of these symptoms. Hematologic toxicity can be expected to occur during whole-abdomen irradiation, but it is usually mild. The incidence of late complications, mainly chronic diarrhea and small bowel obstruction, is generally low (5% to 10%).

In a series of 27 patients treated with surgical stage III endometrial cancer with whole-abdomen irradiation, patients with spread to the adnexa, positive peritoneal cytology, or both had a 5-year, relapse-free survival of 90%, whereas all patients with macroscopic disease beyond the adnexa had recurrence (166). Similar results were reported by others (167). Some have advocated the use of adjuvant whole-abdomen radiotherapy for patients with high-risk stage I and II endometrial carcinoma, including those with deep myometrial invasion, high-grade tumors, and papillary serous histology, because of the high proportion of recurrences in the upper abdomen. A 5-year recurrence-free survival rate of 85% has been reported (169,170). With whole-abdomen irradiation in patients at increased risk for intraabdominal metastatic disease, such as those with nonnodal extrauterine disease and papillary serous histology, an actuarial 5-year relapse-free survival rate of 70% has been reported, with no significant toxicity (171). Similarly, others have noted a 3-year disease-free survival rate of 79% in patients with stage III and IV endometrial adenocarcinoma treated with whole-abdomen irradiation (172). Still other reports of using adjuvant postoperative whole-abdomen irradiation in early-stage uterine papillary serous carcinoma suggest a reduction in recurrence rates (173,174 and 175). Unfortunately, most recurrences are in the upper abdomen in all of these patients, despite this type of radiotherapy. In summary, it is reasonable to use whole-abdomen irradiation postoperatively to treat patients with adnexal or upper abdominal disease, such as in the omentum, that has been completely excised and in patients who are at very high risk for intraabdominal recurrence, such as those with papillary serous tumors, but it should not be used in patients with gross residual intraperitoneal disease.

Intraperitoneal Phosphorus-32

Apparently favorable results for the treatment of positive peritoneal cytology with intraperitoneal ³²P have been reported (105). In 23 patients who had positive washings, treatment with ³²P resulted in a lower recurrence rate than in historical controls, but the groups differed in risk factors, making conclusions regarding the efficacy of the treatment questionable. Subsequently, it was reported that when ³²P was combined with external pelvic irradiation, 20% of patients suffered serious bowel complications requiring surgical intervention, and two patients died of operative complications (176). At present, the role of ³²P in the postoperative management of endometrial cancer patients with positive cytology is limited because of the lack of evidence of a therapeutic benefit and the complications when combined with external pelvic irradiation, which these patients often receive for prevention of local pelvic recurrence.

Progestins

Because most endometrial cancers have both estrogen and progesterone receptors and progestins have been used successfully to treat metastatic endometrial cancer, postoperative adjuvant progestin therapy has been attempted to reduce the risk for recurrence. This therapy is attractive because it provides systemic treatment and has few side effects. Unfortunately, several large randomized, placebo-controlled studies have failed to identify a benefit for adjuvant progestin therapy

([177,178,179,180](#) and [181](#)).

Conversely, in a series of 25 patients with positive peritoneal cytology as their only evidence of disease spread outside the uterus who were treated with adjuvant progestin for 1 year postoperatively ([182](#)), 22 patients had a second-look laparoscopy, and only one patient was found to have persistent intraperitoneal malignant cells. No patient had evidence of recurrent cancer. Therefore, progestins may have a role in treating positive peritoneal cytology in this setting.

Chemotherapy

Adjuvant cytotoxic chemotherapy has been studied in a few trials. The GOG treated 181 patients who had poor prognostic factors with postoperative irradiation and then randomly assigned patients to receive no further therapy or *doxorubicin* (*Adriamycin*) chemotherapy. After 5 years of observation, there was no difference in recurrence rates between the two groups ([183](#)).

Researchers at the M. D. Anderson Cancer Center treated 62 high-risk patients with postoperative adjuvant *cisplatin*, *doxorubicin*, and *cyclophosphamide* (PAC) chemotherapy. The presence of extrauterine disease was the only significant risk factor for recurrence, and no benefit to adjuvant chemotherapy could be demonstrated ([184,185](#)).

Clinical Stage II

Endometrial cancer involving the cervix either contiguously or by lymphatic spread has a poorer prognosis than disease confined to the corpus ([186,201](#)). Preoperative assessment of cervical involvement is difficult. **Endocervical curettage has relatively high false-positive (50% to 80%) and false-negative rates.** Histologic proof of cancer infiltration of the cervix or presence of obvious tumor on the cervix is the only reliable means of diagnosing cervical involvement, although ultrasound, hysteroscopy, or MRI may demonstrate cervical invasion.

The relatively small number of true stage II cases in reported series and the lack of randomized, prospective studies preclude formulation of a definitive treatment plan. Three areas must be addressed in any treatment plan:

1. For optimal results, the uterus should be removed in all patients.
2. Because the incidence of pelvic lymph node metastases is about 36% in stage II endometrial cancer, any treatment protocol should include treatment of these lymph nodes.
3. Because the incidence of disease spread outside the pelvis to the paraaortic lymph nodes, adnexal structures, and upper abdomen is higher than in stage I disease, attention should be directed to evaluating and treating extrapelvic disease.

Two approaches have usually been taken to the treatment of clinical stage II disease:

1. Radical hysterectomy, bilateral salpingo-oophorectomy, and pelvic and paraaortic lymphadenectomy.
2. Combined radiation and surgery (external pelvic irradiation and intracavitary radium or cesium followed in 6 weeks by total abdominal hysterectomy and bilateral salpingo-oophorectomy).

An initial radical surgical approach to treatment of clinical stage II endometrial cancer has the advantage of allowing accurate surgical-pathologic information to be obtained. Conversely, many patients with endometrial cancer are elderly and obese and have medical problems that make this approach unsuitable. In addition, reported results are no better than with combined radiation and less radical surgical therapy. The use of radical hysterectomy may be limited to patients with anatomic problems that prevent optimum dosimetry or other conditions that conflict with the use of radiation therapy.

The most common, traditional approach to the management of clinical stage II endometrial cancer has been to use external and intracavitary irradiation followed by extrafascial hysterectomy. This combined approach has resulted in 5-year survival rates of 60% to 80%, with severe gastrointestinal or urologic complications occurring in about 10% of patients. Patients who have medically inoperable disease are usually treated with external-beam irradiation and one or two intracavitary insertions. Compared with combined radiation and surgery, the results with radiation alone are diminished, but about 50% of patients are long-term survivors ([155](#)) ([Table 30.13](#)).

Another method for management of clinical stage II endometrial cancer that is gaining favor is an initial surgical approach followed by irradiation. This method is based on the difficulty in establishing the preoperative diagnosis of cervical involvement in the absence of a gross cervical tumor, the evidence that radiation is equally effective when given after hysterectomy, and the high incidence of extrapelvic disease when the cervix is involved. Exploratory laparotomy with an extrafascial or modified radical hysterectomy, bilateral salpingo-oophorectomy, peritoneal washings for cytology, resection of grossly enlarged pelvic nodes, and selective high common iliac and lower paraaortic lymphadenectomy are performed. These procedures are followed by appropriate pelvic or extended-field external and intravaginal irradiation, depending on the results of surgical staging. Excellent results have been reported using this treatment scheme ([197,198](#) and [199](#)).

Clinical Stages III and IV

Clinical stage III disease accounts for about 7% to 10% of all endometrial carcinomas ([202,203,204,205,206,207,208](#) and [209](#)). Patients usually have clinical evidence of disease spread to the parametria, pelvic sidewall, or adnexal structures; less frequently, there is spread to the vagina or pelvic peritoneum. Treatment for stage III endometrial carcinoma must be individualized, but initial operative evaluation and treatment should be considered because of the high risk for occult lymph node metastases and intraperitoneal spread when disease is known to extend outside of the uterus into the pelvis. In the presence of an adnexal mass, surgery should be performed initially to determine the nature of the mass. Surgery should also be performed to determine the extent of disease and to remove the bulk of the disease if possible. This should include peritoneal washings for cytologic examination, selective paraaortic and pelvic lymphadenectomy, as well as removal of any enlarged lymph nodes, biopsy or excision of any suspicious areas within the peritoneal cavity, and partial omentectomy and peritoneal biopsies. Except in patients with bulky parametrial disease, total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. Surgical eradication of all macroscopic disease should be the goal because this finding is of major prognostic importance in the management of patients with clinical stage III disease. Postoperative radiotherapy can then be tailored to the extent of disease.

Results of therapy depend on the extent and nature of disease. A 5-year survival rate of 54% has been reported for all patients with stage III disease; however, the survival was 80% when only adnexal metastases were present, compared with 15% when other extrauterine pelvic structures were involved ([202](#)). Patients with surgical-pathologic stage III disease have a much better survival rate (40%) than those with clinical stage III disease (16%) ([194](#)). Patients who are treated with combined surgery and irradiation fare better than patients who receive radiation therapy alone ([209](#)).

Stage IV endometrial adenocarcinoma, in which tumor invades the bladder or rectum or extends outside the pelvis, makes up about 3% of cases ([209,210,211,212](#) and [213](#)). Treatment of stage IV disease is patient dependent but usually involves a combination of surgery, radiation therapy, and systemic hormonal or chemotherapy. One objective of surgery and radiation therapy is to achieve local disease control in the pelvis to provide palliative relief of bleeding, discharge, and complications involving the bladder and rectum. Control of pelvic disease has been achieved in 28% of 72 patients with stage IV disease treated with radiation alone or in combination with surgery, progestins, or both ([210](#)). Several reports have noted a positive impact of cytoreductive surgery on survival, the median survival being about 3 times greater with optimal cytoreduction (18 to 34 months versus 8 to 11 months, respectively) ([211,212](#) and [213](#)). Pelvic exenteration may be considered in the very rare patient in whom disease is limited to the bladder, rectum, or both ([214,215](#)).

Recurrent Disease

About one fourth of patients treated for early endometrial cancer develop recurrent disease. More than half of the recurrences develop within 2 years, and about three fourths occur within 3 years of initial treatment. The distribution of recurrences is dependent in large part on the type of primary therapy: surgery alone versus surgery plus local or regional radiotherapy. In a GOG study of 390 patients with surgical stage I disease, vaginal and pelvic recurrences were noted to make up 53% of all recurrences in the group treated with surgery alone, whereas only 30% of recurrences were vaginal or pelvic in the group treated with combined surgery and radiotherapy ([76](#)). Therefore, after combined surgery and radiotherapy (vaginal or external beam), 70% or more of patients who fail treatment have distant

metastases, and most of these patients do not have evidence of local or pelvic recurrence. The most common sites of extrapelvic metastases are the lung, abdomen, lymph nodes (aortic, supraclavicular, inguinal), liver, brain, and bone. In general, patients with isolated vaginal recurrences fare better than those with pelvic recurrences, who in turn have a better chance of cure than those with distant metastases. Patients who initially have well-differentiated tumors or who develop recurrent cancer more than 3 years after the primary therapy also tend to have an improved prognosis.

In a 1984 report on 379 patients with recurrent endometrial cancer seen at the Norwegian Radium Hospital from 1960 to 1976 (216), site of recurrence was local or regional in 190 patients (50%), distant in 108 patients (28%), and local and distant in 81 patients (21%). The median time to reoccur was 14 months for patients with local recurrences and 19 months for patients with distant metastases. Of all recurrences, 34% were detected within 1 year, and 76% were detected within 3 years of primary treatment. At the time of diagnosis of recurrence, 32% of patients had no symptoms. Vaginal bleeding was the most common symptom associated with local recurrence, and pelvic pain was most often present with pelvic recurrence. Hemoptysis was the initial symptom in 32% of patients with lung metastases, but 45% of cases of lung metastases were asymptomatic and picked up on routine chest x-ray. Only 9% of patients with metastases at other sites did not have symptoms; most had pain (37%) or other symptoms such as anorexia, nausea and vomiting, or ascites related to intraabdominal carcinomatosis, neurologic symptoms such as seizures from brain metastases, or jaundice caused by liver metastases.

Overall, only 29 (7.7%) of the 379 patients were alive without evidence of disease from 3 to 19 years. This included 22 patients (12%) with local or pelvic recurrence, 5 patients (5%) with distant metastases, and 2 patients (2%) with both local and distant recurrences. The best results were obtained in the 42 patients with vaginal vault recurrences who were treated with radiotherapy, resulting in a 24% survival rate. None of the 78 patients with pelvic soft tissue recurrence survived. Three patients (7%) with only lung metastases treated with progestins, two patients with lymph node metastases treated with combined radiotherapy and progestins, and two patients with local recurrence and lung metastases treated with radiotherapy, surgery, and progestins survived.

Surgery

A small subset of patients who develop recurrent endometrial cancer may benefit from surgical intervention. Pelvic or vaginal recurrence in patients who have not received prior pelvic irradiation is best treated with external irradiation plus some type of brachytherapy. Surgical resection of a metastatic nodule greater than 2 cm in diameter before irradiation, however, may improve local control. Pretherapy investigation for extrapelvic metastasis in these patients may include surgical evaluation of the peritoneal cavity and retroperitoneal lymph nodes for evidence of subclinical metastases. Upper abdominal disease has been found at laparotomy in 3 (37.5%) of 8 patients with presumed localized pelvic recurrence (217). Presence of subclinical extrapelvic metastases was associated with larger pelvic tumor size (>2 cm) and elevated serum CA125 levels. A few patients with intraperitoneal recurrence may benefit from laparotomy to relieve intestinal obstruction, or tumor-reductive surgery may be performed before whole-abdomen radiation therapy or systemic hormonal or chemotherapy.

Isolated central pelvic recurrence after irradiation is exceedingly rare. In patients with this type of recurrence, exploratory laparotomy may be performed with the plan to proceed with pelvic exenteration if there is no evidence of disease outside the pelvis and no lymph node metastases. Exenterative surgery for recurrent endometrial cancer in the pelvis has rarely been of value because of the high incidence of associated occult extrapelvic metastases. Of 36 patients who underwent pelvic exenteration for recurrent endometrial carcinoma, 75% died of their cancer within 1 year of operation, and only 14% were alive after 5 years (215).

Radiation Therapy

Patients with isolated local or regional recurrences after initial surgical treatment of endometrial cancer should be treated with radiotherapy

(218,219,220,221,222,223,224 and 225). The best local control and subsequent cure are usually achieved by a combination of external-beam radiation therapy followed by a brachytherapy boost to deliver a total tumor dose of at least 6,000 cGy. Women with low-volume disease limited to the pelvis have the best outcome. For patients with isolated vaginal recurrence treated with irradiation, reported survival rates range from 24% to 45%. Conversely, for those patients who have pelvic extension of their disease treated with irradiation, lower survival rates from 0% to 24% have been reported. Initial endometrial cancer grade 1, younger patient age at recurrence, recurrent tumor size 2 cm or less, time to recurrence more than 1 year, vaginal versus pelvic disease, and radiation therapy that included brachytherapy vaginal boost are significant factors in determining control of pelvic disease and survival in patients with locally recurrent endometrial cancer.

Hormone Therapy

Progestational agents for treatment of metastatic endometrial cancer were first described in 1961 (226). The researchers observed an objective response rate of 29% in 21 patients. A beneficial response has been observed in 35% of 308 patients (227). Subsequent reports have noted somewhat less optimistic response rates, probably as a result of more strictly applied criteria for objective responses (228,229,230 and 231) (Table 30.15). Objective response rates of 16% and 11%, respectively, have been noted, with an additional 15% to 40% of patients exhibiting stable disease for at least 3 months (228,229).

Study	Progestin	No. of Patients	Response Rate (%)
Piver et al. (228)	HPC 1,000 mg/qk IM	51	14
	MPA 1,000 mg/qk IM	37	19
Podatz et al. (229)	HPC 1-3 g/wk IM	33	9
	MA 320 mg/d PO	81	11
Thigpen et al. (230,231)	MPA 150 mg/d PO	209	14
	200 mg/d PO	138	26
	1,000 mg/d PO	140	18

Table 30.15. Response to Progestin Therapy in Advanced or Recurrent Endometrial Cancer

In 1986, the GOG initially reported on the use of oral *medroxyprogesterone acetate* for treatment of patients with advanced or recurrent endometrial cancer (230). Of 219 patients with measurable disease, 8% had a complete response, 6% had a partial response, 52% had stable disease, and 34% developed progressive disease within 1 month. The mean survival time for the entire group was 10.4 months. In a follow-up study comparing two different doses of oral *medroxyprogesterone acetate*, similar response rates were achieved (26% for 200 mg/d and 18% for 1,000 mg/d) (231). Neither the type, dose, nor route of administration of the progestin seemed to have an effect on response in these studies.

Response of metastatic endometrial carcinoma to progestin therapy is related to several clinical and pathologic factors. Higher response rates are observed in well-differentiated tumors. A 20.5% response in low-grade tumors and only 1.4% response in high-grade tumors have been noted (229). Likewise, the probability of an objective response to progestin therapy is about 70% for tumors that are estrogen and progesterone receptor positive, compared with about 5% to 15% for tumors that are negative for both receptors. A longer disease-free interval is associated with higher response rates to progestins. The response rate to progestins has been found to range from 6% in patients with an interval from primary treatment to recurrence of less than 6 months to 65% in patients in whom disease recurred more than 5 years after initial treatment (227). Other observed, but less well documented, factors that may have an adverse effect on response to progestins are disease recurrence within a prior radiation field, large tumor burden, and advanced primary versus recurrent disease (227,229).

Tamoxifen, a nonsteroidal antiestrogen with some estrogenic properties, has been evaluated for treatment of metastatic endometrial carcinoma, based on experience in using this agent in breast cancer treatment. Its use as either a single agent or in combination with a progestin is related to its ability to inhibit the binding of estradiol to the estrogen receptor and to increase progesterone receptors. In a review of eight studies using *tamoxifen*, 20 to 40 mg/d, in patients with metastatic endometrial carcinoma, the overall response rate was 22%, with a range of 0% to 53% (232). Responses to *tamoxifen* were more likely to be observed in patients with low-grade, hormone receptor-positive tumors who had demonstrated a prior response to progestin therapy. In an attempt to reverse the hormone receptor downregulation seen with progestin therapy, *tamoxifen* has been given along with progestins, but the overall responses to combined *tamoxifen* and progestin therapy have been similar to

those noted for single-agent progestin therapy.

Progestins are currently recommended as initial treatment for all patients with recurrent endometrial cancer. Radiation therapy, surgery, or both should be used whenever feasible for treatment of localized recurrent cancer such as vaginal, pelvic, bone, and peripheral lymph node disease; however, these patients should also be given long-term progestin therapy unless they are known to have a progesterone receptor–negative tumor. Patients with nonlocalized recurrent tumors, especially if progesterone receptors are known to be positive, are candidates for progestin therapy, either *megestrol acetate*, 80 mg twice daily, or *medroxyprogesterone acetate*, 50 to 100 mg three times daily. Progestin therapy should be continued for at least 2 to 3 months before assessing response. If a response is obtained, the progestin should be continued for as long as the disease is static or in remission. In the presence of a relative contraindication to high-dose progestin therapy (e.g., prior or current thromboembolic disease, severe heart disease, or inability of the patient to tolerate progestin therapy), *tamoxifen*, 20 mg twice daily, is recommended. Failure to respond to hormonal therapy is an indication for initiating chemotherapy.

Chemotherapy

Although several chemotherapeutic agents or combinations of agents are capable of inducing objective responses and even remissions in patients with metastatic endometrial carcinoma, response and survival times are short, and all cytotoxic therapy should be considered palliative ([232,233](#) and [234](#)). The most active chemotherapeutic agents are *doxorubicin*, the *platinum* compounds *cisplatin* and *carboplatin*, and *paclitaxel* (*Taxol*). *Doxorubicin*, in dosages of 50 to 60 mg/m² every 3 weeks, and *carboplatin*, 350 to 400 mg/m² every 4 weeks, have been associated with response rates of 21% to 29%. *Paclitaxel*, 250 mg/m² as a 24-hour infusion with granulocyte colony-stimulating factor support ([235](#)), or 175 mg/m² as a 3-hour infusion every 3 weeks ([236,237](#)), has produced response rates of about 36%. Alkylating agents such as *cyclophosphamide* and *melfalan*, *5-fluoruracil*, and *altretamine* (*hexamethylmelamine*) have shown activity against endometrial cancer. Most responses obtained with use of these agents have been partial, generally averaging only 3 to 6 months, with the median survival time ranging from 4 to 8 months.

Combination chemotherapy regimens employing *doxorubicin* and *cisplatin* (AP), *cyclophosphamide*, *doxorubicin*, and *cisplatin* (CAP), and *paclitaxel* and *cisplatin* with or without *doxorubicin* ([238,239](#)) have resulted in response rates ranging from 38% to 76%. Most responses have been partial, with durations of 4 to 8 months. Despite these fairly impressive response rates, the median survival time has generally been less than 12 months.

Response to chemotherapy in patients with metastatic endometrial cancer does not appear to be affected by prior or concurrent progestin therapy. Metastatic site, age, disease-free interval, histology, and tumor grade also appear to have no effect on chemotherapy response. However, patients with long disease-free intervals and better performance status may live longer. Initial progestin therapy is advised before chemotherapy is undertaken, reserving the use of more toxic chemotherapy agents for situations in which endocrine therapy has failed. Alternatively, eligible patients should be entered into clinical trials.

Treatment Results

Comprehensive survival data for endometrial cancer are provided by FIGO ([240](#)). Survival in relation to clinical and surgical stage is shown in [Table 30.16](#) and in relation to surgical stage and grade in [Table 30.17](#). The overall 5-year survival rate was 76%. Surgically staged patients had much better 5-year survival rates than clinically staged patients across all stages (respectively): stage I, 87% versus 54%; stage II, 76% versus 41%; stage III, 57% versus 23%; stage IV, 18% versus 12%. Survival in surgical stage I disease ranged from 90% to 93% for stage Ia grades 1 and 2 and stage Ib grades 1 and 2 to 63% for stage Ic grade 3.

Stage	Patients treated		Survival (%)	
	No.	%	3-Year	5-Year
Surgical				
I	3,995	70	92	87
II	799	12	82	76

Follow-up after Treatment

History and physical examination remain the most effective methods of follow-up in patients treated for endometrial cancer ([241,242,243](#) and [244](#)). Patients should be examined every 3 to 4 months during the first 2 years and every 6 months thereafter. About half of patients discovered to have recurrent cancer have symptoms, and 75% to 80% of recurrences are detected initially on physical examination. Particular attention should be given to peripheral lymph nodes, the abdomen, and the pelvis. Vaginal cytology should be performed at each visit. Although very few asymptomatic recurrences are detected by vaginal cytology, these early recurrences are often amendable to successful therapy.

Chest x-ray every 12 months is an important method of posttreatment surveillance. Almost half of all asymptomatic recurrences are detected by chest x-ray. Other radiologic studies, such as intravenous pyelography and CT scans, are not indicated for routine follow-up of patients who do not have symptoms.

Serum CA125 measurement has been suggested for posttreatment surveillance of endometrial cancer ([245,246](#)). Elevated CA125 levels have been documented in patients with recurrent tumor, and these levels have correlated with the clinical course of disease. However, CA125 levels may be normal in the presence of small recurrences, making the utility of CA125 measurements for follow-up of patients after treatment of early-stage disease suspect. CA125 determinations should be obtained in patients with elevated levels at the time of diagnosis or with known extrauterine disease.

Estrogen Replacement Therapy after Treatment of Endometrial Cancer

A history of endometrial cancer has long been considered a contraindication to estrogen replacement therapy because of the concern that occult metastatic disease

might be activated by estrogen. Although this is a reasonable concern, the magnitude of this risk has never been quantified and, in fact, **there is no evidence that estrogen therapy after apparently successful treatment of endometrial cancer increases the risk for cancer recurrence.**

In a nonrandomized, retrospective follow-up study of 221 patients with clinical stage I endometrial cancer, 47 patients who had received estrogen after treatment were compared with 174 who had not been treated with estrogen. There were no significant differences between the two groups with respect to known risk factors for cancer recurrence. There were 26 (14.9%) recurrences in the patients not treated with estrogen, compared with only 1 (2.1%) recurrence in the patients treated with estrogen. Moreover, in the group not receiving estrogen, there were 26 deaths (16 from cancer and 10 from intercurrent disease), compared with only 1 death among those taking estrogen (247). Similarly in another report, no recurrent cancers and no intercurrent deaths were found in 44 women who took estrogen after treatment for endometrial cancer, compared with eight recurrences and eight intercurrent deaths (five from myocardial infarction) in 99 women who did not take estrogen (248). In a subsequent study of 123 surgical stage I and II endometrial cancer patients 62 (50.5%) who received estrogen replacement therapy postoperatively were identified. After controlling for risk factors for recurrence, there was no detectable difference in recurrence rate or time to recurrence between those patients who had received estrogen replacement therapy and those who had not (249). More recently, a retrospective cohort study of matched treatment-control pairs found two recurrences (1%) among the 75 women using estrogen, compared with 11 recurrences (14%) in the 75 women not using estrogen after primary therapy for endometrial cancer (250). In all of these studies, however, estrogen replacement therapy did not commence immediately after surgery in most patients.

Because many women who have been successfully treated for endometrial cancer suffer side effects of estrogen deficiency, such as vasomotor instability, vaginal dryness and dyspareunia, as well as the long-term risks of osteoporosis and atherosclerotic heart disease, treatment with estrogen is desirable. The American College of Obstetricians and Gynecologists has stated that for women with a history of endometrial cancer, hormone replacement therapy could be used for the same indications as for any other woman, except that "the selection of appropriate candidates for estrogen treatment should be based on prognostic indicators . . . and the risk she is willing to assume." A compromise between immediate postoperative estrogen replacement therapy and no hormone therapy might be to withhold estrogen for 1 to 3 years after treatment, during which time most recurrences develop, thereby minimizing the chances of administering estrogen to patients with residual cancer. In the interim, symptomatic relief of hot flashes can be achieved by prescribing progestins such as *medroxyprogesterone acetate*, 10 mg orally daily or 150 mg intramuscularly every 3 months, or nonhormonal agents such as *Bellergal*, *clonidine*, and *venlafaxine*.

Uterine Sarcoma

Uterine sarcomas are relatively rare tumors of mesodermal origin. They constitute 2% to 6% of uterine malignancies (251). There is an increased incidence of uterine sarcomas, usually malignant mixed müllerian tumors (MMMTs), after radiation therapy to the pelvis for either carcinoma of the cervix or a benign condition. The relative risk for uterine sarcoma after pelvic radiotherapy has been estimated to be 5.38, with an interval of usually 10 to 20 years (252). Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to diagnosis, clinical behavior, pattern of spread and management.

Classification

The three most common histologic variants of uterine sarcoma are endometrial stromal sarcoma (ESS), leiomyosarcoma (LMS), and MMMTs of both homologous and heterologous type (252) (Table 30.18). Variations in the relative incidences of uterine sarcomas occur in different published series, probably related to the strictness of criteria used to classify smooth muscle and endometrial stromal tumors as sarcomas. In general, LMS and MMMT each make up about 40% of tumors, followed by ESS (15%) and other sarcomas (5%), although MMMTs predominate in more recent reports. Staging of uterine sarcomas is based on the FIGO system for endometrial carcinoma (Table 30.6 and Table 30.7).

I. Pure mesenchymal tumors
A. Hemangiomas
1. Endometrial stromal tumors
a. Low-grade stromal sarcoma
b. High-grade or undifferentiated stromal sarcoma
2. Smooth muscle tumors
a. Leiomyosarcoma
b. Leiomyoma variants
(1) Cellular leiomyoma
(2) Leiomyoblastoma (epithelioid leiomyoma)
c. Single metastatic tumor
(1) Intravenous leiomyomatosis
(2) Single metastatic leiomyoma
(3) Disseminated peritoneal leiomyomatosis
B. Hemangiomas
1. Rhabdomyosarcoma
2. Osteosarcoma
3. Osteosarcoma
4. Liposarcoma
II. Mixed epithelial-mesenchymal tumors
A. Malignant mixed müllerian tumor
1. Hematogenous (carcinosarcoma)
2. Hematogenous
B. Adenosarcoma

Table 30.18. Classifications of Uterine Sarcomas

Endometrial Stromal Tumors

Stromal tumors occur primarily in perimenopausal women between 45 and 50 years of age; about one third occur in postmenopausal women. There is no relationship to parity, associated diseases, or prior pelvic radiotherapy. These tumors are rare in African American women. The most frequent symptom is abnormal uterine bleeding; abdominal pain and pressure due to an enlarging pelvic mass occur less often, and some patients do not have symptoms. Pelvic examination usually reveals regular or irregular uterine enlargement, sometimes associated with rubbery parametrial induration. The diagnosis may be determined by endometrial biopsy, but the usual preoperative diagnosis is uterine leiomyoma. At surgery, the diagnosis is suggested by the presence of an enlarged uterus filled with soft, gray-white to yellow necrotic and hemorrhagic tumors with bulging surfaces associated with wormlike elastic extensions into the pelvic veins.

Endometrial stromal tumors are composed purely of cells resembling normal endometrial stroma. They are divided into three types on the basis of mitotic activity, vascular invasion, and observed differences in prognosis: (a) endometrial stromal nodule, (b) low-grade stromal sarcoma, and (c) high-grade or undifferentiated ESS.

Endometrial stromal nodule is an expansive, noninfiltrating, solitary lesion confined to the uterus with pushing margins, no lymphatic or vascular invasion, and usually less than 3 mitotic figures per 10 high-power microscopic fields (3 MF/10 HPF). These tumors should be considered benign because there have been no recurrences or tumor-associated deaths reported after surgery (254).

Low-grade ESS or endolymphatic stromal myosis is distinguished from high-grade or undifferentiated ESS microscopically by a mitotic rate of less than 10 MF/10 HPF as well as clinically by a more protracted course. Recurrences typically occur late, and local recurrence is more common than distant metastases (255,256,257,258 and 259). Although low-grade stromal sarcoma often behaves in a histologically aggressive fashion, it lacks the aneuploid DNA content and high proliferative index associated with high-grade stromal sarcoma, and flow cytometric analysis can be used to differentiate the two conditions and predict response to therapy.

Low-grade stromal sarcoma has extended beyond the uterus in 40% of cases at the time of diagnosis, but the extrauterine spread is confined to the pelvis in two thirds of the cases. Upper abdominal, pulmonary, and lymph node metastases are uncommon. Recurrence occurs in almost half of cases at an average interval of about 5 years after initial therapy. Prolonged survival and even cure are not uncommon even after the development of recurrent or metastatic disease.

Optimum initial therapy for patients with low-grade stromal sarcoma consists of surgical excision of all grossly detectable tumor. Total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. The adnexa should always be removed because of the propensity for tumor extension into the parametria, broad ligaments, and adnexal structures as well as the possible stimulating effect of estrogen from retained ovaries on the tumor cells. A beneficial effect of radiation therapy has been reported, and pelvic irradiation is recommended for inadequately excised or locally recurrent pelvic disease (255). There is also evidence that low-grade stromal sarcoma is hormone dependent or responsive. Objective responses to progestin therapy have been noted in 6 of 13 patients (48%) (259). Recurrent or metastatic lesions may also be amenable to surgical excision.

High-grade or undifferentiated ESS is a highly malignant neoplasm. Histologically, it exhibits greater than 10 MF/10 HPF and often completely lacks recognizable stromal differentiation. This tumor has a much more aggressive clinical course and poorer prognosis than low-grade stromal sarcoma (253,255,260,261 and 262). The 5-year disease-free survival is about 25%. Treatment of high-grade stromal sarcoma should consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy. The dismal therapeutic results obtained to date suggest that radiation therapy, chemotherapy, or both should be used in combination with surgery. These tumors, unlike low-grade stromal sarcoma, are not responsive to progestin therapy.

Leiomyosarcoma

The median age for women with leiomyosarcoma (43 to 53 years) is somewhat lower than that for other uterine sarcomas, and premenopausal patients have a better chance of survival. This malignancy has no relationship with parity, and the incidence of associated diseases is not as high as in MMMT or endometrial adenocarcinoma. There is a higher incidence and a poorer prognosis in African American women. A history of prior pelvic radiation therapy can be elicited in about 4% of patients with leiomyosarcoma. The incidence of sarcomatous change in benign uterine leiomyomas is reported to be between 0.13% and 0.81% (263,264,265,266,267,268,269 and 270).

Presenting symptoms that are usually of short duration (mean, 6 months) and that are not specific to the disease include vaginal bleeding, pelvic pain or pressure, and awareness of an abdominopelvic mass. The principal physical finding is the presence of a pelvic mass. The diagnosis should be suspected if rapid uterine enlargement occurs, especially in a postmenopausal woman. Endometrial biopsy, although not as useful as in other sarcomas, may establish the diagnosis in up to one third of cases when the lesion is submucosal.

Survival rates for patients with uterine leiomyosarcoma range from 20% to 63% (mean, 47%). The pattern of tumor spread is to the myometrium, pelvic blood vessels and lymphatics, contiguous pelvic structures, abdomen, and then distantly, most often to the lungs. The number of mitoses in the tumor has traditionally been the most reliable microscopic indicator of malignant behavior (Fig. 30.8).

Figure 30.8 Leiomyosarcoma of the uterus. Interlacing bundles of spindle cells have fibrillar cytoplasm, irregular and hyperchromatic nuclei, and multiple mitotic figures. (Reproduced or modified from Berek JS, Hacker NF. *Practical gynecologic oncology*. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Generally, tumors with less than 5 MF/10 HPF behave in a benign fashion and tumors with more than 10 MF/10 HPF are frankly malignant with a poor prognosis. Tumors with 5 to 10 MF/10 HPF, termed *cellular leiomyomas* or *smooth muscle tumors of uncertain malignant potential*, are less predictable. Therefore, in addition to mitotic index greater than 10, other histologic indicators used to classify uterine smooth muscle tumors as malignant are severe cytologic atypia and coagulative tumor cell necrosis (271). Uterine smooth muscle tumors with any two of these three features are associated with a poor prognosis. Gross presentation of the tumor at the time of surgery is also an important prognostic indicator. Tumors with infiltrating tumor margins or extension beyond the uterus are associated with poor prognosis, whereas tumors less than 5 cm in size, originating within myomas, or with pushing margins are associated with prolonged survival.

Five other clinical pathologic variants of uterine smooth muscle tumors deserve special comment: (a) myxoid leiomyosarcoma, (b) leiomyoblastoma, (c) intravenous leiomyomatosis, (d) benign metastasizing uterine leiomyoma, and (e) disseminated peritoneal leiomyomatosis.

Myxoid leiomyosarcoma is characterized grossly by a gelatinous appearance and apparent circumscribed border, but microscopically the tumors have a myxomatous stroma and extensively invade adjacent tissue and blood vessels (272). The mitotic rate is low (0 to 2 MF/10 HPF), which belies their aggressive behavior and poor prognosis. Surgical excision by hysterectomy is the mainstay of treatment. The low mitotic rate and abundance of intracellular myxomatous tissue suggest that these tumors would not be responsive to radiation therapy or chemotherapy.

Leiomyoblastoma includes smooth muscle tumors designated as epithelioid leiomyomas, clear cell leiomyomas, and plexiform tumorlets (273). This group of atypical smooth muscle tumors is distinguished by the predominance of rounded rather than spindle-shaped cells and by a clustered or cordlike pattern. These lesions should be regarded as specialized low-grade leiomyosarcomas with fewer than 5 MF/10 HPF and an excellent prognosis. Standard treatment should be hysterectomy.

Intravenous leiomyomatosis is characterized by the growth of histologically benign smooth muscle into venous channels within the broad ligament and then into uterine and iliac veins (274,275,276 and 277). The intravascular growth takes the form of visible, wormlike projections that extend out from a myomatous uterus into the parametria toward the pelvic sidewalls and may be confused with low-grade stromal sarcoma. Symptoms are related to the associated uterine myomas. Most patients are in the late fifth and early sixth decades of life. The prognosis is excellent, even when tumor is left in pelvic vessels. Late local recurrences can occur, and deaths from extension into the inferior vena cava or metastases to the heart have been reported. Estrogen may stimulate the proliferation of these intravascular tumors. Treatment should be total abdominal hysterectomy and bilateral salpingo-oophorectomy with removal of as much of the tumor as possible.

Benign metastasizing uterine leiomyoma is a rare condition in which a histologically benign uterine smooth muscle tumor acts in a somewhat malignant fashion and produces benign metastases, usually to the lungs or lymph nodes (278). In most instances, intravenous leiomyomatosis is not demonstrable. The metastasizing myomas are capable of growth at distant sites, whereas the intravenous tumors spread only by direct extension within blood vessels. Both experimental and clinical evidence suggests that these tumors are stimulated by estrogen. Therefore, removing the source of estrogen, by castration or withdrawal of exogenous estrogen, or treatment with progestins, tamoxifen, or a gonadotropin agonist has an ameliorating effect (279). Surgical treatment should consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy as well as resection of pulmonary metastases if possible.

Disseminated peritoneal leiomyomatosis is a rare clinical entity characterized by benign smooth muscle nodules scattered throughout the peritoneal cavity (280). This condition probably arises as a result of metaplasia of subperitoneal mesenchymal stem cells to smooth muscle, fibroblasts, myofibroblasts, and decidual cells under the influence of estrogen and progesterone. Most reported cases have occurred in 30- to 40-year-old women who are or who have recently been pregnant or who have a long history of oral contraceptive use. Intriguing features of this disease are its grossly malignant appearance, benign histology, and favorable clinical outcome. Intraoperative diagnosis requires frozen-section examination. Extirpative surgery, including total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and excision of as much gross disease as possible may be indicated after the reproductive years. Removal of the source of excess estrogen, treatment with progestins, or both treatments have resulted in regression of unresected tumor masses. Almost all patients have done well.

Malignant Mixed Müllerian Tumors

MMMTs are composed histologically of a mixture of sarcoma and carcinoma. The carcinomatous element is usually glandular, whereas the sarcomatous element may resemble the normal endometrial stroma (homologous or the so-called carcinosarcoma), or it may be composed of tissues foreign to the uterus, such as cartilage, bone, or striated muscle (heterologous). These tumors are most likely derived from totipotent endometrial stromal cells (281,282 and 283).

Almost all of these tumors occur after menopause, at a median age of 62 years. There is a higher incidence in African American women. These tumors are often found

in association with other medical conditions, such as obesity, diabetes mellitus, and hypertension. A history of previous pelvic irradiation can be obtained in 7% to 37% of patients.

The most frequent presenting symptom is postmenopausal bleeding, which occurs in 80% to 90% of cases. Other less common symptoms are vaginal discharge, abdominopelvic pain, weight loss, and passage of tissue from the vagina. The duration of symptoms is usually only a few months. On physical examination, uterine enlargement is present in 50% to 95% of patients, and a polypoid mass may be seen within or protruding from the endocervical canal in up to 50% of patients. Diagnosis can usually be determined by biopsy of an endocervical mass or endometrial curettage.

The tumor grows as a large, soft, polypoid mass filling and distending the uterine cavity; necrosis and hemorrhage are prominent features. The myometrium is invaded to various degrees in almost all cases. The most frequent areas of spread are the pelvis, lymph nodes, peritoneal cavity, lungs, and liver. This metastatic pattern suggests that these neoplasms spread by local extension and regional lymph node metastasis in a manner similar to that of endometrial adenocarcinoma but behave more aggressively.

The most important single factor affecting prognosis in patients with MMMT is the extent of tumor at the time of treatment. In patients with tumor apparently confined to the uterine corpus (stage I), a 53% 2-year survival rate has been noted, whereas the survival rate dropped to 8.5% when disease had extended to the cervix, vagina, or parametria (stage II and III); no patients with disease outside the pelvis (stage IV) survived ([284](#)).

Unfortunately, disease has clinically already extended outside the uterus in 40% to 60% of cases at the time of diagnosis, indicating the highly malignant nature of this lesion. Even when disease is believed to be confined to the uterus preoperatively and potentially is still curable, surgical and pathologic staging identifies extrauterine spread of disease in a significant number of cases. In one study, 55% of women with clinical stage I MMMT had a higher surgical-pathologic stage. Only 28% of tumors were actually confined to the uterine corpus, 16% had extension to the cervix, and 56% showed extrauterine spread ([285](#)). A significant occurrence of lymph node metastases and positive peritoneal cytology, respectively, has been found in early-stage MMMT ([286,287](#)). Deep myometrial invasion, which is present in about half of stage I cases, is associated with poor prognosis. Almost all patients in whom tumor involves the outer half of the myometrium die from the disease. Patients who die from MMMT also tend to have larger tumors and a higher incidence of LVSI. Patients with a history of prior pelvic irradiation generally have a poorer prognosis. Overall, the 5-year survival rate for patients with MMMT is about 20% to 30%.

Adenosarcoma is an uncommon variant of MMMT ([288,289](#)). It consists of an admixture of benign-appearing neoplastic glands and a sarcomatous stroma. Most patients present with postmenopausal vaginal bleeding, and the disease is diagnosed or suspected based on endometrial curettage. Most adenosarcomas are well circumscribed and limited to the endometrium or superficial myometrium. The treatment is hysterectomy and bilateral salpingo-oophorectomy with or without adjuvant radiotherapy. Recurrences, mostly local pelvic or vaginal, have been reported in 40% to 50% of cases, leading some authors to recommend adjuvant postoperative intravaginal or pelvic irradiation.

Treatment of Uterine Sarcomas

Recurrences develop in more than half of cases of uterine sarcoma, even when disease is apparently localized at the time of treatment ([290,291](#) and [292](#)). At least half of recurrences occur outside the pelvis, with isolated pelvic failures accounting for less than 10% of recurrences. The most common sites of recurrence are the abdomen and lungs. These data emphasize that the major limitation to cure of uterine sarcomas is distant spread.

Based on this type of evidence, treatment of most stage I and II uterine sarcomas should include hysterectomy, bilateral salpingo-oophorectomy, and treatment of the pelvic lymphatics by irradiation or surgery. Strong consideration should also be given to the use of adjuvant chemotherapy to decrease the incidence of distant metastases. Stage III uterine sarcomas are probably best treated by an aggressive approach of combined surgery, radiation therapy, and chemotherapy. Stage IV disease must be treated with combination chemotherapy.

Surgery

The first step in the treatment of early uterine sarcoma should be exploratory laparotomy. Because extirpative survey is the most important aspect of treatment, and knowledge of the extent and spread of the disease is important for further management, one should not forego or delay surgery by using radiation therapy or chemotherapy first. At the time of surgery, the peritoneal cavity should be carefully explored, and special attention should be given to the pelvic and paraaortic lymph nodes. Total abdominal hysterectomy is the standard procedure, and bilateral salpingo-oophorectomy should also be performed in all patients except premenopausal women with leiomyosarcoma. Based on the surgical and pathologic findings, additional therapy with radiation therapy or chemotherapy can then be planned. Rarely, a patient may be cured by excision of an isolated pulmonary metastasis ([293](#)).

Radiation Therapy

Most studies have found adjuvant preoperative or postoperative radiation therapy to be of value in decreasing pelvic recurrences and thereby increasing quality of life in patients with localized ESS and MMMT, but not leiomyosarcoma ([294,295,296,297,298](#) and [299](#)). Radiation therapy thus appears to have a role with surgery in the combined treatment of MMMT and ESS confined to the pelvis by increasing the disease-free progression interval and by increasing pelvic control, thereby probably increasing the overall survival to some degree.

Chemotherapy

Several chemotherapeutic agents have been found to have activity in sarcomas, including *vincristine*, *actinomycin D*, *cyclophosphamide*, *doxorubicin*, dimethyl triazeno imidazole carboxamide (*dacarbazine*, *DTIC*), *cisplatin*, and *ifosfamide* ([300,301](#)). *Doxorubicin* appears to be the most active single agent in the treatment of leiomyosarcoma, producing a 25% response rate ([302](#)). *Ifosfamide* also has some lesser activity ([303](#)). On the other hand, *cisplatin* and *ifosfamide* have demonstrated clear activity in MMMTs, with responses rates of 18% to 42% and 32%, respectively ([304,305](#) and [306](#)). *Doxorubicin* has demonstrated less than a 10% response rate in MMMTs ([302](#)).

Combination chemotherapy with *doxorubicin* and *DTIC* or these two drugs plus *vincristine* (VAD) and *cyclophosphamide* (CYVADIC) has been reported to yield somewhat higher response rates ([300,301,307](#)). More recently, *ifosfamide* with *mesna* uroprotection, *Doxorubicin* and *DTIC* (MAID) have been combined to treat metastatic sarcomas. Combined *ifosfamide* and *cisplatin* chemotherapy has resulted in a higher response rate (54% versus 36%) and a longer progression-free survival than *ifosfamide* chemotherapy alone for treatment of advanced MMMTs ([308](#)).

Because of the relatively low survival rate in localized uterine sarcomas and the high incidence of failure due to subsequent distant metastasis, adjuvant treatment programs employing chemotherapy have been tested. Unfortunately, most reports have been unable to demonstrate a clear improvement in survival by the addition of postoperative adjuvant chemotherapy in early uterine sarcoma. The GOG conducted a trial of postoperative adjuvant *doxorubicin* in stage I and II uterine sarcoma patients. Of the 75 patients randomized to receive *doxorubicin*, 41% developed a recurrence, compared with 53% of 81 patients receiving no adjuvant chemotherapy, but these differences were not significant ([309](#)). Other smaller, nonrandomized adjuvant chemotherapy studies ([310](#)) employing CYVADIC and *cisplatin* plus *doxorubicin* reported recurrence rates of 35% and 24%, respectively ([310,311](#)).

Invasive cervical cancer in the United States is relatively infrequent, and the low incidence of cervical cancer is attributable to the effectiveness of screening with Papanicolaou's (Pap) test and detecting premalignant precursors. However, cervical carcinoma remains a significant health care problem worldwide. In Third World countries where no screening programs exist, cervical carcinoma is a significant cause of mortality. Because cervical cancer is potentially preventable, it is imperative that gynecologists and other primary care providers who administer health care to women be familiar with screening techniques, diagnostic procedures, and risk factors for cervical cancer, especially its premalignant precursors. Vaginal cancer is a relatively uncommon tumor.

Cervical Cancer

Epidemiology and Risk Factors

Invasive cancer of the cervix has been considered a preventable cancer because it has a long preinvasive state, because cervical cytology screening programs are available, and because the treatment of preinvasive lesions is effective. However, 13,000 new cases of invasive cervical cancer resulting in about 4,100 deaths were anticipated in the United States in 2002 ([1](#)). Although cervical cancer has not been eliminated, the incidence of invasive disease is decreasing, and it is being diagnosed earlier, leading to better survival rates ([1,2](#)). The mean age for cervical cancer is 52.2 years, and the distribution of cases is bimodal, with peaks at 35 to 39 years and 60 to 64 years of age ([1](#)).

There are numerous risk factors for cervical cancer: young age at first intercourse (<16 years), multiple sexual partners, cigarette smoking, race, high parity, and low socioeconomic status. The relationship to oral contraceptive use has been debated in the literature. Some investigators have proposed that use of oral contraceptives may increase the incidence of cervical glandular abnormalities of the cervix ([3,4](#)); however, this hypothesis has not been consistently supported. Many of these risk factors are linked to sexual activity and exposure to sexually transmitted diseases. Infection with herpes virus was previously thought to be the initiating event in cervical cancer. However, infection with the human papillomavirus (HPV) has now been determined to be involved in the development of cervical cancer.

The initiating event in cervical dysplasia and carcinogenesis is likely to be infection with HPV. HPV infection has been detected in up to 99% of women with squamous cervical carcinoma ([5](#)). There are more than 80 different types of HPV, 25 of which affect the lower genital tract. There are 13 high-risk HPV subtypes; two of the high-risk subtypes, 16 and 18, are found in up to 62% of cervical carcinomas. The mechanism by which HPV affects cellular growth and differentiation is by interactions of viral E6 and E7 proteins with p53 and Rb, resulting in gene inactivation ([6](#)). The role of human immunodeficiency virus (HIV) in cervical cancer is thought to be mediated through immune suppression. The Centers for Disease Control and Prevention have described cervical cancer as an illness that defines acquired immune deficiency syndrome (AIDS) in patients infected with HIV ([7](#)).

Evaluation

Vaginal bleeding is the most common symptom occurring in patients with cancer of the cervix. Most often, this is postcoital bleeding, but it may occur as irregular or postmenopausal bleeding. Patients with advanced disease may have a malodorous vaginal discharge, weight loss, or obstructive uropathy.

On general physical examination, the supraclavicular and groin lymph nodes should be palpated to exclude the presence of metastatic disease. On pelvic examination, a speculum is inserted into the vagina, and the cervix is inspected for suspicious areas. The vagina is inspected for extension of disease. With invasive cancer, the cervix is usually firm and expanded, and these features should be evaluated by digital examination. Rectal examination is important to help establish cervical consistency and size, particularly in patients with endocervical carcinomas. It is the only way to determine cervical size if the vaginal fornices have been obliterated by menopausal changes or by the extension of disease. Parametrial extension of disease is best determined by the finding of nodularity beyond the cervix on rectal examination.

When obvious tumor growth is present, cervical biopsy performed on an outpatient basis is usually sufficient for diagnosis. Colposcopy may be helpful in directing the examiner toward the most invasive area for biopsy. If the diagnosis cannot be established conclusively with outpatient biopsy, diagnostic conization may be necessary.

Cervical conization is required to assess correctly the depth and the linear extent of involvement of microinvasion. The earliest invasion is characterized by a protrusion from the stromae epithelial junction. This focus consists of cells that appear better differentiated than the adjacent noninvasive cells and have abundant

pink-staining cytoplasm, hyperchromatic nuclei, and small- to medium-sized nucleoli (8). **These early invasive lesions in the form of tongue-like processes without measurable volume are classified as International Federation of Gynecology and Obstetrics (FIGO) stage Ia1.** With further progression, more tongue-like processes and isolated cells occur in the stroma (Fig. 31.1). The stroma responds by a proliferation of fibroblasts (desmoplasia) and a bandlike infiltration of chronic inflammatory cells. **With increasing depth of invasion, lesions occur at multiple sites, and the growth becomes measurable by depth and linear extent. Lesions that are smaller than 3 mm are classified as FIGO stage Ia1. Lesions that are 3 to 5 mm or more in depth and up to 7 mm in linear extent are classified as FIGO stage Ia2 (9).** With increasing stromal invasion, the involvement of capillary–lymphatic spaces is increased. Dilated capillaries, lymphatic spaces, and foreign-body multinucleated giant cells containing keratin debris often are seen in the stroma.

Figure 31.1 Microinvasive squamous carcinoma. Multiple irregular tongue-like processes and isolated nests of malignant cells are seen, some surrounded by clear spaces, simulating capillary lymphatic invasion. This is an artifact caused by tissue shrinkage. The depth of stromal invasion is measured from the basement membrane of the overlying cervical intraepithelial neoplasia (CIN). In this case, it is 1.5 mm. (From **Berek JS, Hacker F.** *Practical gynecologic oncology*. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

The depth of invasion should be measured with the micrometer from the base of the epithelium to the deepest point of invasion. **The depth of invasion is significant for the development of pelvic lymph node metastasis and tumor recurrence. Although lesions that have invaded 3 mm or less rarely metastasize, patients in whom lesions invade more than 3 to 5 mm have positive pelvic lymph nodes in 3% to 8% of cases (10).** Although the significance of the cutoff at 3 mm has not been identified completely, it may be postulated that capillary–lymphatic spaces are extremely small at this level, and it is unclear whether they can carry tumor cells beyond the specific zone. Uneven shrinkage of tissue by fixative often creates space between the tumor nests and the surrounding fibrous stroma, stimulating vascular lymphatic invasion (Fig. 31.1). A suspected vascular involvement with invasion of less than 3 mm should be interpreted with care. A lack of endothelial lining indicates that the space is an artifact of shrinkage rather than true vascular invasion.

Colposcopic Findings

For patients with suspected early invasive cancer based on Pap test results and a grossly normal-appearing cervix, colposcopic examination is mandatory. Colposcopic findings that suggest invasion are (a) abnormal blood vessels, (b) irregular surface contour with loss of surface epithelium, and (c) color tone change. Colposcopically directed biopsies may permit the diagnosis of frank invasion and thus avoid the need for diagnostic cone biopsy, allowing treatment to be administered without delay. If there is debate about the depth of invasion based on the cervical biopsies, and if the clinical stage may be upstaged to stage Ia2 or Ib1, the patient should undergo cold knife conization. A large cervical biopsy showing invasion greater than 3 mm or two biopsy specimens separated by 7 mm showing invasive cervical carcinoma would allow no delay in therapy, and the patient could undergo a radical hysterectomy or radiation therapy.

Abnormal Blood Vessels Abnormal vessels may be looped, branching, or reticular. Abnormal looped vessels are the most common finding and arise from the punctation and mosaic vessels present in cervical intraepithelial neoplasia (CIN). As the neoplastic growth process proceeds, the need for nutrition leads to proliferation of the blood vessels, and the punctate vessels at the surface produce double and triple loops. These surface tufting vessels then proliferate and push out over the surface of the epithelium in an erratic fashion. Some are straight, although most have a loop, a corkscrew, or a J-shaped pattern (Fig. 31.2). Abnormal branching vessels arise from the cervical stroma and are pushed to the surface as the underlying cancer invades and pushes upward. The normally branching cervical stromal vessels are best observed over nabothian cysts. In this area, the branches are generally at acute angles, with the caliber of vessels becoming smaller after branching, much like the arborization of a tree. The abnormal branching blood vessels seen with cancer tend to form obtuse or right angles, with the caliber sometimes enlarging after branching (Fig. 31.3). Sharp turns, dilations, and narrowings also mark the behavior of these vessels. The surface epithelium may be lost in these areas, leading to irregular surface contour and friability.

Figure 31.2 Abnormal looped vessels in invasive cervical cancer. (From **Berek JS, Hacker F.** *Practical gynecologic oncology*. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Figure 31.3 Abnormal branching vessels in invasive cervical cancer. (From **Berek JS, Hacker F.** *Practical gynecologic oncology*. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Abnormal reticular vessels represent the terminal capillaries of the cervical epithelium. Normal capillaries are best seen in a postmenopausal woman with atrophic

epithelium. When cancer involves this epithelium, the surface is again eroded, and the capillary network is exposed. These vessels are very fine, short, and composed of small commas without an organized pattern (Fig. 31.4). They are not specific to invasive cancer; atrophic cervicitis may also have this appearance.

Figure 31.4 Abnormal reticular vessels in invasive cervical cancer. (From Berek JS, Hacker F. *Practical gynecologic oncology*. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Irregular Surface Contour Abnormal surface patterns are observed as the tumor growth proceeds. The surface epithelium ulcerates as the cells lose intercellular cohesiveness secondary to the loss of desmosomes. Irregular contour also may occur because of a papillary characteristic of the lesion (Fig. 31.5). **This finding sometimes can be confused with an HPV papillary growth on the cervix; for that reason, biopsies should be performed on all papillary cervical growths.**

Figure 31.5 Irregular surface growth in invasive cervical cancer. (From Berek JS, Hacker F. *Practical gynecologic oncology*. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Color Tone Color tone may change as a result of increasing vascularity, surface epithelial necrosis, and in some cases, production of keratin. The color tone is yellow-orange rather than the expected pink of intact squamous epithelium or the red of the endocervical epithelium.

Adenocarcinoma Adenocarcinoma of the cervix does not have a specific colposcopic appearance. All of the aforementioned blood vessels may be seen in these lesions as well. Because adenocarcinomas tend to develop within the endocervix, endocervical curettage is required as part of the colposcopic examination.

Clinical Staging

The current FIGO staging system is presented in Table 31.1 and Fig. 31.6. The staging procedures allowed by FIGO are listed in Table 31.2. **When there is doubt concerning the stage to which a cancer should be allocated, the earlier stage should be selected. After a clinical stage is assigned and treatment has been initiated, the stage must not be changed because of subsequent findings by either extended clinical staging or surgical staging.** The “upstaging” of patients during treatment will produce an erroneous improvement in the results of treatment of low-stage disease. Following is a breakdown of the incidence of cervical cancer by stage at diagnosis: 38%, stage I; 32%, stage II; 26%, stage III; and 4%, stage IV (2,9,12).

Stage	Description
Stage 0	in situ squamous intraepithelial lesion of stage 0 should not be considered as a clinical stage.
Stage I	Stage I is divided into IA and IB. IA is further divided into IA1 and IA2. IB is further divided into IB1 and IB2. IA1 is defined as carcinoma in situ of the cervix. IA2 is defined as carcinoma in situ of the cervix with a maximum depth of invasion of the stroma of not more than 3 mm. IA1 and IA2 are considered as early-stage disease. IB1 and IB2 are considered as late-stage disease.
Stage II	Stage II is divided into IIA and IIB. IIA is defined as carcinoma of the cervix that has not penetrated into the parametrium. IIB is defined as carcinoma of the cervix that has penetrated into the parametrium.
Stage III	Stage III is divided into IIIA and IIIB. IIIA is defined as carcinoma of the cervix that has not penetrated into the parametrium and has not extended to the lower third of the vagina. IIIB is defined as carcinoma of the cervix that has not penetrated into the parametrium and has extended to the lower third of the vagina.
Stage IV	Stage IV is divided into IVA and IVB. IVA is defined as carcinoma of the cervix that has penetrated into the parametrium and has not extended to the bladder or rectum. IVB is defined as carcinoma of the cervix that has penetrated into the parametrium and has extended to the bladder or rectum.

Table 31.1. FIGO Staging of Carcinoma of the Cervix Uteri

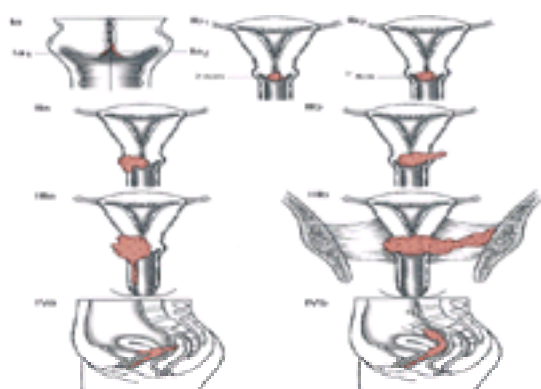

Figure 31.6 Carcinoma of the cervix uteri: staging cervical cancer (primary tumor and metastases). (From Benedet JL, Odicino F, Maisonneuve P, et al. Carcinoma of the cervix. *J Epidemiol Biostat* 2001;6:5–44, with permission.)

Physical examination*	Palpate lymph nodes Examine vagina Bimanual rectovaginal examination (under anesthesia recommended)
Radiologic studies*	Intravenous pyelogram Barium enema Chest x-ray Skeletal x-ray
Procedures*	Biopsy Conization Hysteroscopy Colposcopy Endocervical curettage Cytoscopy Proctoscopy
Optional studies ^b	Computerized axial tomography Lymphangiography Ultrasonography Magnetic resonance imaging Radioisotope scanning Laparoscopy

*Allowed by the International Federation of Gynecology and Obstetrics (FIGO).
^bInformation that is not allowed by FIGO to change the clinical stage.

Table 31.2. Staging Procedures

Extended Clinical Staging

Various investigators have used lymphangiography, computed tomography (CT), ultrasonography, and magnetic resonance imaging (MRI) in an attempt to improve clinical staging ([11](#),[12](#),[13](#),[14](#),[15](#) and [16](#)). Because these tests are not generally available throughout the world and because the interpretation of results is variable, the findings of these studies are not used for assigning the FIGO stage. However, they may be useful in planning therapy.

Evaluation of the paraaortic lymph nodes with lymphangiography is associated with a false-positive rate of 20% to 40% and a false-negative rate of 10% to 20% ([11](#),[12](#) and [13](#)). The accuracy of CT scanning is 80% to 85%; the false-negative rate is 10% to 15%, and the false-positive rate is 20% to 25% ([14](#),[15](#) and [16](#)). Early MRI data are comparable to CT scanning ([17](#)). When abnormalities are noted by these procedures, fine-needle aspiration (FNA) showing metastatic disease allows the radiation treatment field to be extended and obviates the need for exploratory laparotomy to determine the status of the lymph nodes.

Surgical Staging

The clinical staging system developed by FIGO is based on the belief that cervical cancer is a local disease and that, because most cases of cervical cancer occur in developing countries, surgical staging is not feasible with limited health care resources. The accuracy of clinical staging is somewhat limited, and surgical evaluation, which is not practical or feasible in many patients, is more accurate. Surgical staging has been advocated by providers in the United States who believe that this information details the extent of disease and affects treatment ([18](#)). Radiation oncologists may desire this information when designing treatment plans for patients. However, other providers believe that surgical staging should be limited to patients who are enrolled in a clinical trial or research protocol. These beliefs are based on the fact that there is no randomized control study demonstrating a survival benefit in patients who have had surgical staging. The specifics of surgical staging are discussed later in this chapter.

Pathology

Squamous Cell Carcinoma

Invasive squamous cell carcinoma is the most common variety of invasive cancer in the cervix. Histologically, there are large cell keratinizing, large cell nonkeratinizing, and small cell types ([19](#)). Large cell keratinizing tumors are made up of tumor cells forming irregular infiltrative nests with laminated keratin pearls in the center. Large cell nonkeratinizing carcinomas reveal individual cell keratinization but do not form keratin pearls ([Fig. 31.7](#)). The category of small cell carcinoma includes poorly differentiated squamous cell carcinoma and small cell anaplastic carcinoma. If possible, these two tumors should be differentiated. The former contains cells that have small- to medium-sized nuclei, open chromatin, small or large nucleoli, and more abundant cytoplasm than those of the latter. The designation of small cell anaplastic carcinoma should be reserved for lesions resembling oat cell carcinoma of the lung. It infiltrates diffusely and consists of tumor cells that have scanty cytoplasm, round to oval small nuclei, coarsely granular chromatin, and high mitotic activity. The nucleoli are absent or small. Immunohistochemistry or electron microscopy differentiates the small cell neuroendocrine tumors. Patients with the large cell type of carcinoma, with or without keratinization, have a better prognosis than those with the small cell variant. Furthermore, small cell anaplastic carcinomas behave more aggressively than poorly differentiated squamous carcinomas that contain small cells. Infiltration of parametrial tissue and pelvic lymph node metastasis affect the prognosis.

Figure 31.7 Invasive squamous cell carcinoma, large cell nonkeratinizing type. Tumor cells form irregular nests and have abundant eosinophilic cytoplasm and distinct cell borders indicative of squamous differentiation. (From **Berek JS, Hacker F.** *Practical gynecologic oncology*. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Adenocarcinoma

In recent years, there has been an increasing number of cervical adenocarcinomas affecting young women in their 20s and 30s. Adenocarcinoma *in situ* is believed to be the precursor of invasive adenocarcinoma, and it is not surprising that the two often coexist ([20](#)). In addition, squamous neoplasia, intraepithelial or invasive, also occurs in 30% to 50% of cervical adenocarcinomas. It should be noted that adenocarcinoma *in situ* appears to pose a diagnostic and therapeutic dilemma when compared with squamous cell carcinoma. The incidence of residual adenocarcinoma *in situ* after conization has led some investigators to recommend hysterectomy in patients with this preneoplastic lesion. However, in two recent reports, patients with negative cone biopsy margins were followed conservatively, with few requiring repeat surgical procedures ([21](#),[22](#)). Because cervical adenocarcinoma *in situ* tends to affect women during their reproductive years, a thorough risk and benefit discussion should take place, and treatment should be individualized.

Adenocarcinoma may be detected by cervical sampling, but less reliably so than squamous carcinomas. A definitive diagnosis may require cervical conization. Invasive adenocarcinoma may be pure ([Fig. 31.8](#)) or mixed with squamous cell carcinoma—adenosquamous carcinoma. Within the category of pure adenocarcinoma, the tumors are quite heterogeneous ([19](#)), with a wide range of cell types, growth patterns, and differentiation. About 80% of cervical adenocarcinomas are made up predominantly of cells of the endocervical type with mucin production. The remaining tumors are populated by endometrioid cells, clear cells, intestinal cells, or a mixture of more than one cell type. By histologic examination alone, some of these tumors are indistinguishable from those arising elsewhere in the endometrium or ovary.

Figure 31.8 Invasive adenocarcinoma of the cervix, well-differentiated. Irregular glands are lined with tall columnar cells with vacuolated mucinous cytoplasm resembling endocervical cells. Nuclear stratification, mild nuclear atypism, and mitotic figures are evident. (From **Berek JS, Hacker F.** *Practical gynecologic oncology*. 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Within each tumor type, the growth patterns and nuclear abnormalities vary according to the degree of differentiation. In well-differentiated tumors, tall columnar cells line the well-formed branching glands and papillary structures, whereas pleomorphic cells tend to form irregular nests and solid sheets in poorly differentiated neoplasms. The latter may require mucicarmine and periodic acid–Schiff (PAS) staining to confirm their glandular differentiation.

There are several special variants of adenocarcinoma. *Minimal deviation adenocarcinoma (adenoma malignum)* is an extremely well-differentiated form of adenocarcinoma in which the branching glandular pattern strongly simulates that of the normal endocervical glands. In addition, the lining cells have abundant mucinous cytoplasm and uniform nuclei (23,24). Because of this, the tumor may not be recognized as malignant in small biopsy specimens, thereby causing considerable delay in diagnosis. Earlier studies reported a dismal outcome for women with this tumor, but more recent studies have found a favorable prognosis if the disease is detected early (25). Although rare, similar tumors have also been reported in association with endometrioid, clear, and mesonephric cell types (26).

An entity described as *villoglandular papillary adenocarcinoma* also deserves special attention (27). It primarily affects young women, some of whom are pregnant or users of oral contraceptives. Histologically, the tumors have smooth, well-defined borders, are well differentiated, and are either *in situ* or superficially invasive. The follow-up information is encouraging, however; none of these tumors has recurred after cervical conization or hysterectomy. Among women undergoing pelvic nodal dissection, no metastases have been detected. This tumor appears to have limited risk for spread beyond the uterus.

In mature adenosquamous carcinomas, the glandular and squamous carcinomas are readily identified on routine histologic evaluation and do not cause diagnostic problems. In poorly differentiated or immature adenosquamous carcinomas, however, glandular differentiation can be appreciated only with special stains, such as mucicarmine and PAS. In one study (26), 30% of squamous cell carcinomas demonstrated mucin secretion when stained with mucicarmine. These squamous cell carcinomas with mucin secretion have a higher incidence of pelvic lymph node metastases than squamous cell carcinomas without mucin secretion (26) and are similar to the signet-ring variant of adenosquamous carcinoma (28).

Glassy cell carcinoma has been recognized as a poorly differentiated form of adenosquamous carcinoma (28). Individual cells have abundant eosinophilic, granular, ground-glass cytoplasm, large round to oval nuclei, and prominent nucleoli. The stroma is infiltrated by numerous lymphocytes, plasma cells, and eosinophils. About half of these tumors contain glandular structures or stain positive for mucin. The poor diagnosis of this tumor is linked to understaging and resistance to radiotherapy.

Other variants of adenosquamous carcinoma include *adenoid basal carcinoma* and *adenoid cystic carcinoma*. Adenoid basal carcinoma simulates the basal cell carcinoma of the skin (29). Nests of basaloid cells extend from the surface epithelium deep into the underlying tissue. Cells at the periphery of tumor nests form a distinct parallel nuclear arrangement, the so-called peripheral palisading. An “adenoid” pattern occasionally develops, with “hollowed-out” nests of cells. Mitoses are rare, and the tumor often extends deep into the cervical stroma.

Adenoid cystic carcinoma of the cervix behaves much like such lesions elsewhere in the body. The tumors tend to invade into the adjacent tissues and metastasize late, often 8 to 10 years after the primary tumor has been removed. Like other adenoid cystic tumors, they may metastasize directly to the lung. The pattern simulates that of the adenoid basal tumor, but there is a cystic component, and the glands of the cervix are involved (29). Mitoses may be seen but are not numerous.

Sarcoma

The most important sarcoma of the cervix is the *embryonal rhabdomyosarcoma*, which occurs in children and young adults. The tumor has grapelike polypoid nodules—the botryoid sarcoma—and the diagnosis depends on the recognition of rhabdomyoblasts (14). Leiomyosarcomas and mixed mesodermal tumors involving the cervix may be primary but are more likely to be secondary to uterine tumors. Cervical adenosarcoma has been described as a low-grade tumor with a good prognosis (30). If recurrence develops, it is generally a central recurrence that may be treated with resection and hormonal therapy.

Malignant Melanoma

On rare occasions, melanosis has been seen in the cervix. Thus, malignant melanoma may arise *de novo* in this area. Histopathologically, it simulates melanoma elsewhere, and the prognosis depends on the depth of invasion into the cervical stroma.

Metastatic Cancer

The cervix is commonly involved in cancer of the endometrium and vagina. The latter is rare, and most lesions that involve the cervix and vagina are designated cervical primaries. Consequently, the clinical classification is that of cervical neoplasia extending to the vagina, rather than vice versa. Endometrial cancer may extend into the cervix by three modes: direct extension from the endometrium, submucosal involvement by lymph vascular extension, and multifocal disease. The latter is most unusual, but occasionally a focus of adenocarcinoma may be seen in the cervix, separate from the endometrium. This lesion should not be diagnosed as metastasis but rather as multifocal disease. Malignancies involving the peritoneal cavity (e.g., ovarian cancer) may be found in the cul-de-sac and extend directly into the vagina and cervix. Carcinomas of the urinary bladder and colon occasionally extend into the cervix. Cervical involvement by lymphoma, leukemia, and carcinoma of the breast, stomach, and kidney is usually part of the systemic spread. However, an isolated metastasis to the cervix may be the first sign of a primary tumor elsewhere in the body.

Neuroendocrine Carcinoma

The classification of neuroendocrine cervical carcinoma includes four histologic subtypes: small cell, large cell, classical carcinoid, and atypical carcinoid (31). Neuroendocrine tumors of the cervix are rare, and treatment regimens have been based on small case series of patients. *Small cell (neuroendocrine type) carcinoma of the cervix* is aggressive in nature and is similar to cancer arising from the bronchus (32). At the time of diagnosis, it is usually disseminated, with bone, brain, liver, and bone marrow being the most common sites of metastases. In one study, 11 patients with what was apparent disease confined to the cervix and were found to have a high rate of lymph node metastasis (33). Pathologically, the diagnosis is aided by the finding of neuroendocrine granules on electron microscopy as well as by immunoperoxidase studies that are positive for a variety of neuroendocrine proteins such as calcitonin, insulin, glucagon, somatostatin, gastrin, and adrenocorticotrophic hormone (ACTH). In addition to the traditional staging for cancer of the cervix, these patients should undergo bone, liver, and brain scanning as well as bone marrow aspiration and biopsy. Therapy generally consists of surgery, chemotherapy, and radiation. Patients with early-stage disease have a chance of distant metastases, and it has been recommended that patients should have multimodal therapy. The main active chemotherapeutic agent is *etoposide*. The hallmark of neuroendocrine tumors is their aggressive malignant behavior with the propensity to metastasize.

Patterns of Spread

Cancer of the cervix spreads by (a) direct invasion into the cervical stroma, corpus, vagina, and parametrium; (b) lymphatic metastasis; (c) blood-borne metastasis; and (d) intraperitoneal implantation. The incidence of pelvic and paraaortic nodal metastasis is shown in [Table 31.3](#).

Stage	No. of Patients	Positive Pelvic Nodes (%)	Positive Paraortic Nodes (%)
Ia1 (<3 mm)	179 ^a	0.5	0
Ia2 (>3-5 mm)	84 ^a	4.8	<1
Ib	1506 ^a	15.9	2.2
Ila	110 ^a	24.5	11
Ilb	224 ^a	31.4	19
II	125 ^a	44.8	30
IIa	23 ^a	55	40

Table 31.3. Incidence of Pelvic and Paraaortic Nodal Metastasis by Stage

Treatment

The treatment of cervical cancer is similar to the treatment of any other type of malignancy; that is, both the primary lesion and potential sites of spread should be treated. The therapeutic modalities for achieving this goal include primary treatment with surgery, radiotherapy, or chemoradiation. Whereas radiation therapy can be used in all stages of disease, surgery alone is limited to patients with stage I and IIa disease. The 5-year survival rate for stage I cancer of the cervix is about 85% with either radiation therapy or radical hysterectomy. A recent study using the National Cancer Institute's Surveillance Epidemiology and End Results data showed by an intent-to-treat analysis that patients who were in the surgery arm had an improved survival when compared with patients in the intent-to-treat radiation arm ([34](#)). In general, optimal therapy would consist of radiation or surgery to limit the increased morbidity when the two treatment modalities are combined. There have recently been great strides in the treatment of cervical carcinoma, including adjuvant radiation and chemoradiation in patients discovered to have high-risk cervical carcinoma after radical hysterectomy and in patients with locally advanced cervical carcinoma. The Gynecologic Oncology Group (GOG) released results from five randomized control trials evaluating radiation therapy and chemoradiation for high-risk early cervical carcinoma and advanced cervical carcinoma (discussed later).

Surgery

There are advantages to the use of surgery instead of radiotherapy, particularly in younger women for whom conservation of the ovaries is important.

Chronic bladder and bowel problems that require medical or surgical intervention occur in up to 8% of patients undergoing radiation therapy ([35](#)). Such problems are difficult to treat because they result from fibrosis and decreased vascularity. This is in contrast to surgical injuries, which in general are easily repaired and without long-term complications. Sexual dysfunction after radiation therapy is more likely to occur because of vaginal shortening, fibrosis, and atrophy of the epithelium. The surgical procedure shortens the vagina, but gradual lengthening can be brought about by sexual activity. The epithelium does not become atrophic because it responds either to the patient's endogenous estrogen or to exogenous *estrogens* if the patient is postmenopausal.

In general, radical hysterectomy is reserved for women who are in good physical condition. Chronologic age should not be a deterrent. With improvements in anesthesia, elderly patients withstand radical surgery almost as well as their younger counterparts ([36](#)). Generally, it is prudent not to operate on lesions that are larger than 4 cm in diameter because these patients will require postoperative radiation therapy. When selected in this manner, the urinary fistula rate is less than 2% ([37](#)), and the operative mortality rate is less than 1% ([38](#)). An advantage of radiotherapy is its applicability to all stages and to most patients regardless of their age, height, weight, and medical condition. A summary of the surgical management of early cervical cancer is presented in [Table 31.4](#).

Stage Ia1	<3 mm invasion No lymph-vascular space invasion	Conization Type I hysterectomy
	With lymph-vascular space invasion	Type I or II hysterectomy with (R) pelvic lymph node dissection
Stage Ia2	>3-5 mm invasion	Type II hysterectomy with pelvic lymphadenectomy
Stage Ib	>5 mm invasion	Type II hysterectomy with pelvic lymphadenectomy

Table 31.4. Surgical Management of Early Invasive Cancer of the Cervix

Radical Hysterectomy and Pelvic Node Dissection

The radical hysterectomy performed most often in the United States is that described by Meigs ([39](#)) in 1944. The operation includes pelvic lymph node dissection along with removal of most of the uterosacral and cardinal ligaments and the upper one third of the vagina. This operation has been referred to as the type III radical hysterectomy ([40](#)).

The hysterectomy described by Wertheim is less extensive than a radical hysterectomy and removes the medial half of the cardinal and uterosacral ligaments ([40](#)). This procedure is often referred to as the modified radical or type II hysterectomy. Wertheim's original operation did not include pelvic lymph node dissection but instead included selective removal of enlarged lymph nodes.

Radical hysterectomies can be further classified as extended radical hysterectomy (type IV). In the type IV operation, the periureteral tissue, superior vesicle artery, and up to three fourths of the vagina are removed ([40](#)). In the type V operation, portions of the distal ureter and bladder are resected. This procedure is rarely performed because radiotherapy should be used when such extensive disease is encountered ([40](#)).

The abdomen is opened through either a midline incision or a low transverse incision after the methods of Maylard or Cherney. The low transverse incision requires division of the rectus muscles and provides excellent exposure of the lateral pelvis. It allows adequate pelvic node dissection and wide resection of the primary tumor. After the abdomen is entered, the peritoneal cavity is explored to exclude metastatic disease. The stomach is palpated to ensure that it has been decompressed to facilitate packing of the intestines. The liver is palpated, and the omentum is inspected for metastases. Both kidneys are palpated to ensure their proper placement and lack of congenital and other abnormalities. The paraaortic nodes are palpated transperitoneally.

During exploration of the pelvis, the fallopian tubes and ovaries are inspected for any abnormalities. In patients younger than 40 years of age, the ovaries are generally conserved. The peritoneum of the vesicouterine fold and the rectouterine pouch should be inspected for signs of tumor extension or implantation. The cervix is then palpated between the thumb anteriorly and the fingers posteriorly to determine its extent, and the cardinal ligaments are palpated for evidence of lateral tumor extension or nodularity.

Paraortic Lymph Node Evaluation If the patient has no evidence of disease extending beyond the cervix or vaginal fornix (i.e., surgical stage Ib or IIa), the

procedure is continued. The bowel is packed to expose the peritoneum overlying the bifurcation of the aorta. The peritoneum is incised medial to the ureter and over the right common iliac artery. A retractor is placed retroperitoneally to expose the aorta and the vena cava. Any enlarged paraaortic lymph nodes are dissected, hemaclips are applied for hemostasis, and specimens are sent for analysis by frozen section. If the lymph nodes are positive for metastatic cancer, an option is to discontinue the operation and use radiation therapy (39). If the lymph nodes are negative for disease, the left side of the aorta is palpated through the peritoneal incision with a finger passed under the inferior mesenteric artery. The lymph nodes on this side of the aorta are more lateral and nearly behind the aorta and the common iliac artery. If the left paraaortic lymph nodes appear healthy and the cervical tumor is small with no suspicious pelvic lymph nodes, these additional lymph nodes are not submitted for frozen-section analysis. If they are removed, they may be dissected through the incision made for the right paraaortic nodes, or they may be dissected after reflection of the sigmoid colon medially.

Development of Pelvic Spaces The pelvic spaces are developed by sharp and blunt dissection (Fig. 31.9). The paravesical space is bordered by the following structures:

Figure 31.9 The pelvic ligaments and spaces. (From Berek JS, Hacker F. *Practical gynecologic oncology*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000, with permission.)

1. The obliterated umbilical artery running along the bladder medially
2. The obturator internus muscle along the pelvic sidewall laterally
3. The cardinal ligament posteriorly
4. The pubic symphysis anteriorly

The attachments of the vagina to the tendinous arch form the floor of the paravesical space.

The pararectal space is bordered by the following structures:

1. The rectum medially
2. The cardinal ligament anteriorly
3. The hypogastric artery laterally
4. The sacrum posteriorly

The coccygeus (levator ani) muscle forms the floor of the pararectal space. The development of these spaces before pelvic lymphadenectomy will aid in identification and dissection of the pelvic lymph nodes as well as dissection of the ureter as it passes into the vesicouterine ligament tunnel.

Pelvic Lymphadenectomy Pelvic lymphadenectomy can proceed after lymph node evaluation or it can be deferred until the hysterectomy has been completed, depending on the preference of the surgeon. The pelvic lymph node dissection is begun by opening the round ligaments at the pelvic sidewall and developing the paravesical and pararectal spaces. The ureter is elevated on the medial flap by a Deaver retractor to expose the common iliac artery. The common iliac and external iliac nodes are dissected, with care taken to avoid injuring the genitofemoral nerve, which lies laterally on the psoas muscle. At the bifurcation of the common iliac artery, the external iliac node chain is divided into lateral and medial portions.

The lateral chain is stripped free from the artery to the circumflex iliac vein distally. A hemaclip is placed across the distal portion of the lymph node chain to reduce the incidence of lymphocyst formation. The medial chain is then dissected. The obturator lymph nodes are dissected next; for this procedure, the lymph nodes are grasped just under the external iliac vein, and traction is applied medially. Although most patients have both the obturator artery and vein dorsal to the obturator nerve, 10% have an aberrant vein arising from the external iliac vein. The node chain is separated from the nerve and vessels and clipped caudally. They are dissected cephalad to the hypogastric artery. The cephalad portion of the obturator space should be entered lateral to the external iliac artery and medial to the psoas muscle, where the remainder of the obturator node tissue can be dissected as far cephalad as the common iliac artery. In general, drainage of the pelvic and paraaortic lymph node beds is not performed because of the increase in complications in patients in whom drains have been used (41).

Dissection of the Bladder A critical step is the dissection of the bladder from the anterior part of the cervix and vagina. Occasionally, tumor extension into the base of the bladder (which cannot be detected with cystoscopy) precludes adequate mobilization of the bladder flap, leading to the abandonment of the operation. Therefore, this portion of the operation should be undertaken early in the procedure. The dissection should be performed in a manner to mobilize the bladder off of the upper third of the vagina in order to remove the tumor safely and with adequate margins.

Dissection of the Uterine Artery The superior vesicle artery is dissected away from the cardinal ligament at a point near the uterine artery. The uterine artery, which usually arises from the superior vesicle artery, is thus isolated and divided, and the vesicle arteries are preserved. The uterine vessels are then brought over the ureter by application of gentle traction. Occasionally, the uterine vein passes under the ureter.

Dissection of the Ureter The ureter is dissected free from its medial peritoneal flap at the level of the uterosacral ligament. As the ureter passes near the uterine artery, there is a consistent branch from the uterine artery to the ureter. This branch is sacrificed in the standard radical (type III) hysterectomy but preserved in the modified radical (type II) hysterectomy. Dissection of the ureter from the vesicouterine ligament (ureteral tunnel) now may be accomplished. If the patient has a deep pelvis, ligation of the uterosacral and cardinal ligaments may be undertaken first to bring the ureteral tunnel dissection closer to the operator. The roof of the ureteral tunnel is the anterior vesicouterine ligament. It should be ligated and divided to expose the posterior ligament. This ligament is also divided in the radical (type III) hysterectomy but conserved in the modified radical (type II) hysterectomy (Fig. 31.10).

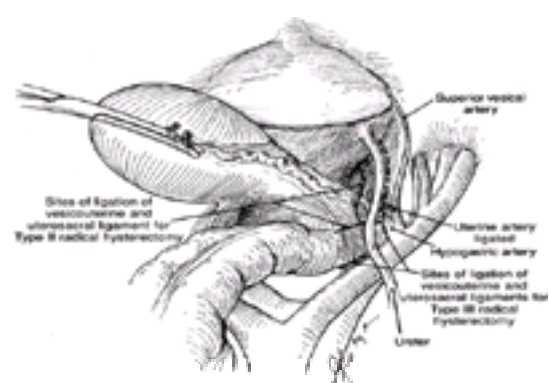

Figure 31.10 Radical hysterectomy. Uterine artery is ligated, ureter is dissected, and sites for division of the vesicouterine and uterosacral ligaments are shown.

(From **Berek JS, Hacker F.** *Practical gynecologic oncology*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000, with permission.)

Posterior Dissection The peritoneum across the cul-de-sac is incised, exposing the uterosacral ligaments. The rectum is rolled free from the uterosacral ligaments, and these ligaments are divided midway to the sacrum in a radical (type III) hysterectomy and near the rectum in the modified radical (type II) operation. This allows the operator to develop the cardinal ligament separate from the rectum. A surgical clamp is placed on the cardinal ligament at the lateral pelvic sidewall in a radical hysterectomy and at the level of the ureteral bed in the modified radical procedure. A clamp is placed on the specimen side to maintain traction and is left on to ensure that the full cardinal ligament is excised with the specimen. A right-angled clamp then is placed caudad to this clamp across the paravaginal tissues. A second paravaginal clamp is usually needed to reach the vagina.

The vagina is entered anteriorly, and the upper one third of the vagina is removed with the specimen. More vaginal epithelium can be excised if necessary, depending on the previous colposcopic findings. The vaginal edge may be sutured in a hemostatic fashion and left open with a drain from the pelvic space or closed with a suction drain placed percutaneously. The ureteral fistula and pelvic lymphocyst rates from these two techniques are similar.

Modified Radical Hysterectomy

The modified radical hysterectomy differs from the radical hysterectomy in the following ways:

1. The uterine artery is transected at the level of the ureter, thus preserving the ureteral branch to the ureter.
2. The cardinal ligament is not divided near the sidewall but instead is divided at about its midportion near the ureteral dissection.
3. The anterior vesicouterine ligament is divided, but the posterior vesicouterine ligament is conserved.

A smaller margin of vagina is removed.

Complications of Radical Hysterectomy

Acute Complications The acute complications of radical hysterectomy include the following (42):

- Blood loss (average, 0.8 l)
- Ureterovaginal fistula (1% to 2%)
- Vesicovaginal fistula (1%)
- Pulmonary embolus (1% to 2%)
- Small bowel obstruction (1%)
- Febrile morbidity (25% to 50%)

Febrile morbidity is most often pulmonary (10%) and frequently is seen with pelvic cellulitis (7%) and urinary tract infection (6%). Wound infection, pelvic abscess, and phlebitis all occur in fewer than 5% of patients (43).

Subacute Complications The subacute effects of radical hysterectomy are postoperative bladder dysfunction and lymphocyst formation. For the first few days after radical hysterectomy, bladder volume is decreased, and filling pressure is increased. The sensitivity to filling is diminished, and the patient is unable to initiate voiding. The cause of this dysfunction is unclear. It is important to maintain adequate bladder drainage during this time to prevent overdistention. Bladder drainage is accomplished with a suprapubic catheter. It is more comfortable for the patient and allows the physician to perform cystometrography and determine residual urine volume without the need for frequent catheterization. In addition, the patient is able to accomplish trial voiding at home by clamping the catheter, voiding, and releasing to check the residual urine level. Cystometrography may be performed 3 to 4 weeks after surgery. For use of the catheter to be discontinued, the patient must be able to sense the fullness of the bladder, initiate voiding, and void with a residual urine level of less than 75 mL. Otherwise, voiding trials should continue at home until these criteria can be fulfilled.

Lymphocyst formation occurs in fewer than 5% of patients (43), and the cause is uncertain. Adequate drainage of the pelvis after radical hysterectomy may be an important step in prevention. However, routine placement of retroperitoneal drains has not been shown to reduce this morbidity (41). Ureteral obstruction and partial venous obstruction and thrombosis may occur from lymphocyst formation. Simple aspiration of the lymphocyst is generally not curative, but percutaneous catheters with chronic drainage may allow healing. If this treatment is unsuccessful, operative intervention with excision of a portion of the lymphocyst wall and placement of either large bowel or omentum into the lymphocyst should be performed.

Chronic Complications The most common chronic effect of radical hysterectomy is bladder hypotonia or, in extreme instances, atony. This condition occurs in about 3% of patients, regardless of the method of bladder drainage used (44,45). It may be a result of bladder denervation and not simply a problem associated with bladder overdistention (46). Voiding every 4 to 6 hours, increasing intraabdominal pressure with Credé's maneuver, and intermittent self-catheterization may be used to manage the hypotonic bladder.

Ureteral strictures are uncommon in the absence of postoperative radiation therapy, recurrent cancer, or lymphocyst formation (37). If the stricture is associated with lymphocyst formation, treatment of the lymphocyst usually alleviates the problem. Strictures that occur after radiation therapy should be managed with ureteral stenting. If a ureteral stricture is noted in the absence of radiotherapy or lymphocyst formation, recurrent carcinoma is the most common cause. A CT scan of the area of obstruction should be obtained and cytologic assessment by FNA cytology should be performed to exclude carcinoma if there is a target lesion. If the results of these tests are negative, a ureteral stent may be placed to relieve the stricture. Close observation for recurrent carcinoma is necessary, and the diagnosis of recurrence may ultimately require laparotomy.

Surgical Treatment of Early-stage Cervical Cancer

Stage Ia Microinvasive Carcinoma Until 1985, no FIGO recommendation existed concerning the size of lesion or the depth of invasion that should be considered microinvasive (stage Ia). This led to considerable confusion and controversy in the literature. Over the years, as many as 18 different definitions have been used to describe "microinvasion." In 1974, the Society of Gynecologic Oncologists recommended a definition that is now accepted by FIGO: **A microinvasive lesion is one in which neoplastic epithelium invades the stroma to a depth of more than 3 mm beneath the basement membrane and in which lymphatic or blood vascular involvement is not demonstrated.** The purpose of defining microinvasion is to identify a group of patients who are not at risk for lymph node metastases or recurrence and who therefore may be treated with less than radical therapy.

Diagnosis must be determined on the basis of a cone biopsy of the cervix. The treatment decision rests with the gynecologist and should be determined based on a review of the conization specimen with the pathologist. It is important that the pathologic condition be described in terms of (a) depth of invasion, (b) width and breadth of the invasive area, and (c) presence or absence of lymph-vascular space invasion. These variables are used to determine how extensive the operation should be and whether the regional lymph nodes should be treated (9).

Stage Ia1 & 3 mm Invasion Lesions with invasion that is less than or equal to 3 mm deep have a less than 1% incidence of pelvic node metastases. Although this observation is controversial, it appears that the patients most at risk for nodal metastases or central pelvic recurrence are those with definitive evidence of tumor emboli in lymph vascular spaces (42,47). Therefore, patients with less than 3 mm invasion and no lymph-vascular space invasion may be treated with extrafascial hysterectomy without lymph node dissection. Therapeutic conization appears to be adequate therapy for these patients if childbearing capability is desired. Surgical margins must be free of disease. If there is lymph-vascular space invasion, an alternative is a pelvic node dissection with a type I (extrafascial) or II (modified radical) hysterectomy.

Treatment of microinvasive cervical adenocarcinoma has been complicated by a lack of agreement on approaches in the literature. Recent reports have shown that patients with stage Ia1 cervical adenocarcinoma may be treated in a fashion similar to patients with this stage and a squamous lesion. Some providers disagree with this interpretation because of the difficulty of establishing a pathologic diagnosis of microinvasion from a glandular lesion. Patients diagnosed with microinvasive

cervical adenocarcinoma should have expert pathologic assessment before considering treatment with extrafascial hysterectomy.

Stage Ia2 >3–5 mm Invasion Lesions with invasion of 3 to 5 mm have a 3.8% incidence of pelvic node metastases ([47,48](#) and [49](#)); thus, pelvic node dissection is necessary for these lesions. The primary tumor may be treated with a modified radical hysterectomy (type II).

Surgical Treatment of Stage Ib to IIa

Stage Ib and IIa Invasive Cancer Stage Ib lesions are subdivided into stage Ib1, which denotes lesions that are 4 cm or smaller in maximum diameter, and stage Ib2, which denotes lesions that are larger than 4 cm. Stage IIa is direct extension to the proximal vagina. **Surgical therapy of stage Ib and IIa carcinoma of the cervix involves radical hysterectomy, pelvic lymphadenectomy, and paraaortic lymph node evaluation.**

A comparison of radical hysterectomy with radiation has resulted in similar survival rates for the two treatment modalities. A randomized study comparing patients treated by either radical hysterectomy or radiation therapy showed similar survival rates for both groups ([50](#)). Similar outcomes also were reported when patients were treated with radiation therapy or radical surgery ([51](#)). However, patients treated with type III radical hysterectomy who subsequently received postoperative radiation had a higher rate of intestinal and urinary morbidity. Therefore, many advocate using radiation and avoiding surgery in these patients because many will require adjuvant postoperative radiation. The results from the GOG showing that patients with stage Ib (>4 cm) and IIa disease treated with concurrent chemoradiation had improved survival are presented below. Thus many would advocate that the treatment of choice in patients with stage Ib and IIa disease who have a primary lesion that is larger than 5 cm should be treated with chemoradiation.

Prognostic Variables for Early-stage Cervical Cancer

The survival of patients with early-stage cervical cancer after radical hysterectomy and pelvic lymphadenectomy depends on several factors ([42,51,52,53,54,55,56,57,58,59,60,61,62,63,64](#) and [65](#)):

1. Status of the lymph nodes
2. Size of the tumor
3. Involvement of parametrial tissue
4. Depth of invasion
5. Presence or absence of lymph–vascular space invasion

Lymph Nodes The most dependent variable associated with survival is the status of the lymph nodes. Patients with negative nodes have an 85% to 90% 5-year survival rate ([64,66](#)), whereas the survival rate for those with positive nodes ranges from 20% to 74%, depending on the number of nodes involved and the location and size of the metastases ([60,61](#) and [62,66,67,68](#) and [69](#)).

Data on lymph node status can be summarized as follows:

1. When the common iliac lymph nodes are positive, the 5-year survival rate is about 25%, compared with about 65% when only the pelvic lymph nodes are involved ([70,71](#) and [72](#)).
2. Bilateral positive pelvic lymph nodes portend a less favorable prognosis (22% to 40% survival rate) than unilateral positive pelvic nodes (59% to 70%) ([70,71](#)).
3. The presence of more than three positive pelvic lymph nodes is accompanied by a 68% recurrence rate, compared with 30% to 50% when three or fewer lymph nodes are positive ([60,67](#)).
4. Patients in whom tumor emboli are the only findings in the positive pelvic lymph node have an 82.5% 5-year survival rate, whereas the survival rate with microscopic invasion of the lymph nodes is 62.1% and with macroscopic disease is 54% ([51](#)).

Lesion Size Lesion size is an independent predictor of survival. Patients with lesions smaller than 2 cm have a survival rate of about 90%, and patients with lesions larger than 2 cm have a 60% survival rate ([54](#)). When the primary tumor is larger than 4 cm, the survival rate drops to 40% ([52,63](#)). An analysis of a GOG prospective study of 645 patients showed a 94.6% 3-year disease-free survival rate for patients with occult lesions, 85.5% for those with tumors smaller than 3 cm, and 68.4% for patients with tumors larger than 3 cm ([64](#)).

Depth of Invasion Patients in whom depth of invasion is less than 1 cm have a 5-year survival rate of about 90%, but the survival rate falls to 63% to 78% if the depth of invasion is more than 1 cm ([42,64,68](#)). Patients with spread to the parametrium have a 5-year survival rate of 69%, compared with 95% when the parametrium is negative. When the parametrium is involved and pelvic lymph nodes are also positive, the 5-year survival rate falls to 39% to 42% ([55,65](#)).

Lymph–Vascular Space Involvement The significance of the finding of lymph–vascular space involvement is somewhat controversial. Several reports have shown a 50% to 70% 5-year survival rate when lymph–vascular space invasion is present and a 90% 5-year survival rate in its absence ([42,54,58,72,73,74,75](#) and [76](#)). Others have found no significant difference in survival if the study is controlled for other risk factors ([63,64,77,78](#) and [79](#)). Lymph–vascular space involvement may be a predictor of lymph node metastasis and not an independent predictor of survival.

Postoperative Radiation

In an effort to improve survival rates, postoperative radiotherapy has been recommended for patients with high-risk factors such as metastasis to pelvic lymph nodes ([42,52,66,72](#)), invasion of paracervical tissue ([55,56](#)), deep cervical invasion ([80](#)), or positive surgical margins ([67,81](#)). Although most authors agree that postoperative radiotherapy is necessary in the presence of positive surgical margins, the use of radiation in patients with other high-risk factors is controversial. Increasing evidence supports the use of adjuvant radiation, however. Particularly controversial but best studied is the use of radiation in the presence of positive pelvic lymph nodes. The rationale for treatment is the knowledge that radiotherapy can sterilize cancer in pelvic lymph nodes and that pelvic node dissection does not remove all of the nodal and lymphatic tissue. The hesitancy to recommend postoperative radiotherapy relates to the significant rate of postradiotherapy bowel and urinary tract complications ([82](#)). Most of the data currently available are retrospective. However, the GOG has recently completed a randomized study comparing radiation with no further treatment for patients at high risk for recurrence with negative pelvic nodes ([83](#)).

Based on retrospective studies, it appears that postoperative radiation therapy for positive pelvic nodes can decrease pelvic recurrence but does not improve 5-year actuarial survival rates. One multiinstitutional study showed no difference in survival in patients with three or fewer positive pelvic nodes (59% versus 60%) ([68](#)). However, there seemed to be a benefit when radiotherapy was given to those with more than three positive nodes.

In a study of 60 pairs of irradiated and nonirradiated women matched for age, lesion size, and number and location of positive nodes after radical hysterectomy ([84](#)), no significant difference was found in projected 5-year survival rates (72% for surgery alone, 64% for surgery plus radiation). The proportion of recurrences confined to the pelvis was 67% in patients treated with surgery only and 27% in patients treated with postoperative radiation ($p = 0.03$). In a Cox regression analysis of 320 women who underwent radical hysterectomy, 72 of whom received postoperative radiation ([61](#)), there was a significant decrease in pelvic recurrence but no survival benefit. A multiinstitutional retrospective study was performed in 185 women with positive pelvic nodes after radical hysterectomy, 103 of whom received postoperative radiotherapy ([63](#)). Multivariate analysis disclosed that radiotherapy was not an independent predictor of survival, whereas age, lesion diameter, and number of positive nodes were found to influence survival. These authors concluded that additional treatment is needed to improve survival rates. Because survival is limited by distant site recurrence, the addition of chemotherapy to postoperative radiotherapy has been proposed. A 75% disease-free survival rate was reported at 3 years in 40 high-risk patients given cisplatin, vinblastine, and bleomycin after radical hysterectomy, and a 46% disease-free survival rate was found in 79 comparable patients who refused treatment ([85](#)). Only 4 (11.8%) of 34 patients with positive pelvic nodes had recurrences, whereas disease recurred in 8 (33%) of 24 untreated patients with positive nodes. An 82% rate of disease-free survival was reported at 2 years among 32 patients who were treated with postoperative radiation therapy plus cisplatin and bleomycin ([86](#)).

The location of lymph node metastases is apparently relevant to postirradiation recurrence rates. When common iliac lymph nodes are involved, the survival rate drops to 20% ([73](#)). As the number of positive pelvic nodes increases, the percentage of positive common iliac and low paraaortic nodes increases ([73](#)) (i.e., 0.6% when pelvic lymph nodes are negative, 6.3% with one positive pelvic node, 21.4% with two or three positive nodes, and 73.3% with four or more positive nodes). This information has been used to recommend extended-field radiotherapy to patients with positive pelvic lymph nodes in an attempt to treat undetected extrapelvic nodal disease ([73](#)). A 3-year disease-free survival rate of 85% occurred in patients with positive pelvic nodes and a survival rate of 51% in patients with positive common

iliac nodes; these rates are better than the survival rates of 50% and 23%, respectively, for historical control groups receiving radiotherapy to the pelvis alone.

A randomized controlled trial initiated by the GOG has recently reported results of a study on patients with cervical cancer treated by radical hysterectomy and found to have at least two of the following risk factors: capillary lymphatic space invasion, more than one third stromal invasion, and larger tumor (84). A total of 277 patients were entered into the study, with 140 randomized to no further therapy and 137 patients randomized to adjuvant pelvic radiotherapy. The results showed that patients with these risk factors who were treated with postoperative radiation therapy had a statistically significant (47%) decrease in recurrent disease. The study results have not had adequate follow-up to show a statistically significant decrease in mortality. The data, however, do demonstrate improved survival rates. The morbidity with the combination of therapy was acceptable, with a low rate of enteric and urinary complications. A second GOG study reporting on patients with high-risk cervical cancer randomized patients to concurrent chemoradiation therapy or radiation therapy alone (87). The results of this study are presented in the section discussing chemoradiation.

Chemotherapy

The use of chemotherapy in the treatment of cervical carcinoma has been limited in part by the success of treating this disease with surgery or radiation therapy. However, neoadjuvant chemotherapy has been used to shrink the tumor before radical hysterectomy or radiotherapy. No randomized study on the effectiveness of this technique has been reported. However, the information available from current studies suggests that, compared with historical controls, neoadjuvant therapy can achieve a 22% to 44% complete response rate, decrease the number of positive pelvic lymph nodes, and improve the 2- and 3-year disease-free survival rates, particularly in patients with stage I or II disease. In a study in which cisplatin, vinblastine, and bleomycin were used before radical hysterectomy in 54 patients with stage I or IIa tumors larger than 4 cm, a complete response rate of 44% and a partial response rate of 50% based on evaluation of the radical hysterectomy specimen were found (88). Tumors recurred in only three patients, giving a 94% disease-free survival with a minimum of 2 years follow-up. Of the 11 patients with positive nodes, 3 had recurrences, and all had three or more positive nodes. A comparison with historical controls for a tumor of this size revealed a 40% disease-free survival rate. In treating 75 patients with stage I, II, or III disease whose tumors were larger than 4 cm, cisplatin, bleomycin, and methotrexate were administered before surgery or radiation therapy (89). Three-year disease-free survival rates of 100%, 81%, and 66% were achieved for stages I, II, and III, respectively. Initial large tumor size and parametrial infiltration significantly correlated with a lower response to neoadjuvant therapy. Recurrence was significantly correlated with FIGO stage, parametrial infiltration, and residual cervical tumor. Of the 12 recurrences, 9 involved the pelvis, indicating that additional local treatment is needed for this high-risk group.

In treating 151 patients who had stage IIb and III tumors, cisplatin, vinblastine, and bleomycin were administered before surgery plus radiation (62.5%) or radiation alone (37.7%) (90). These investigators reported a 2-year disease-free survival rate in stages II and III of 79% and 50%, respectively, compared with survival rates of 47% and 26% in historical controls treated with radiation alone. For the 25 patients (22%) who experienced a complete response to the chemotherapy, there was a 96% disease-free survival rate and a 0% incidence of lymph node metastasis. To determine the efficacy of neoadjuvant chemotherapy, randomized trials have been initiated by the GOG and other centers.

Radiation

Radiotherapy can be used to treat all stages of cervical squamous cell cancer, with cure rates of about 70% for stage I, 60% for stage II, 45% for stage III, and 18% for stage IV (2). A comparison of surgery and radiation for treatment of low-stage disease is shown in Table 31.5. The radiation treatment plan generally consists of a combination of external teletherapy to treat the regional nodes and to shrink the primary tumor and intracavitary brachytherapy to boost the central tumor. Intracavitary therapy alone may be used in patients with early disease when the incidence of lymph node metastasis is negligible.

	Surgery	Radiation
Survival	85%	85%
Serious complications	Urologic fistulas 1%-2%	Intestinal and urinary strictures and fistulas 1.4%-5.3%
Vagina	Initially shortened, but may lengthen with regular intercourse	Fibrosis and possible stenosis, particularly in postmenopausal patients
Ovaries	Can be conserved	Destroyed
Chronic effects	Bladder atony in 3%	Radiation fibrosis of bowel and bladder in 5%-8%
Applicability	Best candidates are younger than 65 years of age, <200 lb, and in good health	All patients are potential candidates
Surgical mortality	1%	1% (from pulmonary embolism during intracavitary therapy)

Table 31.5. Comparison of Surgery versus Radiation for Stage Ib/IIa Cancer of the Cervix

The treatment sequence depends on tumor volume. Stage Ib lesions smaller than 2 cm may be treated first with an intracavitary source to treat the primary lesion, followed by external therapy to treat the pelvic nodes. Larger lesions require external radiotherapy first to shrink the tumor and to reduce the anatomic distortion caused by the cancer. This enables the therapist to achieve better intracavitary dosimetry. The usual doses delivered are 7,000 to 8,000 cGy to point A and 6,000 cGy to point B, limiting the bladder and rectal dosage to less than 6,000 cGy. To achieve this level, it is necessary to have adequate packing of the bladder and bowel away from the intracavitary sources. Localization films and careful calculation of dosimetry are mandatory to optimize the dose of radiation and to reduce the incidence of bowel and bladder complications. Local control depends on adequate dose to the tumor from the intracavitary source.

Clinical staging fails to predict the extension of disease to the paraaortic nodes in 7% of patients with stage Ib, 18% with stage IIb, and 28% with stage III disease (91). Such patients will have “geographic” treatment failures if standard pelvic radiotherapy ports are used. Thus, treatment plans for these patients are individualized based on CT scans and biopsy of the paraaortic lymph nodes for consideration of extended-field radiotherapy. The routine use of extended-field radiation without documentation of distant metastasis to the paraaortic nodes has been evaluated and is typically not practiced because of the increased enteric morbidity associated with this radiation.

Surgical “Staging” before Radiation

Surgical staging procedures designed to discover the presence of positive nodes have been devised. Transperitoneal exploration was first used, but it was associated with a 16% to 33% mortality rate from radiotherapy-induced bowel complications and a 5-year survival rate of only 9% to 12% (92,93). The radiotherapy dose to the paraaortic chain was 5,500 to 6,000 cGy, which is now known to be excessive. Postsurgical adhesions entrap the intestine in the radiotherapy field; therefore, the bowel receives the full dose of radiation. In the absence of postsurgical adhesions, the small bowel would move in and out of the radiotherapy field and receive a lesser dose. To avoid these postsurgical adhesions, extraperitoneal dissection of the paraaortic nodes is now recommended, and the radiation dose should be reduced to 5,000 cGy or less (94,95). When such an approach is used, postradiotherapy bowel complications occur in fewer than 5% of patients (96,97), and the 5-year survival rate is 15% to 26% in patients with positive paraaortic nodes (16,97). Survival appears to be related to the amount of disease in the paraaortic nodes and to the size of the primary tumor. In patients whose metastases to the paraaortic lymph nodes are microscopic and whose central tumor has not extended to the pelvic sidewall, the 5-year survival rate improves to 20% to 50% (98,99). Surgical staging techniques have improved to include laparoscopic assessment of the paraaortic and pelvic lymph nodes. Studies have demonstrated benefit from surgical staging with improved survival and changes in treatment plans of 40% of patients (95,96).

Supraclavicular Lymph Node Biopsy

Although not standard practice, the performance of a supraclavicular lymph node biopsy has been advocated in patients with positive paraaortic lymph nodes before the initiation of extended-field irradiation as well as in patients with a central recurrence before exploration for possible exenteration. The incidence of metastatic disease in the supraclavicular lymph nodes in patients with positive paraaortic lymph nodes is 5% to 30% (100). FNA cytologic assessment can obviate the need for an excisional biopsy and thus should be performed if any enlarged nodes are present. If the scalene lymph nodes are found to be positive, the disease is incurable,

and treatment is palliative.

Complications during Brachytherapy

Perforation of the uterus may occur at the time of insertion of the uterine tandem. This is a problem particularly for elderly patients and those who have had a previous diagnostic conization procedure. When perforation is recognized, the tandem should be removed, and the patient should be observed for bleeding or signs of peritonitis. Survival may be decreased in patients who have had uterine perforation ([101](#)), possibly because these patients have more extensive uterine disease, which predisposes them to perforation. Fever may occur after insertion of the uterine tandem and ovoids. Fever most often results from infection of the necrotic tumor and occurs 2 to 6 hours after insertion of the intracavitary system. If uterine perforation has been excluded by ultrasonography, intravenous broad-spectrum antibiotic coverage, usually with a cephalosporin, should be administered. If the fever does not decrease promptly or if the temperature is higher than 38.5°C, an aminoglycoside and a *Bacteroides* species-specific antibiotic should be administered. If fever persists or if the patient shows signs of septic shock or peritonitis, the intracavitary system must be removed. Antibiotics are continued until the patient has recovered, and the intracavitary application is delayed for 1 to 2 weeks.

Acute Morbidity The acute effects of radiotherapy occur after 2,000 to 3,000 cGy and are caused by ionizing radiation on the epithelium of the intestine and bladder. Symptoms include diarrhea, abdominal cramps, nausea, frequent urination, and occasionally bleeding from the bladder or bowel mucosa. The bowel symptoms can be treated with a low-gluten, low-lactose, and low-protein diet. Antidiarrheal and antispasmodic agents also may help. The bladder symptoms may be treated with antispasmodic medication. Severe symptoms may require a week of rest from radiotherapy.

Chronic Morbidity The chronic effects of radiotherapy result from the induction of vasculitis and fibrosis, and they are more serious than the acute effects. These complications occur several months to several years after radiotherapy has been completed. The bowel and bladder fistula rate after pelvic radiation therapy for cervical cancer is 1.4% to 5.3% ([35,37](#)). Other serious toxicity (e.g., bowel bleeding, stricture, stenosis, or obstruction) occurs in 6.4% to 8.1% of patients ([35,37](#)).

Proctosigmoiditis Bleeding from proctosigmoiditis should be treated with a low-residue diet, antidiarrheal medications, and steroid enemas. In extreme cases, a colostomy may be required to rest the bowel completely, and occasionally resection of the rectosigmoid must be performed.

Rectovaginal Fistula Rectovaginal fistulas or rectal strictures occur in fewer than 2% of patients. The successful closure of fistulas with bulbo cavernosus flaps has been reported ([102](#)), as has a technique of sigmoid colon transposition to repair rectosigmoid fistulas or rectal strictures ([103](#)). Occasionally, resection with anastomosis is feasible. Diversion resulting in colostomy may be the optimal therapy in patients who have poor vascular supply to the pelvis and a history of anastomotic leak or breakdown from prior repairs.

Small Bowel Complications Patients with previous abdominal surgery are more likely to have pelvic adhesions and thus sustain more radiotherapy complications in the small bowel. The terminal ileum may sustain chronic damage because of its relatively fixed position at the cecum. The patient typically has a long history of crampy abdominal pain, intestinal rushes, and distention characteristic of partial small bowel obstruction. Often, low-grade fever and anemia accompany the symptoms. Patients who have no evidence of disease should be treated aggressively with total parenteral nutrition, nasogastric suction, and early operation after the anemia has resolved and good nutritional status has been attained. The type of procedure performed depends on individual circumstances ([104](#)). Small bowel fistulas that occur after radiotherapy rarely close spontaneously while total parenteral nutrition is maintained. Recurrent cancer should be excluded; then aggressive fluid replacement, nasogastric suction, and wound care should be instituted. Fistulography and a barium enema should be performed to exclude a combined large and small bowel fistula. The fistula-containing loop of bowel may be either resected or isolated and left *in situ*. In the latter case, the fistula will act as its own mucous fistula.

Urinary Tract Chronic urinary tract complications occur in 1% to 5% of patients and depend on the dose of radiation to the base of the bladder. Vesicovaginal fistulas are the most common complication and usually require supraventricular urinary diversion. Occasionally, a small fistula can be repaired with either a bulbo cavernosus flap or an omental pedicle. Ureteral strictures are usually a sign of recurrent cancer, and an FNA cytologic sample should be obtained at the site of the obstruction under CT scan control. If the findings are negative, the patient should undergo exploratory surgery to determine the status of the disease. If radiation fibrosis is the cause, ureterolysis may be possible, or indwelling ureteral stents may be passed through the open urinary bladder.

Treatment of Stage IIb to IVb

Traditional therapy for patients with stage IIb or greater cervical cancer was radiation therapy. In certain clinical situations, such as with patients who have stage IVa disease and present with vesicovaginal or rectovaginal fistula, urinary or rectal diversion should be performed, followed by radiation therapy. Patients with stage IVb cervical carcinoma are considered candidates for palliative radiation therapy because cure is not attainable for these patients. Control of symptoms with the least morbidity is of concern in this patient population.

Primary pelvic radiotherapy fails to control the disease in 30% to 82% of patients with cervical carcinoma ([2](#)). About two thirds of these failures occur in the pelvis ([105](#)). A variety of agents have been used in an attempt to increase the effectiveness of radiation therapy in patients with large primary tumors. *Hydroxyurea* has produced some improvement in response rate and survival rates when compared with radiation therapy alone in a controlled series of patients ([106,107](#)). The use of *5-fluorouracil* (5-FU) and *mitomycin C* has also been reported to improve response rates for advanced cervical cancer ([108](#)). *Cisplatin* has been shown to have cytotoxic activity against cervical carcinoma ([109](#)) and recently has been demonstrated to be a radiation sensitizer ([110](#)). It has produced some improvement in response and survival rates when used with radiation therapy for cervical cancer as compared with radiation therapy alone ([110,111](#)). The results of GOG studies presented later in this chapter demonstrate that combination chemoradiation is superior to radiation therapy.

Concurrent Chemoradiation

Radiation therapy has failed to achieve control of cancer in 20% to 65% of patients with advanced cervical cancer. Chemotherapy, despite its lack of success in treating patients with cervical cancer, has been studied as neoadjuvant treatment in combination with surgery. Concomitant chemotherapy with radiation has been studied extensively by GOG, and results of five randomized studies have been reported. The concept of chemoradiation encompasses the benefits of regional therapy with radiation and the use of chemotherapy to sensitize cells to radiation therapy, thus improving locoregional control. These new results have changed the way cervical cancer is treated in many medical centers.

An intergroup trial involving the GOG, the Southwestern Oncology Group, and the Radiation Therapy Oncology Group evaluated postoperative chemoradiation therapy in patients with stage Ia2, Ib, or IIa cervical cancer who were found to have positive pelvic lymph nodes, positive parametrial extension, or positive vaginal margins at the completion of radical hysterectomy ([86](#)). A total of 243 patients were assessed in this trial, with 127 receiving chemoradiation (*cisplatin*, 5-FU, radiation therapy) and 116 receiving radiation. The results of this trial showed a statistically significant improvement in progression-free survival and overall survival at 43 months for the patients receiving concurrent chemoradiation. The 4-year survival rates for the patients receiving chemoradiation and radiation alone were 81% and 71%, respectively. The toxicity in the two groups was acceptable, with a higher rate of hematologic toxicity in the concurrent chemoradiation arm. **This study showed that in patients with these high-risk factors after radical hysterectomy for stage Ia2, Ib, and IIa disease, chemoradiation is the postoperative treatment of choice.**

Concurrent chemoradiation was evaluated in patients with advanced cervical carcinoma. The GOG protocol 85 was a prospective study that enrolled patients with stage IIb to IVa cervical cancer and compared concurrent chemoradiation ([112](#)). There were 177 patients treated with *cisplatin*, 5-FU, and radiation. These patients were compared with the 191 patients treated with *hydroxyurea* and radiation. The median follow-up of patients who were alive at the time of the analysis was 8.7 years. Patients who received concurrent chemoradiation and were treated with *cisplatin* and 5-FU had a statistically significant improvement in progression-free interval and overall survival ([112](#)). The hematologic toxicity between the two groups was similar. This study showed that *cisplatin*-based concurrent chemoradiation was a superior treatment when compared with *hydroxyurea* and concurrent radiation.

The GOG protocol 120 was initiated to evaluate patients with negative paraaortic nodes and cervical carcinoma stage IIb to IVa and concurrent chemoradiation. The treatment arms in this study consisted of radiation plus weekly *cisplatin*, or *cisplatin*, 5-FU, and *hydroxyurea*; or *hydroxyurea*. There were 176 patients in the weekly *cisplatin* arm; 173 patients in the *cisplatin*, 5-FU, and *hydroxyurea* arm; and 177 patients in the *hydroxyurea* arm ([113](#)). The two treatment arms with *cisplatin*-based chemotherapy and radiation showed an improvement in progression-free interval and overall survival at a median follow-up of 35 months. The relative risks for progression of disease or death were 0.55 and 0.57, respectively, for patients treated with *cisplatin*-based chemotherapy and radiation, compared with the patients treated with *hydroxyurea* and radiation ([114](#)). **This study confirmed the findings of GOG 85 and again suggested that *cisplatin*-based concurrent**

chemoradiation is the treatment of choice for patients with advanced-stage cervical cancer.

A third GOG trial evaluated patients with stage Ib to IVa cervical cancer. Of the patients enrolled in this study, 70% had stage Ib or IIa disease ([115](#)). A total of 403 patients were enrolled and evaluated. The 5-year survival rates were 73% in patients treated with chemoradiation and 58% in patients treated with radiation therapy alone. The cumulative rates of disease-free survival at 5 years were 67% in patients treated with concurrent chemoradiation and 40% in patients treated with radiation therapy alone. Survival and progression-free intervals for patients receiving concurrent chemoradiation were significantly improved ([115](#)). **The results of this study suggested that chemoradiation is the treatment for stage IIb to IVa disease and that those patients with stage Ib2 and IIa disease also may benefit from chemoradiation.** The role of extended-field radiation was evaluated in this trial, but its role in therapy for patients with no evidence of paraaortic metastasis still needs to be defined.

A GOG study of chemoradiation comparing concurrent cisplatin and radiation with radiation alone in patients with bulky Ib cervical cancer also included adjuvant hysterectomy after completion of the radiation ([115](#)). There were 183 patients assigned to the concurrent chemotherapy and radiation arm, and 186 patients treated with radiation alone. The median duration of follow-up was 36 months, with disease recurrence detected in 37% of the patients treated with radiation alone, compared with 21% who were treated with concurrent chemoradiation ([114](#)). The 3-year survival rates were 83% in the group who received concurrent chemoradiation and 74% in the group that received radiation alone ([114](#)). The study also included adjuvant hysterectomy after completion of radiation treatment. However, with the results of GOG 71 not showing an improvement in survival by using adjuvant hysterectomy, the authors concluded that adjuvant hysterectomy would not be part of their recommendations. This study supported the results of previous studies and showed that patients with bulky stage Ib and IIa cervical cancer had survival rates superior to those in patients treated with concurrent chemoradiation. **These two studies suggest that patients with bulky stage Ib and IIa disease should have primary treatment consisting of chemoradiation, with the chemotherapy agent being weekly cisplatin.**

Patient Evaluation and Follow-up after Therapy

Patients who receive radiotherapy should be closely monitored to assess their response. Tumors may be expected to regress for up to 3 months after radiotherapy. During the pelvic examination, progressive shrinkage of the cervix and possible stenosis of the cervical os and surrounding upper vagina should be noted. During rectovaginal examination, careful palpation of the uterosacral and cardinal ligaments for nodularity is most important. FNA cytologic assessment of suspicious areas should be performed to allow early diagnosis of persistent disease. In addition to the pelvic organs, the supraclavicular and inguinal lymph nodes should be carefully examined, and cervical or vaginal cytologic assessment should be performed every 3 months for 2 years and then every 6 months for the next 3 years. Endocervical curettage may be performed in patients with large central tumors.

An x-ray film of the chest may be obtained yearly in patients who have advanced disease. Metastasis to the lung has been reported in 1.5% of cases; solitary nodules are present in 25% of cases. Resection of a solitary nodule in the absence of any other persistent disease may yield some long-term survivors ([116](#)). Although intravenous pyelography (IVP) is not a part of routine postradiotherapy surveillance, it should be performed if a pelvic mass is detected or if urinary symptoms warrant it. The finding of ureteral obstruction after radiotherapy in the absence of a palpable mass may indicate unresectable pelvic sidewall disease, but this finding should be confirmed, usually by FNA cytologic assessment ([117](#)).

Patients who have had radical hysterectomy and who are at high risk for recurrence may benefit from early recognition of recurrence because they might be saved with radiation therapy. In these patients, a routine IVP 6 to 12 months after surgery may be beneficial. After radical hysterectomy, about 80% of recurrences are detected within 2 years ([118](#)). The larger the primary lesion, the shorter the median time to recurrence ([119](#)).

Special Considerations

The incidence of adenocarcinoma of the cervix appears to be increasing relative to that of squamous cancers. Older reports indicated that 5% of all cervical cancers were adenocarcinomas ([120](#)), whereas newer reports show a proportion as high as 18.5% to 27% ([121,122](#)). The FIGO annual report indicates a poorer prognosis for adenocarcinoma than for squamous cell carcinoma in every stage. A Cox proportional hazard analysis of 203 women with adenocarcinoma and 756 women with squamous carcinoma supports these findings ([122](#)). This study showed 5-year survival rates of 90% versus 60%, 62% versus 47%, and 36% versus 8% for stages I, II, and III, respectively. Although some have attributed these rates to a relative resistance to radiation, they are more likely a reflection of the tendency of adenocarcinomas to grow endophytically and to be undetected until a large volume of tumor is present.

The clinical features of stage I adenocarcinomas have been well studied ([121,123,124](#) and [125](#)). These studies have identified size of tumor, depth of invasion, grade of tumor, and age of the patient as significant correlates of lymph node metastasis and survival. When matched with squamous carcinomas for lesion size, age, and depth of invasion, the incidence of lymph node metastases and the survival rate appear to be the same ([123,124](#)). Patients with stage I adenocarcinomas can be selected for treatment according to the same criteria as for those with squamous cancers ([124](#)).

The choice of treatment for bulky stage I and II tumors is controversial. Radiation alone has been advocated by some ([126](#)), but others support radiation plus extrafascial hysterectomy ([127,128](#)). In 1975, Rutledge and associates ([127](#)) reported an 85.2% 5-year survival rate for all patients with stage I disease treated with radiation alone and an 83.8% survival rate for those who had radiation plus surgery. The central persistent disease rate was 8.3%, compared with 4% for those who had radiation plus surgery. In stage II disease, the 5-year survival rate was 41.9% for radiation alone and 53.7% for radiation plus surgery. A subsequent report revealed no significant difference in survival among patients treated with radiation alone or radiation plus extrafascial hysterectomy ([129](#)).

Patients with adenosquamous carcinoma of the cervix have been reported to have a poorer prognosis than those with pure adenocarcinoma or squamous carcinoma ([130](#)). Whether this is true when corrected for size of lesion is controversial ([123,124](#)).

The association of adenocarcinoma with squamous intraepithelial neoplasia is well documented ([131](#)). A squamous intraepithelial lesion may be observed colposcopically and treated with outpatient therapy, and the coexistent adenocarcinoma in the canal may be overlooked. Performing endocervical curettage at colposcopy will help prevent such an occurrence.

Cervical Cancer during Pregnancy

A review of the literature concluded that the incidence of invasive cervical cancer associated with pregnancy was one in 2,200 ([132](#)). A Pap test should be performed on all pregnant patients at the initial prenatal visit, and any grossly suspicious lesions should be excised for biopsy. Diagnosis is often delayed during pregnancy because bleeding is attributed to pregnancy-related complications. If the results of the Pap tests are positive for malignant cells and invasive cancer cannot be diagnosed using colposcopy and biopsy, a diagnostic conization procedure may be necessary. Because conization subjects the mother and fetus to complications, it should be performed only in the second trimester and only in patients with colposcopy findings consistent with cancer and biopsy-proven microinvasive cervical cancer or strong cytologic evidence of invasive cancer. Inadequate colposcopic examination may be encountered during pregnancy in patients who have had prior ablative therapy. Close follow-up throughout pregnancy may allow the cervix to evert and develop an ectropion, allowing satisfactory colposcopy in the second or third trimester. Conization in the first trimester of pregnancy is associated with an abortion rate of up to 33% ([132,133](#)). Patients with an obvious cervical carcinoma may undergo cervical biopsy and clinical staging similar to that of nonpregnant patients.

After conization, there appears to be no harm in delaying definitive treatment until fetal maturity is achieved in patients with stage Ia cervical cancer ([132,134,135](#)). Patients with less than 3 mm of invasion and no lymphatic or vascular space involvement may be followed to term and delivered vaginally. A vaginal hysterectomy may be performed 6 weeks postpartum if further childbearing is not desired.

Patients with 3 to 5 mm of invasion and those with lymph-vascular space invasion may also be followed to term ([132,135](#)). They may be delivered by cesarean birth, followed immediately by modified radical hysterectomy and pelvic lymph node dissection. Patients with more than 5 mm invasion should be treated as having frankly invasive carcinoma of the cervix. Treatment depends on the stage of gestation and the wishes of the patient. Modern neonatal care affords a 75% survival rate for infants delivered at 28 weeks of gestation and 90% for those delivered at 32 weeks of gestation. Fetal pulmonary maturity can be determined by amniocentesis, and prompt treatment can be instituted when pulmonary maturity is documented. Although timing is controversial, it is probably unwise to delay therapy for longer than 4 weeks ([134,135](#)). The recommended treatment is classic cesarean delivery followed by radical hysterectomy with pelvic lymph node dissection. There should be a thorough discussion of the risks and options with both parents before any treatment is undertaken.

Patients with cervical cancer in stages II to IV should be treated with radiotherapy. If the fetus is viable, it is delivered by classic cesarean birth, and therapy is begun postoperatively. If the pregnancy is in the first trimester, external radiation therapy can be started with the expectation that spontaneous abortion will occur before the delivery of 4,000 cGy. In the second trimester, a delay of therapy may be entertained to improve the chances of fetal survival. If the patient wishes to delay therapy, it is important to ensure fetal pulmonary maturity before delivery is undertaken.

The clinical stage is the most important prognostic factor for cervical cancer during pregnancy. Overall survival is slightly better for patients with cervical cancer in pregnancy because an increased proportion of these patients have stage I disease. For patients with advanced disease, there is evidence that pregnancy impairs the prognosis ([132,135](#)). The diagnosis of cancer in the postpartum period is associated with a more advanced clinical stage and a corresponding decrease in survival.

Cancer of the Cervical Stump

Cancer of the cervical stump is less common today than it was several decades ago when supracervical hysterectomy was popular. Early-stage disease is treated surgically, with very little change in technique from that used when the uterus is intact ([136](#)). Advanced-stage disease may present a therapeutic problem for the radiotherapist if the length of the cervical canal is less than 2 cm. This length is necessary to allow satisfactory placement of the uterine tandem. If the uterine tandem cannot be placed, radiation therapy can be completed with vaginal ovoids or with an external treatment plan in which lateral ports are used to augment the standard anterior and posterior ports. Such a technique will reduce the dosage to the bowel and bladder and thus reduce the incidence of complications.

Pelvic Mass

The origin of a pelvic mass must be clarified before treatment is initiated. An IVP can exclude a pelvic kidney, and a barium enema helps to identify diverticular disease or carcinoma of the colon. An abdominal x-ray film may show calcifications typically associated with benign ovarian teratomas or uterine leiomyomas. Pelvic ultrasonography differentiates between solid and cystic masses and indicates uterine or adnexal origin. Solid masses of uterine origin are most often leiomyomas and generally do not need further investigation.

Pyometra and Hematometra

An enlarged fluid-filled uterine cavity may be a pyometra or a hematometra. The hematometra can be drained by dilation of the cervical canal and will not interfere with treatment. The pyometra also should be drained, and the patient should be given antibiotics to cover *Bacteroides* species, *anaerobic Staphylococcus* and *Streptococcus* species, and aerobic coliform bacterial infection. Placement of a large mushroom catheter through the cervix has been advocated, but the catheter itself may become obstructed, leading to further occlusion of the drainage. Repeated dilation of the cervix with aspiration of pus every 2 to 3 days is more effective.

If the disease is stage I, a radical hysterectomy and pelvic node dissection may be performed. However, a pyometra is usually found in patients with advanced disease, and thus radiotherapy is required. External-beam therapy can begin when the pyometra has healed. Patients often have a significant amount of pus in the uterus or a tuboovarian abscess without signs of infection; therefore, a normal temperature and a normal white blood cell count do not necessarily exclude infection. Repeat physical examination or pelvic ultrasonography is necessary to ensure adequate drainage.

Cervical Carcinoma after Extrafascial Hysterectomy

When invasive cervical cancer is found after simple hysterectomy, it may be treated with radiotherapy or reoperation involving a pelvic node dissection and radical excision of parametrial tissue, cardinal ligaments, and the vaginal stump ([137](#)).

Reoperation Reoperation is indicated particularly for a young patient who has a small lesion and in whom preservation of ovarian function is desirable. It is not indicated for patients who have positive margins or obvious residual disease ([137](#)). Survival rates after radical reoperation are similar to those after radical hysterectomy for stage I disease.

Radiation Therapy Survival after radiotherapy depends on the volume of disease, the status of the surgical margins, and the length of delay from surgery to radiotherapy. Patients with microscopic disease have a 95% to 100% 5-year survival rate; the 5-year survival rate is 82% to 84% in those with macroscopic disease and free margins, 38% to 87% in those with microscopically positive margins, and 20% to 47% in those with obvious residual cancer ([138,139](#) and [140](#)). A delay in treatment of more than 6 months is associated with a 20% survival rate ([140](#)).

Stage IVa

Although primary exenteration may be considered for patients with direct extension to the rectum or bladder, it is rarely performed. For patients with extension to the bladder, the survival rate with radiation therapy is as high as 30%, with a urinary fistula rate of only 3.8% ([141](#)). The presence of tumor in the bladder may prohibit cure with radiation therapy alone; thus, consideration must be given to removal of the bladder on completion of external-beam radiation treatment. This is particularly true if the disease persists at that time and the geometry is not conducive to implant therapy. Rectal extension is less commonly observed but may require diversion of the fecal stream before therapy to avoid septic episodes from fecal contamination.

Acute Hemorrhage

Occasionally, a large lesion can produce life-threatening hemorrhage. A biopsy of the lesion should be performed to verify neoplasia, and a vaginal pack soaked in Monsel's solution (*ferric subsulfate*) should be packed tightly against the cervix. After proper staging, external radiation therapy can be started with the expectation that control of bleeding may require 8 to 10 daily treatments at 180 to 200 cGy/d. Broad-spectrum antibiotics should be used to reduce the incidence of infection. If the patient becomes febrile, the pack should be removed. Rapid replacement of the pack may be necessary, and a fresh pack should be immediately available. This approach to management of hemorrhage in patients previously untreated is preferable to exploration and vascular ligation. Occasionally, vascular embolization under fluoroscopic control may be required in severe cases, and this procedure may obviate a laparotomy. However, vascular occlusion ultimately may lead to decreased blood flow and oxygenation of the tumor; because the effect of radiotherapy is dependent on tissue oxygen content, the efficacy of the radiotherapy may be compromised.

Ureteral Obstruction

Treatment of bilateral ureteral obstruction and uremia in previously untreated patients should be determined on an individual basis. Transvesical or percutaneous ureteral catheters should be placed in patients with no evidence of distant disease, and radiotherapy with curative intent should be instituted. Patients with metastatic disease beyond curative treatment fields should be presented with the options of ureteral stenting, palliative radiotherapy, and chemotherapy for the metastatic disease. A median survival rate of 17 months for these patients may be achieved with aggressive management ([142](#)).

Barrel-shaped Cervix

The expansion of the upper endocervix and lower uterine segment by tumor has been referred to as a *barrel-shaped cervix*. Patients with tumors larger than 6 cm in diameter have a 17.5% central failure rate when treated with radiotherapy alone because the tumor at the periphery of the lower uterine segment is too far from the standard intracavitary source to receive an adequate tumoricidal dose ([143](#)). Attempts have been made to overcome this problem radiotherapeutically by means of interstitial implants into the tumor with a perineal template, but high central failure rates have also been reported with this technique ([144](#)).

Most oncologists prefer a combination of radiotherapy and surgery for treatment of patients with a barrel-shaped cervix. The usual approach is to perform an extrafascial hysterectomy 6 weeks after the completion of radiation therapy in an effort to resect a small, centrally persistent tumor. The dose of external radiotherapy is reduced to 4,000 cGy, and a single intracavitary treatment is given, which is followed by an extrafascial hysterectomy ([145,146](#)). This approach appears to result in a lower rate of central failure (2%), although it is not clear that the overall survival rate is improved. There is disagreement concerning the need for extrafascial

hysterectomy, and the GOG is undertaking a randomized study to compare adjuvant hysterectomy with radiotherapy alone in patients who have no evidence of occult metastases in the paraaortic nodes.

The narrow upper vagina of older patients may preclude the use of an intracavitary source of radiation. Such patients must receive their entire course of therapy from external sources, leading to a higher central failure rate and more significant bowel and bladder morbidity. If stage I disease is present in such a patient, a radical hysterectomy with pelvic node dissection is preferable if the patient's medical condition allows such an approach.

Small Cell Carcinoma

Local therapy alone gives almost no chance of cure of small cell carcinoma. Regimens of combination chemotherapy have improved the median survival rates in small cell bronchogenic carcinoma, and these regimens are now being used for treatment of small cell (neuroendocrine type) carcinoma of the cervix. Combination chemotherapy may consist of either *vincristine*, *doxorubicin*, and *cyclophosphamide* (VAC) or VP-16 (*etoposide*) and *cisplatin* (EP) (147). Patients must be monitored carefully because they are at high risk for developing recurrent metastatic disease (148).

Recurrent Cervical Cancer

Treatment of recurrent cervical cancer depends on the mode of primary therapy and the site of recurrence. Patients who have been treated initially with surgery should be considered for radiation therapy, and those who have had radiation therapy should be considered for surgical treatment. Chemotherapy is palliative only and is reserved for patients who are not considered curable by the other two modalities.

Radiotherapy for recurrence after surgery consists primarily of external treatment. Vaginal ovoids also may be placed in patients with isolated vaginal cuff recurrences. Patients with a regional recurrence may require interstitial implantation with a Syed type of template in addition to external therapy. A 25% survival rate can be expected in patients treated with radiation for a postsurgical recurrence (118).

Radiation Retreatment

Retreatment of recurrent pelvic disease by means of radiotherapy with curative intent is confined to patients who had suboptimal or incomplete primary therapy. This may allow the radiotherapist to deliver curative doses to the tumor. The proximity of the bladder and rectum to the cancer and their relative sensitivity to radiation injury are the major deterrents to retreatment with radiation. The insertion of multiple interstitial radiation sources into the locally recurrent cancer through a perineal template may help overcome these dosimetric considerations (137,149). However, the fistula rates are high, and the consequences must be considered seriously before interstitial therapy is initiated. In general, for patients considered curable with interstitial implant therapy, pelvic exenteration is a better treatment choice. Radiotherapy can be palliative with localized metastatic lesions. Painful bony metastases, central nervous system lesions, and severe urologic or vena caval obstructions are specific indications.

Surgical Therapy

Surgical therapy for postirradiation recurrence is limited to patients with central pelvic disease. A few carefully selected patients with small-volume disease limited to the cervix may be treated with an extrafascial or radical hysterectomy. However, the difficulty of assessing tumor volume and the 30% to 50% rate of serious urinary complications in these previously irradiated patients have led most gynecologic oncologists to recommend pelvic exenteration as the patient's last chance for cure (150,151).

Exenteration

The operation can be an anterior exenteration (removal of the bladder, vagina, cervix, and uterus), a posterior exenteration (removal of the rectum, vagina, cervix, and uterus), or a total exenteration (removal of both bladder and rectum with the vagina, cervix, and uterus). A total exenteration that includes a large perineal phase includes the entire rectum and leaves the patient with a permanent colostomy as well as a urinary conduit. In selected patients, a total exenteration may take place above the levator muscle (supralelevator), leaving a rectal stump that may be anastomosed to the sigmoid, thus avoiding a permanent colostomy.

Preoperative Evaluation and Patient Selection The search for metastatic disease is imperative. Physical examination includes careful palpation of the peripheral lymph nodes with FNA cytologic sampling of any nodes that appear suspicious. A random biopsy of nonsuspicious supraclavicular lymph nodes has been advocated but is not routinely practiced (100,152). A CT scan of the lung can detect disease missed on routine x-ray examination of the chest. Abdominal and pelvic CT scans are helpful in the detection of liver metastases and enlarged paraaortic nodes. CT-directed FNA cytologic study of any abnormality should be undertaken. If a positive cytologic diagnosis is obtained, it will obviate the need for exploratory laparotomy.

Extension of the tumor to the pelvic sidewall is a contraindication to exenteration; however, this may be difficult for even the most experienced examiner to determine because of radiation fibrosis. If any question of resectability arises, exploratory laparotomy and parametrial biopsies, the patient's last hope for cure, should be offered (153,154,155 and 156). **The clinical triad of unilateral leg edema, sciatic pain, and ureteral obstruction is nearly always pathognomonic of unresectable disease on the pelvic sidewall.** Preoperatively, the patient should be prepared for a major operation. Total parenteral nutrition may be necessary to place the patient in an anabolic state for optimal healing. A bowel preparation, preoperative antibiotics, and prophylaxis for deep venous thrombosis with low-dose heparin or pneumatic calf compression should be used (157). Surgical mortality increases with age, and the operation should rarely be considered in a patient who is older than 70 years of age. Other medical illnesses should be taken into account; when life expectancy is limited, exenterative surgery is unwise.

Anterior Exenteration Candidates for anterior exenteration are those in whom the disease is limited to the cervix and anterior portion of the upper vagina. Proctoscopic examination should be performed because a positive finding would mandate a total exenteration. However, a negative proctoscopic examination finding does not exclude disease in the rectal muscularis, and findings at laparotomy still must be considered. Generally, the presence of disease in the posterior vaginal mucosa directly over the rectum mandates removal of the underlying rectum.

Posterior Exenteration A posterior exenteration is rarely performed for recurrent cervical cancer. It is indicated, however, for the patient with an isolated posterior vaginal recurrence in which dissection of the ureters through the cardinal ligaments will not be necessary.

Total Exenteration Total exenteration with a large perineal phase is indicated when the disease extends down to the lower part of the vagina. Because distal vaginal lymphatics may empty into the inguinal node region, these nodes should be carefully evaluated preoperatively. A supralelevator total exenteration with low rectal anastomosis is indicated in the patient whose disease is confined to the upper vagina and cervix (158,159). Frozen-section margins of the rectal edge should be obtained because occult metastases to the muscularis may occur.

The development of techniques to establish continent urinary diversion has helped improve a woman's physical appearance after exenteration (160,161 and 162). When both a rectal anastomosis and a continent diversion are performed, the patient has no permanent external appliance, and the associated psychological trauma is avoided. Every effort should be made to create a neovagina simultaneously with the exenteration (163). This procedure also helps in the reconstruction of the pelvic floor after extirpation of the pelvic viscera. Whether or not a neovagina is constructed, it is desirable to mobilize the omentum on the left gastroepiploic artery and use it to create a new pelvic floor.

Surgical mortality has steadily decreased to an acceptable level of less than 10%. The most common causes of postoperative death are sepsis, pulmonary thromboembolism, and hemorrhage. Fistulas of the gastrointestinal and genitourinary tract are serious surgical complications, with a 30% to 40% mortality rate despite attempts at surgical repair. The risk for such fistulas has been decreased by the use of nonirradiated segments of bowel for formation of the urinary conduit (157). The 5-year survival rate is 33% to 60% for patients undergoing anterior exenteration and 20% to 46% for those undergoing total exenteration (154,153,154,155,156,157,158,159,160,161,162 and 163). Survival rates are poorer for patients with recurrent disease larger than 3 cm, invasion into the bladder, positive pelvic lymph nodes, and recurrence diagnosed within 1 year after radiotherapy (156). The 5-year survival rate of patients with positive pelvic lymph nodes is less than 5%. Thus, the performance of an extensive lymphadenectomy in the irradiated field is not warranted, but discontinuation of the procedure is advisable if any

nodes are positive for metastatic cancer. Patients who have any disease in the peritoneal cavity have no chance of survival.

Chemotherapy for Recurrent Cervical Cancer

Recurrent cervical cancer is not considered curable with chemotherapy. The delivery of chemotherapy to recurrent tumor in a prior radiated field may be compromised because of altered blood supply caused by radiation. *Topotecan* has been reported to have a response rate of 17%, with a median duration of 14 months (164). Many other agents have shown activity against cervical cancer and may be used in attempt to help control symptoms of the cancer. A number of clinical trials with various drugs have shown response rates of up to 45% (165). Complete responses are unusual and are generally limited to patients with chest metastases, in whom the dose of drug delivered to the disease is stronger than that delivered to the fibrotic postirradiation pelvis (166).

In a review of the literature on the role of chemotherapy in cervical cancer, the author concludes that present data do not support the claim that toxic combination chemotherapy regimens are superior to cisplatin alone in terms of survival benefit, although further studies are required to determine whether combination chemotherapy may offer a benefit for certain subgroups of patients (16,17). The response rates for single-agent chemotherapy in cervical cancer are about 10% to 25%; *cisplatin* and *carboplatin* are among the most active agents. The response rate for *cisplatin* combination therapies is about 20% to 40% (167). The GOG currently has completed two trials (GOG 149 and 169) evaluating recurrent cervical carcinoma. GOG 169 is comparing *cisplatin* to *cisplatin* with *paclitaxel*. Results of these studies may alter first-line therapy for recurrent cervical carcinoma.

Vaginal Carcinoma

Primary vaginal cancer is a relatively uncommon tumor, representing only 1% to 2% of malignant neoplasms of the female genital tract (168,169). The incidence of invasive vaginal cancer is 0.42 per 100,000 women and has remained relatively unchanged since the 1980s (170). Primary vaginal cancer should be differentiated from cancers metastatic to the vagina. Metastatic cancers constitute the majority of vaginal cancers (80% to 90%) (171).

Staging

The FIGO staging of vaginal cancer requires that a tumor that has extended to the vagina from the cervix be regarded as a cancer of the cervix, whereas a tumor that involves both the vulva and the vagina should be classified as a cancer of the vulva.

The FIGO staging for vaginal carcinoma is shown in Table 31.6. Staging is done by clinical examination and, if indicated, cystoscopy, proctoscopy, chest x-rays, and skeletal x-ray. Information derived from lymphangiography, CT, and MRI cannot be used to change the FIGO stage, but it can be used for planning treatment. Unfortunately, 75% of patients present with stage II to IV disease, indicating delay in diagnosis and complicating the treatment and subsequent cure rates (172,173 and 174).

Stage 0	Carcinoma in situ, intraepithelial carcinoma.
Stage I	The carcinoma is limited to the vaginal wall.
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall.
Stage III	The carcinoma has extended to the pelvic wall.
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum.
Stage IVa	Spread of the growth to adjacent organs.
Stage IVb	Spread to distant organs.

FIGO, International Federation of Gynecology and Obstetrics.

Table 31.6. FIGO Staging of Vaginal Cancer

Surgical staging and resection of enlarged lymph nodes may be indicated in selected patients. FIGO staging does not include a category for microinvasive disease. Because vaginal cancer is rare and treatment is generally by radiotherapy, there is very little information concerning the spread of disease in relation to depth of invasion, lymph-vascular space invasion, and size of the lesion.

Etiology

The cause of squamous cell carcinoma of the vagina is unknown. The association of cervical cancer with HPV suggests that vaginal cancer may have a similar association (175). In addition, up to 30% of women with vaginal cancer have a history of cervical cancer treated at least 5 years earlier (176,177 and 178). Similar to cervical cancer, there appears to be a premalignant phase called *vaginal intraepithelial neoplasia* (VAIN) (see Chapter 16). The exact incidence of progression to invasive vaginal cancer from VAIN is not known; however, there are documented cases of invasive disease occurring despite adequate treatment of VAIN (179,180).

By convention, any new vaginal carcinoma developing at least 5 years after the cervical cancer should be considered a new primary lesion. There are three possible mechanisms for the occurrence of vaginal cancer after cervical neoplasia:

1. Residual disease in the vaginal epithelium after treatment of the cervical neoplasia
2. New primary disease arising in a patient with increased susceptibility to lower genital tract carcinogenesis; the role of HPV in this setting is suspected.
3. Increased susceptibility of carcinogenesis caused by radiation therapy

Screening

Routine screening of all patients for vaginal cancer is inappropriate. For women who have had a cervical or vulvar neoplasm, the Pap test is an important part of routine follow-up with each physician visit. This increased risk for vaginal cancer continues for the lifetime of the patient. It is recommended that Pap test surveillance for vaginal cancer be performed yearly after the patient has completed surveillance for cancer of the cervix or vulva. For women who have had a hysterectomy for benign disease, Pap testing every 3 to 5 years has been standard practice in the United States. When adjusted for age and prior cervical disease, the incidence of vaginal cancer is not increased in women who have had hysterectomy for benign disease (181).

Symptoms

Painless vaginal bleeding and discharge are the most common symptoms of vaginal cancer. With more advanced tumors, urinary retention, bladder spasm, hematuria, and frequency of urination may occur. Tumors developing on the posterior vaginal wall may produce rectal symptoms, such as tenesmus, constipation, or blood in the stool.

Diagnosis

The diagnostic workup includes a complete history and physical examination, careful speculum examination and palpation of the vagina, and bimanual pelvic and rectal examinations. It is important to rotate the speculum to obtain a careful view of the entire vagina because posterior wall lesions frequently occur and may be

overlooked.

In early squamous cell lesions, the diagnosis is suggested by an abnormal Pap test result; however, this is not true for clear cell adenocarcinomas, which are characterized by submucosal growth. In these cases, the diagnosis is confirmed by a targeted biopsy using the same instruments as those used for cervical biopsies. The most common site of vaginal cancer is in the upper one third of the vagina on the posterior wall. The developing tumor may be missed during initial inspection because the speculum blades may have obscured it (182). Colposcopy is valuable in evaluating patients with abnormal Pap test results, unexplained vaginal bleeding, or ulcerated erythematous patches in the upper vagina. A colposcopically targeted biopsy may not allow a definitive diagnosis, and a partial vaginectomy to determine invasion may be necessary. Occult invasive carcinoma may be detected by such an excision, particularly in patients who had previous hysterectomies, in whom the vaginal vault closure may bury some of the vaginal epithelium that is at risk for cancer (183).

Pathology

Cancer of the vagina spreads most often by direct extension into the pelvic soft tissues and adjacent organs. Metastases to the pelvic and, subsequently, the paraaortic lymph nodes may occur in advanced disease. Lesions in the lower one third of the vagina may spread directly to the inguinal femoral lymph nodes as well as the pelvic nodes (184). Hematogenous dissemination to the lungs, liver, or bone may occur as a late phenomenon.

Squamous cell carcinomas are the most common form of vaginal cancer, occurring in 80% to 90% of vaginal cancers. These tumors most commonly occur in the upper, posterior wall of the vagina. The mean age of patients with squamous cell cancer is 60 years (185,186). Malignant melanoma is the second most common cancer of the vagina, accounting for 2.8% to 5% of all vaginal neoplasms (187,188 and 189). Other histologic subtypes include adenocarcinoma and sarcoma.

Primary adenocarcinoma of the vagina is rare, constituting 9% of primary tumors of the vagina. However, the most common adenocarcinoma of the vagina is metastatic. Metastatic adenocarcinoma of the vagina may originate from the colon, endometrium, ovary, or rarely, pancreas and stomach. In general, they affect a younger population of women, regardless of whether they were exposed to *diethylstilbestrol (DES) in utero* (190). Adenocarcinomas may arise in wolffian rest elements, periurethral glands, and foci of endometriosis (191). In women exposed to *DES in utero*, adenocarcinoma may develop in vaginal adenosis.

DES was used in the United States from 1940 until 1971 to maintain high-risk pregnancies in women with a history of spontaneous abortions. In 1970, Herbst and Scully reported on seven young women with clear cell adenocarcinoma of the vagina (Fig. 31.11). Later, an association between this cancer and maternal ingestion of *DES* during pregnancy was identified (192). Subsequently, more than 500 cases of clear cell cancer of the vagina and cervix have been reported to the Registry for Research on Hormonal Transplacental Carcinogenesis.

Figure 31.11 Vaginal clear cell carcinoma. Note the formation of tubules with hobnail cells lining the lumen. These cells are characterized by nuclear protrusion into the apical cytoplasm. (From **Berek JS, Hacker F. Practical gynecologic oncology.** 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

The estimated risk for developing clear cell adenocarcinoma from an exposed offspring is 1 in 1,000 or less. The mean age of diagnosis is 19 years (193). Clear cell adenocarcinoma in women with a history of *in utero* exposure to *DES* typically presents in the exocervix or upper third of the vagina. These tumors vary greatly in size, and are most frequently exophytic and superficially invasive. Stage is the most important prognostic factor. Other statistically significant factors include a tubulocystic growth pattern, size less than 3 cm², and less than 3 mm stromal invasion. Because the use of *DES* in pregnant women was discontinued in 1971, most of these tumors probably have been discovered. It is uncertain, however, what will happen to this cohort of women as they move into their fifth, sixth, and seventh decades of life. Continued surveillance of these women is indicated.

Ninety-seven percent of cases of vaginal clear cell adenocarcinoma are associated with adenosis. Adenosis is characterized by the presence of persistent müllerian-type glandular epithelium. Although adenosis is the most common histologic abnormality in women exposed to *DES in utero*, adenosis can also be found in women without a history of exposure. Adenosis typically appears as red, grapelike clusters in the vagina.

Malignant melanoma of the vagina is rare and extremely lethal. The average age of these patients is 58 years, and malignant melanoma occurs most often in white women (194). Most lesions are deeply invasive, corresponding to a level IV when compared with the staging for vulvar melanomas. The most common location of these tumors is in the lower third of the vagina (195). Melanomas have a wide variety of size, color, and growth patterns (193,196). Radical excision (vaginectomy, hysterectomy, and pelvic lymphadenectomy) has been the mainstay of treatment. The goal of treatment is to avoid local (vaginal) recurrence, which is the most common site of recurrence (194,195). The need to dissect regional lymph nodes is uncertain. Because the disease is deeply invasive, hematogenous spread is the most common lethal recurrence. This finding is consistent with more conservative local excision because there is no difference in overall survival of patients with local as opposed to radical excision (194). The survival rate is about 10% at 5 years.

The most common benign and malignant mesenchymal tumors of the vagina in adult women are smooth muscle tumors (197). Vaginal sarcomas are usually fibrosarcomas or leiomyosarcomas and are extremely rare. Radical local excision, followed by adjuvant chemotherapy or radiation therapy, is the indicated treatment.

The most common malignant mesenchymal tumor of the vagina in children and infants is botryoid rhabdomyosarcoma (Fig. 31.12). Botryoid sarcoma is usually found in the vagina during infancy and early childhood, in the cervix during the reproductive years, and in the corpus uteri during postmenopausal years. Preoperative chemotherapy with *vincristine*, *actinomycin D*, and *cyclophosphamide*, followed by conservative surgery or radiation, has led to improved survival as well as organ preservation.

Figure 31.12 Embryonal rhabdomyosarcoma of the vagina (botryoid sarcoma). This lesion consists of primitive mesenchymal cells and rhabdomyoblasts, which have abundant eosinophilic cytoplasm. With further differentiation, cross striations may become evident. (From **Berek JS, Hacker F. Practical gynecologic oncology.**

Treatment

Treatment selection is based on the clinical examination, CT scan results, chest x-ray results, age, and condition of the patient. Most tumors are treated by radiation therapy. Surgery is limited to highly selective cases.

Women with stage I disease involving the upper posterior vagina may be treated by radical vaginectomy and pelvic lymphadenectomy. If the uterus is *in situ*, it is removed as a radical hysterectomy specimen. When margins are clear and lymph nodes are negative, no additional therapy is necessary. Patients with stage IV disease with either rectovaginal or vesicovaginal fistula may be candidates for primary pelvic exenteration with pelvic and paraaortic node dissection (193). Low rectal anastomosis, continent urinary diversion, and vaginal reconstruction are indicated and are more successful in these nonirradiated patients than in patients who received prior radiation therapy (163).

Women with central pelvic recurrence after radiation therapy are candidates for pelvic exenteration similar to that for cervical cancer. Surgical staging with resection of enlarged lymph nodes may improve the control of pelvic disease by radiotherapy techniques. Surgical exploration or laparoscopy at the time of insertion of Syed interstitial implants defines more precisely the placement of the needles and ensures that needles do not pass into adherent loops of bowel.

Radiation therapy is the treatment of choice for all patients except those described previously. Small superficial lesions may be treated with intracavitary radiation alone (193). Larger, thicker lesions should be treated first with external teletherapy to decrease tumor volume and to treat the regional pelvic nodes, followed by intracavitary and interstitial therapy to deliver a high dose to the primary tumor (186,194). If the uterus is intact and the lesion involves the upper vagina, an intrauterine tandem and ovoids can be used. If the uterus has been previously removed, a vaginal cylinder may be used for superficial irradiation. If the lesion is more than 0.5 cm thick, interstitial radiation techniques can improve the dose distribution to the primary tumor. Extended-field radiation may be used for vaginal cancer in a manner similar to its use for cervical carcinoma. There is no experience reported with this technique in the treatment of vaginal cancer. Likewise, there is no reported experience with combination chemoradiation treatment. However, concurrent use of 5-FU and cisplatin has been highly successful in anal and cervical cancer and should be considered.

Sequelae

The proximity of the rectum, bladder, and urethra leads to a major complication rate of 10% to 15% for both surgery and radiation treatment. For large tumors, the risk for bladder or bowel fistula is significant. Radiation cystitis and proctitis are common, as are rectal strictures or ulcerations. Radiation necrosis of the vagina occasionally occurs, requiring débridement and often leading to fistula formation. Vaginal fibrosis, stenosis, and stricture are common after radiation therapy. Use of vaginal dilators and resumption of regular sexual relations should be encouraged, along with the use of topical estrogen to maintain adequate vaginal function.

Survival

The overall 5-year survival rate for patients with vaginal cancer is 42% (Table 31.7). Even for patients with stage I disease, the 5-year survival rate is less than 70%, which is 15% lower than that for comparable stages of cervical or vulvar cancer (195,196,197,198 and 199). Most recurrences are in the pelvis, either from enlarged regional nodes or from large central tumors to which it is difficult to deliver an adequate dose of radiation. Radiation techniques, such as interstitial implants with Syed applicator and combination chemoradiation, may improve these results. Careful evaluation of patients who receive radiation therapy to detect central recurrence may allow some patients to be salvaged by pelvic exenteration. Because of the rarity of vaginal cancer, these patients should be treated in a center that is familiar with the complexity of treatment and modalities of therapy.

Stage	No. of Patients	No. Surviving 5 Years	Percentage
I	172	118	68.6
II	236	108	45.8
III	203	62	30.5
IV	114	20	17.5
Total	725	308	42.5

Of all the gynecologic cancers, ovarian malignancies represent the greatest clinical challenge. Epithelial cancers are the most common ovarian malignancies, and because they are usually asymptomatic until they have metastasized, patients have advanced disease at diagnosis in more than two-thirds of the cases. Ovarian cancer represents a major surgical challenge, requires intensive and often complex therapies, and is extremely demanding of the patient's psychological and physical energy. It has the highest fatality-to-case ratio of all the gynecologic malignancies. There are more than 23,300 new cases annually in the United States, and 13,900 women can be expected to succumb to their illness (1). A woman's risk at birth of having ovarian cancer sometime in her life is nearly 1.5%, and that of dying from ovarian cancer almost 1% (2).

Epithelial Ovarian Cancer

Approximately 90% of ovarian cancers are derived from tissues that come from the coelomic epithelium or mesothelium (2). The cells are a product of the primitive mesoderm, which can undergo metaplasia. A classification of the histologic types of epithelial tumors of the ovary is presented in [Table 32.1](#). Neoplastic transformation can occur when the cells are genetically predisposed to oncogenesis or exposed to an oncogenic agent or both (3).

Histologic Type	Cellular Type
I. Serous	Endothelial
A. Serous	
B. Serous	
C. Serous	
II. Mucinous	Endothelial
A. Serous	
B. Serous	
C. Serous	
III. Endometrioid	Endothelial
A. Serous	
B. Serous	
C. Serous	
IV. Clear cell "mesonephroid"	Mesonephric
A. Serous	
B. Serous	
C. Serous	
V. Brenner	Transitional
A. Serous	
B. Serous	
C. Serous	
VI. Atypical epithelial	Mixed
A. Serous	
B. Serous	
C. Serous	
VII. Undifferentiated	Angiosarcoma
VIII. Undifferentiated	Angiosarcoma, etc.

Table 32.1. Epithelial Ovarian Tumors

Pathology

Invasive Cancer

Seventy-five percent of epithelial cancers are of the serous histologic type. Less common types are mucinous (20%), endometrioid (2%), clear cell, Brenner, and undifferentiated carcinomas; each of the last three types represents less than 1% of epithelial lesions (2). Each tumor type has a histologic pattern that reproduces the mucosal features of a section of the lower genital tract (3). For example, the serous or papillary pattern has an appearance similar to that of the glandular epithelial lining and fallopian tube. Mucinous tumors contain cells that resemble the endocervical glands, and the endometrioid tumors resemble the endometrium.

Borderline Tumors

An important group of tumors to distinguish is the *tumor of low malignant potential*, also called the *borderline tumor*. Borderline tumors are lesions that tend to remain confined to the ovary for long periods, occur predominantly in premenopausal women, and are associated with a very good prognosis (2,3,4,5,6,7 and 8). They are encountered most frequently in women between the ages of 30 and 50 years, whereas invasive carcinomas occur more often in women between the ages of 50 and 70 years (2).

Although uncommon, metastatic implants may occur with borderline tumors. Such implants have been divided into noninvasive and invasive forms. The latter group has a higher likelihood of developing into progressive, proliferative disease in the peritoneal cavity, which can lead to intestinal obstruction and death (2,6).

The criteria for the diagnosis of borderline tumors (Fig. 32.1) are as follows (7):

Figure 32.1 Borderline malignant serous tumor of the ovary. Complex papillary fronds are lined with pseudostratified columnar cells. The epithelium and the stroma are clearly separated by a basement membrane, indicating no stromal invasion. (From **Berek JS, Hacker NF. Practical gynecologic oncology**, 2nd ed. Baltimore: Williams & Wilkins, 1994:138, with permission.)

1. Epithelial proliferation with papillary formation and pseudostratification
2. Nuclear atypia and increased mitotic activity
3. Absence of true stromal invasion (i.e., without tissue destruction).

It should be emphasized that about 20% to 25% of borderline malignant tumors spread beyond the ovary. The diagnosis of borderline malignant versus malignant ovarian tumor must be based on the histologic features of the primary tumor (7).

Classification of Epithelial Ovarian Tumors

Serous Tumors

Serous tumors develop by invagination of the surface ovarian epithelium and are so classified because they secrete serous fluid (as do tubal secretory cells). *Psammoma bodies*, more correctly foci of foreign material, frequently are associated with these invaginations and may be a response to irritative agents that produce adhesion formation and the entrapment of the surface epithelium. In the wall of the mesothelial invaginations, papillary ingrowths are common, representing the early stages of development of a papillary serous cystadenoma. There are many variations in the proliferation of these mesothelial inclusions. Several foci may be lined with flattened inactive epithelium; in adjacent cavities, papillary excrescences are present, often resulting from local irritants (2).

Borderline Serous Tumors Approximately 10% of all ovarian serous tumors fall into the category of a tumor of low malignant potential or borderline tumor, and 50% occur before the age of 40 years. As many as 10% of women with ovarian serous borderline tumors have extraovarian implants, and some will eventually die of the disease (9). Although multiple foci of disease have been documented in the abdominal cavity with secondary deposits in the pelvis, omentum, and adjacent tissues, including lymph nodes, metastases outside the abdominal cavity are rare. Death can occur as the result of intestinal obstruction (10,11 and 12).

The implants are divided histologically into invasive and noninvasive groups (6,10). In the noninvasive group, papillary proliferations of atypical cells involve the peritoneal surface and form smooth invaginations (6). The invasive implants resemble well-differentiated serous carcinoma and are characterized by atypical cells forming irregular glands with sharp borders. Bell and associates (6) have reported that only three of 50 women with noninvasive implants died, whereas four of six women with invasive implants died. In the series of McCaughey, two of 13 patients with noninvasive implants and all five patients with invasive implants died (9). Others have noted no differences in prognosis (10,11).

Rare examples of borderline malignant serous tumors with foci of microinvasion have been reported by Bell and Scully (12). Most patients are young, International Federation of Gynecology and Obstetrics (FIGO) stage I, and sometimes pregnant. Only one of 30 such patients died of disease, and she had stage III disease (12).

Malignant Serous Carcinomas In the malignant tumors, stromal invasion is present (2). The grade of tumor should be identified. In well-differentiated serous adenocarcinomas, papillary and glandular structures predominate (Fig. 32.2); poorly differentiated neoplasms are characterized by solid sheets of cells, nuclear pleomorphism, and high mitotic activity; and moderately differentiated carcinomas are intermediate between these two lesions. Laminated, calcified psammoma

bodies are found in 80% of serous carcinomas.

Figure 32.2 Well-differentiated serous papillary adenocarcinoma of the ovary. Clusters and papillae of malignant cells are in direct contact with fibrous stroma indicative of stromal invasion. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:140, with permission.)

Mucinous Tumors

These cystic tumors have loculi lined with mucin-secreting epithelium. They represent about 8% to 10% of epithelial ovarian tumors. They may reach enormous size, filling the entire abdominal cavity ([2](#)).

Borderline Mucinous Tumors The mucinous tumor of low malignant potential is often a diagnosis difficult to make. Although it is common to find a rather uniform pattern from section to section in the borderline malignant serous lesions, this is not true in the mucinous tumors. **Frequently, well-differentiated mucinous epithelium may be seen immediately adjacent to a poorly differentiated focus. Therefore, it is important to take multiple sections from many areas in the mucinous tumor to identify the most malignant alteration.**

Malignant Mucinous Carcinomas **Bilateral tumors occur in 8% to 10% of cases.** The mucinous lesions are intraovarian in 95% to 98% of cases ([Fig. 32.3](#)). Because most ovarian mucinous carcinomas contain intestinal type cells, they cannot be distinguished from metastatic carcinoma of the gastrointestinal tract on the basis of histology alone. Primary ovarian neoplasms rarely metastasize to the mucosa of the bowel, although they commonly involve the serosa, whereas gastrointestinal lesions frequently involve the ovary by direct extension of vascular lymphatic spread.

Figure 32.3 Mucinous adenocarcinoma of the ovary. Irregular glandular spaces are lined with a layer of tall columnar cells with abundant mucinous cytoplasm, resembling endocervical cells. The nuclei are mildly atypical. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:142, with permission.)

Pseudomyxoma Peritonei In pseudomyxoma peritonei, the neoplastic epithelium secretes large amounts of gelatinous mucinous material. It is most commonly secondary to a well-differentiated appendiceal carcinoma, an ovarian mucinous carcinoma or, less commonly, a mucocele of the appendix.

Endometrioid Tumors

Endometrioid lesions constitute 6% to 8% of epithelial tumors. Endometrioid neoplasia includes all the benign demonstrations of endometriosis. In 1925, Sampson ([13](#)) suggested that certain cases of adenocarcinoma of the ovary probably arose in areas of endometriosis. The adenocarcinomas are similar to those seen in the uterine cavity. The malignant potential of endometriosis is very low, although a transition from benign to malignant epithelium may be demonstrated ([Fig. 32.4](#)).

Figure 32.4 Endometrioid cancer arising in adjacent endometriosis. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:143, with permission.)

Borderline Endometrioid Tumors The endometrioid tumor of low malignant potential has a wide morphologic spectrum. Tumors may resemble an endometrial polyp or complex endometrial hyperplasia with crowding of glands. When there are back-to-back glands with no intervening stroma, the tumor is classified as a well-differentiated endometrioid carcinoma. Some borderline malignant tumors have a prominent fibromatous component. In such cases, the word *adenofibroma* is used.

Malignant Endometrioid Carcinomas Endometrioid tumors are characterized by an adenomatous pattern with all the potential variations of epithelia found in the uterus.

Multifocal Disease The *endometrial* or endometrioid tumors afford the greatest opportunity to evaluate multifocal disease. **Endometrioid tumors of the ovary are often associated with similar lesions in the endometrium.** Identification of multifocal disease is important, because patients with disease metastatic from the uterus

to the ovaries have a 30% to 40% 5-year survival, whereas those with synchronous multifocal disease have a 75% to 80% 5-year survival (14). When the histologic appearance of endometrial and ovarian tumors is different, the two tumors most likely represent two separate primary lesions. When they appear similar, the endometrial tumor can be considered a separate primary tumor if it is well differentiated and only superficially invasive.

Clear Cell Carcinomas

Several basic histologic patterns are present in the clear cell adenocarcinoma (i.e., tubulocystic, papillary, and solid). The tumors are made up of clear cells and hobnail cells that project their nuclei to the apical cytoplasm. The tall clear cells have abundant clear or vacuolated cytoplasm, hyperchromatic irregular nuclei, and nucleoli of various sizes (Fig. 32.5). Focal areas of endometriosis and endometrioid carcinoma sometimes occur. The clear cell carcinoma seen in the ovary is histologically identical to that seen in the uterus or vagina of the young patient who has been exposed to diethylstilbestrol (DES) in utero.

Figure 32.5 Clear cell mesonephroid carcinoma of the ovary. Note the solid variant of clear cell carcinoma with sheets of cells that have clear cytoplasm (“hobnail” cells). (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:144, with permission.)

Brenner Tumors

Borderline Brenner Tumors Borderline, or proliferating, Brenner tumors have been described. In such cases, the epithelium does not invade the stroma. Some investigators subclassify those tumors that resemble low-grade papillary transitional cell carcinoma of the urinary bladder as proliferating tumors and those with a higher grade of transitional cell carcinoma *in situ* as borderline malignant Brenner tumors (15). Complete surgical removal usually results in cure.

Malignant Brenner Tumors These are rare and are defined as benign Brenner tumors coexisting with invasive transitional cells or another type of carcinoma. The tumor infiltrates the tissue with associated destruction.

Transitional Cell Tumors

The designation *transitional cell tumor* refers to a primary ovarian carcinoma resembling transitional cell carcinoma of the urinary bladder without a recognizable Brenner tumor. An important finding is that those ovarian carcinomas that contain more than 50% of transitional cell carcinoma are more sensitive to chemotherapy and have a more favorable prognosis than other poorly differentiated ovarian carcinomas of comparable stage (16,17). Transitional cell tumors differ from malignant Brenner tumors in that they are more frequently diagnosed in an advanced stage and, therefore, are associated with a poorer survival rate (18).

Small cell carcinoma occurs mainly in young women, who may have symptoms of hypercalcemia. Immunohistochemical stains are helpful to differentiate this tumor from a lymphoma, leukemia, or sarcoma.

Peritoneal Carcinomas

Primary peritoneal tumors are histologically indistinguishable from primary ovarian serous tumors. In the case of borderline serous peritoneal tumors and serous peritoneal carcinomas, the ovaries are normal or minimally involved, and the tumors affect predominantly the uterosacral ligaments, pelvic peritoneum, or omentum. The overall prognosis for borderline serous peritoneal tumors is excellent and comparable to that of ovarian borderline serous tumors (21,22 and 23). In the review of 38 cases of peritoneal borderline serous tumors from the literature, 32 women had no persistent disease, four were well after resection of recurrence, one developed an invasive serous carcinoma, and one died from the effects of the tumor (21).

Peritoneal serous carcinomas have the appearance of a moderately to poorly differentiated serous ovarian carcinoma. Primary peritoneal endometrioid carcinoma is less common.

More than 80% of epithelial ovarian cancers are found in postmenopausal women (Fig. 32.6). These cancers are relatively uncommon in women under age 45.

Figure 32.6 Ovarian cancer incidence: distribution by age. (From *J Natl Cancer Inst* 1995;87:1280, with permission.)

Mesotheliomas

Peritoneal malignant mesotheliomas fall into the following four categories (19): (a) fibrosarcomatous, (b) tubulopapillary (papillary-alveolar), (c) carcinomatous, and (d) mixed. These lesions appear as multiple intraperitoneal masses and can develop after hysterectomy and bilateral salpingo-oophorectomy for benign disease. Malignant mesotheliomas should be distinguished from ovarian tumor implants and primary peritoneal müllerian neoplasms.

The primary malignant transformation of the peritoneum has been called primary *peritoneal carcinoma* or *primary peritoneal papillary serous carcinoma*. Peritoneal carcinoma simulates ovarian cancer clinically. In patients for whom exploratory surgery is performed, there may be microscopic or small macroscopic cancer on the surface of the ovary and extensive disease in the upper abdomen, particularly in the omentum. This phenomenon can thus produce a condition in which so-called *ovarian cancer* can arise in a patient whose ovaries were surgically removed many years earlier (20).

Clinical Features

The peak incidence of invasive epithelial ovarian cancer is at 56 to 60 years of age ([2,3,24](#)). The age-specific incidence of ovarian epithelial cancer rises precipitously from 20 to 80 years of age and subsequently declines ([24](#)). Fewer than 1% of epithelial ovarian cancers occur before the age of 21 years, two-thirds of ovarian malignancies in such patients being germ cell tumors ([2,24,25](#)). About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant ([2,3](#)).

The average age of patients with borderline tumors is approximately 46 years ([2,3,5](#)). Eighty to ninety percent of ovarian cancers, including borderline forms, occur after the age of 40 years, whereas 30% to 40% of malignancies occur after the age of 65 years. The chance that a primary epithelial tumor will be of borderline or invasive malignancy in a patient younger than 40 years is approximately 1 in 10, but after that age it rises to one in three ([2,3](#)). Fewer than 1% of epithelial ovarian cancers occur before the age of 20 years, with two thirds of ovarian malignancies in such patients being germ cell tumors. Approximately 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only approximately 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant ([2](#)).

Etiology

Ovarian cancer has been associated with low parity and infertility ([26](#)). Although there have been a variety of epidemiologic variables correlated with ovarian cancer, such as talc use, galactose consumption, and tubal ligation (see [Chapter 4](#)), none has been so strongly correlated as prior reproductive history and duration of the reproductive career ([26,27](#)). Early menarche and late menopause increase the risk of ovarian cancer ([27](#)). These factors and the relationship of parity and infertility to the risk of ovarian cancer have led to the hypothesis that suppression of ovulation may be an important factor. Theoretically, the surface epithelium undergoes repetitive disruption and repair. It is thought that this process might lead to a higher probability of spontaneous mutations that can unmask germline mutations or otherwise lead to the oncogenic phenotype (see [Chapter 6](#)).

Prevention

Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective of the disease, with a risk reduction of 0.3 to 0.4. Oral contraceptive use reduces the risk of epithelial ovarian cancer ([26](#)). Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer). Women who have had two children and have used oral contraceptives for 5 or more years have a relative risk of ovarian cancer as low as 0.3, or a 70% reduction ([28](#)). **Therefore, the oral contraceptive pill is the only documented method of chemoprevention for ovarian cancer, and it should be recommended to women for this purpose. When counseling patients regarding birth control options, this important benefit of oral contraceptive use should be emphasized. This is also important for women with a strong family history of ovarian cancer** (see discussion below).

Fenretinide (4-hydroxyretinoic acid), a vitamin A derivative, has been given to women with unilateral breast cancer in an effort to reduce the risk of contralateral breast cancer. In a prospective, randomized, placebo-controlled trial conducted in Italy ([29](#)), women with unilateral breast cancer were given for 6 months either fenretinide orally or a placebo. In the treatment group, no ovarian cancers developed, whereas there were six cases of ovarian cancer in the control group. A larger trial is planned in the United States in an attempt to verify these data.

The performance of a prophylactic oophorectomy reduces, but does not eliminate, the risk of ovarian cancer ([20,21](#)). Because the entire peritoneum is at risk, peritoneal carcinomas can occur even after prophylactic oophorectomy. Because the ovaries provide protection from cardiovascular and orthopedic diseases, prophylactic oophorectomy should not be routinely performed in premenopausal women at low risk for ovarian cancer.

Screening

The value of tumor markers and ultrasonography to screen for epithelial ovarian cancer has not been clearly established by prospective studies. Screening results with transabdominal ultrasonography have been encouraging ([30,31](#) and [32](#)), but specificity has been limited. However, advances in transvaginal ultrasonography have been shown to have a very high (>95%) sensitivity for the detection of early-stage ovarian cancer, although this test alone might require as many as 10 to 15 laparotomy procedures be performed for each case of ovarian cancer detected ([30,31](#)). Routine annual pelvic examinations have had disappointing results in the early detection of ovarian cancer ([33](#)). Transvaginal color-flow Doppler to assess the vascularity of the ovarian vessels has been shown to be a useful adjunct to ultrasonography ([34,35](#)), but it has not been shown to be useful in screening.

CA125 has been shown to contribute to the early diagnosis of epithelial ovarian cancer ([36,37,38,39,40,41](#) and [42](#)). Regarding the sensitivity of the test, CA125 can detect 50% of patients with stage I disease and 60% of patients if those with stage II disease are included ([36](#)). Data suggest that the specificity of CA125 is improved when the test is combined with transvaginal ultrasonography ([43](#)) or when the CA125 levels are followed over time ([42,43](#)). These data have encouraged the development of prospective screening studies in Sweden and the United Kingdom ([38,39](#)). In these studies, patients with elevated CA125 levels (>30 U/ml) have undergone abdominal ultrasonography and 14 ovarian cancers have been discovered among 27,000 women screened. About four laparotomies were performed for each case of cancer detected.

A randomized trial of nearly 22,000 women aged 45 years or older was performed in the United Kingdom ([43](#)). The patients were assigned to either a control group of routine pelvic examination (n = 10,977) or to a screening group (n = 10,958). The screening consisted of three annual screens that involved measurement of serum CA125, pelvic ultrasonography if the CA125 was 30 U/ml or higher, and referral for gynecologic examination if the ovarian volume was 8.8 ml or greater on the ultrasonography. Of the 468 women in the screened group with an elevated CA125, 29 were referred for surgery, 6 cancers were discovered, and 23 had false-positive screening results, yielding a positive predictive value of 20.7%. During a 7-year follow-up period, cancer developed in 10 additional women in the screened group, as it did in 20 women in the control group. Although the median survival of women in whom cancer developed in the screened group was 72.9 months, compared with 41.8 months in the control group ($p = 0.0112$), the number of deaths did not differ significantly between the control and screened groups [18/10,977 versus 9/10,958; relative risk 2.0 (0.78 to 5.13)]. Therefore, these data show that a multimodal approach to ovarian cancer screening is feasible, but a larger trial is necessary to determine whether this approach affects mortality. Such a three-arm randomized trial is ongoing in the United Kingdom, and the anticipated accrual is approximately 50,000 women per study arm and 100,000 women in the control arm.

Given the false-positive results for both CA125 and transvaginal ultrasonography, particularly in premenopausal women, these tests are not cost effective and should not be used routinely to screen for ovarian cancer. In the future, new markers or technologies may improve the specificity of ovarian cancer screening, but proof of this will require a large, prospective study ([40,41](#)). Screening in women who have a familial risk may have a better yield, but additional study is necessary ([44,45](#)).

Genetic Risk for Epithelial Ovarian Cancer

The lifetime risk of ovarian carcinoma for women in the United States is about 1.4% ([1,2](#) and [3](#)).

The risk of ovarian cancer is higher than that in the general population in women with certain family histories ([46,47,48,49,50,51,52,53,54](#) and [55](#)). **Most epithelial ovarian cancer is sporadic, with familial or hereditary patterns accounting for 5% to 10% of all malignancies** ([47](#)).

Hereditary Ovarian Cancer

BRCA1 and *BRCA2*

Most hereditary ovarian cancer is associated with mutations in the *BRCA1* gene, located on chromosome 17 ([46](#)). **A small proportion of inherited disease has been traced to another gene, *BRCA2*, located on chromosome 13** ([48](#)). Discovered through linkage analyses, these two genes are associated with the genetic predisposition to both ovarian and breast cancer. There may be other, yet undiscovered genes that predispose to ovarian and breast cancer ([55](#)).

In the past, it had been thought that there were two distinct syndromes associated with a genetic risk, *site-specific hereditary ovarian cancer and hereditary breast-ovarian cancer syndrome*. However, it is now believed that these groups essentially represent a continuum of mutations with different degrees of penetrance

within a given family (50,55). In addition, there is a higher-than-expected risk of ovarian and endometrial cancer in the *Lynch II syndrome*, known also as the *hereditary nonpolyposis colorectal cancer syndrome (HNPCC syndrome)* (56).

The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family) must be carefully evaluated (50). There are numerous distinct mutations that have been identified on each of these genes, and the mutations have different degrees of penetrance that may account for the preponderance of either breast cancer, ovarian cancer, or both, in any given family. **Based on analysis of women who have a mutation in the *BRCA1* gene and are from high-risk families, the lifetime risk of ovarian cancer may be as high as 28% to 44%, and the risk has been calculated to be as high as 27% for those women with a *BRCA2* mutation (47,48,54).** The risk of breast cancer in women with a *BRCA1* or *BRCA2* mutation may be as high as 56% to 87%.

Hereditary ovarian cancers in general occur in women approximately 10 years younger than those with nonhereditary tumors (47). Because the median age of epithelial ovarian cancer is in the mid- to late 50s, a woman with a first- or second-degree relative who had premenopausal ovarian cancer may have a higher probability of carrying an affected gene.

Breast and ovarian cancer may exist in a family in which there is a combination of epithelial ovarian and breast cancers, affecting a mixture of first- and second-degree relatives. Women with this syndrome tend to have these tumors at a young age, and the breast cancers may be bilateral. If two first-degree relatives are affected, this pedigree is consistent with an autosomal dominant mode of inheritance (43,46).

Founder Effect

There is a higher carrier rate of *BRCA1* and *BRCA2* mutations in women of Ashkenazi Jewish descent and in Icelandic women (52,53,55). There have been three specific mutations carried by the Ashkenazi population, 185delAG and 5382insC on *BRCA1*, and 6174delT on *BRCA2*. The total carrier rate for a patient of Ashkenazi Jewish descent to have at least one of these three mutations is 1 in 40, or 2.5%, and thus there is a substantial risk in this population. The increased risk is a result of the *founder effect*, in which a higher rate of mutations occurs in a defined geographic area.

Pedigree Analysis

The risk of ovarian cancer depends on the number of first- or second-degree relatives (or both) with a history of epithelial ovarian carcinoma or breast cancer (or both), and on the number of malignancies that occur at an earlier age. The degree of risk is difficult to determine precisely unless a full pedigree analysis is performed.

1. In families with two first-degree relatives (i.e., mother, sister, or daughter) with documented premenopausal epithelial ovarian cancer, the risk that a female first-degree relative has an affected gene could be as high as 35% to 40% (48).
2. In families with a single first-degree relative and a single second-degree relative (i.e., grandmother, aunt, first cousin, or granddaughter) with epithelial ovarian cancer, the risk that a woman has an affected gene also may be increased. The risk may be 2- to 10-fold higher than in those without a familial history of the disease (48).
3. In families with a single postmenopausal first-degree relative with epithelial ovarian carcinoma, a woman may not have an increased risk of having an affected gene because the case is most likely to be sporadic. However, if the ovarian cancer occurs in a premenopausal relative, this could be significant, and a full pedigree analysis should be undertaken.
4. Women with a primary history of breast cancer have twice the expected incidence of subsequent ovarian cancer (47).

Lynch II Syndrome

This syndrome, which includes multiple adenocarcinomas, involves a combination of familial colon cancer (known as the Lynch I syndrome), a high rate of ovarian, endometrial, and breast cancers, and other malignancies of the gastrointestinal and genitourinary systems (56). The mutations that have been associated with this syndrome are *MSH2*, *MLH1*, *PMS1*, and *PMS2*. The risk that a woman who is a member of one of these families will develop epithelial ovarian cancer depends on the frequency of this disease in first- and second-degree relatives, although these women appear to have at least 3 times the relative risk of the general population. A full pedigree analysis of such families should be performed by a geneticist to determine the risk more accurately.

Management of Women at High Risk for Ovarian Cancer

The management of a woman with a strong family history of epithelial ovarian cancer must be individualized and depends on her age, her reproductive plans, and the extent of risk. In all of these syndromes, women at risk benefit from a thorough pedigree analysis. A geneticist should evaluate the family pedigree for at least three generations. Decisions about management are best made after careful study and, whenever possible, verification of the histologic diagnosis of the family members' ovarian cancer.

The value of testing for *BRCA1* and *BRCA2* has yet to be clearly established, although some guidelines for testing now exist (50,55,57). The importance of genetic counseling cannot be overemphasized because the decision is complex. The American Society of Clinical Oncology has offered guidelines that emphasize careful evaluation by geneticists, careful maintenance of medical records, and a clear understanding in a genetic screening clinic of how to counsel and manage these patients. Concerns remain over how the information should be used, the impact on insurability, how the results will be interpreted, and how the information will be used within a specific family (e.g., to counsel children).

Although there are some conflicting data, the behavior of breast cancers arising in women with germline mutations in *BRCA1* or *BRCA2* is comparable to that of sporadic tumors (49). Women with breast cancer who carry these mutations, however, are at a greatly increased risk of ovarian cancer as well as a second breast cancer.

Although recommended by the National Institutes of Health Consensus Conference on Ovarian Cancer (58), the value of screening with transvaginal ultrasonography, CA125 levels, or other procedures has not been clearly established in women at high risk. Bourne and co-workers (45) have shown that, using this approach, tumors can be detected approximately 10 times more often than in the general population, and thus they recommend screening in high-risk women.

Data derived from a multicenter consortium of genetic screening centers indicate that the use of the oral contraceptive pill is associated with a lower risk for development of ovarian cancer in women who have a mutation in either *BRCA1* or *BRCA2* (59). The risk reduction is significant: in women who have taken oral contraceptives for 5 or more years, the relative risk of ovarian cancer is 0.4, or a 60% reduction in the incidence of the disease.

Prophylactic Oophorectomy

The value of prophylactic oophorectomy in these patients is controversial (60,61). Although the risk of ovarian cancer is significantly diminished, there remains the small risk of peritoneal carcinoma, a tumor for which women who have mutations in *BRCA1* and *BRCA2* may have a higher predisposition. Women at high risk for ovarian cancer who undergo prophylactic oophorectomy have a risk of harboring occult neoplasia. In one series of 42 such operations, four patients (9.5%) had a malignancy, one of which was noted at surgery and three that were microscopic; all were smaller than 5 mm (61).

Recommendations

Current recommendations for management of women at high risk for ovarian cancer are summarized as follows (57,58):

1. Women who appear to be at high risk for ovarian or breast cancer should undergo genetic counseling and, if the risk appears to be substantial, may be offered genetic testing for *BRCA1* and *BRCA2*.
2. Women who wish to preserve their reproductive capacity can undergo screening by transvaginal ultrasonography every 6 months, although the efficacy of this approach is not clearly established.

3. Oral contraceptives should be recommended to young women before they embark on an attempt to have a family.
4. Women who do not wish to maintain their fertility or who have completed their families may undergo prophylactic bilateral salpingo-oophorectomy. The risk should be clearly documented, preferably established by *BRCA1* and *BRCA2* testing, before oophorectomy is performed. These women should be counseled that this operation does not offer absolute protection, because peritoneal carcinomas occasionally can occur after bilateral oophorectomy ([20,21](#)).
5. In women who also have a strong family history of breast cancer, annual mammographic screening should be performed beginning at age 30 years.
6. Women with a documented HNPCC syndrome should undergo periodic screening mammography, colonoscopy, and endometrial biopsy ([56](#)).

Symptoms

Most women with epithelial ovarian cancer have no symptoms for long periods of time. When symptoms do develop, they are often vague and nonspecific ([3](#)). In early-stage disease, the patient may experience irregular menses if she is premenopausal. If a pelvic mass is compressing the bladder or rectum, she may report urinary frequency or constipation ([62,63](#)). Occasionally, she may perceive lower abdominal distention, pressure, or pain, such as dyspareunia. Acute symptoms, such as pain secondary to rupture or torsion, are unusual.

In advanced-stage disease, patients most often have symptoms related to the presence of ascites, omental metastases, or bowel metastases. The symptoms include abdominal distention, bloating, constipation, nausea, anorexia, or early satiety. Premenopausal women may complain of irregular or heavy menses, whereas vaginal bleeding may occur in postmenopausal women ([64](#)).

Signs

The most important sign of epithelial ovarian cancer is the presence of a pelvic mass on physical examination. A solid, irregular, fixed pelvic mass is highly suggestive of an ovarian malignancy. If, in addition, an upper abdominal mass or ascites is present, the diagnosis of ovarian cancer is almost certain. Because the patient usually complains of abdominal symptoms, she may not have a pelvic examination, and a tumor may be missed.

In patients who are at least 1 year past menopause, the ovaries should have become atrophic and not palpable. It has been proposed that any palpable pelvic mass in these patients should be considered potentially malignant, a situation that has been referred to as the postmenopausal palpable ovary syndrome ([65](#)). This concept has been challenged, because subsequent authors have reported that only about 3% of palpable masses measuring <5 cm in postmenopausal women are malignant ([45](#)).

Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries. A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomas, can simulate ovarian cancer. Nongynecologic causes of a pelvic tumor, such as an inflammatory (e.g., diverticular) disease or neoplastic colonic mass, must be excluded ([3](#)). A pelvic kidney can simulate ovarian cancer.

Serum CA125 levels have been shown to be useful in distinguishing malignant from benign pelvic masses ([66](#)). For a postmenopausal patient with an adnexal mass and a very high serum CA125 level (>95 U/ml), there is a 96% positive predictive value for malignancy. For premenopausal patients, however, the specificity of the test is low because the CA125 level tends to be elevated in common benign conditions.

For the premenopausal patient, a period of observation is reasonable provided the adnexal mass does not have characteristics that suggest malignancy (i.e., it is mobile, mostly cystic, unilateral, and of regular contour). Generally, an interval of no more than 2 months is allowed, during which hormonal suppression with the oral contraceptive may be used. If the lesion is not neoplastic it should regress, as measured by pelvic examination and pelvic ultrasonography. If the mass does not regress or if it increases in size, it must be presumed to be neoplastic and must be removed surgically.

The size of the lesion is important. If a cystic mass is >8 cm in diameter, the probability is high that the lesion is neoplastic, unless the patient has been taking clomiphene citrate or other agents to induce ovulation ([30,31,32](#) and [33](#)). Patients whose lesions are suggestive of malignancy (i.e., predominantly solid, relatively fixed, or irregularly shaped) should undergo laparotomy, as should postmenopausal patients with adnexal masses.

The diagnosis of an ovarian cancer requires an exploratory laparotomy. Before the planned exploration, the patient should undergo routine hematologic and biochemical assessments. A preoperative evaluation in a patient undergoing laparotomy should include a radiograph of the chest and an assessment of the urinary tract with intravenous pyelography. Abdominal and pelvic computed tomography (CT) or magnetic resonance imaging (MRI) are of no value for a patient with a definite pelvic mass. A CT or MRI should be performed for patients with ascites and no pelvic mass to look for liver or pancreatic tumors. The findings only rarely preclude laparotomy ([67](#)). If the hepatic enzyme values are normal, the likelihood of liver disease is low. Liver-spleen scans, bone scans, and brain scans are unnecessary unless symptoms or signs suggest metastases to these sites.

The preoperative evaluation should exclude other primary cancers metastatic to the ovary. A barium enema or colonoscopy is indicated in some patients over 45 years of age to exclude a primary colonic lesion with ovarian metastasis. This study should be performed for any patient who has evidence of occult blood in the stool or of intestinal obstruction. An upper gastrointestinal radiographic series or gastroscopy is indicated if symptoms indicate gastric involvement ([3,68](#)). Bilateral mammography is indicated if there is any breast mass, because occasionally breast cancer metastatic to the ovaries can simulate primary ovarian cancer.

Cervical cytologic study should be performed, although its value for the detection of ovarian cancer is very limited. Patients who have irregular menses or postmenopausal vaginal bleeding should have endometrial biopsy and endocervical curettage to exclude the presence of uterine or endocervical cancer metastatic to the ovary.

Patterns of Spread

Ovarian epithelial cancers spread primarily by exfoliation of cells into the peritoneal cavity, by lymphatic dissemination, and by hematogenous spread.

Transcoelomic The most common and earliest mode of dissemination of ovarian epithelial cancer is by exfoliation of cells that implant along the surfaces of the peritoneal cavity. The cells tend to follow the circulatory path of the peritoneal fluid. The fluid tends to move with the forces of respiration from the pelvis, up the paracolic gutters, especially on the right, along the intestinal mesenteries, to the right hemidiaphragm. Therefore, metastases are typically seen on the posterior cul-de-sac, paracolic gutters, right hemidiaphragm, liver capsule, the peritoneal surfaces of the intestines and their mesenteries, and the omentum. The disease seldom invades the intestinal lumen but progressively agglutinates loops of bowel, leading to a functional intestinal obstruction. This condition is known as carcinomatous ileus ([3](#)).

Lymphatic Lymphatic dissemination to the pelvic and paraaortic lymph nodes is common, particularly in advanced-stage disease ([69,70](#) and [71](#)). Spread through the lymphatic channels of the diaphragm and through the retroperitoneal lymph nodes can lead to dissemination above the diaphragm, especially to the supraclavicular lymph nodes ([69](#)). Burghardt and others ([71](#)) reported that 78% of patients with stage III disease have metastases to the pelvic lymph nodes. In another series ([70](#)), the rate of paraaortic lymph nodes positive for metastasis was 18% in stage I, 20% in stage II, 42% in stage III, and 67% in stage IV.

Hematogenous Hematogenous dissemination at the time of diagnosis is uncommon. Spread to vital organ parenchyma, such as the lungs and liver, occurs in only about 2% to 3% of patients. Most patients with disease above the diaphragm when diagnosed have a right pleural effusion ([3](#)). Systemic metastases are seen more frequently in patients who have survived for some years. Dauplat and others ([72](#)) reported that distant metastasis consistent with stage IV disease ultimately occurred in 38% of the patients whose disease was originally intraperitoneal.

Prognostic Factors

The outcome of treatment can be evaluated in the context of prognostic factors, which can be grouped into pathologic, biologic, and clinical factors (73).

Pathologic Factors

The morphology and histologic pattern, including the architecture and grade of the lesion, are important prognostic variables (3). Histologic type has not generally been believed to be of prognostic significance, but several papers recently have contained suggestions that clear cell carcinomas are associated with a prognosis worse than that of other histologic types (73,74).

Histologic grade, as determined either by the pattern of differentiation or by the extent of cellular anaplasia and the proportion of undifferentiated cells, seems to be of prognostic significance (75,76,77 and 78). However, studies of the reproducibility of grading ovarian cancers have shown a high degree of intraobserver and interobserver variation (79,80). Because there is significant heterogeneity of tumors and observational bias, the value of histologic grade as an independent prognostic factor has not been clearly established. Baak and colleagues (81) have presented a standard grading system based on morphometric analysis, and the system seems to correlate with prognosis, especially in its ability to distinguish low-grade or borderline patterns from other tumors.

Biologic Factors

Several biologic factors have been correlated with prognosis in epithelial ovarian cancer. Using flow cytometry, Friedlander and co-workers (82) showed that ovarian cancers were commonly aneuploid. Furthermore, they and others showed that there was a high correlation between FIGO stage and ploidy; low-stage cancers tend to be diploid and high-stage tumors tend to be aneuploid (82,83,84,85 and 86). Patients with diploid tumors have a significantly longer median survival than those with aneuploid tumors: 5 years versus 1 year, respectively (82). Multivariate analyses have demonstrated that ploidy is an independent prognostic variable and one of the most significant predictors of survival (82). Flow cytometric analysis also provides data on the cell cycle, and the proliferation fraction (S phase) determined by this technique has correlated with prognosis in some studies (82,83,84,85 and 86).

More than 60 protooncogenes have been identified, and studies have focused on the amplification or expression of these genetic loci and their relationship to the development and progression of ovarian cancer (87,88). For example, Slamon and others (89) reported that 30% of epithelial ovarian tumors expressed HER-2/ neu oncogene and that this group had a poorer prognosis, especially patients with more than five copies of the gene. Berchuck and associates (90) reported a similar incidence (32%) of HER-2/neu expression. In their series, patients whose tumors expressed the gene had a poorer median survival (15.7 months versus 32.8 months). Others have not substantiated this finding (92,93,94 and 95), and a review of the literature by Leary and others (92) revealed an overall incidence of HER-2/neu expression of only 11%. Thus, the prognostic value of HER-2/ neu expression in ovarian cancer is unclear and further study is required.

The most commonly expressed tumor suppressor gene in ovarian cancer is p53 (97,98 and 99). Indeed, as many as one-half of all epithelial ovarian cancers have evidence of mutated p53 in the tumor.

The *in vitro* clonogenic assay has been studied in relation to ovarian cancer. A significant inverse correlation has been reported between clonogenic growth *in vitro* and survival (100,101 and 102). Multivariate analysis has found that clonogenic growth in a semisolid culture medium is a significant independent prognostic variable (102), but further study will be needed to evaluate the clinical usefulness of this assay.

Clinical Factors

In addition to stage, the extent of residual disease after primary surgery, the volume of ascites, patient age, and performance status are all independent prognostic variables (103,104,105,106,107,108,109,110 and 111). Among patients with stage I disease, Dembo and co-workers (108) showed, in a multivariate analysis, that tumor grade and dense adherence to the pelvic peritoneum had a significant adverse impact on prognosis, whereas intraoperative tumor spillage or rupture did not. Sjövall and others (109) confirmed that **eries ovarian cancers that undergo intraoperative rupture or spillage do not worsen prognosis**, whereas tumors found to have already ruptured preoperatively do have a poorer prognosis. A multivariate analysis of these and several other studies was performed by Vergote (111), who found that **eries for early-stage disease, poor prognostic variables were tumor grade, capsular penetration, surface excrescences, and malignant ascites, but not iatrogenic rupture.**

Initial Surgery for Ovarian Cancer

Staging

Ovarian epithelial malignancies are staged according to the FIGO system listed in Table 32.2 (24). The FIGO staging is based on findings at surgical exploration. A preoperative evaluation should exclude the presence of extraperitoneal metastases.

Stage	Criteria
Stage I	Carcinoma limited to the ovaries
Stage Ia	Carcinoma limited to one ovary; no ascites containing malignant cells; no tumor on the external surface; capsule intact
Stage Ib	Carcinoma limited to both ovaries; no ascites containing malignant cells; no tumor on the external surface; capsule intact
Stage Ic	Same as Ia or Ib, but with capsular rupture or tumor on the external surface
Stage II	Carcinoma involving one or both ovaries with pelvic extension
Stage IIA	Extension to upper pelvic peritoneum
Stage IIB	Extension to lower pelvic peritoneum
Stage IIC	Extension to both upper and lower pelvic peritoneum
Stage III	Extension to one or both hemipelvi with peritoneal carcinomatosis involving the greater than 50% of the peritoneal surface
Stage IIIa	Extension to one or both hemipelvi with peritoneal carcinomatosis involving the greater than 50% of the peritoneal surface
Stage IIIb	Extension to one or both hemipelvi with peritoneal carcinomatosis involving the greater than 50% of the peritoneal surface
Stage IIIc	Extension to one or both hemipelvi with peritoneal carcinomatosis involving the greater than 50% of the peritoneal surface
Stage IV	Carcinoma involving one or both ovaries with distant metastases

Table 32.2. FIGO Staging for Primary Carcinoma of the Ovary

The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment will be determined by the stage of disease. For patients in whom exploratory laparotomy does not reveal any macroscopic evidence of disease on inspection and palpation of the entire intraabdominal space, a careful search for microscopic spread must be undertaken. In earlier series in which patients did not undergo careful surgical staging, the overall 5-year survival for patients with apparent stage I epithelial ovarian cancer was only about 60% (112). Since then, survival rates of 90% to 100% have been reported for patients who were properly staged and were found to have stage Ia or Ib disease (113,114).

Technique for Surgical Staging

For patients whose preoperative evaluation suggests a probable malignancy, a midline or paramedian abdominal incision is recommended to allow adequate access to the upper abdomen (3). When a malignancy is unexpectedly discovered in a patient who has a lower transverse incision, the rectus muscles can be either divided or detached from the symphysis pubis to allow better access to the upper abdomen. If this is not sufficient, the incision can be extended on one side to create a "J" incision (3).

The ovarian tumor should be removed intact, if possible, and a frozen histologic section should be obtained. If ovarian malignancy is present and the tumor is apparently confined to the ovaries or the pelvis, thorough surgical staging should be performed. Staging involves the following steps (3):

1. Any free fluid, especially in the pelvic cul-de-sac, should be submitted for cytologic evaluation.
2. If no free fluid is present, peritoneal washings should be performed by instilling and recovering 50 to 100 ml of saline from the pelvic cul-de-sac, each

paracolic gutter, and beneath each hemidiaphragm. Obtaining the specimens from under the diaphragms can be facilitated with the use of a rubber catheter attached to the end of a bulb syringe.

3. **A systematic exploration of all the intraabdominal surfaces and viscera is performed,** proceeding in a clockwise fashion from the cecum cephalad along the paracolic gutter and the ascending colon to the right kidney, the liver and gallbladder, the right hemidiaphragm, the entrance to the lesser sac at the paraaortic area, across the transverse colon to the left hemidiaphragm, down the left gutter and the descending colon to the rectosigmoid colon. The small intestine and its mesentery from the Treitz ligament to the cecum should be inspected.
4. **Any suspicious areas or adhesions on the peritoneal surfaces should be sampled for biopsy.** If there is no evidence of disease, multiple intraperitoneal biopsies should be performed. Tissue from the peritoneum of the pelvic cul-de-sac, both paracolic gutters, the peritoneum over the bladder, and the intestinal mesenteries should be taken for biopsy.
5. **The diaphragm should be sampled either by biopsy or by scraping with a tongue depressor and obtaining a sample for cytologic assessment.** Biopsies of any irregularities on the surface of the diaphragm can be facilitated by use of the laparoscope and the associated biopsy instrument.
6. **The omentum should be resected from the transverse colon, a procedure called an *infracolic omentectomy*.** The procedure is initiated on the underside of the greater omentum, where the peritoneum is incised just a few millimeters away from the transverse colon. The branches of the gastroepiploic vessels are clamped, ligated, and divided, along with all the small branching vessels that feed the infracolic omentum. If the gastrocolic ligament is palpably normal, it does not need to be resected.
7. **The retroperitoneal spaces should be explored to evaluate the pelvic and paraaortic lymph nodes.** The retroperitoneal dissection is performed by incision of the peritoneum over the psoas muscles. This may be performed on the ipsilateral side only for unilateral tumors. Any enlarged lymph nodes should be resected and submitted for frozen section. If no metastases are present, a formal pelvic lymphadenectomy should be performed.

Results

Metastases in apparent stage I and II epithelial ovarian cancer occur in as many as 3 in 10 patients whose tumors appear to be confined to the pelvis but who have occult metastatic disease in the upper abdomen or the retroperitoneal lymph nodes (70,113,114,115,116,117,118,119,120,121,122 and 123). In a review of the literature (112), occult metastases were found in biopsies of the diaphragm in 7.3% of such patients, biopsies of the omentum in 8.6%, the pelvic lymph nodes in 5.9%, the aortic lymph nodes in 18.1%, and in 26.4% of peritoneal washings.

The importance of careful initial surgical staging is emphasized by the findings of a cooperative national study (113) in which 100 patients with apparent stage I and II disease who were referred for subsequent therapy underwent additional surgical staging. In this series, 28% of the patients initially believed to have stage I disease were "upstaged" and 43% of those believed to have stage II disease had more advanced lesions. A total of 31% of the patients were upstaged as a result of additional surgery, and 77% were reclassified as having stage III disease. Histologic grade was a significant predictor of occult metastasis. Sixteen percent of the patients with grade 1 lesions were upstaged, compared with 34% with grade 2 disease and 46% with grade 3 disease.

Stage I

The primary surgical treatment for stage I epithelial ovarian cancer is surgical, and patients should undergo total abdominal hysterectomy, bilateral salpingo-oophorectomy, and surgical staging (112,113). In certain circumstances, a unilateral oophorectomy may be performed. Based on the findings at surgery and the pathologic evaluation, patients with stage I ovarian cancer can be grouped into low-risk and high-risk categories (Table 32.3).

Low Risk	High Risk
Low grade	High grade
Non-clear cell histologic type	Clear cell histologic type
Intact capsule	Tumor growth through capsule
No surface excrescences	Surface excrescences
No ascites	Ascites
Negative peritoneal cytologic findings	Malignant cells in fluid
Unruptured or intraperitoneal rupture	Preoperative rupture
No dense adherence	Dense adherence
Diploid tumor	Aneuploid tumor

Table 32.3. Prognostic Variables in Early-stage Epithelial Ovarian Cancer

Borderline Tumors

The principal treatment of borderline ovarian tumors is surgical resection of the primary tumor. There is no evidence that either subsequent chemotherapy or radiation therapy improves survival. After a frozen section has determined that the histology is borderline, premenopausal patients who desire preservation of ovarian function may undergo a conservative operation, a unilateral oophorectomy (3,123,124). In a study of patients who underwent unilateral ovarian cystectomy only for apparent stage I borderline serous tumors, Lim-Tan and associates (124) found that this conservative operation was also safe; only 8% of the patients had recurrences 2 to 18 years later, all with curable disease confined to the ovaries. Recurrence was associated with positive margins of the removed ovarian cyst (124). Thus, hormonal function and fertility can be maintained (3,123,124). For patients in whom an oophorectomy or cystectomy has been performed and a borderline tumor is later documented in the permanent pathology, no additional immediate surgery is necessary.

Stage I Low-grade, Low-risk

For patients who have undergone a thorough staging laparotomy and for whom there is no evidence of spread beyond the ovary, abdominal hysterectomy and bilateral salpingo-oophorectomy are appropriate therapy. The uterus and the contralateral ovary can be preserved in women with stage Ia, grade 1 to 2 disease who desire to preserve fertility. The conditions of the women should be monitored carefully with routine periodic pelvic examinations and determinations of serum CA125 levels. Generally, the other ovary and the uterus are removed at the completion of childbearing.

Guthrie and others (122) studied the outcome of 656 patients with early-stage epithelial ovarian cancer. No untreated patients who had stage Ia, grade 1 cancer died of their disease; thus, adjuvant radiation and chemotherapy are unnecessary. Furthermore, the Gynecologic Oncology Group (GOG) carried out a prospective, randomized trial of observation versus melphalan for patients with stage Ia and Ib, grade 1 disease (74). Five-year survival for each group was 94% and 96%, respectively, confirming that no further treatment is needed for such patients.

Stage I High-grade, High-risk

For patients whose disease is more poorly differentiated or in whom there are malignant cells either in ascitic fluid or in peritoneal washings, complete surgical staging must be performed (3). The surgery should include the performance of a hysterectomy and bilateral salpingo-oophorectomy in addition to the staging laparotomy (3). Additional therapy is indicated, and although the optimal therapy for these patients is not known, most patients are treated with chemotherapy, as outlined below.

Cytoreductive Surgery for Advanced-stage Disease

Patients with advanced-stage epithelial ovarian cancer documented at initial exploratory laparotomy should undergo cytoreductive surgery to remove as much of the tumor and its metastases as possible (125,126,127,128,129,130,131,132,133,134,135,136,137,138,139,140,141,142,143,144 and 145) (Fig 32.7). The operation to remove the primary tumor as well as the associated metastatic disease is referred to as *debulking* surgery. The operation typically includes the performance of a total abdominal hysterectomy and bilateral salpingo-oophorectomy, along with a complete omentectomy and resection of any metastatic lesions from the peritoneal surfaces or from the intestines. The pelvic tumor often directly involves the rectosigmoid colon, the terminal ileum, and the cecum (Fig. 32.8). In a minority of patients,

most or all of the disease is confined to the pelvic viscera and the omentum, so that removal of these organs will result in extirpation of all gross tumor, a situation that is associated with a reasonable chance of prolonged progression-free survival.

Figure 32.7 Treatment scheme for patients with advanced-stage ovarian cancer. (*under selected circumstances or clinical trials). (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:474, with permission.)

Figure 32.8 Extensive ovarian carcinoma involving the bladder, rectosigmoid, and ileocecal area. (From **Heintz APM, Berek JS.** *Cytoreductive surgery for ovarian carcinoma*. In: **Piver MS**, ed. *Ovarian malignancies*. Edinburgh: Churchill Livingstone, 1987:134, with permission.)

The removal of bulky tumor masses may reduce the volume of ascites present. Often, ascites will completely disappear after removal of the primary tumor and a large omental “cake.” Also, removal of the omental cake often alleviates the nausea and early satiety that many patients experience. Removal of intestinal metastases may restore adequate intestinal function and lead to an improvement in the overall nutritional status of the patient, thereby facilitating the patient’s ability to tolerate subsequent chemotherapy.

A large, bulky tumor may contain areas that are poorly vascularized, and such areas will be exposed to suboptimal concentrations of chemotherapeutic agents. Similarly, these areas are poorly oxygenated, so that radiation therapy, which requires adequate oxygenation to achieve maximal cell kill, will be less effective. Thus, surgical removal of these bulky tumors may eliminate areas that are most likely to be relatively resistant to treatment.

In addition, larger tumor masses tend to be composed of a higher proportion of cells that are either nondividing or in the “resting” phase (i.e., G_0 cells, which are essentially resistant to the therapy). A low growth fraction is characteristic of bulky tumor masses, and cytoreductive surgery can result in smaller residual masses with a relatively higher growth fraction.

Goals of Cytoreductive Surgery

The principal goal of cytoreductive surgery is removal of all of the primary cancer and, if possible, all metastatic disease. If resection of all metastases is not feasible, the goal is to reduce the tumor burden by resection of all individual tumors to an optimal status. Griffiths (125) initially proposed that all metastatic nodules should be reduced to <1.5 cm in maximal diameter and showed that survival was significantly longer in patients for whom this was achieved.

Subsequently, Hacker and Berek (126,127 and 128) showed that patients whose largest residual lesions were <5 mm had a superior survival rate, which was substantiated by Van Lindert and co-workers (129). The median survival of patients in this category was 40 months, compared with 18 months for patients whose lesions were <1.5 cm and 6 months for patients with nodules >1.5 cm. Patients whose disease has been completely resected to no macroscopic residual disease have the best overall survival (Fig. 32.9).

Figure 32.9 Survival of patients with stage IIIc epithelial ovarian cancer based on the maximal size of residual tumor after exploratory laparotomy and tumor resection. (From **Pecorelli S, Odicino F, Maisonneuve P, et al.** *Carcinoma of the ovary*. Annual Report of the Results of Treatment of Gynaecological Cancer. *J Epidemiol Biostat* 1998;3:75–102, with permission.)

The resectability of the metastatic tumor is usually determined by the location of the disease. Optimal cytoreduction is difficult to achieve in the presence of extensive disease on the diaphragm, in the parenchyma of the liver, along the base of the small-bowel mesentery, in the lesser omentum, or in the porta hepatis.

The ability of cytoreductive surgery to influence survival is limited by the extent of metastases before cytoreduction, presumably because of the presence of phenotypically resistant clones of cells in large metastatic masses. A patient whose metastatic tumor is very large (i.e., >10 cm before cytoreductive surgery) has a shorter survival than those with smaller areas of disease (128). Extensive carcinomatosis, the presence of ascites, poor tumor grade, even with lesions that measure <5 mm, may also shorten the survival (131).

Exploration

The supine position on the operating table may be sufficient for surgical exploration of most patients. However, for those with extensive pelvic disease for whom a low resection of the colon may be necessary, the low lithotomy position should be used. Debulking operations should be performed through a vertical incision to gain adequate access to the upper abdomen as well as to the pelvis.

After the peritoneal cavity is opened, ascitic fluid, if present, should be evacuated. In some centers, fluid is submitted routinely for appropriate *in vitro* research studies, such as molecular analyses. In cases of massive ascites, careful attention must be given to hemodynamic monitoring, especially for patients with borderline cardiovascular function.

The peritoneal cavity and retroperitoneum are thoroughly inspected and palpated to assess the extent of the primary tumor and the metastatic disease. All abdominal viscera must be palpated to exclude the possibility that the ovarian disease is metastatic, particularly from the stomach, colon, or pancreas. If optimal status is not considered achievable, extensive bowel and urologic resections are not indicated, except to overcome a bowel obstruction. However, removal of the primary tumor and omental cake is usually both feasible and desirable.

Pelvic Tumor Resection

The essential principle of removal of the pelvic tumor is to use the retroperitoneal approach. To accomplish this, the retroperitoneum is entered laterally, along the surface of the psoas muscles, which avoids the iliac vessels and the ureters. The procedure is initiated by division of the round ligaments bilaterally if the uterus is present. The peritoneal incision is extended cephalad, lateral to the ovarian vessels within the infundibulopelvic ligament, and caudally toward the bladder. With careful dissection, the retroperitoneal space is explored, and the ureter and pelvic vessels are identified. The pararectal and paravesicular spaces are identified and developed as described in [Chapter 31](#).

The peritoneum overlying the bladder is dissected to connect the peritoneal incisions anteriorly. The vesicouterine plane is identified, and with careful sharp dissection the bladder is mobilized from the anterior surface of the cervix. The ovarian vessels are isolated, doubly ligated, and divided.

Hysterectomy, which is often not a simple operation, is then performed. The ureters must be carefully displayed to avoid injury. During this procedure, the uterine vessels can be identified. The hysterectomy and resection of the contiguous tumor are completed by ligation of the uterine vessels and the remainder of the tissues within the cardinal ligaments.

Because epithelial ovarian cancers tend not to invade the lumina of the colon or bladder, it is usually feasible to resect pelvic tumors without having to resect portions of the lower colon or the urinary tract ([137,138](#)). However, if the disease surrounds the rectosigmoid colon and its mesentery, it may be necessary to remove that portion of the colon to clear the pelvic disease ([Fig. 32.10](#)) ([137](#)). This is justified if the patient will be left with optimal disease at the end of the cytoreduction. After the pararectal space is identified in such patients, the proximal site of colonic involvement is identified, the colon and its mesentery are divided, and the rectosigmoid is removed along with the uterus *en bloc*. A reanastomosis of the colon is performed. It is rarely necessary to resect portions of the lower urinary tract. Resection of a small portion of the bladder may be required and, if so, a cystotomy should be performed to assist in resection of the disease ([138](#)).

Figure 32.10 The resection of the pelvic tumor may include removal of the uterus, tubes, and ovaries, as well as portions of the lower intestinal tract. The arrows represent the plane of resection. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:480, with permission.)

Omentectomy

Advanced epithelial ovarian cancer often completely replaces the omentum, forming an omental cake. This disease may be adherent to the parietal peritoneum of the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the transverse colon. The peritoneum is incised to open the appropriate plane, which is developed by sharp dissection along the serosa of the transverse colon. Small vessels are ligated with hemoclips. The omentum is then separated from the greater curvature of the stomach by ligation of the right and left gastroepiploic arteries and ligation of the short gastric arteries ([Fig. 32.11](#)).

Figure 32.11 Separation of the omentum from stomach and transverse colon. (From **Heintz APM, Berek JS.** *Cytoreductive surgery for ovarian carcinoma*. In: **Piver MS**, ed. *Ovarian malignancies*. Edinburgh: Churchill Livingstone, 1987:134, with permission.)

The disease in the gastrocolic ligament can extend to the hilus of the spleen and splenic flexure of the colon on the left and to the capsule of the liver and the hepatic flexure of the colon on the right. Usually, the disease does not invade the parenchyma of the liver or spleen, and a plane can be found between the tumor and these organs. However, it will occasionally be necessary to perform splenectomy to remove all the omental disease ([139](#)).

Intestinal Resection

The disease may involve focal areas of the small or large intestine, and resection should be performed if it would permit the removal of all or most of the abdominal metastases. Apart from the rectosigmoid colon, the most frequent sites of intestinal metastasis are the terminal ileum, the cecum, and the transverse colon. Resection

of one or more of these segments of bowel may be necessary ([137,139](#)).

Resection of Other Metastases

Other large masses of tumor that are located on the parietal peritoneum should be removed, particularly if they are isolated masses and their removal will permit optimal cytoreduction. Resection of extensive disease from the surfaces of the diaphragm is generally neither practical nor feasible, although solitary metastases may be resected, the diaphragm sutured, and a chest tube placed for a few days ([140,141](#)). The use of the Cavitron Ultrasonic Surgical Aspirator (CUSA) and the argon beam coagulator may help facilitate resection of small tumor nodules, especially those on flat surfaces ([142,143](#)).

Feasibility and Outcome

Although no randomized prospective study has ever been performed to define the value of primary cytoreductive surgery, a prospective trial of *interval* cytoreductive surgery (performed after three cycles of platinum combination chemotherapy) demonstrated a survival benefit for patients who had optimal resection of their disease at that time compared with those who did not ([135](#)). All retrospective studies indicate that the diameter of the largest residual tumor nodule before the initiation of chemotherapy is significantly related to progression-free survival in patients with advanced ovarian cancer. In addition, quality of life is likely to be significantly enhanced by removal of bulky tumor masses from the pelvis and upper abdomen ([136](#)).

An analysis of the retrospective data available suggests that these operations are feasible for 70% to 90% of patients when performed by gynecologic oncologists ([133,139,144](#)). Major morbidity is in the range of 5% and operative mortality is in the range of 1% ([139,145](#)). Intestinal resection in these patients does not appear to increase the overall morbidity caused by the operation ([137,139](#)). The performance of a pelvic lymphadenectomy in patients with stage III disease has been reported to prolong survival ([71](#)), although verification of this awaits a prospective, randomized study.

Treatment with Chemotherapy

Stage I Epithelial Ovarian Cancer

Stage I Low-grade, Low-risk

Guthrie and others ([122](#)) studied the outcome of 656 patients with early-stage epithelial ovarian cancer. No patients who had stage Ia, grade 1 cancer who did not receive radiation or chemotherapy died of their disease; thus adjuvant therapy is unnecessary. Furthermore, the GOG carried out a prospective, randomized trial of observation versus *melfalan* for patients with stage Ia and Ib, grade 1 disease ([74](#)). **Five-year survival for each group was 94% and 96%, respectively, confirming that adjuvant treatment did not improve survival. Therefore, no adjuvant chemotherapy is recommended for these patients.**

Stage I High-grade, High-risk

In patients whose disease is high-risk (e.g., more poorly differentiated or in whom there are malignant cells either in ascitic fluid or in peritoneal washings), additional therapy is indicated. Most investigators recommend chemotherapy for these patients ([146,147,148,149,150,151,152,153,154,155,156,157,158,159,160](#) and [161](#)). Chemotherapy for patients with early stage high-risk epithelial ovarian cancer can be either single agent or multiagent. Some researchers have questioned the wisdom of overly aggressive chemotherapy in women with early stage disease, suggesting that the evidence for a durable impact on survival is marginal ([148,149,155](#)). Furthermore, the risk of leukemia with alkylating agents and *platinum* make the administration of adjuvant therapy risky unless there is a significant benefit ([160,161](#)).

Because *cisplatin*, *carboplatin*, *cyclophosphamide*, and *paclitaxel* (*Taxol*) are active single agents against epithelial ovarian cancer, these drugs have been administered in various combinations. There are some series in which *cisplatin* or *cyclophosphamide* (PC) or both have been used to treat patients with stage I disease ([150,151](#) and [152](#)). In a GOG trial of three cycles of *cisplatin* and *cyclophosphamide* versus intraperitoneal chromic phosphate (³²P) in patients with stage Ib and Ic disease, the progression-free survival of women receiving the *platinum*-based chemotherapy was 31% higher than those receiving the radiocolloid ([152](#)). Similar results were also reported by a multicenter trial performed in Italy by the Gruppo Italiano Collaborativo Oncologica Ginecologica (GICOG) for progression-free survival, although there was no overall survival advantage. *Carboplatin* can be substituted for *cisplatin* in the therapy of these patients ([158](#)), although it is unclear if there is a survival benefit. The current GOG trial consists of three cycles of *carboplatin* and *paclitaxel* followed by a randomization to either observation versus 26 weeks of weekly low-dose (40 mg/m²) *paclitaxel*.

The recommendations for therapy follow:

- Patients with high-grade, high-risk stage I epithelial ovarian cancer be given adjuvant chemotherapy. The type depends on the patient's overall health and status.
- Treatment with *carboplatin* and *paclitaxel* chemotherapy for three to six cycles seems desirable in most patients, whereas a short course of a single agent, either *carboplatin* or *paclitaxel*, may be preferable for older women.

Advanced-stage Epithelial Ovarian Cancer

Systemic multiagent chemotherapy is the standard treatment for metastatic epithelial ovarian cancer ([162,163,164,165,166,167,168,169,170,171,172,173,174,175,176,177,178,179](#) and [180](#)). After the introduction of *cisplatin* in the latter half of the 1970s, *platinum*-based combination chemotherapy became the most frequently used treatment regimen in the United States. *Paclitaxel* became available in the 1980s, and this drug was incorporated into the combination chemotherapy in the 1990s ([162,163,164,165,166](#) and [167](#)). Comparative trials of *paclitaxel*, *cisplatin*, and *carboplatin* are summarized below.

In a meta-analysis performed on studies of patients with advanced-stage disease, those patients given *cisplatin*-containing combination chemotherapy were compared with those treated with regimens that did not include *cisplatin* ([171](#)). Survival differences between the groups were seen from 2 to 5 years, with the *cisplatin* group having a slight survival advantage, but this difference disappeared by 8 years.

The major advance in the treatment of advanced-stage disease was the incorporation of *paclitaxel* into the chemotherapeutic regimens. A series of randomized, prospective clinical trials with *paclitaxel*-containing arms have defined the current recommended treatment protocol in advanced epithelial ovarian cancer ([165,166,175,176](#)).

Reporting the GOG data (Protocol 111), McGuire and others showed that the combination of *cisplatin* (75 mg/m²) and *paclitaxel* (135 mg/m²) was superior to *cisplatin* (75 mg/m²) and *cyclophosphamide* (600 mg/m²), each given for six cycles ([165](#)). In suboptimally resected patients, the *paclitaxel*-containing arm produced a 36% reduction in mortality. These data were verified in a trial conducted jointly by the European Organization for the Research and Treatment of Cancer (EORTC), the Nordic Ovarian Cancer Study Group (NOCOVA), and the National Cancer Institute of Canada (NCIC) in which patients with both optimal and suboptimal disease were treated ([166](#)). In this study the *paclitaxel*-containing arm produced a significant improvement in both progression-free interval and overall survival in both optimal and suboptimal groups ([Fig 32.12](#)). **Based on these two studies, *paclitaxel* should be included in the primary treatment of all women with advanced-stage epithelial ovarian cancer, unless precluded by toxicity.**

Figure 32.12 Survival of patients with stage III and IV epithelial ovarian cancer treated with *paclitaxel* and *cisplatin* or *cyclophosphamide* and *cisplatin*: results of a European cooperative group trials study. (From Stuart G, Bertelsen K, Mangioni C, et al. Updated analysis shows a highly significant survival for *cisplatin-paclitaxel* as first line treatment of advanced-stage epithelial ovarian cancer: mature results of the EORTC-GCCG, NOCOVA, NCIC-CTC and Scottish Intergroup Trial. *J Clin Oncol*. 2000, with permission.)

A three-arm comparison of *paclitaxel* (T) versus *cisplatin* (P) versus PT in suboptimal stage III and IV patients (protocol 132) showed equivalency in the three groups, but crossover from one drug to the other was permitted (167). The study essentially showed that the combination regimen was better tolerated than the sequential administration of the agents in suboptimally resected patients.

The second-generation *platinum* analogue, *carboplatin*, was introduced and developed to have less toxicity than its parent compound, *cisplatin*. In early trials, *carboplatin* was shown to have lower overall toxicity (169). Fewer gastrointestinal side effects, especially nausea and vomiting, were observed than with *cisplatin*, and there was less nephrotoxicity, neurotoxicity, and ototoxicity. *Carboplatin* is, however, associated with a higher degree of myelosuppression.

The initial studies showed that *carboplatin* and *cisplatin* had approximately a 4:1 equivalency ratio. Thus a standard single-agent dose of about 400 mg/m² has been used in most phase II trials. The dose is calculated by using the area under the curve (AUC) and the glomerular filtration rate (GFR) according to the *Calvert formula* (181). The target AUC is 5–6 for untreated patients with ovarian cancer. Alternatively, a dose of approximately 350 to 450 mg/m² *carboplatin* can be used initially in patients with a normal serum creatinine and adjusted to toxicity. A platelet nadir of approximately 50,000/ml is a suitable target (169).

Carboplatin and Paclitaxel

Two randomized, prospective clinical studies have compared the combination of *paclitaxel* and *carboplatin* to *paclitaxel* and *cisplatin* (175,176). In both studies, the efficacy and survivals were similar, but the toxicity was more acceptable with the *carboplatin*-containing regimen. In the first trial, GOG Protocol 158, the randomization was *carboplatin* AUC = 7.5 and *paclitaxel* 175 mg/m² over 3 hours versus *cisplatin* 75 mg/m² and *paclitaxel* 135 mg/m² over 24 hours. The disease progression-free survival of the *carboplatin*-containing arm was 22 months versus 21.7 months for the control arm (175). The gastrointestinal and neurotoxicity of the *carboplatin* arm were appreciably lower than that of the *cisplatin* arm. A similar result was obtained in a large randomized trial in Germany (176), in which the dose of *carboplatin* was AUC = 6 and *paclitaxel* was 185 mg/m² over 3 hours compared with the same dose of *paclitaxel* and *cisplatin* 75 mg/m². Ongoing trials are comparing the combination of *carboplatin* and *paclitaxel* with single-agent *carboplatin* or combination *cisplatin* chemotherapy (177). **The preferred regimen in patients with advanced-stage disease is the *paclitaxel* plus *carboplatin* combination.**

Intraperitoneal Chemotherapy

A randomized, prospective trial of intraperitoneal *cisplatin* versus intravenous *cisplatin* (100 mg/m²), each given with 750 mg/m² *cyclophosphamide*, has been performed jointly by the Southwest Oncology Group (SWOG) and the GOG in patients with minimal residual disease (182). The intraperitoneal *cisplatin* arm had a somewhat longer overall median survival than the intravenous arm, 49 versus 41 months ($p = 0.03$). In the patients with minimal residual disease (<0.5 cm maximal residual), however, there was no difference between the two treatments, 51 versus 46 months ($p = 0.08$).

In a follow-up trial (GOG Protocol 114), the dose-intense arm was initiated by giving a moderately high dose of *carboplatin* (dose AUC = 9) for two induction cycles, followed by intraperitoneal *cisplatin* 100 mg/m² and intravenous *paclitaxel* 135 mg/m² over 24 hours, versus intravenous *cisplatin* 75 mg/m² and intravenous *paclitaxel* 135 mg/m² (183). The dose-intense arm results were slightly better—the disease progression-free median survival was 27.6 months compared with 22.5 months for the control arm ($p = 0.02$). However, there was no difference in overall survival (52.9 months versus 47.6 months, $p = 0.056$). Thus, it is unclear if dose intensification with intraperitoneal *hype cisplatin* will have a sustained long-term impact on the survival of these patients. A randomized prospective GOG study is comparing intraperitoneal *hype cisplatin* and *hype paclitaxel* versus intravenous *hype cisplatin* and *hype paclitaxel*.

Based on these two studies, the value of intraperitoneal chemotherapy in the primary treatment of optimally resected stage III ovarian cancer remains unclear.

Neoadjuvant Chemotherapy

Some authors have suggested that, for patients with suboptimal stage III and stage IV disease, chemotherapy may be given in lieu of debulking surgery. A series performed by Schwartz and co-workers (184) suggested that the survival of these patients treated with neoadjuvant or cytoreductive chemotherapy was comparable to those patients historically treated in the same institution with debulking surgery followed by conventional chemotherapy. As other authors have shown a benefit to debulking patients prior to chemotherapy (135), the issue would need to be resolved by a prospective clinical trial.

However, two or three cycles of chemotherapy prior to cytoreductive surgery may be helpful in patients with massive ascites and large pleural effusions. The chemotherapy may dry up the effusions, improve the patient's performance status, and decrease postoperative morbidity, particularly chest morbidity.

Chemotherapeutic Recommendation in Advanced Epithelial Ovarian Cancer

For the treatment of advanced-stage epithelial ovarian cancer, the following is recommended (Table 32.4):

Drugs	Dose	Administration (d)	Interval	No. of Treatments
Standard regimens				
Paclitaxel ^a	175 mg/m ²	24	Every 3 weeks	Six cycles
Carboplatin	AUC = 5–6	3	Every 3 weeks	Six cycles
Paclitaxel	135 mg/m ²	24	Every 3 weeks	Six cycles
Cisplatin	75 mg/m ²	3	Every 3 weeks	Six cycles
Alternative drugs^b				
(Can be given with platinum)				
Cyclophosphamide	600–750 mg/m ²	—	Every 3 weeks	—
Topotecan	1.0–1.25 mg/m ²	—	Daily × 5 days	—
Gemcitabine	800–1000 mg/m ²	—	Every 3 weeks	—

AUC, area under the curve; dose by Calvert formula (181).
^aDrugs that can be substituted for paclitaxel if hypersensitivity to that drug occurs.
 From Benkt U, Hader H, eds. *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:491, with permission.

Table 32.4. Combination Chemotherapy for Advanced Epithelial Ovarian Cancer: Recommended Regimens

- **Combination chemotherapy with *hapt* carboplatin and *hapt* paclitaxel as the treatment of choice for patients with advanced disease. The recommended doses and schedule are *hapt* carboplatin (starting dose AUC = 5 to 6) and *hapt* paclitaxel (175 mg/m²) given over 3 hours every 3 weeks for six cycles.**
- **In patients who cannot tolerate the combination, single-agent *hapt* carboplatin (AUC = 5 to 6) can be given.**
- **In those who have a hypersensitivity to *hapt* paclitaxel, an alternative active drug can be substituted (e.g., *hapt* cyclophosphamide or *hapt* topotecan).**
- **In patients who cannot tolerate intravenous chemotherapy, an oral alkylating agent can be substituted.**

The treatment of all patients with advanced-stage disease is approached in a similar manner, with modifications based on the overall status and general health of the patient, as well as the extent of residual disease present at the time treatment is initiated.

Immunotherapy

There is currently a great deal of interest in the use of immunotherapies in ovarian cancer. Cytokines have been used extensively in second-line therapy, and the activity of *hapt* interferon- α , interferon- γ , and *hapt* interleukin-2 has been demonstrated, as discussed below (3). In a recent trial of *hapt* interferon- γ plus *hapt* cisplatin combination chemotherapy versus chemotherapy alone, patients who received the *hapt* interferon had a longer disease progression-free survival (185).

Trials of monoclonal antibodies directed toward ovarian cancer-associated antigens are being conducted. Antibodies directed toward CA125 and toward the HMFG (human milk fat globulin) tumor-associated antigens are underway. *Herceptin*, an antibody directed toward the extracellular protein produced when the HER-2/ *neu* oncogene is overexpressed, has been used extensively in breast cancer where it has been shown to improve the response rate to chemotherapy in selected patients. Trials of this antibody in patients whose ovarian cancers overexpress HER-2/ *neu* are ongoing. Antibodies against mutated *p53* tumor suppressor gene are also undergoing clinical testing (3).

Hormonal Therapy

There is no evidence that hormonal therapy alone is appropriate primary therapy for advanced ovarian cancer. The use of progestational agents in the treatment of recurrent well-differentiated endometrioid carcinomas is supported by the current data. In a study by Rendina and co-workers (186), 30 evaluable patients with recurrent epithelial cancers were treated; 17 (57%) had an objective response, and three (10%) of these patients achieved a complete response. All responding patients had well-differentiated, estrogen receptor-positive tumors. A trial of *hapt* tamoxifen in combination with multiagent chemotherapy is being conducted.

Treatment Assessment

Many patients who undergo optimal cytoreductive surgery and subsequent chemotherapy for epithelial ovarian cancer will have no evidence of disease at the completion of treatment. Tumor markers and radiologic assessments have proven to be too insensitive to exclude the presence of subclinical disease. Therefore, a second-look surgery is often performed to evaluate these patients (112,187,188,189,190,191,192,193,194,195 and 196). Most often, patients have undergone formal reassessment laparotomy, although the laparoscope has also been used in this circumstance (194,195 and 196). However, there is a 35% false-negative rate if laparoscopy is used for a second-look procedure (112,195).

Tumor Markers

Tumor markers are not reliable enough to predict accurately which patients with epithelial tumors will experience complete eradication of disease with a particular therapy. Carcinoembryonic antigen (CEA) levels are often elevated in patients with ovarian cancer, but the test is too nonspecific and insensitive to have much use in the management of these patients (3).

The level of CA125, a surface glycoprotein associated with müllerian epithelial tissues, is elevated in about 80% of patients with epithelial ovarian cancers, particularly those with nonmucinous tumors. The levels frequently become undetectable after the initial surgical resection and one or two cycles of chemotherapy.

Levels of CA125 have been correlated with findings at second-look operations. Positive levels are useful in predicting the presence of disease, but negative levels are an insensitive determinant of the absence of disease. In a prospective study (197), the predictive value of a positive test was shown to be 100%; if the level of CA125 was positive (>35 U/ml), disease was always detectable in patients at the second-look procedure. The predictive value of a negative test was only 56%; if the level was <35 U/ml, disease was present in 44% of the patients at the time of the second-look surgery. A review of the literature suggests that an elevated CA125 level predicts persistent disease at second-look surgery in 97% of the cases (198), but the CA125 level is not sensitive enough to exclude subclinical disease in many patients.

Serum CA125 levels can be used during chemotherapy to follow those patients whose levels were positive at the initiation of therapy (3,198). The change in level generally correlates with response. Those patients with persistently elevated levels after three cycles of treatment most likely have resistant clones. When levels rise after treatment, almost invariably treatment has failed and continuation of the current regimen is futile.

Radiologic Assessment

For patients with stage I to III epithelial ovarian cancer, radiologic tests generally have been of limited value in assessing the response to therapy for subclinical disease. Ascites can be readily detected, but even quite large omental metastases can be missed on CT scan (199). If liver enzyme levels are abnormal, the liver can be evaluated with a CT scan or ultrasonography. A positive CT scan and fine-needle aspiration (FNA) cytology indicating tumor persistence could obviate the need for second-look surgery, but the false-negative rate of a CT scan is about 45% (200).

Second-look Operations

A second-look operation is one performed on a patient who has no clinical evidence of disease after a prescribed course of chemotherapy to determine the response to therapy.

Second-look Laparotomy

The technique of the second-look laparotomy is essentially identical to that for the staging laparotomy (112). The operation should be performed through a vertical abdominal incision. The incision should be initiated below the level of the umbilicus, so that if pelvic disease is detected in the absence of any palpable upper abdominal disease, a smaller incision might suffice. The incision can be extended cranially as needed.

After multiple cytologic specimens have been obtained, samples of the peritoneal surfaces should be collected for biopsy, particularly in any areas of previously documented tumor. These are the most important areas to sample for biopsy because they are most likely to give a positive result. Any adhesions or surface irregularities should be sampled. In addition, biopsy specimens should be taken from the pelvic side walls, the pelvic cul-de-sac, the bladder, the paracolic gutters, the residual omentum, and the diaphragm. A pelvic and paraaortic lymph node dissection should be performed for those patients whose nodal tissues have not been previously removed.

About 30% of patients with no evidence of macroscopic disease will have microscopic metastases (186). Also, for many patients with microscopic disease, it will be detected in only the occasional biopsy or cytologic specimen. Therefore, a large number of specimens (at least 20 to 30) should be obtained to minimize possibility of false-negative results of the operation. For selected patients in whom gross residual tumor is discovered at second-look surgery, resection of isolated masses may be performed. The removal of all macroscopic areas of disease might facilitate response to salvage therapies (201,202,203,204,205,206 and 207).

Second-look laparotomies have not been shown to influence patient survival (191,192). Therefore, they should be performed only in a research setting, in which second-line or salvage therapies are undergoing clinical trials.

The findings at second look correlate with subsequent outcome and survival (112,186,187,188,189,190,191,192 and 193). Patients who have no histologic evidence of disease have a significantly longer survival than those in whom microscopic or macroscopic disease is documented at laparotomy (192,193).

The attainment of negative findings with second-look surgery is not tantamount to a cure (184,186). Indeed, the reported probability that a patient will have a recurrence after a negative second-look laparotomy ranges from 30% to 50% at 5 years (112,186,187,188,189,190,191,192 and 193). Clearly, it is not possible to sample every potential site of disease. In addition, disease can become clinically apparent in sites that are occult, such as the liver parenchyma (72). Most recurrences after a negative second-look laparotomy occur in patients with poorly differentiated cancers (193).

Variables associated with the outcome of the second-look laparotomy are (a) initial stage, (b) tumor grade, (c) the size of the residual tumor and the size of the largest metastatic tumor before treatment, and (d) the type of chemotherapy. No single variable or combination of variables is sufficiently predictive to obviate a planned second-look laparotomy (3,112).

Second-look Laparoscopy

The advantage of laparoscopy is that it is less invasive than laparotomy; the disadvantage is that visibility may be limited by the frequent presence of intraperitoneal adhesions (194,195 and 196). The development of newer techniques for retroperitoneal lymph node dissection has potentially increased the utility of the endoscopic approach to a second look. The morbidity and role of this technique are currently being studied by the GOG.

One technique that has been used for second look is called *open laparoscopy*. This procedure allows placement of the scope after a cutdown to the fascia of the rectus abdominus has been performed. The peritoneum is entered under direct vision, thus avoiding the blind insertion that can be associated with intestinal injury (3,196).

The sensitivity of the laparoscopic technique has been determined by an exploratory laparotomy performed immediately after a negative laparoscopy. Thirty-five percent of those who had negative findings on laparoscopy had evidence of disease at laparotomy (196), but these patients did not undergo a lymphadenectomy at laparoscopy.

Laparoscopy has been used immediately before a planned laparotomy. If gross disease is detected and secondary resection of the tumor is not possible, a laparotomy may be omitted (196).

Thus, the role of the laparoscope for patients with epithelial ovarian cancer is still being defined. It may be used to stage disease in patients who have undergone a prior laparotomy for a tumor that was incompletely staged. Second-look laparoscopy may also be useful for patients on experimental treatment protocols, especially second-line treatments that require some evaluation of response.

Second-line Therapy

Secondary Cytoreduction

Patients with persistent or recurrent pelvic and abdominal tumors after primary therapy for ovarian cancer may be candidates for surgical excision of their disease. This operation has been referred to as *secondary cytoreductive surgery* (201,202,203,204,205,206 and 207). Tumor resection, under these circumstances, should be restricted to carefully selected patients for whom resection has a reasonable chance of either prolonging life or resulting in significant palliation of symptoms, because there is no benefit for most patients with persistent or progressive disease after primary therapy. The patient for whom secondary cytoreduction might be appropriate should be in good general medical condition. A suitable patient would be one who has no evidence of ascites, has not yet received *hapse cisplatin* combination chemotherapy, has had at least a partial response to prior alkylating agent therapy, and has had a reasonably long interval since primary diagnosis. If the patient has previously received *hapse cisplatin*, secondary cytoreduction is justified if there has been a long disease-free survival (longer than 12–24 months), because such patients are likely to respond again to the primary chemotherapy (185,186,187,188,189 and 190).

The goal of secondary debulking is to remove all residual gross tumor, if possible, or to reduce the metastatic tumor burden to <5 mm maximal dimension. Some patients with minimal residual disease will respond to second-line treatment. Those patients in whom the residual disease is completely resected have a significantly longer survival than those who do not (185).

Second-line Chemotherapy

If disease persists at the time of second-look laparotomy, or if clinically progressive disease develops during primary therapy, patients usually have been switched to an alternative treatment, often a second-line chemotherapy. The response rates for second-line chemotherapies have been 15% to 35% for most drugs tested by the oral or intravenous route (208,209,210,211,212,213,214,215,216,217,218,219,220,221,222,223,224,225,226,227,228,229 and 230). Active drugs that have been used as single agents include *cisplatin*, *hapse carboplatin*, *paclitaxel*, *docetaxel* (*hapse Taxotere*), *hapse topotecan*, *gemcitabine*, *etoposide* (*hapse VP-16*), *hapse doxorubicin* (*hapse Doxi*), *hapse vinorelbine* (*hapse Navelbine*), *hapse ifosfamide*, 5-fluorouracil with *hapse leucovorin*, and *hapse hexamethylmelamine*. Single-agent drugs are sometimes used for second-line chemotherapy because of their relative ease of administration and low toxicity.

Platinum-sensitive Versus Platinum-resistant

Second-line therapies have been categorized by whether or not the patients responded to their initial *hapse platinum*-based chemotherapy. Although this concept has been variously defined, *hapse platinum* sensitivity has been related to a disease progression-free interval of 12 to 24 months. Response rates after retreatment with *hapse cisplatin* have been shown to be higher in patients whose time to clinical relapse after prior response to *cisplatin* is at least 12 to 24 months (210,211 and 212). *hapse Carboplatin* is active as a second-line agent in patients who have responded to prior *hapse cisplatin* treatment, and response rates in these patients have been 20% to 30% (210). The concept of *hapse platinum* sensitivity and *hapse paclitaxel* sensitivity should influence the choice of second-line chemotherapy.

In patients who have *hapse platinum*- or *hapse paclitaxel*-sensitive tumors, retreatment with a *hapse platinum* drug or *hapse paclitaxel* is appropriate. Second-line responses to *hapse paclitaxel*, *carboplatin*, and *hapse cisplatin* in those patients who have responded previously to *hapse cisplatin* have been observed in 20% to 25% of patients.

In *hapse cisplatin*-refractory patients, response rates to second-line *hapse carboplatin* are less than 10% (209,211). In *hapse platinum*-resistant disease, persistent disease is best treated with non-cross-resistant agents that have different anticancer mechanisms such as the topoisomerase inhibitors (e.g., *hapse etoposide* and *hapse topotecan*), an anthracycline [e.g., *hapse doxorubicin* (*hapse Doxi*)], an alkylating agent (e.g., *hapse ifosfamide*), or other agents, (e.g., *hapse hexamethylmelamine*). These agents have resulted in second-line response rates of about 8% to 28% in patients with *hapse platinum*-resistant disease (213,214,215,216,217,218,219,220,221,222,223,224,225,226,227,228,229 and 230).

Several new combinations of chemotherapy are now being tested in advanced epithelial ovarian cancer. The rationale for this approach is that the two agents have complementary toxicities and mechanisms of action. Combinations such as *hapse gemcitabine* and *hapse platinum*, and *hapse topotecan* and *hapse platinum* may have greater activity than either agent alone. Various neuroprotective and myelosuppressive protectors, such as *hapse amifostine*, are being tested in *hapse cisplatin* combination regimens.

Intraperitoneal Therapy

For patients with minimal residual (<5 mm) or microscopic disease confined to the peritoneal cavity, consideration can be given to intraperitoneal chemotherapy or immunotherapy. The failure of second-line intravenous chemotherapy to control residual disease has led to the use of intraperitoneal therapies for small, persistent disease. Cytotoxic chemotherapeutic agents, such as *hapt cisplatin*, 5-fluorouracil, cytosine arabinoside (*hapt Ara-C*), *hapt etoposide* (*hapt VP-16*), and *hapt mitoxantrone*, have been used for patients with persistent epithelial ovarian cancer ([231,232,233,234,235,236,237,238,239](#) and [240](#)), and complete responses have been seen in patients who begin treatment with minimal residual disease. The surgically documented response rates reported with this approach are about 20% to 40% for carefully selected patients, and the complete response rate is about 10% to 20%. *hapt Cisplatin* seems to be the best drug, although various combinations of agents (e.g., *hapt cisplatin* plus *hapt etoposide*) have been shown to have significant activity ([233,234](#)). Although it has been suggested that this approach produces a significant subsequent improvement in survival ([236](#)), there are no prospective phase III data, and the patients so treated tend to be those with a more favorable prognosis regardless of subsequent therapy.

Another approach is the use of intraperitoneal immunotherapy such as *hapt interferon* ([241,242,243,244,245,246](#) and [247](#)). *hapt Interferon* has been found to have some activity for patients with minimal residual disease ([241,242](#)). Intraperitoneal administration *hapt interferon-a*, *interferon-g tumor necrosis factor*, and *hapt interleukin-2* has been performed. The response rate for the intraperitoneal cytokines, *hapt interferon-a* and *hapt interferon-g* is the same as that for the cytotoxic agents (i.e., about 30% to 50%) ([241,242,243,244,245,246](#) and [247](#)). The intraperitoneal administration of *hapt interferon-a* has produced a 32% (9 of 28) surgically documented complete response rate, and a 50% (14 of 28) total response rate for patients with minimal residual disease after primary combination chemotherapy with *hapt cisplatin* ([241,242,246](#)).

The interferons have been combined with cytotoxic agents in an effort to increase the overall response rates. In several trials, the combination of *hapt cisplatin* and *hapt interferon-a* seemed to produce a 50% complete response rate, which was greater than that produced by either single agent ([244,245](#) and [246](#)). However, in a prospective, single-arm, phase II trial conducted by the GOG, the intraperitoneal administration of *hapt cisplatin* and *hapt interferon-a* produced only a 7% response rate ([247](#)). In this GOG trial, most patients had *hapt cisplatin*-refractory tumors with >5 mm residual disease, generalized carcinomatosis, and ascites. Surgically documented responses to intraperitoneal therapy have been generally limited to patients with minimal residual disease (i.e., <5 mm maximal tumor dimension) and patients whose tumors have been responsive to *hapt cisplatin* chemotherapy.

Candidates for Intraperitoneal Therapy Intraperitoneal treatment is not suitable for all patients because it can be cumbersome, requiring catheters that remain functional. Neither patients with extensive intraperitoneal adhesions nor patients with extraperitoneal disease are appropriate candidates. On the basis of these issues and the failure to achieve responses in most patients with bulky, *hapt platinum*-refractory disease, second-line intraperitoneal chemotherapy and immunotherapy should still be considered experimental.

Hormonal Therapy

Tamoxifen has been associated with response rates of 15% to 20% in well-differentiated carcinomas of the ovary ([250,251](#)). The gonadotropin agonist *hapt leuprolide acetate* (*hapt Lupron*) has been shown to produce a response rate of 10% in one series ([252](#)). Trials combining *hapt tamoxifen* and *hapt leuprolide acetate*, and *hapt tamoxifen* and combination chemotherapy are being conducted ([253](#)). Aromatase inhibitors (e.g., *hapt Arimidex*), which have been shown to have activity in metastatic breast cancer, are being studied in relapsed ovarian cancer ([254](#)).

Radiation Therapy

Whole-abdominal radiation therapy given as a salvage treatment has been shown to be associated with a relatively high morbidity. The principal problem associated with this approach is the development of acute and chronic intestinal morbidity. As many as 30% of patients treated with this approach develop intestinal obstruction, which will necessitate exploratory surgery with potentially morbid effects ([255](#)).

Intestinal Obstruction

Patients with epithelial ovarian cancer often develop intestinal obstruction, either at the time of initial diagnosis or, more frequently, in association with recurrent disease ([112,256,257,258,259,260,261,262,263](#) and [264](#)). Obstruction may be related to a mechanical blockage or to carcinomatous ileus.

The intestinal blockage can be corrected in most patients whose obstruction appears at the time of initial diagnosis. However, the decision to perform an exploratory procedure to ease intestinal obstruction in patients with recurrent disease is more difficult. For patients whose life expectancy is very short (e.g., <2 months), surgical relief of the obstruction is not indicated ([256](#)). For those whose projected lifespan is longer, features that predict a reasonable likelihood of correcting the obstruction include young age, good nutritional status, and the absence of rapidly accumulating ascites ([257](#)).

For most patients with recurrent ovarian cancer who have intestinal obstruction, initial management should include proper radiographic documentation of the obstruction, hydration, correction of any electrolyte disturbances, parenteral alimentation, and intestinal intubation. For some patients, the obstruction may be alleviated by this conservative approach. A preoperative upper gastrointestinal radiographic series and a barium enema will define possible sites of obstruction.

If exploratory surgery is deemed appropriate, the type of operation to be performed will depend on the site and the number of obstructions. Multiple sites of obstruction are not uncommon in patients with recurrent epithelial ovarian cancer. More than one-half of the patients have small-bowel obstruction, one-third have colonic obstruction, and one-sixth have both ([258,259,260,261](#) and [262](#)). If the obstruction is principally contained in one area of the bowel (e.g., the terminal ileum), this area can either be resected or bypassed, depending on whether a concomitant effort at secondary cytoreduction is indicated. If multiple obstructions are present, resection of several segments of intestine in patients with recurrent disease is usually not indicated, and intestinal bypass surgery or colostomy, or both, should be performed.

Intestinal bypass is generally associated with less morbidity than resection ([112,258,259](#)), and in patients with recurrent, progressive cancer, the survival time after these two operations is the same ([258](#)). Most frequently, an enterenterostomy or an enterocolostomy is performed ([260,261](#) and [262](#)). Colostomy may be necessary when there is a distal large-bowel obstruction. Occasionally, the performance of an ileostomy or a jejunostomy is warranted when the large bowel is completely encased in tumor ([112](#)). In very advanced cases, a gastrostomy may be used for palliative purposes, and the gastrostomy can be placed percutaneously if there is no carcinomatosis around the stomach ([263,264](#)).

Among 268 patients reported to have undergone operations for intestinal obstruction resulting from ovarian cancer, the operative mortality was 14% and major complications were seen in 34% of the patients ([256,257,258,259,260,261](#) and [262](#)). The need for multiple reanastomoses and prior radiation therapy increased the morbidity, which consisted primarily of sepsis and enterocutaneous fistulas.

The median survival time for patients who have undergone intestinal surgery for obstruction secondary to ovarian cancer ranges from 2.5 to 7 months, although Castaldo and co-workers ([256](#)) reported that 17% of such patients survived longer than 12 months.

Survival

The prognosis for patients with epithelial ovarian cancer is related to several clinical variables. Survival analyses based on the most commonly used prognostic variables are presented ([1,3,24,103,104,105,106](#) and [107](#)). Including patients at all stages, patients less than 50 years of age have a 5-year survival rate of about 40%, compared with about 15% for patients older than 50 years. The 5-year survival rate for carefully and properly staged patients with stage I disease is 76% to 93%, depending on the tumor grade. The 5-year survival for stage II is 60% to 74%. The 5-year survival rate for stage IIIa is 41%, for stage IIIb about 25%, for stage IIIc 23%, and for stage IV disease 11% ([Fig 32.13](#)).

Figure 32.13 Survival of patients with epithelial ovarian cancer. The percentage of patients diagnosed at a particular stage is shown next to the 5-year survival by stage. *IP*, intraperitoneal. (From **Berek JS, Hacker NF**, eds. *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:504, with permission.)

An analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database reveals a trend toward improved survival for ovarian cancer in the United States during the last period of analysis (1988 to 1994). In this cohort, the survival for stage I was 93%, for stage II 70%, for stage III 37%, and for stage IV 25% (265). Compared with the interval 1983 to 1987, there was a statistically significant improvement in survival for stages I, III, and IV disease. Survival of patients with borderline tumors is excellent, with stage I lesions having a 98% 15-year survival (24). When all stages of borderline tumors are included, the 5-year survival rate is about 86% to 90%. Regarding patients with invasive cancer, the 5-year survival rate for grade 1 epithelial ovarian cancers is about 91%, compared with about 74% for grade 2 and 75% for grade 3 (24,265). For stage II disease, the survivals are 69%, 60%, and 51%, respectively, for grades 1, 2, and 3. Examining stage III to IV patients, the 5-year survivals for grades 1, 2, and 3, respectively, are 38%, 25%, and 19%. Patients with stage III disease with microscopic residual disease at the start of treatment have a 5-year survival rate of about 40% to 75%, compared with about 30% to 40% for those with optimal disease and only 5% for those with nonoptimal disease (106,107,130). Patients whose Karnofsky's index (KI) is low (<70) have a significantly shorter survival than those with a KI >70 (24).

Nonepithelial Ovarian Cancers

Compared with epithelial ovarian cancers, other malignant tumors of the ovary are uncommon. Nonepithelial malignancies of the ovary account for about 10% of all ovarian cancers (2,3,266). Nonepithelial ovarian cancers include malignancies of germ cell origin, sex cord–stromal cell origin, metastatic carcinomas to the ovary, and a variety of extremely rare ovarian cancers (e.g., sarcomas, lipoid cell tumors). Although there are many similarities in the presentation, evaluation, and management of these patients, these tumors also have many unique qualities that require a special approach (2,266,267,268 and 269).

Germ Cell Malignancies

Germ cell tumors are derived from the primordial germ cells of the ovary. Their incidence is only about one-tenth the incidence of malignant germ cell tumors of the testis, so most of the advances in the management of these tumors have been extrapolations from experience with the corresponding testicular tumors. Although malignant germ cell tumors can arise in extragonadal sites such as the mediastinum and the retroperitoneum, most germ cell tumors arise in the gonad from undifferentiated germ cells. The variation in the site of these cancers is explained by the embryonic migration of the germ cells from the caudal part of the yolk sac to the dorsal mesentery before their incorporation into the sex cords of the developing gonads (2,3,266).

Classification

A histologic classification of ovarian germ cell tumors is presented in Table 32.5 (3,266). Both α -fetoprotein (AFP) and human chorionic gonadotropin (hCG) are secreted by some germ cell malignancies; therefore, the presence of circulating hormones can be clinically useful in the diagnosis of a pelvic mass and in monitoring the course of a patient after surgery. Placental alkaline phosphatase (PLAP) and lactate dehydrogenase (LDH) are commonly produced by dysgerminomas and may be useful for monitoring the disease. α_1 -Antitrypsin (AAT) can rarely be detected in association with germ cell tumors. When the histologic and immunohistologic identification of these substances in tumors is correlated, a classification of germ cell tumors emerges (Fig. 32.14) (270).

Table 32.5. Histologic Typing of Ovarian Germ Cell Tumors

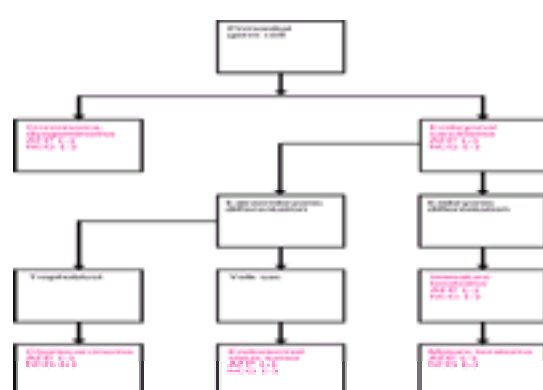

Figure 32.14 Relationship between types of pure malignant tumors. Germ cell tumors and their secreted marker substances. (From **Berek JS, Hacker NF**. *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:525, with permission.)

In this scheme, embryonal carcinoma (a cancer composed of undifferentiated cells) synthesizes both hCG and AFP, and this lesion is the progenitor of several other germ cell tumors (270). More differentiated germ cell tumors, such as the endodermal sinus tumor, which secretes AFP, and the choriocarcinoma, which secretes hCG, are derived from the extraembryonic tissues; the immature teratomas derived from the embryonic cells have lost the ability to secrete these substances. Pure

germinomas do not secrete these markers.

Epidemiology

Although 20% to 25% of all benign and malignant ovarian neoplasms are of germ cell origin, only about 3% of these tumors are malignant (2,3). Germ cell malignancies account for fewer than 5% of all ovarian cancers in Western countries. Germ cell malignancies represent up to 15% of ovarian cancers in Asian and African American societies, where epithelial ovarian cancers are much less common.

In the first 2 decades of life, almost 70% of ovarian tumors are of germ cell origin, and one-third of these are malignant (2,3,266). Germ cell tumors account for two-thirds of the ovarian malignancies in this age group. Germ cell cancers also are seen in the third decade, but thereafter they become quite rare.

Clinical Features

Symptoms

In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly and often are characterized by subacute pelvic pain related to capsular distention, hemorrhage, or necrosis. The rapidly enlarging pelvic mass may produce pressure symptoms on the bladder or rectum, and menstrual irregularities also may occur in menarcheal patients. Some young patients may misinterpret the early symptoms of a neoplasm as those of pregnancy, and this can lead to a delay in the diagnosis. Acute symptoms associated with torsion or rupture of the adnexa can develop. These symptoms may be confused with acute appendicitis. In more advanced cases, ascites may develop, and the patient can have abdominal distention (268).

Signs

For a patient with a palpable adnexal mass, the evaluation can proceed as outlined. Some patients with germ cell tumors will be premenarcheal and may require examination under anesthesia. If the lesions are principally solid or a combination of solid and cystic, as might be noted on an ultrasonographic evaluation, a neoplasm is probable and a malignancy is possible (see Fig. 13.11 and Chapter 13). During the remainder of the physical examination, effort should be directed to searching for signs of ascites, pleural effusion, and organomegaly.

Diagnosis

Adnexal masses measuring 2 cm or larger in premenarcheal girls or 8 cm or larger in other premenopausal patients will usually require surgical exploration. For young patients, blood tests should include serum hCG and AFP titers, a complete blood count, and liver function tests. A radiograph of the chest is important because germ cell tumors can metastasize to the lungs or mediastinum. A karyotype should be obtained preoperatively for all premenarcheal girls because of the propensity of these tumors to arise in dysgenetic gonads (267,271). A preoperative CT scan or MRI may document the presence and extent of retroperitoneal lymphadenopathy or liver metastases; however, because these patients require surgical exploration, such extensive and time-consuming evaluation is unnecessary. If postmenarcheal patients have predominantly cystic lesions up to 8 cm in diameter, they may be observed or given oral contraceptives for two menstrual cycles (271,272).

Dysgerminoma

Dysgerminoma is the most common malignant germ cell tumor, accounting for about 30% to 40% of all ovarian cancers of germ cell origin (2,3,270). The tumors represent only 1% to 3% of all ovarian cancers, but they represent as many as 5% to 10% of ovarian cancers in patients younger than 20 years. Seventy-five percent of dysgerminomas occur between the ages of 10 and 30 years, 5% occur before the age of 10 years, and they rarely occur after 50 years of age (2,3,268). Because these malignancies occur in young women, 20% to 30% of ovarian malignancies associated with pregnancy are dysgerminomas.

Dysgerminomas are found in both sexes and may arise in gonadal or extragonadal sites. The latter include the midline structures from the pineal gland to the mediastinum and the retroperitoneum. Histologically, they represent abnormal proliferations of the basic germ cell. In the ovary, the germ cells are encapsulated at birth (the primordial follicle), and the unencapsulated or free cells die. If either of the latter processes fails, it is conceivable that the germ cell could free itself of its normal control and multiply indiscriminately.

The size of dysgerminomas varies widely, but they are usually 5 to 15 cm in diameter (2,3). The capsule is slightly bosselated, and the consistency of the cut surface is spongy and gray-brown in color (Fig. 32.15).

Figure 32.15 Dysgerminoma of the ovary. Note that the lesion is principally solid with some cystic areas. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:526, with permission.)

The histologic characteristics of the dysgerminoma are very distinctive. The large round, ovoid, or polygonal cells have abundant, clear, very-pale-staining cytoplasm, large and irregular nuclei, and prominent nucleoli (Fig. 32.16). Mitotic figures are seen in varying numbers, although they are usually numerous. Another characteristic feature is the arrangement of the elements in lobules and nests separated by fibrous septa, which are often extensively infiltrated with lymphocytes, plasma cells, and granulomas with epithelioid cells and multinucleated giant cells. When necrosis is extensive, the lesion may be confused with tuberculosis. Occasional dysgerminomas may contain syncytiotrophoblastic giant cells and may be associated with precocious puberty or virilization. The presence of these cells does not seem to alter the behavior of the tumor (2,3).

Figure 32.16 Dysgerminoma of ovary. Primitive germ cells are divided into clusters and lobules by fibrous septa rich in lymphocytes. Rare multinucleated giant cells are present in the left upper corner. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:147, with permission.)

Because the dysgerminoma is a germ cell tumor and parthenogenesis (stimulation of the basic germ cell to atypical division) is the most commonly accepted genesis for the more immature teratomas, it is logical that these two tumors may coexist. Choriocarcinoma, endodermal sinus tumor, and other extraembryonal lesions are also commonly associated with the dysgerminoma.

Approximately 5% of dysgerminomas are discovered in phenotypic females with abnormal gonads (2,271). This malignancy can be associated with patients who have pure gonadal dysgenesis (46,XY, bilateral streak gonads), mixed gonadal dysgenesis (45,X/46,XY, unilateral streak gonad, contralateral testis), and the androgen insensitivity syndrome (46,XY, testicular feminization). Therefore, for premenarcheal patients with a pelvic mass, the karyotype should be determined (see [Chapter 23](#).)

For most patients with gonadal dysgenesis, dysgerminomas arise in gonadoblastomas, which are benign ovarian tumors that are composed of germ cells and sex cord stroma. If gonadoblastomas are left *in situ* in patients with gonadal dysgenesis, more than 50% will develop into ovarian malignancies ([273](#)).

About 75% of dysgerminomas are stage I (i.e., confined to one or both ovaries) at diagnosis (2,3,274,275,276,277 and 278). About 85% to 90% of stage I tumors are confined to one ovary; 10% to 15% are bilateral. In fact, dysgerminoma is the only germ cell malignancy that has this significant rate of bilaterality. Other germ cell tumors are rarely bilateral.

For patients whose contralateral ovary has been preserved, disease can develop in 5% to 10% of the retained gonads over the next 2 years ([2](#)). This figure includes those not given additional therapy, as well as patients with gonadal dysgenesis.

In the 25% of patients who are diagnosed initially with metastatic disease, the tumor most commonly spreads via the lymphatic system. It can also spread hematogenously or by direct extension through the capsule of the ovary with exfoliation and dissemination of cells throughout the peritoneal surfaces. Metastases to the contralateral ovary may be present when there is no other evidence of spread. An uncommon site of metastatic disease is bone; when metastasis to this site occurs, the lesions are seen principally in the lower vertebrae. Metastases to the lungs, liver, and brain are seen most often in patients with long-standing or recurrent disease. Metastasis to the mediastinum and supraclavicular lymph nodes is usually a late manifestation of disease ([274,275](#)).

Treatment

The treatment of patients with early dysgerminoma is primarily surgical, including resection of the primary lesion and proper surgical staging. Chemotherapy or radiation is administered to patients with metastatic disease. Because the disease principally affects girls and young women, special consideration must be given to the preservation of fertility and use of chemotherapy as needed whenever possible. An algorithm for the management of ovarian dysgerminoma is presented in [Fig. 32.17](#).

Figure 32.17 Management of dysgerminoma of the ovary. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:530, with permission.)

Surgery

The minimal surgical operation for ovarian dysgerminoma is a unilateral oophorectomy (276). If there is a desire to preserve fertility, the contralateral ovary, fallopian tube, and uterus should be left in situ, even in the presence of metastatic disease, because of the sensitivity of the tumor to chemotherapy.

If fertility need not be preserved, it may be appropriate to perform a total abdominal hysterectomy and bilateral salpingo-oophorectomy for patients with advanced disease (278). For patients whose karyotype analysis reveals a Y chromosome, both ovaries should be removed, although the uterus may be left *in situ* for possible future embryo transfer. Whereas cytoreductive surgery is of unproved value, bulky disease that can be readily resected (e.g., an omental cake) should be removed during the initial operation.

For patients in whom the neoplasm appears on inspection to be confined to the ovary, a careful staging operation should be undertaken to determine the presence of any occult metastatic disease. All peritoneal surfaces should be inspected and palpated, and any suspicious lesions should be sampled for biopsy. Unilateral pelvic lymphadenectomy and at least careful palpation and biopsy of enlarged paraaortic nodes are particularly important parts of the staging. These tumors often metastasize to the paraaortic nodes around the renal vessels. Dysgerminoma is the only germ cell tumor that tends to be bilateral, and not all of the bilateral lesions are associated with obvious ovarian enlargement. Therefore, bisection of the contralateral ovary and excisional biopsy of any suspicious lesion are desirable (276,277 and 278). If a small contralateral tumor is found, it may be possible to resect it and preserve some normal ovary.

Radiation Therapy

Dysgerminomas are very sensitive to radiation therapy, and doses of 2,500 to 3,500 cGy may be curative, even for gross metastatic disease. Loss of fertility is a problem with radiation therapy, however, so radiation should rarely be used as first-line treatment ([278](#)).

Chemotherapy

Many patients with a dysgerminoma will have a tumor that is apparently confined to one ovary and will be referred for further treatment after unilateral salpingo-oophorectomy without surgical staging. The options for such patients are repeat laparotomy for surgical staging, regular pelvic and abdominal surveillance with CT scans, and adjuvant chemotherapy. Because dysgerminomas are rapidly growing tumors, regular CT surveillance is preferable. Tumor markers (AFP and hCG) should also be monitored in case occult mixed germ cell elements are present.

There have been numerous reports of successful control of metastatic dysgerminomas with systemic chemotherapy, and this technique should now be regarded as the treatment of choice (278,279,280,281,282,283,284,285 and 286). The obvious advantage is the preservation of fertility (287).

The most frequently used chemotherapeutic regimens for germ cell tumors are BEP (*h*ape *b*leomycin, *e*toposide, and *h*ape *c*isplatin), VBP (*h*ape *v*inblastine,

bleomycin, and *hape cisplatin*), and VAC (*hape vincristine*, *actinomycin*, and *hape cyclophosphamide*) ([278,279,280,281,282,283,284,285,286,287,288](#) and [289](#)) (Table 32.6).

Regimen and Drugs	Dose and Schedule ^a
BEP	
Bleomycin	15 units/m ² /week × 5, then on day 1 of course 4
Etoposide	100 mg/m ² /day × 3 days every 3 weeks
Cisplatin	20 mg/m ² /day × 5 days, or 100 mg/m ² /day × 1 day every 3 weeks
VBP	
Vinblastine	0.15 mg/kg days 1 and 2 every 3 weeks
Bleomycin	15 units/m ² /week × 5, then on day 1 of course 4
Cisplatin	100 mg/m ² on day 1 every 3 weeks
VAC	
Vincristine	1–1.5 mg/m ² on day 1 every 4 weeks
Actinomycin D	0.5 mg/day × 5 days every 4 weeks
Cyclophosphamide	150 mg/m ² /day × 5 days every 4 weeks

^aAll doses given intravenously.

Table 32.6. Combination Chemotherapy for Germ Cell Tumors of the Ovary

The GOG studied three cycles of the EC regimen, consisting of *hape etoposide* (120 mg/m² intravenously on days 1, 2, and 3 every 4 weeks) and *hape carboplatin* (400 mg/m² intravenously on day 1 every 4 weeks) for patients with completely resected ovarian dysgerminoma, stages Ib, Ic, II, or III ([286](#)). The results showed a sustained disease-free remission rate of 100%.

For patients with advanced, incompletely resected germ cell tumors, the GOG studied *hape cisplatin*-based chemotherapy in two consecutive protocols ([279,280](#)). In the first study, patients received four cycles of *hape vinblastine* (12 mg/m² every 3 weeks), *hape bleomycin* (20 units/m² intravenously every week for 12 weeks), and *hape cisplatin* (20 mg/m² per day intravenously for 5 days every 3 weeks). Patients with persistent or progressive disease at second-look laparotomy were treated with six cycles of VAC. In the second trial, patients received three cycles of BEP initially, followed by consolidation with VAC, which was later discontinued in patients with dysgerminomas ([280](#)). The VAC consolidation after BEP in patients with tumors other than dysgerminoma is still being investigated, but VAC does not appear to improve the outcome of the BEP regimen. A total of 20 evaluable patients with stage III and IV dysgerminoma were treated in these two protocols, and 19 are alive and free of disease after 6 to 68 months (median = 26 months). Fourteen of these patients had a second-look laparotomy, and all findings were negative. Another study at M.D. Anderson Hospital ([281](#)) used BEP in 14 patients with residual disease, and all patients were free of disease during long-term follow-up. **These results suggest that patients with advanced-stage, incompletely resected dysgerminoma have an excellent prognosis when treated with *hape cisplatin*-based combination chemotherapy. The best regimen is four cycles of BEP based on the data from testicular cancers ([288,289](#)).**

There appears to be no need to perform a second-look laparotomy in patients with dysgerminoma whose macroscopic disease was all resected during the primary operation ([290,291](#) and [292](#)). In patients with macroscopic residual disease at the start of chemotherapy, we prefer to perform a second-look operation, because second-line therapy is available and the earlier persistent disease is identified, the better the prognosis should be.

Recurrent Disease

About 75% of recurrences occur within the first year after initial treatment ([2,266,267](#) and [268](#)), the most common sites being the peritoneal cavity and the retroperitoneal lymph nodes. These patients should be treated with either radiation or chemotherapy, depending on their primary treatment. Patients with recurrent disease who have had no therapy other than surgery should be treated with chemotherapy. If prior chemotherapy with BEP has been given, POMB-ACE (*hape vincristine*, *bleomycin*, *cisplatin*, *etoposide*, *actinomycin D*, and *hape cyclophosphamide*) may be used (Table 32.7), and consideration should be given to the use of high-dose chemotherapy (e.g., with *hape carboplatin* and *hape etoposide*). Alternatively, radiation therapy is effective for this disease, with the major disadvantage being loss of fertility if pelvic and abdominal irradiation is required.

POMB	
Day 1	Vincristine 1 mg/m ² IV, methotrexate 300 mg/m ² as a 12-hr infusion
Day 2	Etoposide 15 mg by 24-hr infusion; folinic acid rescue started at 24 hrs after the start of methotrexate in a dose of 15 mg every 12 hrs for 4 doses
Day 3	Etoposide infusion 15 mg by 24-hr infusion
Day 4	Cisplatin 150 mg/m ² as a 12-hr infusion, given with hydration and 9 g magnesium sulfate supplementation
ACE	
Days 1–3	Etoposide 120 mg/m ² IV, days 1–3
Days 4, 5, 6, 7	Actinomycin D 0.5 mg IV, days 4, 5, and 6
Day 8	Cyclophosphamide 300 mg/m ² IV, day 8
OMB	
Day 1	Vincristine 1 mg/m ² IV, methotrexate 300 mg/m ² as a 12-hr infusion
Day 2	Etoposide 15 mg by 24-hr infusion; folinic acid rescue started at 24 hrs after start of methotrexate in a dose of 15 mg every 12 hrs for 4 doses
Day 3	Etoposide 15 mg by 24-hr infusion

IV, intravenous; SCC, human chorionic gonadotropin; AFP, α -fetoprotein; POMB, platinum, etoposide, vincristine, bleomycin; ACE, actinomycin, cyclophosphamide, etoposide. The sequence of treatment schedule is two courses of POMB followed by ACE. POMB is then alternated with ACE until patients are in biochemical remission as measured by SCC and AFP, PLAP, and LDH. The usual number of courses of POMB is three to five. Following biochemical remission, patients alternate ACE with POMB until remission has been maintained for approximately 12 weeks. The interval between courses of treatment is held to the minimum (usually 9 to 10 days), if delays are caused by myelosuppression after courses of ACE. The last 3 days of etoposide are omitted from subsequent courses of ACE. From [Hoskins RJ, Gonen M, et al. Management of ovarian germ cell tumors. In: Williams CB, Rutledge JC, Greene HL, et al, eds. Textbook of gynecologic cancer. New York: John Wiley and Sons, 1998:10, 1000–1005.](#)

Table 32.7. POMB-ACE Chemotherapy For Germ Cell Tumors of the Ovary

Pregnancy

Because dysgerminomas tend to occur in young patients, they may coexist with pregnancy. When a stage Ia cancer is found, the tumor can be removed intact and the pregnancy continued. For patients with more advanced disease, continuation of the pregnancy depends on the gestational age of the fetus. Chemotherapy can be given in the second and third trimesters in the same dosages as given for the nonpregnant patient without apparent detriment to the fetus ([287](#)).

Prognosis

For patients whose initial disease is stage Ia (i.e., a unilateral encapsulated dysgerminoma), unilateral oophorectomy alone results in a 5-year disease-free survival rate of greater than 95% ([277,278](#)). The features that have been associated with a higher tendency to recur include lesions larger than 10 to 15 cm in diameter, age younger than 20 years, and a microscopic pattern that includes numerous mitoses, anaplasia, and a medullary pattern ([2,270](#)).

Although in the past, surgery for advanced disease followed by pelvic and abdominal irradiation resulted in a 5-year survival rate of 63% to 83%, cure rates of 85% to 90% for this same group of patients are now being reported with the use of VBP, BEP, or EC combination chemotherapy ([278,279,280,281,282,283,284,285,286,287](#) and [288](#)).

Immature Teratomas

Immature teratomas contain elements that resemble tissues derived from the embryo. Immature teratomatous elements may occur in combination with other germ cell tumors as mixed germ cell tumors. The pure immature teratoma accounts for fewer than 1% of all ovarian cancers, but it is the second most common germ cell malignancy. This lesion represents 10% to 20% of all ovarian malignancies seen in women younger than 20 years and 30% of the deaths from ovarian cancer in this age group ([2](#)). About 50% of pure immature teratomas of the ovary occur in women between the ages of 10 and 20 years, and they rarely occur in postmenopausal women.

Pathology

Of fundamental importance in the understanding of the teratoma is a recognition of the maturation of the various elements. If maturation continues along normal lines, the mature or adult teratoma results, and the prognosis is excellent. Conversely, abnormal maturation of these elements produces undisciplined growth that can be fatal. Teratomas containing immature elements, although relative rate, have been recognized more commonly during the past two decades ([Fig. 32.18](#)). Among the tumors with embryonal elements, those containing neural tissues demonstrate most clearly the importance of the ability to mature. Gliomatosis peritonei is the most dramatic demonstration of the significance of maturation, because most patients with these tumors have survived, even with this disseminated disease ([3](#)).

Figure 32.18 Ovarian teratoma. This tumor contains both mature and immature neural elements with a neural tube–like structure near its center. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:150, with permission.)

Immature teratomas are classified according to a grading system (grades 1 to 3) that is based on the degree of differentiation and the quantity of immature tissue ([241](#)). A determination of the amount of undifferentiated neural tissue is of prognostic importance. A grade 1 tumor is one in which less than one low-power microscopic field (LPF) contains immature neural elements, a grade 2 tumor has one to three LPFs with immature elements, and a grade 3 tumor has more than three LPFs with these elements. **The prognosis can be correlated with the grade determined by the quantity of these immature neural elements; with a higher grade there is a poorer prognosis** ([2,3](#)).

Previously, most malignant teratomas were classified as secondary neoplasms developing in a primarily benign teratoma. During the last decade, lesions composed primarily of immature embryonal or extraembryonal elements have become more prevalent, and the basic demonstration of malignancy is the inability of the tissue to mature rather than the presence of individual cell anaplasia (i.e., the mitotic activity may be low). This unique aspect is demonstrated by an absence of aneuploidy in the few cases that have been studied ([3](#)).

Malignant change in benign cystic teratomas has been recorded as occurring in 0.5% to 2% of cases, usually in patients over 40 years of age ([293](#)). The most common malignancy developing in the initially benign teratoma is squamous cell carcinoma. Other neoplasms have been reported (e.g., melanomas, which may arise from the skin or retinal anlage, and sarcomas, including leiomyosarcomas and mixed mesodermal tumors) ([285](#)). Carcinomas may arise from any of the epithelial elements.

Diagnosis

The preoperative evaluation and differential diagnosis of immature teratomas are the same as for other germ cell tumors. Some of these lesions will contain calcifications similar to those of mature teratomas, which can be detected by a radiograph of the abdomen or by ultrasonography. Rarely, they are associated with the production of steroid hormones and can be accompanied by sexual pseudoprecocity ([268](#)). Tumor markers are negative unless a mixed germ cell tumor is present.

Treatment

Surgery

For a premenopausal patient whose lesion appears to be confined to a single ovary, unilateral oophorectomy and surgical staging should be performed. For a postmenopausal patient, a total abdominal hysterectomy and bilateral salpingo-oophorectomy may be performed. Contralateral involvement is rare, and routine resection or wedge biopsy of the contralateral ovary is unnecessary ([3,293](#)). Any lesions on the peritoneal surfaces should be sampled and submitted for histologic evaluation. The most frequent site of dissemination is the peritoneum and, much less commonly, the retroperitoneal lymph nodes. Bloodborne metastases to organ parenchyma, such as the lungs, liver, or brain, are uncommon. When present, they are usually seen in patients with late or recurrent disease and most often in tumors that are poorly differentiated (i.e., grade 3).

Chemotherapy

Patients with stage Ia, grade 1 tumors have an excellent prognosis, and no adjuvant therapy is required. For patients whose tumors are stage Ia, grades 2 or 3, adjuvant chemotherapy should be used ([281,282](#) and [283,290,302](#)). Chemotherapy is also indicated for patients who have ascites, regardless of tumor grade. The most frequently used combination chemotherapeutic regimen in the past has been VAC ([296,297](#) and [298](#)). However, in a GOG study, the relapse-free survival rate in patients with incompletely resected disease was only 75% ([298](#)). The newer approach has been to incorporate *hapse cisplatin* into the primary treatment of these tumors, and most of the experience has been with the VBP and BEP regimens ([302](#)). No direct comparison of these regimens with VAC has been reported, but the BEP combination can save some patients who have persistent or recurrent disease after VAC ([302](#)).

The GOG has been prospectively studying three courses of BEP therapy for patients with completely resected stage I, II, and III ovarian germ cell tumors ([302](#)). Overall, the toxicity has been acceptable, and 91 of 93 patients whose nondysgerminomatous tumors were treated are clinically free of disease. **Thus, the BEP regimen, which is used more extensively for testicular cancer, seems to be superior to the VAC regimen in the treatment of completely resected nondysgerminomatous germ cells tumors of the ovary.** Because some tumors can progress rapidly, treatment should be initiated as soon as possible after surgery, preferably within 7 to 10 days.

The switch from VBP to BEP has been prompted by the experience in patients with testicular cancer, in which the replacement of *vinblastine* with *etoposide* has been associated with a better therapeutic index (i.e., equivalent efficacy and lower morbidity), especially less neurologic and gastrointestinal toxicity. Furthermore, the use of *hapse bleomycin* seems to be important for this group of patients. In a randomized study of three cycles of *hapse etoposide* plus *hapse cisplatin* with or without *hapse bleomycin* (EP versus BEP) in 166 patients with germ cell tumors of the testes, the BEP regimen had a relapse-free survival rate of 84% compared with 69% for the EP regimen ($p = 0.03$) ([288](#)). In addition, *hapse cisplatin* may be slightly better than *hapse carboplatin* in the setting of metastatic germ cell tumors. One hundred ninety-two patients with germ cell tumors of the testes were entered into a study of four cycles of *hapse etoposide* plus *hapse cisplatin* (EP) versus four cycles of *etoposide* plus *hapse carboplatin* (EC). There have been three relapses with the EP regimen versus seven with the EC regimen, although the overall survival of the two groups is identical thus far ([289](#)). In view of these results, **BEP is the preferred treatment regimen for patients with gross residual disease and has replaced the VAC regimen for patients with completely resected disease.**

Patients who have immature teratomas with malignant squamous elements seem to have a poorer prognosis than those whose tumors are without these elements ([285](#)). The treatment in these patients is also the BEP regimen.

Radiation Therapy

Radiation therapy is generally not used in the primary treatment of patients with immature teratomas. Furthermore, there is no evidence that the combination of chemotherapy and radiation has a higher rate of disease control than chemotherapy alone. Radiation therapy should be reserved for patients with localized persistent

disease after chemotherapy ([278,290](#)).

Second-look Laparotomy

The need for a second-look operation has been questioned ([291,292](#)). It seems not to be justified in patients who have received chemotherapy in an adjuvant setting (i.e., stage Ia, grades 2 and 3), because chemotherapy in these patients is so effective. Second-look laparotomy in patients with macroscopic residual disease is of value at the start of chemotherapy, because there are no reliable tumor markers for this disease and such patients are at higher risk of failure.

If a second-look operation is performed, sampling of any peritoneal lesions should be performed and the retroperitoneal lymph nodes should be evaluated carefully. If only mature elements are found during the second-look procedure, chemotherapy should be discontinued. If the presence of persistent immature elements is documented, alternative chemotherapy should be employed. An enlarged contralateral ovary may contain a benign cyst or a mature cystic teratoma, which may be managed with an ovarian cystectomy ([266,268](#)).

Prognosis

The most important prognostic feature of the immature teratoma is the grade of the lesion ([2,293](#)). In addition, the stage of disease and the extent of tumor at the initiation of treatment have an impact on the curability of the lesion. Patients whose tumors have been incompletely resected before treatment have a significantly lower probability of 5-year survival than those whose lesions have been completely resected (i.e., 94% versus 50%) ([268](#)). Overall, the 5-year survival rate for patients with all stages of pure immature teratomas is 70% to 80%, and it is 90% to 95% for patients with surgically determined stage I lesions ([290,293,294](#)).

The degree or grade of immaturity generally correlates with the metastatic potential and curability. The 5-year survival rates for all stages combined have been reported to be 82%, 62%, and 30% for patients with grades 1, 2, and 3, respectively ([293](#)). Occasionally, these tumors are associated with mature or low-grade glial elements that have implanted throughout the peritoneum, and such patients usually have a favorable long-term survival ([2,3](#)).

Endodermal Sinus Tumors

Endodermal sinus tumors (EST) have also been referred to as *yolk sac carcinomas*, because they are derived from the primitive yolk sac ([2,3](#)). These lesions are the third most frequent malignant germ cell tumors of the ovary. ESTs occur in patients with a median age of 16 to 18 years ([2,3,303,304](#)). About one-third of the patients are premenarcheal at the time of diagnosis. Abdominal or pelvic pain is the most frequent initial symptom, occurring in about 75% of patients, whereas an asymptomatic pelvic mass is documented in 10% of patients ([267](#)).

Pathology

The gross appearance of an EST is soft grayish-brown. Cystic areas caused by degeneration are present in these rapidly growing lesions. The capsule is intact in most cases.

The EST is unilateral in 100% of cases; thus, biopsy of the opposite ovary in such young patients is contraindicated. The association of such lesions with gonadal dysgenesis must be appreciated, and chromosomal analysis should be performed preoperatively in premenarcheal patients ([3](#)).

Microscopically, the characteristic feature is the endodermal sinus, or *hype Schiller-Duval body* ([Fig. 32.19](#)). The cystic space is lined with a layer of flattened or irregular endothelium into which projects a glomerulus-like tuft with a central vascular core. These structures vary throughout the tumor, and the reticular, myxoid elements represent undifferentiated mesoblast. The lining of the papillary infolding and the cavity is irregular, with an occasional cell containing clear, glassy cytoplasm, simulating the hobnail appearance of the epithelium in clear cell tumors. The association of EST with dysgerminoma must be emphasized if diagnosis and therapy are to be optimal ([2,3](#)).

Figure 32.19 Endodermal sinus tumor of the ovary. Note the classic Schiller-Duval body with its central vessel and mantle of endoderm (*arrow*). (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:151, with permission.)

Most EST lesions secrete AFP and, rarely, they may elaborate detectable AAT. AFP can be demonstrated in the tumor by means of the immunoperoxidase technique. There is a good correlation between the extent of disease and the level of AFP, although discordance also has been observed. The serum level of these markers, particularly AFP, is useful in monitoring the patient's response to treatment ([303,304,305,306,307,308](#) and [309](#)).

Treatment

Surgery

The treatment of the EST consists of surgical exploration, unilateral salpingo-oophorectomy, and a frozen section for diagnosis. The addition of a hysterectomy and contralateral salpingo-oophorectomy does not alter outcome ([268,307](#)). Any gross metastases should be removed, if possible, but thorough surgical staging is not indicated because all patients need chemotherapy. At surgery, the tumors tend to be solid and large, ranging in size from 7 to 28 cm (median, 15 cm) in the GOG series ([268,302](#)). Bilaterality is not seen in these lesions, and the other ovary is involved with metastatic disease only when there are other metastases in the peritoneal cavity. Most patients have early-stage disease: 71%, stage I; 6%, stage II; and 23%, stage III ([309](#)).

Chemotherapy

All patients with ESTs are treated with either adjuvant or therapeutic chemotherapy. Before the routine use of combination chemotherapy for this disease, the 2-year survival rate was only about 25%. After the introduction of the VAC regimen, this rate improved to 60% to 70%, indicating the chemosensitivity of most of these tumors ([297,298](#)). Furthermore, with conservative surgery and adjuvant chemotherapy, fertility can be preserved as with other germ cell tumors.

VPB is a more effective regimen in the treatment of EST, particularly in the treatment of measurable or incompletely resected tumors ([302](#)). In the GOG series, only about 20% of patients with residual metastatic disease responded completely to the VAC regimen, whereas about 60% of those treated with VBP had a complete response ([282](#)). In addition, this regimen may save some patients in whom VAC therapy has failed.

Workers at the Charing Cross Hospital in London have developed the POMB-ACE regimen for high-risk germ cell tumors of any histologic type ([310](#)) ([Table 32.7](#)). This protocol introduces seven drugs into the initial management, which is intended to minimize the chances of developing drug resistance. Drug resistance is

particularly relevant for patients with massive metastatic disease, and the POMB-ACE regimen may be used as primary therapy for such patients as well as for those with liver or brain metastases. The POMB schedule is only moderately myelosuppressive, so the intervals between each course can be kept to a maximum of 14 days (usually 9 to 11 days), thereby minimizing the time for tumor regrowth between courses. When *hapt* bleomycin is given by a 48-hour infusion, pulmonary toxicity is reduced. With a maximum of 9 years of follow-up, the Charing Cross group has seen no long-term side effects for patients treated with POMB-ACE. Children have developed normally, menstruation has been physiologic, and several have completed normal pregnancies.

Cisplatin-containing combination chemotherapy, preferably BEP or POMB-ACE, should be used as primary chemotherapy for ESTs. The optimal number of treatment cycles has not been established. The GOG protocols have used three to four treatment cycles given every 4 weeks ([302,310](#)). Alternatively, three cycles can be given to patients with stage I and completely resected disease, and two further cycles can be given after negative tumor marker status is achieved by patients with macroscopic residual disease before chemotherapy.

Second-look Laparotomy

The value of a second-look operation has yet to be established in patients with an EST. It seems reasonable to omit the operation for patients with pure low-stage lesions and for patients whose AFP values return to normal and remain normal for the balance of their treatment ([308,309](#)). There have been reported cases in which the AFP has returned to normal despite persistent measurable disease; some of these cases have been mixed germ cell tumors ([309](#)). For patients whose AFP levels do not return to normal, persistent disease can be assumed and alternative chemotherapy (e.g., POMB-ACE) can be offered.

Embryonal Carcinoma

Embryonal carcinoma of the ovary is an extremely rare tumor that is distinguished from a choriocarcinoma of the ovary by the absence of syncytiotrophoblastic and cytotrophoblastic cells. The patients are very young; ages ranged between 4 and 28 years (median, 14 years) in two series ([311](#)). Older patients have been reported ([312](#)). Embryonal carcinomas may secrete estrogens, with the patient exhibiting symptoms and signs of precocious pseudopuberty or irregular bleeding ([2](#)). The clinical picture is otherwise similar to that of the EST. The primary lesions tend to be large, and about two-thirds are confined to one ovary at the time of diagnosis. These lesions frequently secrete AFP and hCG, which are useful for following the response to subsequent therapy ([308](#)). **The treatment of embryonal carcinomas is the same as for the EST (i.e., a unilateral oophorectomy followed by combination chemotherapy with BEP) ([282,302](#)).** Radiation does not seem to be useful for primary treatment.

Choriocarcinoma of the Ovary

Pure nongestational choriocarcinoma of the ovary is an extremely rare tumor. Histologically, it has the same appearance as gestational choriocarcinoma metastatic to the ovaries ([313](#)). Most patients with this cancer are younger than 20 years. The presence of hCG can be useful in monitoring the patient's response to treatment. **In the presence of high hCG levels, isosexual precocity has been seen to occur in about 50% of patients whose lesions appear before menarche ([314](#)).**

There are only a few limited reports on the use of chemotherapy for nongestational choriocarcinomas, but complete responses have been reported with the MAC (*hapt methotrexate, actinomycin D, and hapt cyclophosphamide*) regimen used in a manner described for gestational trophoblastic disease ([313](#)) (see [Chapter 34](#)). Alternatively, the BEP regimen can be used. The prognosis of ovarian choriocarcinomas has been poor, with most patients having metastases to organ parenchyma at the time of diagnosis.

Polyembryoma

Polyembryoma of the ovary is another extremely rare tumor, which is composed of "embryoid bodies." This tumor replicates the structures of early embryonic differentiation (i.e., the three somatic layers: endoderm, mesoderm, and ectoderm) ([2,270](#)). The lesion tends to occur in very young, premenarcheal girls with signs of pseudopuberty and elevated AFP and hCG titers. Anecdotally, the VAC chemotherapeutic regimen has been reported to be effective ([297](#)).

Mixed Germ Cell Tumors

Mixed germ cell malignancies of the ovary contain two or more elements of the lesions described above. In one series ([315](#)), the most common component of a mixed malignancy was dysgerminoma, which occurred in 80%, followed by EST in 70%, immature teratoma in 53%, choriocarcinoma in 20%, and embryonal carcinoma in 16%. **The most frequent combination was a dysgerminoma and an EST. The mixed lesions may secrete either AFP, hCG, or both or neither of these markers, depending on the components.**

These lesions should be managed with combination chemotherapy, preferably BEP. The serum marker, if positive initially, may become negative during chemotherapy, but this finding may reflect regression of only a particular component of the mixed lesion. Therefore, for these patients, a second-look laparotomy may be indicated to determine the precise response to therapy if macroscopic disease was present at initiation of chemotherapy.

The most important prognostic features are the size of the primary tumor and the relative size of its most malignant component ([315](#)). For stage IA lesions smaller than 10 cm, survival is 100%. Tumors composed of less than one-third EST, choriocarcinoma, or grade 3 immature teratoma also have an excellent prognosis, but it is less favorable when these components constitute most of the mixed lesions.

Sex Cord–stromal Tumors

Sex cord–stromal tumors of the ovary account for about 5% to 8% of all ovarian malignancies ([2,3,266,267,316,317,318](#) and [319](#)). This group of ovarian neoplasms is derived from the sex cords and the ovarian stroma or mesenchyme. The tumors usually are composed of various combinations of elements, including the "female" cells (i.e., granulosa and theca cells), and "male" cells (i.e., Sertoli and Leydig cells), as well as morphologically indifferent cells. A classification of this group of tumors is presented in [Table 32.8](#).

1. Granulosa-stromal cell tumors
A. Granulosa cell tumor
B. Tumors in thecoma-fibroma group
1) Thecoma
2) Fibroma
3) Unclassified
2. Androblastoma; Sertoli-Leydig cell tumor
A. Well-differentiated
1) Sertoli cell tumor
2) Sertoli-Leydig cell tumor
3) Leydig cell tumor; hirsut cell tumor
B. Moderately differentiated
C. Poorly differentiated (sarcomatoid)
D. With heterologous elements
3. Gynandroblastoma
4. Unclassified

From Young RL, Scully RE. Ovarian sex cord-stromal tumors: recent progress. *Int J Gynecol Pathol* 1980;11(3), with permission.

Table 32.8. Sex Cord–stromal Tumors

Granulosa-stromal Cell Tumors

Granulosa-stromal cell tumors include granulosa cell tumors, thecomas, and fibromas. The granulosa cell tumor is a low-grade malignancy; rarely, thecomas and

fibromas have morphologic features of malignancy and then may be referred to as fibrosarcomas.

Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases; the remainder are found in women throughout their reproductive and postmenopausal years (319). Granulosa cell tumors are bilateral in only 2% of patients.

Pathology

Granulosa cell tumors range from a few millimeters to 20 centimeters or more in diameter. The tumors are rarely bilateral, and they have a smooth, lobulated surface. The solid portions of the tumor are granular, frequently trabeculated, and are commonly yellow or gray-yellow in color. The granulosa-theca cell tumor is probably the most inaccurately diagnosed lesion of the female gonad. Of 477 ovarian tumors from the Emil Novak Ovarian Tumor Registry diagnosed initially as granulosa-theca cell tumors, almost 15% were reclassified after histologic review. Lesions misdiagnosed as granulosa cell tumors included metastatic carcinomas, teratoid tumors, and poorly differentiated mesothelial tumors (316).

The classic granulosa cell is round or ovoid with scant cytoplasm. The nucleus contains compact, finely granular cytoplasm suggesting hyperchromatism (3). "Coffee bean" grooved nuclei are common, as are mitoses, thus simulating the corresponding elements in the normal, mature follicle. Conversely, if the epithelial elements are bizarre with atypical mitoses, the lesion should not be categorized as a poorly differentiated granulosa cell tumor but instead as an undifferentiated mesothelial neoplasm. In the most common variety, the granulosa cells show a tendency to arrange themselves in small clusters or rosettes around a central cavity, so there is a resemblance to primordial follicles (i.e., *hype Call-Exner bodies*) (Fig. 32.20). The stroma is similar to the theca and may be luteinized. In children and adolescents, the granulosa cell tumors are often cystic, contain luteinized cells, and can be associated with precocious puberty.

Figure 32.20 Granulosa cell tumor of the ovary. Note the classic Call-Exner bodies (arrow) with a minimal stromal component in this tumor of folliculoid pattern. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:153, with permission.)

Diagnosis

Of the rare prepubertal lesions, 75% are associated with sexual pseudoprecocity because of the estrogen secretion (319). For women of reproductive age, most patients have menstrual irregularities or secondary amenorrhea, and cystic hyperplasia of the endometrium is frequently present. For postmenopausal women, abnormal uterine bleeding is frequently the initial symptom. Indeed, the estrogen secretion in these patients can be sufficient to stimulate the development of endometrial cancer. **Endometrial cancer occurs in association with granulosa cell tumors in at least 5% of cases, and 25% to 50% are associated with endometrial hyperplasia** (2,314,316,317,318 and 319).

The other symptoms and signs of granulosa cell tumors are nonspecific and the same as most ovarian malignancies. Ascites is present in about 10% of cases, and rarely a pleural effusion is present (316,317,318 and 319). Granulosa tumors tend to be hemorrhagic; occasionally, they rupture and produce a hemoperitoneum.

Granulosa cell tumors are usually stage I at diagnosis but may recur 5 to 30 years after initial diagnosis (318). The tumors may also spread hematogenously, and metastases can develop in the lungs, liver, and brain years after initial diagnosis. When granulosa cell tumors do recur, they can progress quite rapidly. Malignant thecomas are extremely rare, and their signs and symptoms, management, and outcome are similar to those of the granulosa cell tumors (316). **Inhibin is secreted by some granulosa cell tumors and is a useful marker for the disease** (320,321 and 322).

Treatment

The treatment of granulosa cell tumors depends on the age of the patient and the extent of disease. For most patients, surgery alone is sufficient primary therapy; radiation and chemotherapy are reserved for the treatment of recurrent or metastatic disease (319,320,321 and 322).

Surgery

Because granulosa cell tumors are bilateral in only about 2% of patients, a unilateral salpingo-oophorectomy is appropriate therapy for stage Ia tumors in children or in women of reproductive age (317). At the time of laparotomy, if a granulosa cell tumor is identified by frozen section, a staging operation is performed, including an assessment of the contralateral ovary. If the opposite ovary appears enlarged, it should be sampled for biopsy. For perimenopausal and postmenopausal women for whom ovarian preservation is not important, a hysterectomy and bilateral salpingo-oophorectomy should be performed. For premenopausal patients in whom the uterus is left *in situ*, an endometrial biopsy should be performed, because of the possibility of a coexistent adenocarcinoma of the endometrium (319).

Radiation Therapy

There is no evidence to support the use of adjuvant radiation therapy for granulosa cell tumors, although pelvic irradiation may help to palliate isolated pelvic recurrences (319).

Chemotherapy

There is no evidence that adjuvant chemotherapy will prevent recurrence of disease. Metastatic lesions and recurrences have been treated with a variety of antineoplastic drugs. The most effective chemotherapeutic regimen appears to be BEP. In a GOG study (323), 37% (14 of 30) patients treated with BEP had a negative second-look laparotomy, and completely responding patients had a median time to progression of 24.4 months. The use of hormonal agents such as progestins or antiestrogens has been suggested, but there are no data available to suggest effectiveness (317).

Prognosis

Granulosa cell tumors have a prolonged natural history and a tendency toward late relapse, reflecting their low-grade biology. As such, 10-year survival rates of about 90% have been reported, with 20-year survival rates dropping to 75% (317,318 and 319). Most histologic types have the same prognosis, but patients with the more poorly differentiated diffuse or sarcomatoid type tend to do worse (316).

The DNA ploidy of the tumors has recently been correlated with survival. Holland and colleagues (324) reported DNA aneuploidy in 13 of 37 patients (35%) with primary granulosa cell tumors. The presence of residual disease was found to be the most important predictor of progression-free survival, but DNA ploidy was an independent prognostic factor. **Patients with residual-negative DNA diploid tumors had a 10-year progression-free survival of 96%.**

Sertoli-Leydig Tumors

Sertoli-Leydig tumors occur most frequently in the third and fourth decades of life; 75% of the lesions are seen in women younger than 40 years. These lesions are extremely rare and account for less than 0.2% of ovarian cancers (2). Sertoli-Leydig cell tumors are most frequently low-grade malignancies, although occasionally a poorly differentiated variety may behave more aggressively.

The tumors typically produce androgens, and clinical virilization is noted in 70% to 85% of patients (325). Signs of virilization include oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, clitoromegaly, deepening of the voice, and a receding hairline. Measurement of plasma androgens may reveal elevated testosterone and androstenedione, with normal or slightly elevated dehydroepiandrosterone sulphate (2,325). Rarely, the Sertoli-Leydig tumor can be associated with manifestations of estrogenization (i.e., isosexual precocity, irregular or postmenopausal bleeding).

Treatment

Because these low-grade lesions are only rarely bilateral (<1%), the usual treatment is unilateral salpingo-oophorectomy and evaluation of the contralateral ovary for patients who are in their reproductive years (3,319). For older patients, hysterectomy and bilateral salpingo-oophorectomy are appropriate.

There are insufficient data to document the utility of radiation or chemotherapy for patients with persistent disease, but some responses in patients with measurable disease have been reported with pelvic irradiation and the VAC chemotherapy regimen (3,268).

Prognosis

The 5-year survival rate is 70% to 90%, and recurrences thereafter are uncommon (3,325). Most fatalities occur in the presence of poorly differentiated lesions.

Uncommon Ovarian Cancers

There are several varieties of malignant ovarian tumors that together constitute only 0.1% of ovarian malignancies (2). Two of these lesions are the lipid (or lipid) cell tumors and the primary ovarian sarcomas.

Lipoid Cell Tumors

Lipoid cell tumors are believed to arise in adrenal cortical rests that reside in the vicinity of the ovary. More than 100 cases have been reported, and bilateral disease has been noted in only a few (2). Most are associated with virilization and, occasionally, with obesity, hypertension, and glucose intolerance reflecting corticosteroid secretion. Rare cases of estrogen secretion and isosexual precocity have been reported.

Most of these tumors have benign or low-grade behavior, but about 20%, most of which are initially larger than 8 cm in diameter, are associated with metastatic lesions. Metastases are usually in the peritoneal cavity but rarely occur at distant sites. The primary treatment is surgical extirpation of the primary lesion. There are no data regarding the effectiveness of radiation or chemotherapy for this disease.

Sarcomas

Malignant mixed mesodermal sarcomas of the ovary are extremely rare; only about 100 cases have been reported. Most lesions are heterologous, and 80% occur in postmenopausal women. The signs and symptoms are similar to those of most ovarian malignancies. These lesions are biologically aggressive, and most patients have evidence of metastases.

There is no effective treatment for ovarian sarcomas, and most patients die within 2 years. *hape Doxorubicin*, with or without *hape cyclophosphamide*, has produced an occasional partial response, and *hape cisplatin* is currently undergoing clinical trials (326,327 and 328). For patients in whom all macroscopic disease can be resected, we have observed disease-free survival of more than 3 years in two patients treated with six cycles of *hape cisplatin* and *hape epirubicin*.

Small Cell Carcinomas

This rare tumor occurs at an average age of 24 years (range 2 to 46 years) (389). The tumors are all bilateral. Approximately two-thirds of the tumors are accompanied by paraendocrine hypercalcemia. This tumor accounts for one-half of all of the cases of hypercalcemia associated with ovarian tumors. About 50% of the tumors have spread beyond the ovaries when they are diagnosed (329).

The management of these malignancies consists of surgery followed by platinum-based chemotherapy or radiation therapy or both. In addition to the primary treatment of the disease, control of the hypercalcemia may require aggressive hydration, loop diuretics, and the use of bisphosphonates or *hape calcitonin*. The prognosis tends to be poor, with most patients dying within 2 years of diagnosis in spite of treatment.

Metastatic Tumors

About 5% to 6% of ovarian tumors are metastatic from other organs, most frequently from the female genital tract, the breast, or the gastrointestinal tract (330,331,332,333,334 and 335). The metastases may occur from direct extension of another pelvic neoplasm, by hematogenous spread, lymphatic spread, or transcoelomic dissemination, with surface implantation of tumors that spread in the peritoneal cavity.

Gynecologic

Nonovarian cancers of the genital tract can spread by direct extension or they may metastasize to the ovaries. Tubal carcinoma involves the ovaries secondarily in 13% of cases (2,3), usually by direct extension. Under some circumstances, it is difficult to know whether the tumor originated in the tube or in the ovary when both are involved. Cervical cancer spreads to the ovary only in rare cases (<1%), and most of these are of an advanced clinical stage or are adenocarcinomas. Although adenocarcinoma of the endometrium can spread and implant directly onto the surface of the ovaries in as many as 5% of cases, two synchronous primary tumors probably occur with greater frequency. In these cases, an endometrioid carcinoma of the ovary is usually associated with the adenocarcinoma of the endometrium.

Nongynecologic

The frequency of metastatic breast carcinoma to the ovaries varies according to the method of determination, but the phenomenon is common (Fig. 32.21). **In autopsy data of women who died of metastatic breast cancer, the ovaries were involved in 24% of cases, and 80% of the involvement was bilateral (330,331,332 and 333).** Similarly, when ovaries are removed to palliate advanced breast cancer, about 20% to 30% of the cases reveal ovarian involvement, 60% of those bilaterally. The involvement of ovaries in early-stage breast cancer seems to be considerably lower, but precise figures are not available. In almost all cases, either ovarian involvement is occult or a pelvic mass is discovered after other metastatic disease becomes apparent.

Figure 32.21 Metastatic carcinoma in the ovary. Note the “Indian file” pattern found in this metastatic breast carcinoma. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:157, with permission.)

Krukenberg Tumor

The Krukenberg tumor, which can account for 30% to 40% of metastatic cancers to the ovaries, arises in the ovarian stroma and has characteristic mucin-filled, signet-ring cells (334) (Fig. 32.22). The primary tumor is most frequently located in the stomach and less commonly in the colon, breast, or biliary tract. Rarely, the cervix or the bladder may be the primary site. Krukenberg tumors can account for about 2% of ovarian cancers at some institutions, and they are usually bilateral. The lesions are usually not discovered until the primary disease is advanced and, therefore, most patients die of their disease within 1 year. In some cases, a primary tumor is never found.

Figure 32.22 Krukenberg tumor of the ovary metastatic from a gastric carcinoma. Malignant cells have discrete vacuoles that push nuclei eccentrically, giving a signet-ring appearance. Mucicarmine stain demonstrates the cytoplasmic vacuoles to be mucin. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:158, with permission.)

Other Gastrointestinal Tumors

In other cases of metastasis from the gastrointestinal tract to the ovary, the tumor does not have the classic histologic appearance of a Krukenberg tumor; most of these are from the colon and, less commonly, the small intestine. As many as 1% to 2% of women with intestinal carcinomas will develop metastases to the ovaries during the course of their disease (332). Before exploration for an adnexal tumor in a woman older than 40 years, a barium enema is indicated to exclude a primary gastrointestinal carcinoma with metastases to the ovaries, particularly if there are any gastrointestinal symptoms. Metastatic colon cancer can mimic a mucinous cystadenocarcinoma of the ovary histologically (331,332).

Melanoma

Rare cases of malignant melanoma metastatic to the ovaries have been reported (335). In these circumstances, the melanomas are usually widely disseminated. Removal would be warranted for palliation of abdominal or pelvic pain, bleeding, or torsion.

Carcinoid Tumors

Metastatic carcinoid tumors represent fewer than 2% of metastatic lesions to the ovaries (336). Conversely, only about 2% of patients with primary carcinoids have evidence of ovarian metastasis, and only 40% of them have the carcinoid syndrome at the time of discovery of the metastatic carcinoid. However, in perimenopausal and postmenopausal women explored for an intestinal carcinoid, it is reasonable to remove the ovaries to prevent subsequent ovarian metastasis. Furthermore, the discovery of an ovarian carcinoid should prompt a careful search for a primary intestinal lesion.

Lymphoma and Leukemia

Lymphomas and leukemia can involve the ovary. When they do, the involvement is usually bilateral (337,338). About 5% of patients with Hodgkin's disease will have lymphomatous involvement of the ovaries, but this involvement occurs typically with advanced-stage disease. **With Burkitt's lymphoma, ovarian involvement is very common. Other types of lymphoma involve the ovaries much less frequently, and leukemic infiltration of the ovaries is uncommon.** Sometimes the ovaries can be the only apparent site of involvement of the abdominal or pelvic viscera with a lymphoma; if this circumstance is found, a careful surgical exploration may be necessary. Intraoperatively, a hematologist-oncologist should be consulted to determine the need for these procedures if frozen section of a solid ovarian mass reveals a lymphoma. In general, most lymphomas no longer require extensive surgical staging, although biopsy of enlarged lymph nodes should generally be performed. In some cases of Hodgkin's disease, a more extensive evaluation may be necessary. Treatment involves that of the lymphoma or leukemia in general. Removal of a large ovarian mass may improve patient comfort and facilitate a response to subsequent radiation or chemotherapy.

Fallopian Tube Cancer

Carcinoma of the fallopian tube accounts for 0.3% of all cancers of the female genital tract (2,3,339,340,341,342 and 343). In histologic features and behavior, fallopian tube carcinoma is similar to ovarian cancer; thus, the evaluation and treatment are also essentially the same (Fig. 32.23). The fallopian tubes are frequently involved secondarily from other primary sites, most often the ovaries, endometrium, gastrointestinal tract, or breast. They may also be involved in primary peritoneal carcinomatosis. Almost all cancers are of epithelial origin, most frequently of serous histology. Rarely, sarcomas have also been reported.

Figure 32.23 Carcinoma of the fallopian tube. This is the mixed papillary and the papillary-alveolar pattern. (From **Berek JS, Hacker NF. Practical gynecologic oncology**, 2nd ed. Baltimore: Williams & Wilkins, 1994:159, with permission.)

Clinical Features

Tubal cancers are seen most frequently in the fifth and sixth decades, with a mean age of 55 to 60 years ([339](#)). There are no known predisposing factors.

Symptoms and Signs

The classic triad of symptoms and signs associated with fallopian tube cancer is (a) a prominent watery vaginal discharge (i.e., hydrops tubae profluens), (b) pelvic pain, and (c) a pelvic mass. However, this triad is noted in fewer than 15% of patients ([3](#)).

Vaginal discharge or bleeding is the most common symptom reported by patients with tubal carcinoma and is documented in more than 50% of patients ([3,340](#)). Lower abdominal or pelvic pressure and pain also are noted in many patients. However, the symptoms may be rather vague and nonspecific. For perimenopausal and postmenopausal women with unusual, unexplained, or persistent vaginal discharge, even in the absence of bleeding, the clinician should be concerned about the possibility of occult tubal cancer. Fallopian tube cancer is often found incidentally in asymptomatic women at the time of abdominal hysterectomy and bilateral salpingo-oophorectomy.

On examination, a pelvic mass is present in about 60% of patients, and ascites may be present if advanced disease exists. For patients with tubal carcinoma, the results of dilation and curettage will be negative ([342](#)), although abnormal or adenocarcinomatous cells may be seen in cytologic specimens obtained from the cervix in 10% of patients.

Spread Pattern

Tubal cancers spread in much the same manner as epithelial ovarian malignancies, principally by the transcoelomic exfoliation of cells that implant throughout the peritoneal cavity. In about 80% of the patients with advanced disease, metastases are confined to the peritoneal cavity at the time of diagnosis ([341](#)).

The fallopian tube is richly permeated with lymphatic channels, and spread to the paraaortic and pelvic lymph nodes is common. Metastases to the paraaortic lymph nodes have been documented in at least 33% of the patients with all stages of disease ([343](#)).

Staging

Fallopian tube cancer is staged according to FIGO ([339](#)). The staging is based on the surgical findings at laparotomy ([Table 32.9](#)). According to this system, about 20% to 25% of patients have stage I disease, 20% to 25% have stage II disease, 40% to 50% have stage III disease, and 5% to 10% have stage IV disease ([339](#)). A somewhat lower incidence of advanced disease is seen in these patients than in patients with epithelial ovarian carcinomas, presumably because of the earlier occurrence of symptoms, particularly vaginal bleeding or unusual vaginal discharge.

Stage	Description
Stage 0	Carcinoma in situ (confined to tubal mucosa)
Stage I	Carcinoma is limited to the fallopian tube
Stage Ia	Carcinoma is limited to one fallopian tube without extension into the abdominal cavity
Stage Ib	Carcinoma is limited to both fallopian tubes without extension into the abdominal cavity
Stage Ic	Carcinoma is limited to both fallopian tubes with extension into the abdominal cavity
Stage II	Carcinoma involving one or both fallopian tubes with pelvic extension
Stage IIA	Extension within the pelvis to the uterus, ovaries, or bladder
Stage IIB	Extension to other pelvic organs
Stage III	Tumor of any stage that has spread to the peritoneum through or over the fallopian tube
Stage IIIa	Extension of tumor to the peritoneum, but not to the greater omentum, liver, or spleen
Stage IIIb	Extension of tumor to the greater omentum, liver, or spleen
Stage IIIc	Extension of tumor to the greater omentum, liver, or spleen and to the peritoneum
Stage IV	Tumor is grossly found to have spread to distant sites
Stage IVa	Extension to distant sites within the abdominal cavity
Stage IVb	Extension to distant sites outside the abdominal cavity
Stage IVc	Extension to distant sites outside the abdominal cavity with ascites

Table 32.9. Modified FIGO Staging of Fallopian Tube Cancer (Based on Operative Findings Before Debulking and Pathologic Findings)

Treatment

The treatment of this disease is the same as that of epithelial ovarian cancer ([339,342,344](#)). Exploratory laparotomy is necessary to remove the primary tumor, to stage the disease, and to resect metastases. After surgery, the most frequently employed treatment is combination chemotherapy, although radiation therapy is also used in selected cases.

Surgery

Patients with tubal carcinoma should undergo total abdominal hysterectomy and bilateral salpingo-oophorectomy ([3](#)). If there is no evidence of gross tumor spread, a staging operation is performed. The retroperitoneal lymph nodes should be adequately evaluated, and peritoneal cytologic studies and biopsies should be performed, along with an infracolic omentectomy.

In patients with metastatic disease, an effort should be made to remove as much tumor bulk as possible. The role of cytoreductive surgery in this disease is unclear, but extrapolation from the experience with epithelial ovarian cancer indicates that significant benefit might be expected, particularly if all macroscopic disease can be resected.

Chemotherapy

The most active combination chemotherapy for epithelial ovarian cancer is *hype carboplatin* and *hype paclitaxel*, and it is appropriate, therefore, to use the same chemotherapy for patients with epithelial tubal malignancies ([3](#)).

Data on well-staged lesions are scarce. Therefore, it is unclear whether patients with disease confined to the fallopian tube (i.e., a stage Ia, grade 1 or 2 carcinoma), benefit from additional therapy.

Radiation Therapy

Although most patients with tubal cancers have been treated with radiation therapy in the past, its role in the management of the disease remains unclear, because patients have not been treated in any consistent manner and the small numbers treated preclude any meaningful conclusions (342). Pelvic irradiation alone was once popular, but this approach seems inappropriate when the pattern of spread of this disease to the upper abdomen is considered (340). Whole-abdominal irradiation with a pelvic boost has been used in patients with no evidence of gross disease in the abdomen (i.e., completely resected disease or microscopic metastases only) (3,339).

Prognosis

The overall 5-year survival for patients with epithelial tubal carcinomas is about 40%. This number is higher than for patients with ovarian cancer and reflects the somewhat higher proportion of patients diagnosed with early-stage disease. The outlook is clearly related to the stage of disease, but the available data relate to patients who have not been surgically staged. Thus, the reported 5-year survival rate for patients with stage I disease is only about 65%. The 5-year survival rate for patients with stage II disease is 50% to 60%, but it is only 10% to 20% for patients with stages III and IV disease (339).

Tubal Sarcomas

Tubal sarcomas, particularly malignant mixed mesodermal tumors, have been described but are rare. They occur mainly in the sixth decade and are typically advanced at the time of diagnosis. If all gross disease can be resected, platinum-based combination chemotherapy should be tried. However, survival is generally poor, and most patients die of their disease within 2 years (2,326).

References

With 3,800 new cases and 800 deaths annually in the United States (1), vulvar cancer is uncommon, representing 3% to 5% of malignancies of the female genital tract. Squamous cell carcinomas account for about 90% of all primary vulvar malignancies, whereas melanomas, adenocarcinomas, basal cell carcinomas, and sarcomas are much less common. **The incidence of *in situ* vulvar cancer nearly doubled between the mid-1970s and the mid-1980s, whereas the overall rate of invasive squamous cell carcinoma has remained relatively stable** (2). However, in women younger than 50 years there has been a striking increase in the incidence of not only *in situ* but also invasive squamous cell carcinoma of the vulva (3).

Following the reports of Taussig (4) in the United States and Way (5) in Great Britain, radical vulvectomy and *en bloc* groin dissection, with or without pelvic lymphadenectomy, has been considered standard treatment for all patients who have operable disease. Postoperative morbidity was high and prolonged hospitalization common. During the past 20 years, a number of significant advances have been made in the management of vulvar cancer. The following changes have markedly decreased the physical and psychological morbidity associated with the treatment:

1. Individualization of treatment for all patients with invasive disease (6,7)
2. Vulvar conservation for patients with unifocal tumors and an otherwise normal vulva (6,7,8,9 and 10)
3. Omission of the groin dissection for patients with T₁ tumors and <1mm of stromal invasion (6,7)
4. Elimination of routine pelvic lymphadenectomy (11,12,13,14 and 15)
5. The use of separate incisions for the groin dissection to improve wound healing (16,17)
6. Omission of the contralateral groin dissection in patients with lateral T₁ lesions and negative ipsilateral nodes (7,18)
7. The use of preoperative radiation therapy to obviate the need for exenteration in patients with advanced disease (19,20)
8. The use of postoperative radiation therapy to decrease the incidence of groin recurrence in patients with multiple positive groin nodes (15).

Etiology

The etiology of vulvar cancer has been only partially elucidated and is likely to be multifactorial. Based on histopathologic and environmental factors, there appear to be at least two distinct etiologic entities of squamous cell carcinoma of the vulva.

1. *Basaloid or warty types*, which tend to be multifocal, occur generally in younger patients and are related to human papillomavirus (HPV) infection, vulvar intraepithelial neoplasia (VIN), and cigarette smoking.
2. *Keratinizing types*, which tend to be unifocal, occur predominantly in older patients, are not related to HPV, and often are found in areas adjacent to lichen sclerosus and squamous hyperplasia.

High-grade vulvar intraepithelial neoplasia (VIN 3) has been most closely studied as a potential precancerous lesion. The direct progression of VIN to cancer is difficult to document, but 10% to 20% of vulvar carcinoma *in situ* lesions harbor an occult invasive component (21,22), and VIN is found adjacent to basaloid or warty vulvar squamous cell carcinomas in more than 80% of cases. DNA of HPV has been documented in 89% of patients with VIN 3 and in up to 86% of warty or basaloid type carcinomas of the vulva, but it occurs in less than 10% of the keratinizing type of carcinomas of the vulva (23). Epidemiologic risk factors for the basaloid or warty type squamous cell carcinoma of the vulva are similar to those for cervical cancer and include a history of multiple lower genital tract neoplasias, immunosuppression, and smoking (23,24). Frequently implied as an etiologic variable for the keratinizing carcinoma is the itch–scratch cycle associated with lichen sclerosus and squamous hyperplasia, with atypical changes occurring in the repaired epithelium. In keratinizing carcinoma, associated lichen sclerosus or squamous hyperplasia is found in more than 80% of patients (25,26), yet their causative role remains controversial. Supportive evidence that some of these lesions could be precancerous comes from molecular studies that demonstrate aneuploid DNA content, *p53* overexpression, and monoclonal expansion of keratinocytes in lichen sclerosus and associated squamous hyperplasia (27,28). In the past, some studies have reported vulvar cancer to be more common in patients who are obese, have hypertension and diabetes mellitus, or are nulliparous (29,30), but a recent case-control study of vulvar cancer was unable to confirm any of these as risk factors (24).

Types of Invasive Vulvar Cancer

The varieties of invasive vulvar cancer are shown in [Table 33.1](#).

Type	Percent
Squamous	92
Melanoma	2-4
Basal cell	2-3
Bartholin gland	1
(adenocarcinoma, squamous cell, transitional cell, adenoid cystic)	
Metastatic	1
Verrucous	<1
Sarcoma	<1
Appendage (e.g., hidradenocarcinoma)	Rare

Table 33.1. Types of Vulvar Cancer

Squamous Cell Carcinoma

Approximately 90% to 92% of all invasive vulvar cancers are of the squamous cell type. As discussed previously, squamous carcinomas of the vulva can be divided into distinct histologic subtypes designated as *basaloid carcinoma*, *warty carcinoma*, and *keratinizing squamous carcinoma* (25). Mitoses are noted in these malignancies, but atypical keratinization is the histologic hallmark of invasive vulvar cancer (31). Most vulvar squamous carcinomas reveal keratinization (Fig. 33.1). Histologic features that correlate with the occurrence of inguinal lymph node metastasis are lymph–vascular space invasion, tumor thickness, depth of stromal invasion, histologic pattern of invasion (spray and stellate versus broad and pushing), and increased amount of keratin (32,33,34 and 35).

Figure 33.1 Squamous cell carcinoma of the vulva, keratinizing type. The multiple pearl formations consist of laminated keratin. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Microinvasive Squamous Carcinoma

Microinvasive carcinoma of the vulva has been defined as a lesion >2 cm in diameter with <1 mm stromal invasion (36). Depth of stromal invasion is measured vertically from the epithelial–stromal junction (basement membrane) of the most superficial dermal papilla to the deepest point of tumor invasion (Fig. 33.2). **When the tumor invades <1 mm, metastasis to the inguinal lymph nodes is extremely rare among reported series. However, when invasion is >1 mm, there is a significant risk of inguinal lymph node metastasis.**

Figure 33.2 Early invasive carcinoma of vulva originating from vulvar intraepithelial neoplasia. Multiple irregular nests of malignant cells extend from the base of rete pegs. Desmoplastic stromal reaction and chronic inflammation are useful diagnostic signs of stromal invasion. The depth of stromal invasion is measured from the base of the most superficial dermal papilla vertically to the deepest tumor cells. In this tumor, it is 3.6 mm in depth. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Clinical Features

Squamous cell carcinoma of the vulva is predominantly a disease of postmenopausal women; the mean age at diagnosis is about 65 years. However, 15% of patients who develop vulvar cancer do so before age 40. There may be a long-standing history of an associated vulvar intraepithelial disorder, such as lichen sclerosus, squamous hyperplasia, or VIN. Up to 27% of patients with vulvar cancer are reported to have a second primary malignancy, most commonly cervical cancer, followed by cancer of the breast, extragenital skin, and gastrointestinal tract (37,38 and 39).

Most patients are asymptomatic at the time of diagnosis. If symptoms exist, vulvar pruritus, a lump, or a mass are the most common findings. Less frequent symptoms include a bleeding or ulcerative lesion, discharge, pain, or dysuria. Occasionally, a large metastatic mass in the groin may be the initial complaint.

A careful inspection of the vulva should be part of every gynecologic examination. On physical examination, vulvar carcinoma is usually raised and may be fleshy, ulcerated, leukoplakic, or warty in appearance. It may be pigmented, red or white, tender or painless. The lesion may be clinically indistinct, especially in the presence of VIN or vulvar dystrophies (22,40). Thus, any lesion of the vulva warrants a biopsy.

Most squamous carcinomas of the vulva occur on the labia majora and minora (60%), but the clitoris (15%) and perineum (10%) also may be primary sites. Approximately 10% of the cases are too extensive to determine a site of origin, and about 5% of the cases are multifocal.

As part of the clinical evaluation, a careful assessment of the extent of the lesion, including whether it's unifocal or multifocal, should be performed. The groin lymph nodes should be evaluated carefully, and a complete pelvic examination should be performed. A cytologic sample should be taken from the cervix for Papanicolaou testing, and colposcopy of the cervix and vagina should be performed because of the common association with other squamous intraepithelial or invasive neoplasms of the lower genital tract.

Diagnosis

Diagnosis requires a wedge biopsy specimen, which usually can be obtained in the office using local anesthesia. If the lesion is only about 1 cm in diameter, excisional biopsy is preferable.

Physician delay is a common problem in the diagnosis of vulvar cancer, particularly if the lesion has a warty appearance. Any confluent warty lesion requires biopsy before medical or ablative therapy is initiated.

Routes of Spread

FIGO Stage	FIGO Classification	Clinical/Pathologic Challenge
0	T0	Carcinoma in situ, intraepithelial carcinoma
I	T1, N0, M0	Tumor confined to vulva and/or perineum, <1 cm in greatest dimension, nodes are negative
II	T2, N0, M0	Stromal invasion <1 mm
III	T3, N0, M0	Stromal invasion >1 mm
IV	T4, N0, M0	Tumor confined to vulva and/or perineum, >1 cm in greatest dimension, nodes are negative
IVa	T4, N0, M0	Tumor of any size with 1. Extension beyond the lower anal sphincter, or other or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVb	T4, N1, M0	Tumor of any size with 1. Extension beyond the lower anal sphincter, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVc	T4, N2, M0	Extension beyond the urethra, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVd	T4, N3, M0	Extension beyond the urethra, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVe	T4, N4, M0	Extension beyond the urethra, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVf	T4, N5, M0	Extension beyond the urethra, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVg	T4, N6, M0	Extension beyond the urethra, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVh	T4, N7, M0	Extension beyond the urethra, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVi	T4, N8, M0	Extension beyond the urethra, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVj	T4, N9, M0	Extension beyond the urethra, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina
IVk	T4, N10, M0	Extension beyond the urethra, bladder, rectum, or vagina, and/or 2. Extension beyond the urethra, bladder, rectum, or vagina

Table 33.4. FIGO Surgical Staging for Vulvar Cancer (36)

Prognosis and Survival

Survival of patients with vulvar cancer correlates with FIGO stage. The prognosis for patients with early-stage disease is generally very good (Table 33.5). **The single most important prognostic factor is lymph node status, followed by lesion size (57).** Histologic grade, tumor thickness, depth of stromal invasion, and lymph–vascular space involvement contribute to the risk of lymph node involvement but are not independent predictors of survival (58). Patients with negative lymph nodes have a 5-year survival rate greater than 90%, compared with about 50% for patients with positive lymph nodes (57). The number of positive inguinal-femoral lymph nodes is an important prognostic factor. Patients with only one microscopically involved node have a prognosis comparable to those with negative lymph nodes (10,12), whereas the 2-year survival rate is 20% for patients with three or more metastatic lymph nodes (12). In a Gynecologic Oncology Group (GOG) study, patients with N₀ or N₁ nodes had a 2-year survival rate of 78%, compared with 52% for patients with N₂ nodes and 33% for patients with N₃ nodes (15). The survival rate for patients with positive pelvic nodes is about 11% (59). Tumor ploidy is another important prognostic factor. Data from the Norwegian Radium Hospital (60) demonstrate a 5-year crude survival rate of 62% for diploid and 23% for the aneuploid tumors (*p* < 0.001). In a multivariate Cox regression analysis, tumor ploidy was the second most important prognostic factor after lymph node status.

FIGO Stage	No. of Patients	Corrected 5-Year Survival (%)
I	148 (26%)	98%
II	191 (33%)	85%
III	176 (31%)	74%
IV	62 (11%)	31%
All stages	577	79%

Table 33.5. Five-year Survival for Patients with Vulvar Carcinoma (57)

Treatment

After the pioneering work of Taussig (4) in the United States and Way (5) in Great Britain, *en bloc* radical vulvectomy and bilateral dissection of the groin and pelvic nodes became the standard treatment for most patients with operable vulvar cancer. If the disease involved the anus, rectovaginal septum, or proximal urethra, some type of pelvic exenteration was combined with the dissection.

Although the survival rate improved markedly with this aggressive surgical approach, several factors have led to modifications of this treatment plan during the past 20 years. These factors are summarized as follows:

1. An increasing proportion of patients with early-stage disease—up to 50% of patients in many centers—have T₁ tumors.
2. There were concerns about the postoperative morbidity and associated long-term hospitalization common with the *en bloc* radical dissection.
3. Increasing awareness has emerged of the psychosexual consequences of radical vulvectomy.

In order to individualize the patient's care and determine the appropriate therapy, it is necessary to determine independently the primary lesion as well as groin lymph nodes.

Before initiation of therapy, all patients should undergo colposcopy of the cervix, vagina, and vulva. Preinvasive (and rarely invasive) lesions may be present at other sites along the lower genital tract.

Management of the Primary Lesion

Early Vulvar Cancer (T₁) The modern approach to the management of patients with T₁ carcinoma of the vulva should be individualized (6,7). There is no standard approach applicable to every patient, and emphasis is on performing the most conservative operation that is consistent with cure of the disease.

Radical vulvectomy has been considered the standard treatment for primary vulvar lesions, but this operation is associated with significant surgical morbidity and disturbances of sexual function and body image. Psychosexual sequelae are a major long-term morbidity associated with the treatment of vulvar cancer (8). One study reported that sexual arousal was reduced to the eighth percentile and body image was reduced to the fourth percentile for women who had undergone vulvectomy when compared with healthy adult women (61).

Traditionally, there has been concern that, without an *en bloc* resection, intervening tissue left between the primary tumor and the regional lymph nodes may contain microscopic tumor foci in draining lymphatics. However, experience with a separate incision technique for node dissection has confirmed that metastases rarely occur in the skin bridge in patients without clinically suspicious nodes in the groin (17).

During the past 20 years, several investigators have advocated a radical local excision rather than a radical vulvectomy for the primary lesion for patients with T₁ tumors (6,7,8 and 9). Regardless of whether a radical vulvectomy or a radical local excision is performed, the surgical margins adjacent to the tumor will be the same. An analysis of the available literature indicates that the incidence of local invasive recurrence after radical local excision is not higher than that after radical vulvectomy (9,41,59,62). This finding suggests that in the presence of an otherwise normal-appearing vulva, radical local excision is a safe surgical option, regardless of the depth of invasion. A recent review of 135 patients with all stages of disease assessed the surgical margin that must be obtained to prevent local disease recurrence. In this study, a 1-cm tumor-free surgical margin on the vulvar specimen (0.8-cm on pathologic specimen) resulted in a very high rate of local control (63). Neither clinical tumor size nor the presence of coexisting benign vulvar pathology correlated with local recurrence. It is important to bear in mind that paraffin-embedded tissue shrinks by about 25%. Thus, at the time of radical local excision, at least a 1- to 1.5-cm grossly negative margin, which should extend down to the level of the inferior fascia of the urogenital diaphragm, should be obtained.

When vulvar cancer arises in the presence of VIN or some nonneoplastic epithelial disorder, treatment will be influenced by the patient's age. Elderly patients who often have had many years of chronic itching may not be disturbed by the prospect of a vulvectomy. In younger women, it will be desirable to conserve as much of the

vulva as possible. Thus, radical local excision should be performed for the invasive disease, and the associated intraepithelial disease should be treated in the manner most appropriate to the patient. For example, topical steroids may be required for lichen sclerosus or squamous hyperplasia, whereas VIN may require superficial local excision and primary closure.

Radical local excision is most appropriate for lesions on the lateral or posterior aspects of the vulva (Fig. 33.4). Midline lesions pose special challenges due to their proximity to clitoris, urethra, or anus. For anterior lesions that involve the clitoris or that are in proximity to it, any type of surgical excision will have psychosexual consequences. In addition, marked edema of the posterior vulva may occur. For young patients with periclitoral lesions, the primary lesion can be treated with a small field of radiation therapy, possibly with concomitant sensitizing chemotherapy. Small vulvar lesions should respond very well to about 5,000 cGy external radiation, and biopsy can be performed after therapy to confirm the absence of any residual disease (64).

Figure 33.4 Small (T₁) vulvar carcinoma at the posterior fourchette. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins 2000, pg. 565, with permission.)

T₂ and T₃ Vulvar Cancer

In recent years, the indications for vulvar conservation have been extended by some surgeons to selected patients with T₂ and early T₃ tumors. Although the reported experience is limited (9,10,65), a recent study suggests that the local recurrence rate for patients with conservatively treated T₂ tumors is identical to that for patients with T₁ tumors (66) as long as surgical margins of at least 1 cm are obtained. The tumor-free margin should be the same, whether or not a radical vulvectomy or a radical local excision is performed, so it would seem to be both feasible and desirable to extend the indications for vulvar conservation, particularly for younger patients. **Tumors that are most suitable to a more conservative resection are those involving the posterior half of the vulva, where preservation of the clitoris and mons pubis is feasible.**

For patients with more advanced T₂ and T₃ lesions, management consists of radical vulvectomy and bilateral inguinal-femoral lymphadenectomy. If the disease involves the distal urethra, vagina, or anus, partial resection of these organs will be required. Alternatively, it may be preferable to give preoperative radiation therapy to allow for a less radical resection (see below).

Closure of Large Defects

After radical local excision, primary closure without tension often can be accomplished for smaller defects. However, if a more extensive dissection has been required to treat a large primary lesion, a number of options are available to repair the defect.

1. An area may be left open to granulate, which it will usually do over a period of 6 to 8 weeks (67).
2. Full-thickness skin flaps may be devised (68,69,70 and 71). The rhomboid flap is best suited to covering large defects of the posterior vulva (71), whereas for lateral defects, a mons pubis pedicle flap has been advocated (68).
3. Myocutaneous flaps may be developed to cover the defect. Unilateral or bilateral gracilis myocutaneous grafts are most useful when an extensive area from the mons pubis to the perianal area has been resected. Because the graft brings a new blood supply to the area, it is particularly applicable if the vulva is poorly vascularized from prior surgical resection or radiation (72).
4. If extensive defects exist in the groin and vulva, the tensor fascia lata myocutaneous graft may be the most applicable (73).

Advanced Disease—Large T₃ and T₄ Primary Tumors

To achieve primary surgical clearance for tumors involving the upper urethra, anus, rectum, or rectovaginal septum, pelvic exenteration is needed in addition to radical vulvectomy and inguinal-femoral lymphadenectomy, which carries an extremely high physical and psychological morbidity (61,74). Reported 5-year survival rates are about 50% (75,76,77 and 78). For many of these patients, a combined approach of surgery and radiation therapy offers improved survival and reduced morbidity. Numerous small prospective and retrospective series report on the use of external beam radiation, often with concomitant chemotherapy to shrink the primary tumor. Reported initial response rates to chemoradiation approximate 90% (79,80 and 81). It is important that this chemoradiation is followed by a more limited resection of the tumor bed and lymphadenectomy on an individualized basis. About one-half of the specimens will contain residual tumor (20,82), and local relapse rates are as high as 50% to 79% with external radiation alone (with or without concomitant chemotherapy) (83,84), emphasizing the need for a combined approach that involves radiation and surgery.

As experience with this combination therapy has evolved, it appears that external beam therapy is generally appropriate for most cases, with more selective use of brachytherapy. The extensiveness of the surgery has also been significantly modified. A more limited vulvar resection is now advocated, and bulky N₂ and N₃ nodes are resected without full groin dissection to avoid the leg edema associated with groin dissection and radiation. With this combined radiation-surgical approach, 5-year survival rates as high as 76% have been reported (82). With the experience now accrued, preoperative radiation, with or without concurrent chemotherapy, should be regarded as the treatment of first choice for patients with advanced vulvar cancer who would otherwise require some type of pelvic exenteration.

Management of the Lymph Nodes

Groin dissection is associated with postoperative wound infection and breakdown, as well as chronic leg edema. Although the incidence of wound breakdown is reduced significantly when separate incisions are used for the groin dissection (Fig. 33.5) (17), chronic leg edema remains a major problem. When assessing a patient for groin dissection, the following three facts should be kept in mind:

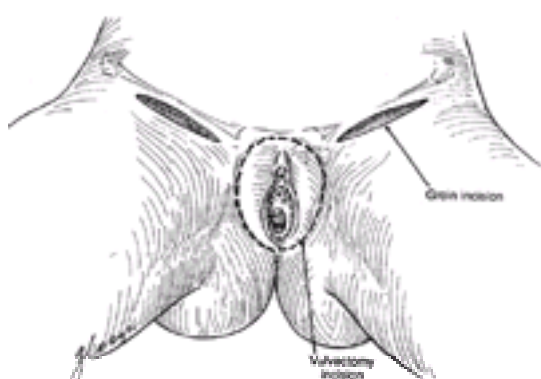

Figure 33.5 Skin incision for groin dissection through a separate incision. A line is drawn 1 cm below and parallel to the groin crease, and a narrow ellipse of

skin is removed. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

1. The only patients with virtually no risk of lymph node metastases are those whose tumor invades the stroma to <1 mm.
2. Patients who develop recurrent disease in an undissected groin have a >90% mortality ([88](#)).
3. Based on the laterality of the vulvar lesions, an ipsilateral or bilateral lymphadenectomy becomes necessary.

Appropriate groin dissection is the single most important factor in decreasing the mortality for early vulvar cancer.

Microinvasive Carcinoma All patients whose tumors demonstrate more than 1 mm of stromal invasion require inguinal-femoral lymphadenectomy. A wedge biopsy specimen of the primary tumor should be obtained, and the depth of invasion should be determined. If it is smaller than 1 mm on the wedge biopsy specimen, the entire lesion should be locally excised and analyzed histologically to determine the depth of invasion. If there is still no invasive focus larger than 1 mm, groin dissection may be omitted provided there is no lymph–vascular space invasion and there are no clinically suspicious groin lymph nodes. Although an occasional patient with less than 1 mm of stromal invasion has had documented groin node metastases ([89](#)), the incidence is so low that it is of no practical significance.

Inguinal-femoral Lymphadenectomy If groin dissection is indicated in patients with early vulvar cancer, it should be a thorough inguinal-femoral lymphadenectomy. The GOG recently reported six groin recurrences among 121 patients with T₁ N₀ tumors after a superficial (inguinal) dissection, even though the removed inguinal nodes were negative ([45](#)). Whether all of these recurrences were in the femoral nodes is unclear, but this large multicenter study does indicate that an incomplete groin dissection will increase the number of groin recurrences and, therefore, mortality. Comparable failure rates have been reported by Burke and colleagues ([9](#)). Furthermore, GOG data indicate that radiation therapy cannot substitute for groin dissection followed by selective radiation as indicated, even in patients with clinically nonsuspicious lymph nodes ([90](#)). This GOG study was closed early because a significantly higher incidence of recurrences occurred in women who were receiving groin radiation therapy only (19% versus 0%). The dose of radiation was 5,000 cGy given in daily 200-cGy fractions to a depth of 3 cm below the anterior skin surface. Although the radiation regimen prescribed has been criticized extensively, the therapeutic effects of an alternative radiation regimen remain to be determined.

Unilateral Versus Bilateral Groin Dissection It is clear that it is not necessary to perform a bilateral groin dissection if the primary lesion is unilateral and the ipsilateral lymph nodes are negative. In a patient with unilateral T₁ lesion and negative ipsilateral groin nodes, the risk of contralateral lymph node metastasis is 0.4% ([41](#)). However, there is an increase in the risk of contralateral nodal involvement proportional to the number of positive ipsilateral inguinal nodes ([15](#)). Thus, it is recommended that patients with any bulky or multiple microscopically positive ipsilateral groin lymph nodes undergo contralateral inguinal-femoral lymphadenectomy as well. Bilateral inguinal-femoral lymphadenectomy should be performed for midline lesions (clitoris, anterior labia minora, posterior fourchette) or those within 2 cm of the midline, because of the more frequent contralateral lymph flow from these regions ([91](#)).

Management of Pelvic Lymph Nodes In the past, pelvic lymphadenectomy has been considered part of the routine surgery for invasive vulvar cancer. However, the incidence of pelvic lymph node metastasis is rare in the absence of groin node involvement ([Table 33.2](#)), thus a more selective approach is preferred. Patients most prone to pelvic lymph node metastasis are those with clinically suspicious or three or more pathologically positive groin nodes ([11,12,14,38](#)). In these patients, the pelvis requires treatment by pelvic lymphadenectomy or radiation. If a preoperative pelvic imaging study reveals enlarged pelvic lymph nodes, resection of these nodes should be performed via an extraperitoneal approach because of the inability of external beam radiation therapy to sterilize bulky positive pelvic nodes.

Sentinel Lymph Node Studies A number of investigators have explored the use of intraoperative lymphatic mapping using lymphoscintigraphy or blue dye to identify a sentinel node that would predict the presence or absence of regional nodal metastases ([46,92,93](#) and [94](#)). Small preliminary studies suggest that a sentinel node can be identified in most patients. Reliable identification of the sentinel node and foregoing a full node dissection in patients with clinically nonsuspicious groin lymph nodes and a negative sentinel node may significantly reduce the number of patients who undergo unnecessary, extensive lymphadenectomy in the absence of disease. However, until the accuracy of the negative predictive value of an uninvolved sentinel node is documented in well-designed and sufficiently powered clinical trials, complete inguinal-femoral lymphadenectomy remains indicated in all but stage Ia disease, given the high mortality of recurrence in an undissected groin.

Postoperative Management

Despite the age and general medical condition of many elderly patients with vulvar cancer, surgery is usually remarkably well tolerated. Patients should be able to commence eating a low-residue diet on the first postoperative day. In the past, bedrest had been advised for 3 to 5 days postoperatively to allow for immobilization of the wounds and foster healing. Because radical local excisions are being performed with increasing frequency and groin dissections are done through separate incisions, patients generally begin ambulation on postoperative day 1 or 2. Pneumatic calf compression or subcutaneous heparin should be given to help prevent deep venous thrombosis, and active leg movements are to be encouraged. Frequent dressing changes are performed to keep the vulvar wound dry. Meticulous perineal hygiene is maintained. Suction drainage of each side of the groin is continued until output is minimal to help decrease the incidence of groin seromas. It is not uncommon for suction drainage to continue for 10 or more days. The Foley catheter is removed once the patient is ambulatory. If there is significant periurethral swelling, prolonged bladder drainage may be advisable. If there is breakdown of the vulvar wound, sitz baths or whirlpool therapy is helpful, followed by drying of the perineum with a hair dryer.

Early Postoperative Complications

The major immediate morbidity is related to groin wound infection, necrosis, and breakdown. This complication has been reported in as many as 53% to 85% of patients having an *en bloc* operation ([37,38](#)). With the separate-incision approach, the incidence of wound breakdown can be reduced to about 44%; major breakdown occurs in about 14% of patients ([17,39,95](#)). With appropriate antibiotics, debridement, and wound dressings, the area will granulate and reepithelialize over the next several weeks and may be managed with home nursing. Whirlpool therapy is effective for areas of extensive breakdown.

Other early postoperative complications include urinary tract infection, seromas in the femoral triangle, deep venous thrombosis, pulmonary embolism, myocardial infarction, hemorrhage and, rarely, osteitis pubis. Lymphocysts or groin seromas occur in about 10% to 15% of cases and should be managed by periodic sterile aspiration. Anesthesia of the anterior thigh resulting from femoral nerve injury is common and usually resolves slowly.

Late Complications

One major late complication is chronic lymphedema, which occurs on average in about 30% of patients ([37,38](#) and [39,95,96](#)). Recurrent lymphangitis or cellulitis of the leg develops in about 10% of patients and usually responds to oral antibiotics. Urinary stress incontinence, with or without genital prolapse, occurs in about 10% of patients after radical vulvectomy and may require corrective surgery. Introital stenosis can lead to dyspareunia and may require a vertical relaxing incision, which is sutured transversely. An uncommon late complication is femoral hernia, which usually can be prevented intraoperatively by closure of the femoral canal with a suture from the inguinal ligament to Cooper's ligament. Pubic osteomyelitis and rectovaginal or rectoperineal fistulas are rare late complications.

Other major long-term treatment complications associated with the extent of vulvar surgery include depression, altered body image, and sexual dysfunction ([61,74](#)). Modifications in the radical extent of the surgical approach and appropriate preoperative and postoperative counseling may help lessen some of the psychological trauma.

Role of Radiation Therapy

Radiation therapy traditionally has been considered to have a limited role in the management of patients with vulvar cancer. In the orthovoltage era, local tissue tolerance was poor and vulvar necrosis was common, but with megavoltage therapy, tolerance has improved significantly. Thus, radiation therapy, with or without concurrent chemotherapy, is likely to have an increasingly important role in the management of patients with vulvar cancer. It is important to remember, though, that with a rare exception, radiation therapy alone has little place in the primary management of vulvar cancer. It is generally indicated in conjunction with surgery.

The indications for radiation therapy for patients with primary vulvar cancer are still evolving. At present, radiation seems to be clearly indicated in the following

situations:

1. Preoperatively, in patients with advanced disease who would otherwise require pelvic exenteration ([19,20](#))
2. Postoperatively, to treat the pelvic lymph nodes and groin of patients with two or more microscopically positive or one grossly positive groin node ([15](#)).

Possible roles for radiation therapy include the following:

1. Postoperatively, to help prevent local recurrences in patients with involved or close surgical margins ([97,98,103](#))
2. As primary therapy for patients with small primary tumors, particularly clitoral or periclitoral lesions in young and middle-aged women, for whom surgical resection would have significant psychological consequences ([64](#)).

No additional treatment is recommended if one microscopically positive groin node is found. The prognosis for this group of patients is excellent ([12](#)), and only careful observation is required. Even if a unilateral groin dissection has been performed for a lateral lesion, there seems to be no indication for dissection of the other side, because contralateral lymph node involvement is likely only if there are multiple microscopic or any gross ipsilateral inguinal node metastases ([12,15](#)).

If clinically evident groin metastases or two or more microscopically positive groin nodes are found, which is unusual in patients with T₁ vulvar cancer, the patient is at increased risk of groin and pelvic recurrence and should receive postoperative groin and pelvic irradiation. In 1977, the GOG initiated a prospective trial in which patients with positive groin nodes were randomized to either ipsilateral pelvic node dissection or bilateral pelvic node dissection plus groin irradiation ([15](#)). Radiation therapy consisted of 4,500 to 5,000 cGy to the midplane of the pelvis at a rate of 180 to 200 cGy per day. The survival rate for the radiation group (68% at 2 years) was significantly better than the survival rate for the pelvic lymphadenectomy group (54% at 2 years) ($p = 0.03$). The survival advantage was limited to patients with clinically evident groin nodes or more than one positive groin node. Groin recurrence occurred in 3 of 59 patients (5%) treated with radiation, compared with 13 of 55 (23.6%) patients treated with lymphadenectomy ($p = 0.02$). Four patients who received radiation had a pelvic recurrence, compared with one who had lymphadenectomy. These data indicate no benefit from pelvic irradiation compared with pelvic lymphadenectomy for the prevention of pelvic recurrence, but they do highlight the value of prophylactic groin irradiation in preventing groin recurrence in patients with multiple positive groin nodes.

Recurrent Vulvar Cancer

Approximately two-thirds of recurrences of vulvar cancer occur within the first 2 years from initial therapy ([99](#)), with groin recurrences occurring sooner (median time to recurrence 6 months) than vulvar recurrences (median time to recurrence 3 years) ([100](#)).

Recurrence of vulvar cancer correlates most closely with the number of positive groin nodes ([12](#)). Patients with fewer than three positive nodes, particularly if the nodes are only microscopically involved, have a low incidence of recurrence at any site, whereas patients with three or more positive nodes have a high incidence of local, regional, and systemic recurrences ([12,15](#)).

Local Recurrence Margin status at the time of radical resection of the vulvar cancer is the most powerful predictor of local vulvar recurrence, with an almost 50% recurrence risk with margins closer than 0.8 cm ([63](#)). Margin status does not, however, predict survival ([57](#)). Local vulvar recurrences are likely in patients with primary lesions larger than 4 cm in diameter, especially if lymph-vascular space invasion is present ([97,101](#)). When detected early, isolated local failure is usually salvageable by additional surgical therapy ([9,17,39,45,102](#)), often with a gracilis myocutaneous graft to cover the defect. Radiation therapy, particularly a combination of external beam therapy plus interstitial needles, at times combined with chemotherapy, has also been used to treat vulvar recurrences ([104](#)). One study reported on 10 patients treated in this manner, nine of whom were still alive with a mean follow-up of 28 months ([105](#)). However, 6 of the 10 patients developed severe radionecrosis at a median of 8.5 months after radiation, and the authors concluded that, although this treatment was highly effective, it also had a high degree of morbidity.

Regional and Distant Recurrence Regional and distant recurrences are difficult to manage and are associated with a poor prognosis ([97,99,100](#)). Radiation therapy may be used in conjunction with surgery for groin recurrence, whereas chemotherapeutic agents that have activity against squamous carcinomas may be offered for distant metastases. The literature on the use of chemotherapy for recurrent vulvar cancer consists of mainly small series. The most extensively studied regimens contain *bleomycin* and *methotrexate*, with or without *cisplatin* or *CCNU* (a nitrosourea) and *bleomycin* and *mitomycin C* ([106,107](#)), but response rates are low and the duration of response is usually disappointing. Long-term survival is very uncommon with regional or distant recurrence.

Melanoma

Vulvar melanomas are rare, with an incidence of 0.1 to 0.19 per 100,000 women ([108,109](#)). They account for 4% to 10% of all cases and are the second most common form of vulvar malignancy ([36](#)). Most melanomas arise *de novo* ([110](#)), but they may arise from a preexisting junctional nevus. Vulvar melanomas occur predominantly in postmenopausal white women. The incidence of cutaneous melanomas worldwide is increasing significantly. Vulvar melanomas appear to behave in a manner similar to that of other cutaneous melanomas ([111,112](#) and [113](#)).

Most patients with vulvar melanoma have no symptoms except for a pigmented lesion that may be enlarging. Some patients have itching or bleeding, and a few have a groin mass. Vulvar melanomas occur most frequently on the labia minora or the clitoris ([Fig. 33.6](#)), and extension into the urethra or vagina at discovery is not uncommon. Any pigmented lesion on the vulva should be excised or, if the lesion is large, sampled for biopsy unless it is known to have been present and unchanged for some years. Most vulvar nevi are junctional and may be precursor lesions to melanoma; thus, any nevus of the vulva should be removed.

Figure 33.6 Melanoma of the vulva involving the right labium minus. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000, pg. 582, with permission.)

Histopathology

There are three basic histologic types of vulvar melanoma ([Fig. 33.7](#)).

Figure 33.7 Vulvar melanoma. Spindle-shaped melanoma cells form interlacing bundles, and some contain melanin pigment (left lower corner). Epidermal invasion is evident in the form of Pagetoid migration (left upper corner). (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

1. The *mucosal lentiginous melanoma* is a flat freckle that may become quite extensive but tends to remain superficial.
2. The most common type is the *superficial spreading melanoma*, which tends to remain relatively superficial early in its development.
3. The *nodular melanoma*, which is the most aggressive, is characterized by a raised lesion that penetrates deeply and may metastasize widely.

In the largest series reported to date, more than one-fourth of the cases of melanomas were macroscopically amelanotic ([108](#)). Vulvar melanoma tends to spread early, not only lymphatically but also hematogenously.

Staging

The FIGO staging used for squamous lesions is not applicable to melanomas, because the lesions are usually much smaller and the prognosis is related to the depth of tumor invasion rather than to the diameter of the lesion ([111,115,117](#)). The leveling system established by Clark and others ([117](#)) for cutaneous melanomas is less readily applicable to vulvar lesions because of the different skin morphology. The vulvar skin lacks a well-defined papillary dermis. Breslow ([118](#)) measured the thickest portion of the melanoma from the surface of intact epithelium to the deepest point of invasion. This system is more adequate for the vulva. Chung and colleagues ([115](#)) proposed a modified system that retained Clark's definitions for levels I and V but arbitrarily defined levels II, III, and IV, using measurements in millimeters. The 1992 American Joint Committee on Cancer (AJCC) staging for melanoma combined the Clark and Breslow systems with clinical staging ([119](#)). A comparison of these systems is shown in [Table 33.6](#).

Clark Level (117)	Chung Depth of Invasion (115)	Breslow Tumor Thickness (118)
I Intraepithelial	Intraepithelial	<0.76 mm
II Into papillary dermis	<1 mm from granular layer	0.76-1.5 mm Superficial invasion
III Filling dermal papillae	1.1-2.0 mm from granular layer	1.51-2.25 mm Intermediate invasion
IV Into reticular dermis	>2 mm from granular layer	2.26-3.0 mm Intermediate invasion
V Into subcutaneous fat	Into subcutaneous fat	>3 mm Deep invasion

Table 33.6. Microstaging of Vulvar Melanoma

Treatment

With better understanding of the prognostic significance of the microstage, some individualization of treatment has developed. However, treatment of vulvar melanoma continues to be controversial, in part because of the lack of large retrospective studies, which makes it difficult to draw conclusions regarding the behavior and best treatment of vulvar melanoma. Currently used treatments are guided by experience from cutaneous melanoma in general and squamous cell carcinomas of the vulva. Paralleling the trend toward more conservative surgical management of cutaneous melanoma, there is a shift toward more conservative management of vulvar melanoma ([112,113,120,121](#)).

It is generally accepted that lesions with less than 1 mm of invasion may be treated with radical local excision alone ([115,116](#)). With more invasive lesions, *en bloc* resection of the primary tumor and regional groin nodes has traditionally been recommended. In the last 15 years, however, radical vulvectomy has been performed less frequently and survival does not seem to be compromised ([122](#)). One study reported on 32 patients with vulvar melanoma who underwent local excision (n = 14), simple vulvectomy (n = 7), or radical resection (n = 11) ([123](#)). No group had a superior survival rate, although the overall survival rate at 5 years was only 25%. More recently, another study reported on 59 patients who underwent radical vulvectomy and 19 who underwent more conservative resections ([112](#)). Survival was not improved by the more radical approach, and they recommended radical local excision for the primary tumor, with groin dissection for tumors with a thickness of more than 1 mm. Current literature on cutaneous melanoma suggests that a 1-cm margin of skin and subcutaneous tissue is sufficient for the treatment of superficial localized melanoma (Breslow tumor thickness <0.76 mm), whereas a 2-cm margin suffices for intermediate-thickness lesions (1 to 4 mm) ([124,125](#)).

Because melanomas commonly involve the clitoris and labia minora, the vaginourethral margin of resection is a common site of failure, and care should be taken to obtain an adequate "inner" resection margin ([126](#)). A 10-year survival rate of 61% has been shown for lateral lesions, compared with 37% for medial lesions ($p = 0.027$) ([111](#)).

Controversy exists as to which patients may benefit from inguinal-femoral lymphadenectomy. A prospective study by the GOG demonstrated that the risk of inguinal-femoral lymph node metastasis correlated with the Breslow microstage ([113](#)). As with cutaneous melanoma, it appears that for superficial lesions (Breslow tumor thickness <0.76 mm) the risk for nodal spread is so low that routine lymphadenectomy is not indicated as long as the nodes appear clinically to be free of disease. For intermediate-thickness (1 to 4 mm) cutaneous melanoma, a randomized controlled trial of elective lymph node dissection versus observation showed a 5-year survival advantage for patients who underwent elective lymph node dissection, who were younger than 60 years, and whose tumors were characterized by 1- to 2-mm thickness and no ulcerations ([127](#)). Patients with deeply invasive cutaneous melanomas (>4-mm tumor thickness) have a high risk of regional and systemic metastases and are unlikely to benefit from regional lymphadenectomy ([128](#)). Given some of the epidemiologic, histologic, and prognostic differences between vulvar and cutaneous melanoma ([114](#)), extrapolation of these data to the vulva should be done with caution. Specific to patients with vulvar melanoma, there is a small body of literature to suggest that there may be a clinical benefit in elective groin lymphadenectomy and the resection of clinically positive nodes ([111,112](#)).

Pelvic node metastases do not occur in the absence of groin node metastases ([126,129,130](#)). In addition, the prognosis for patients with positive pelvic nodes is so poor that there seems to be no value in performing pelvic lymphadenectomy for this disease.

Chemotherapy and immunotherapy for vulvar melanoma have disappointing results. *Interferon- α* has been used with some improvement in survival rates for patients with deep invasive (>4 mm) cutaneous melanoma and those with lymph node metastases, but morbidity is significant ([131,132](#)). Estrogen receptors have been demonstrated in human melanomas ([133](#)), and an occasional response to *tamoxifen* has been reported ([134,135](#)). Cancer vaccines are currently under investigation ([136](#)).

Prognosis

The behavior of melanomas can be quite unpredictable, but the overall prognosis is poor. The reported 5-year survival rate for vulvar melanoma ranges from 25% (123) to 50% (108,109). Because vulvar melanoma has a propensity for late recurrences, 5-year survival may not reflect cure. Prognosis is best predicted by microstaging. Patients with lesions invading to 1 mm or less have a good prognosis, but as depth of invasion increases, the prognosis worsens (Table 33.7). Tumor volume has been reported to correlate with prognosis; patients whose lesions have a volume under 100 mm³ have an excellent prognosis (130). Additional prognostic factors are the patient's age, AJCC stage, presence of multifocal or satellite lesions, tumor ulceration, central tumor location, histologic growth pattern, lymph–vascular space involvement, and aneuploidy (108,111,112 and 113,138).

Breslow Tumor Thickness	No. of Patients	% DOD
<0.76 mm	31 (19)	7 (23%) (15%) ^a
0.76–1.5 mm	35	6 (17%)
1.51–3.0 mm	42	23 (55%)
>3.0 mm	195	131 (67%)

DOD, died of disease.

^aAll but one of these seven deaths were reported in one study with an unusually low 5-year survival of 48% for 12 patients with superficial melanomas of Breslow thickness <0.76 mm. If these 12 cases were excluded, 3% of patients with superficial melanomas of the vulva died of disease. From references 108, 112, 116, 129, 130, 137–140, with permission.

Table 33.7. Prognosis for Patients with Vulvar Melanoma Stratified by Breslow Microstaging

Bartholin Gland Carcinoma

Epidemiology

Primary carcinoma of the Bartholin gland is a rare form of vulvar cancer, which accounts for about 2% to 7% of vulvar malignancies (141). Because of its rarity, individual experience with the tumor is limited, and recommendations for management must be based on the review of small published series. To date, only about 300 cases have been reported (47,141,142). Bartholin gland carcinoma is 5 times more common in postmenopausal than in premenopausal women (143).

Histopathology

The bilateral Bartholin glands are greater vestibular glands situated posterolaterally in the vulva. Their main duct is lined with stratified squamous epithelium, which changes to transitional epithelium as the terminal ducts are reached. Because tumors may arise from the gland or the duct, a variety of histologic types occur, including adenocarcinomas, squamous carcinomas and, rarely, transitional cell, adenosquamous, and adenoid cystic carcinomas.

Classification of a vulvar tumor as a Bartholin gland carcinoma has typically required that it fulfill Honan's criteria, which are as follows:

1. The tumor is in the correct anatomic position.
2. The tumor is located deep in the labium majus.
3. The overlying skin is intact.
4. There is some recognizable normal gland present.

Strict adherence to these criteria will result in underdiagnosis of some cases. Large tumors may ulcerate through the overlying skin and obliterate the residual normal gland. Although transition between normal and malignant tissue is the best criterion, some cases will be diagnosed on the basis of their histologic characteristics and anatomic location.

Signs and Symptoms

The most common initial symptom of Bartholin gland carcinoma is a vulvar mass or perineal pain. About 10% of patients have a history of inflammation of the Bartholin gland and malignancies may be mistaken for benign cysts or abscesses. Therefore, delay of diagnosis is common, particularly for premenopausal patients. The differential diagnosis of any pararectovaginal neoplasm should include cloacogenic carcinoma and secondary neoplasm (142).

Treatment

Traditionally, treatment has been radical vulvectomy with bilateral groin and pelvic node dissection (144). However, there seems to be no indication for dissection of the pelvic nodes in the absence of positive groin nodes, and good results have been reported with hemivulvectomy or radical local excision for the primary tumor (142). Because these lesions are deep in the vulva, extensive dissection is required in the ischioanal fossa; even then, surgical margins are often close. Postoperative radiation to the vulva decreased the likelihood of local recurrence from 27% (6 of 22 patients) to 7% (1 of 14 patients) (142). If the ipsilateral groin nodes are positive, bilateral groin and pelvic irradiation may decrease regional recurrence. If the tumor is fixed to the inferior pubic ramus or involves adjacent structures, such as the anal sphincter or rectum, preoperative radiation and chemotherapy is preferable to avoid ultraradical surgery.

Prognosis

Because of the deep location of the gland, disease tends to be more advanced than squamous carcinomas at the time of diagnosis but, stage for stage, the prognosis is similar. Five-year disease-free survival rates by stage are summarized in Table 33.8.

FIGO Stage	No. of Patients	No. of Patients with Recurrent Disease	No. of Patients NED at Last F/U ^a
I	15 (21%)	3 (20%)	14 (93%)
II	16 (23%)	2 (13%)	15 (94%)
III	30 (42%)	11 (37%)	22 (73%)
IV	10 (14%)	5 (50%)	5 (50%)
Total	71	21	56 (79%)

FIGO, International Federation of Gynecology and Obstetrics; NED, no evidence of disease; F/U, follow-up. ^aMedian follow-up in each study was at least 5 years. From references 47, 141, 142, 145, with permission.

Table 33.8. Survival of Patients with Bartholin Gland Carcinoma

Adenoid Cystic Carcinoma of the Bartholin Gland

The adenoid cystic variety accounts for 15% of Bartholin gland carcinomas. It is less likely to metastasize to lymph nodes and carries a somewhat better prognosis (47,146) (Fig. 33.8). Local recurrences are common, however, and metastases may occur, particularly to the lungs. The slowly progressive nature of these tumors and the tendency for late recurrences is reflected in the disparity between progression-free interval and survival curves (146).

Figure 33.8. Adenoid cystic tumor of the Bartholin gland. Basaloid cells form cribriform, sieve-like spaces containing mucinous material. The hyaline stroma is another distinct feature of this tumor. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Other Adenocarcinomas

Adenocarcinomas of the vulva usually arise in a Bartholin gland or occur in association with Paget's disease. They may rarely arise from the skin appendages, paraurethral glands, minor vestibular glands, aberrant breast tissue, endometriosis, or a misplaced cloacal remnant (147).

Adenosquamous Carcinoma

A particularly aggressive type of carcinoma is the adenosquamous carcinoma. This tumor has a number of synonyms, including cylindroma, pseudoglandular squamous cell carcinoma, adenoid squamous cell carcinoma, and adenoacanthoma of the sweat gland of Lever. The tumor has a propensity for perineural invasion, early lymph node metastasis, and local recurrence. One study noted a crude 5-year survival rate of 5.5% (1 of 18) for adenosquamous carcinoma of the vulva, compared with 62.3% (48 of 77) for patients with squamous cell carcinoma (148). Treatment should be radical vulvectomy and bilateral groin dissection. Postoperative radiation therapy may be appropriate.

Basal Cell Carcinoma

Basal cell carcinomas represent about 2% of vulvar cancers. As with other basal cell carcinomas, vulvar lesions commonly appear as a "rodent ulcer" with rolled edges, although nodules and macules are other morphologic varieties that occur. Most lesions are smaller than 2 cm in diameter and are usually situated on the anterior labia majora. Giant lesions occasionally occur (149). Basal cell carcinoma usually affects postmenopausal white women and is locally aggressive. Symptoms are frequently present for a prolonged period and most frequently include pruritus, soreness, and irritation (150). It is diagnosed by biopsy, and radical local excision is generally adequate treatment. Metastasis to regional lymph nodes has been reported but is rare (151,152 and 153). The local recurrence rate is about 10% to 20% (150,154). Basal cell carcinoma of the vulva is associated with a high incidence of antecedent or concomitant malignancies elsewhere (150). In a series of 28 women with vulvar basal cell carcinoma, 10 patients had other basal cell carcinomas, and 10 patients suffered from other primary malignancies (150).

About 3% to 5% of basal cell carcinomas contain a malignant squamous component, the so-called *basosquamous carcinoma*. These lesions are more aggressive and should be treated as squamous carcinomas (153). Another subtype of basal cell carcinoma is the adenoid basal cell carcinoma, which must be differentiated from the more aggressive adenoid cystic carcinoma arising in a Bartholin gland or the skin (153).

Verrucous Carcinoma

Verrucous carcinoma is a variant of squamous cell carcinoma and has distinctive clinical and pathologic characteristics (155). Although most commonly found in the oral cavity, verrucous lesions may be found on any moist membrane composed of squamous epithelium (156). In the female genital tract, these lesions may develop on the cervix, vulva, and vagina. The cause of the lesion in the female genital tract is not fully understood, but associated HPV-6 and HPV-11 have been found (157).

Grossly, the tumors have a cauliflower-like appearance; microscopically, they contain multiple papillary fronds that lack the central connective tissue core that characterizes condylomata acuminata (Fig. 33.9). The gross and microscopic features of a verrucous carcinoma are very similar to those of the giant condyloma of Buschke-Loewenstein, and they probably represent the same disease entity (147). Adequate biopsy from the base of the lesion is required to differentiate a verrucous carcinoma from a benign condyloma acuminatum or a squamous cell carcinoma with a verrucous growth pattern.

Figure 33.9 Verrucous carcinoma of the vulva. Note the exophytic hyperkeratotic papillary fronds and endophytic bulky rete pegs with smooth borders. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 2nd ed. Baltimore: Williams & Wilkins, 1994, with permission.)

Verrucous carcinomas usually occur in postmenopausal women, and they are slow-growing but locally destructive lesions. Even bone may be invaded.

Metastasis to regional lymph nodes is rare but has been reported (158). Radical local excision is the basic treatment, although any palpably suspicious groin nodes should be evaluated with fine-needle aspiration cytology or excisional biopsy. Usually, enlarged nodes will be caused by inflammatory hypertrophy (159). If the nodes contain metastases, radical vulvectomy and bilateral inguinal-femoral lymphadenectomy are indicated.

Several small studies failed to document any therapeutic advantage with radiation therapy (159,160). In addition, there is concern that radiation may induce anaplastic transformation with subsequent regional and distant metastasis (161). One study reported a corrected 5-year survival rate of 94% for 17 patients treated with surgery alone, compared with 42% for 7 patients treated with surgery and radiation (159). The latter patients had, however, more advanced disease. If there is a recurrence, further surgical excision is the treatment of choice, which occasionally may necessitate some type of exenteration.

Vulvar Sarcoma

Sarcomas represent 1% to 2% of vulvar malignancies and constitute a heterogeneous group of tumors. Leiomyosarcomas are the most common, and other histologic types include fibrosarcomas, neurofibrosarcomas, liposarcomas, rhabdomyosarcomas, angiosarcomas, epithelioid sarcomas, and malignant schwannomas (147).

Leiomyosarcomas usually appear as enlarging, often painful masses, usually in the labium majus. Smooth muscle tumors of the vulva that show at least three of the following four criteria should be regarded as sarcomas: (a) diameter >5 cm, (b) infiltrating margins, (c) 5 or more mitotic figures per 10 high-power fields, (d) moderate-to-severe cytological atypia (162). The absence of one, or even all, of these features does not guarantee against recurrence (163). Lymphatic metastases are uncommon, and radical local excision is the usual treatment.

Epithelioid sarcomas characteristically develop in the soft tissues of the extremities of young adults but rarely may occur on the vulva. In a description of two cases and review of three other reports, the authors concluded that these tumors may mimic a Bartholin cyst, thus leading to inadequate initial treatment (164). They also believed that vulvar epithelioid sarcomas behave more aggressively than their extragenital counterparts, with four of the five patients dying of metastatic disease. They suggested that early recognition and wide excision should improve the prognosis.

Rhabdomyosarcomas are the most common soft tissue sarcomas in childhood, and 20% involve the pelvis or genitourinary tract (165). Dramatic gains have been made in the treatment of these tumors during the past 20 years. Previously, radical pelvic surgery was the standard approach, but results were poor. More recently, a multimodal approach has evolved, and survival rates have improved significantly, with a corresponding decrease in morbidity. In a report of the experience of the Intergroup Rhabdomyosarcoma Study I and II (1972 to 1984) with primary tumors of the female genital tract, nine patients aged 1 to 19 years had primary vulvar tumors, and these tumors were often regarded as a form of Bartholin gland infection before biopsy (166). They were all managed with chemotherapy (*vincristine*, or *actinomycin D* and *cyclophosphamide* and *doxorubicin*), with or without radiotherapy. Wide local excision of the tumor, with or without inguinal-femoral lymphadenectomy, was carried out before or after the chemotherapy. Seven of the nine patients were free of disease 4 or more years from diagnosis, one patient was free of disease when lost to follow-up at 5 years, and one patient was alive with disease.

Rare Vulvar Malignancies

In addition to the previously mentioned tumors, a number of malignancies more commonly seen in other areas of the body may rarely occur as isolated vulvar tumors.

Lymphomas

The genital tract may be involved primarily by malignant lymphomas but, more commonly, involvement is a manifestation of systemic disease. In the lower genital tract, the cervix is most often involved, followed by the vulva and the vagina (147). Most patients are in their third to sixth decade of life, and about three-fourths of the cases involve diffuse large cell or histiocytic non-Hodgkin's lymphomas. The remainder are nodular or Burkitt's lymphomas (134). Treatment is by surgical excision followed by chemotherapy and radiation or both, and the overall 5-year survival rate is about 70% (167).

Endodermal Sinus Tumor

There have been four case reports of endodermal sinus tumor of the vulva, and three of the four patients died of distant metastases (147,168). All patients were in their third decade of life, but none was treated with modern chemotherapy.

Merkel Cell Carcinoma

Merkel cell carcinomas are primary small cell carcinomas of the skin, which resemble oat cell carcinomas of the lung. They metastasize widely and have a very poor prognosis (169,170). They should be locally excised and treated with cisplatin-based chemotherapy.

Dermatofibrosarcoma Protuberans

This rare, low-grade cutaneous malignancy occasionally involves the vulva. It has a marked tendency for local recurrence but a low risk of systemic spread (171). Radical local excision should be sufficient treatment.

Metastatic Tumors of the Vulva

Eight percent of vulvar tumors are metastatic (147). The most common primary site is the cervix, followed by the endometrium, kidney, and urethra. Most patients in whom vulvar metastases develop have advanced primary tumors when diagnosed, and in about one-fourth of the patients the primary lesion and the vulvar metastasis are diagnosed simultaneously (172).

References

Gestational trophoblastic disease (GTD) is among the rare human tumors that can be cured even in the presence of widespread dissemination ([1,2](#)). This classification includes a spectrum of interrelated tumors, including complete and partial hydatidiform mole, placental-site trophoblastic tumor, and choriocarcinoma, which have varying propensities for local invasion and metastasis. Although persistent gestational trophoblastic tumors (GTTs) most commonly follow a molar pregnancy, they may ensue after any gestational event, including therapeutic or spontaneous abortion, ectopic pregnancy, or term pregnancy. Advances in the understanding of the pathogenesis, natural history, and treatment of GTD and the current approach to management are reviewed.

Hydatidiform Mole

Epidemiology

Estimates of the incidence of GTD vary dramatically in different regions of the world. For example, the incidence of molar pregnancy in Japan (2 per 1,000 pregnancies) has been reported to be about threefold higher than the incidence in Europe or North America (about 0.6 to 1.1 per 1,000 pregnancies) ([3](#)). The variation in the incidence rates of molar pregnancy may in part result from differences between reporting population-based versus hospital-based data. The incidences of both complete and partial mole have been investigated in Ireland by reviewing all products of conception from first- and second-trimester abortions ([4](#)). Based on a complete pathologic review, the incidence of complete and partial mole was found to be 1 per 1,945 and 1 per 695 pregnancies, respectively.

Case-control studies have been undertaken to identify risk factors for both complete and partial molar pregnancy. The high incidence of molar pregnancy in some populations has been attributed to nutritional and socioeconomic factors. **Case-control studies from Italy and the United States have shown that low dietary intake of carotene may be associated with an increased risk of complete molar pregnancy (5,6). Areas with a high incidence of molar pregnancy also have a high frequency of vitamin A deficiency. Dietary factors, therefore, may partly explain regional variations in the incidence of complete mole.**

Maternal age older than 35 years has consistently been shown to be a risk factor for complete mole. Ova from older women may be more susceptible to abnormal fertilization. In one study, the risk for complete mole was increased 2.0-fold for women older than 35 years and 7.5-fold for women older than 40 years ([7](#)).

Limited information is available concerning risk factors for partial molar pregnancy. However, the epidemiologic characteristics of complete and partial mole may differ. There is no association between maternal age and the risk for partial mole ([7](#)). The risk for partial mole has been reported to be associated with the use of oral contraceptives and a history of irregular menstruation, but not with dietary factors ([8](#)).

Complete Versus Partial Hydatidiform Mole

Hydatidiform moles may be categorized as either complete or partial moles on the basis of gross morphology, histopathology, and karyotype ([Table 34.1](#)).

Features	Complete Mole	Partial Mole
Fetal or embryonic tissue	Absent	Present
Hydatidiform swelling of chorionic villi	Diffuse	Focal
Trophoblastic hyperplasia	Diffuse	Focal
Scalloping of chorionic villi	Absent	Present
Trophoblastic stromal inclusions	Absent	Present
Karyotype	46,XX (90%); 46,XY	Triploid (90%)

Table 34.1. Features of Complete and Partial Hydatidiform Moles

Complete Hydatidiform Mole

Pathology Complete moles lack identifiable embryonic or fetal tissues, and the chorionic villi exhibit generalized hydatidiform swelling and diffuse trophoblastic hyperplasia (Fig. 34.1).

Figure 34.1 Photomicrograph of complete mole demonstrating diffusely hydropic chorionic villi and diffuse trophoblastic hyperplasia.

Chromosomes Cytogenetic studies have demonstrated that complete hydatidiform moles usually have a 46,XX karyotype, and the molar chromosomes are entirely of paternal origin (Fig. 34.2) (9). It appears that complete moles usually arise from an ovum that has been fertilized by a haploid sperm, which then duplicates its own chromosomes. The ovum nucleus may be either absent or inactivated (10). Although most complete moles have a 46,XX chromosomal pattern, about 10% have a 46,XY karyotype (11). Chromosomes in a 46,XY complete mole also appear to be entirely of paternal origin, although mitochondrial DNA is of maternal origin (12).

Figure 34.2 The karyotype of complete hydatidiform mole.

Partial Hydatidiform Mole

Pathology Partial hydatidiform moles are characterized by the following pathologic features (13) (Fig. 34.3):

Figure 34.3 Photomicrograph of partial mole showing varying-sized chorionic villi with focal trophoblastic hyperplasia, stromal trophoblastic inclusions, and villous scalloping. (From Berkowitz RS, Goldstein OP. Gestational trophoblastic diseases. In: Ryan KJ, Berkowitz R, Barbieri R, eds. *shape Kistner's gynecology principles and practice*, 5th ed. Chicago: Year Book Medical Publishers, 1990:433, with permission.)

1. Chorionic villi of varying size with focal hydatidiform swelling, cavitation, and trophoblastic hyperplasia
2. Marked villous scalloping
3. Prominent stromal trophoblastic inclusions
4. Identifiable embryonic or fetal tissues.

Chromosomes Partial moles generally have a triploid karyotype (69 chromosomes); the extra haploid set of chromosomes usually is derived from the father (Fig. 34.4) (14). One study reported that 93% of partial moles were triploid (14), whereas another found 90% to be triploid (15). When a fetus is present in conjunction with a partial mole, it generally exhibits the stigmata of triploidy, including growth restriction and multiple congenital malformations such as syndactyly and hydrocephaly (Fig. 34.5).

Figure 34.4 The karyotype of partial hydatidiform mole.

Figure 34.5 Photomicrograph of a fetal hand demonstrating syndactyly. The fetus had a triploid karyotype and the chorionic tissues were a partial mole.

Clinical Features

Increasingly, patients with complete molar pregnancy are being diagnosed earlier in pregnancy and are being treated before they develop the classic clinical signs and symptoms. This may be due to changes in clinical practice, such as the frequent use of vaginal probe ultrasonography in early pregnancy in women with vaginal staining and even asymptomatic women. Following is a description of the classic and current clinical features of complete molar pregnancy based on the authors' experience (16).

Complete Hydatidiform Mole

Vaginal Bleeding Vaginal bleeding is the most common symptom causing patients to seek treatment for complete molar pregnancy. Previously, it was reported to occur in 97% of cases, whereas currently it is reported to occur in 84% of patients (17). Molar tissues may separate from the decidua and disrupt maternal vessels, and large volumes of retained blood may distend the endometrial cavity. Because vaginal bleeding may be considerable and prolonged, one-half of these patients had anemia (hemoglobin <10 g/100 ml). Currently anemia is present in only 5% of patients.

Excessive Uterine Size Excessive uterine enlargement relative to gestational age is one of the classic signs of a complete mole, although it was present in only about one-half of patients. The endometrial cavity may be expanded by both chorionic tissue and retained blood. Excessive uterine size is generally associated with markedly elevated levels of human chorionic gonadotropin (hCG), because uterine enlargement results in part from trophoblastic overgrowth. Currently, excessive uterine size is present at diagnosis in only 28% of patients.

Preeclampsia Preeclampsia was once observed in 27% of patients with a complete hydatidiform mole. However, at one center between 1988 and 1993, only 1 of 74 patients with complete mole had preeclampsia at the initial visit (17). Although preeclampsia is associated with hypertension, proteinuria, and hyperreflexia, eclamptic convulsions rarely occur. Preeclampsia develops almost exclusively in patients with excessive uterine size and markedly elevated hCG levels. Hydatidiform mole should be considered whenever preeclampsia develops early in pregnancy.

Hyperemesis Gravidarum Hyperemesis requiring antiemetic or intravenous replacement therapy once occurred in one-fourth of women with a complete mole, particularly those with excessive uterine size and markedly elevated hCG levels. Severe electrolyte disturbances may develop and require treatment with parenteral fluids. Currently, only 8% of patients have hyperemesis.

Hyperthyroidism Clinically evident hyperthyroidism was once observed in 7% of patients with a complete molar gestation. These women may have tachycardia, warm skin, and tremor, and the diagnosis can be confirmed by detection of elevated serum levels of free thyroxine (T_4) and triiodothyronine (T_3). Between 1988 and 1993, none of the author's 74 patients with complete mole had clinical evidence of hyperthyroidism.

If hyperthyroidism is suspected before the induction of anesthesia for molar evacuation, β -adrenergic blocking agents should be administered because anesthesia or surgery may precipitate thyroid storm. Thyroid storms may be manifest by hyperthermia, delirium, convulsions, tachyarrhythmia, high-output heart failure, or cardiovascular collapse. Administration of β -adrenergic blocking agents prevents or rapidly reverses many of the metabolic and cardiovascular complications of thyroid storm. After molar evacuation, thyroid function test results return rapidly to normal.

Hyperthyroidism develops almost exclusively in patients with very high hCG levels. Some investigators have suggested that hCG is the thyroid stimulator in women with GTD, because positive correlations between serum hCG and total T_4 or T_3 concentrations have been observed. However, one study in which thyroid function was measured in 47 patients with a complete mole reported no significant correlation between serum hCG levels and serum values of free T_4 index or free T_3 index (18). Although some investigators have speculated about a separate chorionic thyrotropin, this substance has not yet been isolated.

Trophoblastic Embolization Respiratory distress developed in 2% of patients with a complete mole in the past, but it has occurred in none of the authors' patients. Respiratory distress is usually diagnosed in patients with excessive uterine size and markedly elevated hCG levels. These patients may have chest pain, dyspnea, tachypnea, and tachycardia and may experience severe respiratory distress during and after molar evacuation. Auscultation of the chest usually reveals diffuse rales, and chest radiographic evaluation may demonstrate bilateral pulmonary infiltrates. Respiratory distress usually resolves within 72 hours with cardiopulmonary support. In some circumstances, patients may require mechanical ventilation. Respiratory insufficiency may result from trophoblastic embolization or from the cardiopulmonary complications of thyroid storm, preeclampsia, and massive fluid replacement.

Theca Lutein Ovarian Cysts Prominent theca lutein ovarian cysts (6 cm in diameter) develop in about one-half of patients with a complete mole (19). Theca lutein ovarian cysts result from high serum hCG levels, which cause ovarian hyperstimulation (20). Because the uterus also may be excessively enlarged, theca lutein cysts may be difficult to palpate during physical examination; however, ultrasonography can accurately document their presence and size. After molar evacuation, theca lutein cysts normally regress spontaneously within 2 to 4 months.

Prominent theca lutein cysts may cause symptoms of marked pelvic pressure, and they may be decompressed by laparoscopic or ultrasonographically directed aspiration. If acute pelvic pain develops, laparoscopy should be performed to assess possible cystic torsion or rupture.

Partial Hydatidiform Mole

Patients with partial hydatidiform mole usually do not have the dramatic clinical features characteristic of complete molar pregnancy. **In general, these patients have the signs and symptoms of incomplete or missed abortion, and partial mole can be diagnosed after histologic review of the tissue obtained by curettage (21).**

In a survey of 81 patients with a partial mole, the main initial sign was vaginal bleeding, which occurred in 59 patients (72.8%) (22). Excessive uterine enlargement and preeclampsia were present in only three patients (3.7%) and two (2.5%) patients, respectively. No patients had theca lutein ovarian cysts, hyperemesis, or hyperthyroidism. The initial clinical diagnosis was an incomplete or missed abortion in 74 patients (91.3%) and hydatidiform mole in only five patients (6.2%). Preevacuation hCG levels were measured in 30 patients and were higher than 100,000 mIU/ml in only two patients (6.6%).

Natural History

Complete Hydatidiform Mole

Complete moles have a potential for local invasion and dissemination. **After molar evacuation, local uterine invasion occurs in 15% of patients and metastasis occurs in 4% (19).**

A review of 858 patients with complete hydatidiform mole revealed that two-fifths of the patients had the following signs of marked trophoblastic proliferation at the time they sought treatment (19):

1. hCG level >100,000 mIU/ml
2. Excessive uterine enlargement
3. Theca lutein cysts 6 cm in diameter.

Patients with any one of these signs were considered at high risk. After molar evacuation, local uterine invasion occurred in 31% and metastases developed in 8.8% of the 352 high-risk patients. For the 506 low-risk patients, local invasion was found in only 3.4%, and metastases developed in 0.6%.

Older patients are also at increased risk of developing postmolar GTT. One study reported that persistent tumor developed after a complete molar pregnancy in 37% of women older than 40 years (23), whereas in another study this finding occurred in 56% of women older than 50 years (23,24).

Partial Hydatidiform Mole

Persistent tumor, usually nonmetastatic, develops in approximately 4% of patients with a partial mole, and chemotherapy is required to achieve remission (25). Patients who develop persistent disease have no distinguishing clinical or pathologic characteristics (26). Additionally, it has been reported that 11 (85%) of 13 patients with partial moles who developed persistent tumor had a triploid karyotype (27).

Diagnosis

Ultrasonography is a reliable and sensitive technique for the diagnosis of complete molar pregnancy. Because the chorionic villi exhibit diffuse hydropic swelling, complete moles produce a characteristic vesicular ultrasonographic pattern.

Ultrasonography also may contribute to the diagnosis of partial molar pregnancy by demonstrating focal cystic spaces in the placental tissues and an increase in the transverse diameter of the gestational sac (28). When both of these criteria are present, the positive predictive value for partial mole is 90%.

Treatment

After molar pregnancy is diagnosed, the patient should be evaluated carefully for the presence of associated medical complications, including preeclampsia, hyperthyroidism, electrolyte imbalance, and anemia. After the patient's condition has been stabilized, a decision must be made concerning the most appropriate method of evacuation.

Hysterectomy

If the patient desires surgical sterilization, a hysterectomy may be performed with the mole *in situ*. The ovaries may be preserved at the time of surgery, even though prominent theca lutein cysts are present. Large ovarian cysts may be decompressed by aspiration. Hysterectomy does not prevent metastasis; therefore, patients still require follow-up with assessment of hCG levels.

Suction Curettage

Suction curettage is the preferred method of evacuation, regardless of uterine size, for patients who desire to preserve fertility. It involves the following steps:

1. *Oxytocin infusion*—This procedure is begun in the operating room before the induction of anesthesia.
2. *Cervical dilation*—As the cervix is being dilated, the surgeon frequently encounters increased uterine bleeding. Retained blood in the endometrial cavity may be expelled during cervical dilation. However, active uterine bleeding should not deter the prompt completion of cervical dilation.
3. *Suction curettage*—Within a few minutes of commencing suction curettage, the uterus may decrease dramatically in size, and the bleeding is generally well controlled. The use of a 12-mm cannula is strongly advised to facilitate evacuation. If the uterus is larger than 14 weeks of gestation, one hand should be placed on top of the fundus, and the uterus should be massaged to stimulate uterine contraction and reduce the risk of perforation.
4. *Sharp curettage*—When suction evacuation is believed to be complete, gentle sharp curettage is performed to remove any residual molar tissue.

Because trophoblast cells express RhD factor, patients who are Rh negative should receive Rh immune globulin at the time of evacuation.

Prophylactic Chemotherapy

The use of prophylactic chemotherapy at the time of molar evacuation is controversial (29). The debate concerns the wisdom of exposing all patients to potentially toxic treatment when only about 20% are at risk of developing persistent tumor.

In a study of 247 patients with complete molar pregnancy who received prophylactically a single course of *actinomycin D* at the time of evacuation, local uterine invasion subsequently developed in only 10 patients (4%), and no patients experienced metastasis (29). Furthermore, all 10 patients with local invasion achieved remission after only one additional course of chemotherapy. **Prophylactic chemotherapy, therefore, not only prevented metastasis but also reduced the incidence and morbidity of local uterine invasion.**

In a prospective randomized study of prophylactic chemotherapy in patients with a complete mole, a significant decrease in persistent tumor was detected in patients with high-risk mole who received prophylactic chemotherapy (47% versus 14%) (30). **Prophylaxis may be particularly useful in the management of high-risk complete molar pregnancy, especially when hormonal follow-up is unavailable or unreliable.**

Follow-up

Human Chorionic Gonadotropin

After molar evacuation, patients should be monitored with weekly determinations of b-subunit hCG levels until these levels are normal for 3 consecutive weeks, followed by monthly determinations until the levels are normal for 6 consecutive months. The average time to achieve the first normal hCG level after evacuation is about 9 weeks (31). At the completion of follow-up, pregnancy may be undertaken.

Contraception

Patients are encouraged to use effective contraception during the entire interval of hCG follow-up. Because of the potential risk of uterine perforation, intrauterine devices should not be inserted until the patient achieves a normal hCG level. If the patient does not desire surgical sterilization, the choice is to use either oral contraceptives or barrier methods.

The incidence of postmolar persistent tumor has been reported to be increased among patients who used oral contraceptives before gonadotropin remission (32).

However, more recent data indicate that oral contraceptives do not increase the risk of postmolar trophoblastic disease ([33,34](#)). **It appears that oral contraceptives may be used safely after molar evacuation during the entire interval of hormonal follow-up.**

Persistent Gestational Trophoblastic Tumor

Nonmetastatic Disease

Locally invasive GTT develops in about 15% of patients after molar evacuation and infrequently after other gestations (1). These patients usually are seen clinically with the following symptoms:

1. Irregular vaginal bleeding
2. Theca lutein cysts
3. Uterine subinvolution or asymmetric enlargement
4. Persistently elevated serum hCG levels.

The trophoblastic tumor may perforate through the myometrium, causing intraperitoneal bleeding, or erode into uterine vessels, causing vaginal hemorrhage. Bulky, necrotic tumor may involve the uterine wall and serve as a nidus for infection. Patients with uterine sepsis may have a purulent vaginal discharge and acute pelvic pain.

After molar evacuation, persistent GTT may exhibit the histologic features of either hydatidiform mole or choriocarcinoma. After a nonmolar pregnancy, however, persistent GTT always has the histologic pattern of choriocarcinoma. Histologically, choriocarcinoma is characterized by sheets of anaplastic syncytiotrophoblast and cytotrophoblast without chorionic villi.

Placental-site Trophoblastic Tumor

Placental-site trophoblastic tumor is an uncommon but important variant of choriocarcinoma that consists predominantly of intermediate trophoblast ([35](#)). Relative to their mass, these tumors produce small amounts of hCG and human placental lactogen (hPL), and they tend to remain confined to the uterus, metastasizing late in their course. **In contrast to other trophoblastic tumors, placental-site tumors are relatively insensitive to chemotherapy.**

Metastatic Disease

Metastatic GTT occurs in about 4% of patients after evacuation of a complete mole, but it is seen more often when GTT develops after nonmolar pregnancies (1). Metastasis is usually associated with choriocarcinoma, which has a tendency toward early vascular invasion with widespread dissemination. Because trophoblastic tumors often are perfused by fragile vessels, they are frequently hemorrhagic. Symptoms of metastases may result from spontaneous bleeding at metastatic foci. The most common sites of metastases are lung (80%), vagina (30%), pelvis (20%), liver (10%), and brain (10%).

Pulmonary

At the time of diagnosis, lung involvement is visible on chest radiographs of 80% of patients with metastatic GTT. Patients with pulmonary metastasis may have chest pain, cough, hemoptysis, dyspnea, or an asymptomatic lesion on chest radiograph. Respiratory symptoms may be acute or chronic, persisting over many months.

GTT may produce four principal pulmonary radiographic patterns:

1. An alveolar or "snowstorm" pattern
2. Discrete rounded densities
3. Pleural effusion
4. An embolic pattern caused by pulmonary arterial occlusion.

Because respiratory symptoms and radiographic findings may be dramatic, the patient may be thought to have a primary pulmonary disease. Some patients with extensive pulmonary involvement have minimal, if any, gynecologic symptoms because the reproductive organs may be free of trophoblastic tumor. Unfortunately, the diagnosis of GTT may be confirmed only after thoracotomy has been performed, particularly in patients with a nonmolar antecedent pregnancy.

Pulmonary hypertension may develop in patients with GTT secondary to pulmonary arterial occlusion by trophoblastic emboli. The development of early respiratory failure requiring intubation is associated with a dismal clinical outcome ([36,37](#)).

Vaginal

Vaginal metastases occurs in 30% of the patients with metastatic tumor. These lesions are usually highly vascular and may bleed vigorously if a sample is taken for biopsy. Metastases to the vagina may occur in the fornices or suburethrally and may produce irregular bleeding or a purulent discharge.

Hepatic

Liver metastases occur in 10% of patients with disseminated trophoblastic tumor. Hepatic involvement is encountered almost exclusively in patients with protracted delays in diagnosis and extensive tumor burdens. Epigastric or right upper quadrant pain may develop if metastases stretch the hepatic capsule. Hepatic lesions may be hemorrhagic, causing hepatic rupture and exsanguinating intraperitoneal bleeding.

Central Nervous System

Metastatic trophoblastic disease involves the brain in 10% of patients. Cerebral involvement is generally seen in patients with advanced disease; virtually all patients with brain metastasis have concurrent pulmonary or vaginal involvement or both. Because cerebral lesions may hemorrhage spontaneously, patients may develop acute focal neurologic deficits.

Staging P>

An anatomic staging system for GTT has been adopted by the International Federation of Gynecology and Obstetrics (FIGO) (Table 34.2). It is hoped that this staging system will encourage the objective comparison of data among various centers.

Stage I	Disease confined to uterus
Stage IA	Disease confined to uterus with no risk factors
Stage IB	Disease confined to uterus with one risk factor
Stage IC	Disease confined to uterus with more than one risk factor
Stage II	Central trophoblastic tumor extending outside uterus but limited to genital structures (vagina, vulva, broad ligament)
Stage IIA	Central trophoblastic tumor involving genital structures without risk factors
Stage IIB	Central trophoblastic tumor extending outside uterus but limited to genital structures with one risk factor
Stage IIC	Central trophoblastic tumor extending outside uterus but limited to genital structures with more than one risk factor
Stage III	Central trophoblastic disease extending to lungs with or without known genital tract involvement
Stage IIIA	Central trophoblastic tumor extending to lungs with or without genital tract involvement and with no risk factors
Stage IIIB	Central trophoblastic tumor extending to lungs with or without genital tract involvement and with one risk factor
Stage IIIC	Central trophoblastic tumor extending to lungs with or without genital tract involvement and with more than one risk factor
Stage IV	All other metastatic sites
Stage IVA	All other metastatic sites without risk factors
Stage IVB	All other metastatic sites with one risk factor
Stage IVC	All other metastatic sites with more than one risk factor

Risk factors affecting staging include the following: (a) human chorionic gonadotropin > 100,000 mIU/ml and (b) duration of disease longer than 6 months from termination of antecedent pregnancy. The following factors should be considered and noted in reporting: (a) if no chemotherapy has been given for known gestational trophoblastic tumor, all placental site tumors should be reported separately and (b) histologic verification of disease is not required.

Table 34.2. Staging of Gestational Trophoblastic Tumors

Stage I: Patients have persistently elevated hCG levels and tumor confined to the uterine corpus.

Stage II: Patients have metastases to the vagina and pelvis or both.

Stage III: Patients have pulmonary metastases with or without uterine, vaginal, or pelvic involvement. The diagnosis is based on a rising hCG level in the presence of pulmonary lesions on chest radiograph.

Stage IV: Patients have advanced disease and involvement of the brain, liver, kidneys, or gastrointestinal tract. These patients are in the highest risk category, because they are most likely to be resistant to chemotherapy. The histologic pattern of choriocarcinoma is usually present, and disease commonly follows a nonmolar pregnancy.

Prognostic Scoring System

In addition to anatomic staging, it is important to consider other variables to predict the likelihood of drug resistance and to assist in selecting appropriate chemotherapy (38). **A prognostic scoring system proposed by the World Health Organization reliably predicts the potential for resistance to chemotherapy (Table 34.3).**

	Score			
	0	1	2	4
Age (years)	<30	>30	—	—
Antecedent pregnancy	Hydatidiform mole	Miscarriage	Term	—
Interval between end of antecedent pregnancy and start of chemotherapy (months)	<4	4-12	3-12	>12
Human chorionic gonadotropin (IU/liter)	<10 ³	10 ³ -10 ⁴	10 ⁴ -10 ⁵	>10 ⁵
FIGO group	—	I or II	III or IVB	—
Largest tumor (including uterine size)	<3	3-5	>5	—
Site of metastases	—	Spleen, kidney	Gastrointestinal tract, liver	Brain
Number of metastases	—	1-3	4-8	>8
Prior chemotherapy	—	—	1 drug	≥2 drugs

The total score for a patient is obtained by adding the individual scores for each prognostic factor. Total scores: <4, low risk; 4-7, middle risk; ≥8, high risk.

Table 34.3. Scoring System Based on Prognostic Factors

When the prognostic score is higher than 7, the patient is categorized as high risk and requires intensive combination chemotherapy to achieve remission. Patients with stage I disease usually have a low-risk score, and those with stage IV disease have a high-risk score. The distinction between low and high risk applies mainly to patients with Stage II or III disease.

Diagnostic Evaluation

Optimal management of persistent GTT requires a thorough assessment of the extent of the disease prior to the initiation of treatment. **All patients with persistent GTT should undergo a careful pretreatment evaluation, including the following:**

1. Complete history and physical examination
2. Measurement of the serum hCG value
3. Hepatic, thyroid, and renal function tests
4. Determination of baseline peripheral white blood cell and platelet counts.

The metastatic workup should include the following:

1. Chest radiograph or computed tomography (CT) scan
2. Ultrasonography or CT scan of the abdomen and pelvis
3. CT or magnetic resonance imaging (MRI) scan of the head.

When the pelvic examination and chest radiographic findings are negative, metastatic involvement of other sites is uncommon.

Liver ultrasonography and CT scanning will document most hepatic metastases in patients with abnormal liver function tests. CT or MRI scan of the head has facilitated the early diagnosis of asymptomatic cerebral lesions (39). Chest CT scans may demonstrate micrometastases not visible on a chest radiograph.

In patients with choriocarcinoma or metastatic disease, hCG levels may be measured in the cerebrospinal fluid (CSF) to exclude cerebral involvement if the results of CT scanning of the brain are normal. The ratio of plasma-to-CSF hCG tends to be lower than 60 in the presence of cerebral metastases (40). However, a single plasma-to-CSF hCG ratio may be misleading, because rapid changes in plasma hCG levels may not be reflected promptly in the CSF (41).

Pelvic ultrasonography appears to be useful in detecting extensive trophoblastic uterine involvement and may also aid in identifying sites of resistant uterine tumor (42). Because ultrasonography can accurately and noninvasively detect extensive uterine tumor, it may help identify patients who would benefit from hysterectomy.

Management of Persistent GTT

A protocol for the management of GTT is presented in [Table 34.4](#).

Stage I	
Initial	Single-agent chemotherapy or hysterectomy with adjuvant chemotherapy
Resistant	Combination chemotherapy Hysterectomy with adjuvant chemotherapy Local resection Pelvic inflixion
Stages II and III	
Low risk ^a	Single-agent chemotherapy
Initial	Combination chemotherapy
Resistant	Combination chemotherapy
High risk ^a	Combination chemotherapy
Initial	Combination chemotherapy
Resistant	Second-line combination chemotherapy
Stage IV	
Initial	Combination chemotherapy
Brain	Whole-brain irradiation (3,000 cGy)
Liver	Chemotherapy to manage complications
Resistant ^b	Resection to manage complications Second-line combination chemotherapy Hepatic arterial inflixion

^aLocal resection options:
GTT, gestational trophoblastic tumor.

Table 34.4. Protocol for Treatment of GTT

Stage I

In patients with stage I disease, the selection of treatment is based primarily on whether the patient desires to retain fertility.

Hysterectomy plus Chemotherapy

If the patient does not wish to preserve fertility, hysterectomy with adjuvant single-agent chemotherapy may be performed as primary treatment. Adjuvant chemotherapy is administered for three reasons:

1. To reduce the likelihood of disseminating viable tumor cells at surgery
2. To maintain a cytotoxic level of chemotherapy in the bloodstream and tissues in case viable tumor cells are disseminated at surgery
3. To treat any occult metastases that may already be present at the time of surgery.

Chemotherapy can be administered safely at the time of hysterectomy without increasing the risk of bleeding or sepsis. In a series of 30 patients treated with primary hysterectomy and a single course of adjuvant chemotherapy, all have achieved complete remission with no additional therapy.

Hysterectomy is also performed in all patients with stage I placental-site trophoblastic tumor. Because placental-site tumors are resistant to chemotherapy, hysterectomy for presumed nonmetastatic disease is the only curative treatment. To date, only a small number of patients with metastatic placental-site tumor have been reported to be in sustained remission as a result of chemotherapy (43).

Chemotherapy Alone

Single-agent chemotherapy is the preferred treatment in patients with stage I disease who desire to retain fertility. When primary single-agent chemotherapy was administered to 468 patients with stage I GTT, 431 patients (92.1%) attained complete remission. The remaining 37 resistant patients subsequently achieved remission after combination chemotherapy or surgical intervention.

When patients are resistant to single-agent chemotherapy and desire to preserve fertility, combination chemotherapy should be administered. If the patient is resistant to both single-agent and combination chemotherapy and wants to retain fertility, local uterine resection may be considered. When local resection is planned, a preoperative ultrasonography, MRI, or arteriography may help to define the site of the resistant tumor.

Stages II and III

Low-risk patients are treated with primary single-agent chemotherapy, and high-risk patients are treated with primary intensive combination chemotherapy.

Vaginal and Pelvic Metastasis

In one series, 27 treated patients with stage II disease achieved remission. Single-agent chemotherapy induced complete remission in 16 (84.2%) of 19 low-risk patients. In contrast, only two of eight high-risk patients achieved remission with single-agent treatment; the others required combination chemotherapy.

Vaginal metastases may bleed profusely because they are highly vascular and friable. When bleeding is substantial, it may be controlled by packing the vagina or by wide local excision. Infrequently, arteriographic embolization of the hypogastric arteries may be required to control hemorrhage from vaginal metastases.

Pulmonary Metastasis

Of 143 patients treated with stage III disease, 142 (99%) attained complete remission. Gonadotropin remission was induced with single-agent chemotherapy in 80 of 97 (82.5%) patients with low-risk disease. All patients who were resistant to single-agent treatment subsequently achieved remission with combination chemotherapy.

Thoracotomy Thoracotomy has a limited role in the management of stage III disease. **If a patient has a persistent viable pulmonary metastasis despite intensive chemotherapy, however, thoracotomy may be attempted to excise the resistant focus.** A thorough metastatic workup should be performed before surgery to exclude other sites of persistent disease. Evidence of fibrotic pulmonary nodules may persist indefinitely on chest radiographs, even after complete gonadotropin remission has been attained. In patients undergoing thoracotomy for resistant disease, chemotherapy should be administered postoperatively to treat potential occult sites of micrometastasis.

Hysterectomy

Hysterectomy may be required in patients with metastatic disease to control uterine hemorrhage or sepsis. Furthermore, in patients with extensive uterine tumor, hysterectomy may substantially reduce the trophoblastic tumor burden and thereby limit the need for multiple courses of chemotherapy.

Follow-up

All patients with stage I through stage III disease should receive follow-up with:

1. Weekly measurement of hCG levels until they are normal for 3 consecutive weeks
2. Monthly measurement of hCG values until levels are normal for 12 consecutive months
3. Effective contraception during the entire interval of hormonal follow-up.

Patients with stage IV disease are at greatest risk of developing rapidly progressive and unresponsive tumors despite intensive multimodal therapy. They should preferably be referred to centers with special expertise in the management of trophoblastic disease.

Stage IV

All patients with stage IV disease should be treated with primary intensive combination chemotherapy and the selective use of radiation therapy and surgery. Before 1975, only 6 of 20 patients (30%) treated with stage IV disease attained complete remission, whereas after that time, 14 of 18 patients (77.8%) achieved remission.

This improvement in survival has resulted from the use of primary combination chemotherapy in conjunction with radiation and surgical treatment.

Hepatic Metastasis

The management of hepatic metastasis is particularly difficult. If a patient is resistant to systemic chemotherapy, hepatic arterial infusion of chemotherapy may induce complete remission in selected cases. Hepatic resection may also be required to control acute bleeding or to excise a focus of resistant tumor. New techniques of arterial embolization may reduce the need for surgical intervention.

Cerebral Metastasis

If cerebral metastases are diagnosed, whole-brain irradiation (3,000 cGy in 10 fractions) can be instituted promptly. The risk of spontaneous cerebral hemorrhage may be lessened by the concurrent use of combination chemotherapy and brain irradiation, because irradiation may be both hemostatic and tumoricidal. However, excellent remission rates (86%) have been reported in patients with cranial metastases treated with intensive intravenous combination chemotherapy and intrathecal *methotrexate* (MTX) (44).

Craniotomy Craniotomy may be required to provide acute decompression or to control bleeding. It should be performed to manage life-threatening complications in the hope that the patient ultimately will be cured with chemotherapy. In one study (45), the use of craniotomy to control bleeding in six patients resulted in complete remission in three patients. Infrequently, cerebral metastases that are resistant to chemotherapy may be amenable to local resection. Fortunately, patients with cerebral metastases who achieve sustained remission generally have no residual neurologic deficits.

Follow-up

Patients with stage IV disease should receive follow-up with:

1. Weekly determination of hCG levels until they are normal for 3 consecutive weeks
2. Monthly determination of hCG levels until they are normal for 24 consecutive months.

These patients require prolonged gonadotropin follow-up because they are at increased risk of late recurrence.

An algorithm for the management of persistent GTT is presented in Fig. 34.6.

Figure 34.6 Algorithm for the management of persistent gestational trophoblastic tumor. (From Berkowitz RS, Goldstein DP. Gestational trophoblastic neoplasia. In: Berek JS, Hacker NF, eds. *shape Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincot Williams & Wilkins, 2000;632, with permission.)

Chemotherapy

Single-agent Treatment

Single-agent chemotherapy with either *actinomycin D* (*Act-D*) or *MTX* has achieved comparable and excellent remission rates in both nonmetastatic and low-risk metastatic GTT (46). Several protocols using these agents are available. *Act-D* can be given every other week as a 5-day regimen or in a pulsatile fashion; similarly, *MTX* can be given either in a 5-day regimen or pulsatile weekly. No study has compared all of these protocols with regard to success. An optimal regimen should maximize the response rate while minimizing morbidity and cost.

The administration of *methotrexate* with *folinic acid* (*MTX-FA*) in GTT to limit systemic toxicity was first reported in 1964 (47). Subsequently, it has been confirmed that *MTX-FA* is both effective and safe in the management of GTT (48).

MTX-FA has been the preferred single agent in the treatment of GTT. An evaluation of 185 patients treated in this manner revealed that complete remission was achieved in 162 patients (87.6%); of these patients, 132 (81.5%) required only one course of *MTX-FA* to attain remission (48). *MTX-FA* induced remission in 147 of 163 patients (90.2%) with stage I GTT and in 15 of 22 patients (68.2%) with low-risk stages II and III GTT. Resistance to therapy was more common in patients with choriocarcinoma, metastasis, and pretreatment serum hCG levels higher than 50,000 mIU/ml. After treatment with *MTX-FA*, thrombocytopenia, granulocytopenia, and hepatotoxicity developed in only 3 (1.6%), 11 (5.9%), and 26 (14.1%) patients, respectively. Thus, *MTX-FA* achieved an excellent therapeutic outcome with minimal toxicity and attained this goal with limited exposure to chemotherapy.

Technique of Single-agent Treatment

The serum hCG level is measured weekly after each course of chemotherapy, and the hCG regression curve serves as the primary basis for determining the need for additional treatment.

After the first treatment:

1. Further chemotherapy is withheld as long as the hCG level is falling progressively.
2. Additional single-agent chemotherapy is not administered at any predetermined or fixed interval.

A second course of chemotherapy is administered under the following conditions:

1. If the hCG level plateaus for more than 3 consecutive weeks or begins to rise again
2. If the hCG level does not decline by 1 log within 18 days after completion of the first treatment.

If the patient's response to the first treatment was adequate and a second course of *MTX-FA* is required the dosage of *MTX* is unaltered. An adequate response is defined as a fall in the hCG level by 1 log after a course of chemotherapy.

If the response to the first treatment is inadequate, the dosage of *MTX* is increased from 1.0 mg/kg per day to 1.5 mg/kg per day for each of the 4 treatment days. If the response to two consecutive courses of *MTX-FA* is inadequate, the patient is considered to be resistant to *MTX*, and *Act-D* is promptly substituted. If the hCG levels do not decline by 1 log after treatment with *Act-D*, the patient also is considered resistant to *Act-D* as a single agent. She must then be treated intensively with

combination chemotherapy to achieve remission.

Combination Chemotherapy

Triple Therapy

Triple therapy with *MTX*, *Act-D*, and *cyclophosphamide* is inadequate as an initial treatment in patients with metastasis and a high-risk prognostic score. Collectively, data from various centers indicate that triple therapy induced remission in only 21 (49%) of 43 patients with metastasis and a high-risk score (score >7) ([49,50](#) and [51](#)).

Etoposide has been reported to induce complete remission in 56 (95%) of 60 patients with nonmetastatic and low-risk metastatic GTT ([52](#)). A new combination regimen described in 1984 included *etoposide*, *MTX*, *Act-D*, *cyclophosphamide*, and *vincristine* (*EMA-CO*) and had an 83% remission in patients with metastasis and a high-risk score ([53](#)). Another study ([54](#)) confirmed that primary *EMA-CO* induced complete remission in 76% of the patients with metastatic GTT and a high-risk score ([54](#)). Still another study reported that *EMA-CO* induced complete sustained remission in 61 (94%) of 65 patients with high-risk (score >5) GTT ([55](#)). Furthermore, remission occurred with *EMA-CO* in 13 (86%) of 15 patients with brain metastasis ([44](#)).

The *EMA-CO* regimen is generally well tolerated, and treatment seldom has to be suspended because of toxicity. The *EMA-CO* regimen is the preferred primary treatment in patients with metastasis and a high-risk prognostic score. However, the optimal combination drug protocol for management of GTT has not yet been clearly defined. If patients experience resistance to *EMA-CO*, they may then be treated successfully by substituting *etoposide* and *cisplatin* on day 8 (*EMA-EP*). *EMA-EP* has induced remission alone or with surgery in 16 (76%) of 21 patients who were resistant to *EMA-CO* ([56](#)). The optimal combination drug protocol will most likely include *etoposide*, *MTX*, and *Act-D* and perhaps other agents administered in the most dose-intensive manner.

Duration of Therapy

Patients who require combination chemotherapy must be treated intensively to attain remission. Combination chemotherapy should be given as often as toxicity permits until the patient achieves three consecutive normal hCG levels. After normal hCG levels are attained, at least two additional courses of chemotherapy are administered to reduce the risk of relapse.

Subsequent Pregnancies

Pregnancies After Hydatidiform Mole Patients with hydatidiform moles can anticipate normal reproduction in the future ([57](#)). From 1965 until 1999, patients who were treated for complete mole had 1,239 subsequent pregnancies that resulted in 850 term live births (68.6%), 93 premature deliveries (7.5%), 11 ectopic pregnancies (0.9%), 7 stillbirths (0.5%), and 17 repeat molar pregnancies (1.4%). First- and second-trimester spontaneous abortions occurred in 205 (16.5%) and 18 (1.5%) pregnancies, respectively. Major and minor congenital malformations were detected in 38 infants (4.0%), and primary cesarean delivery was performed in 56 of 345 (16.2%) term or preterm births from 1979 to 1999.

Although data regarding pregnancies after partial mole are limited (205 subsequent pregnancies), the information is reassuring ([57](#)). **Patients with both complete and partial mole should be reassured that they are at no increased risk of complications in later gestations.**

When a patient has had a molar pregnancy, she is at an increased risk of having a molar gestation in subsequent conceptions ([58](#)). After one molar pregnancy, the risk of having molar disease in a future gestation is about 1%. Of 29 patients with at least two documented molar pregnancies, every possible combination of repeat molar pregnancy was observed. After two molar gestations, these 29 patients had 34 later conceptions resulting in 19 (55.9%) term deliveries, 7 (20.6%) moles (6 complete, 1 partial), 3 spontaneous abortions, 3 therapeutic abortions, 1 intrauterine fetal death, and 1 ectopic pregnancy. In six patients, the medical records indicated that the patient had a different partner at the time of different molar pregnancies ([59](#)).

Therefore, for any subsequent pregnancy, it seems prudent to undertake the following approach:

1. Perform pelvic ultrasonographic examination during the first trimester to confirm normal gestational development.
2. Obtain a thorough histologic review of the placenta or products of conception.
3. Obtain an hCG measurement 6 weeks after completion of the pregnancy to exclude occult trophoblastic neoplasia.

Pregnancies After Persistent GTT Patients with GTT who are treated successfully with chemotherapy can expect normal reproduction in the future. Patients who were treated with chemotherapy at the authors' institution from 1965 to 1999 had 522 subsequent pregnancies that resulted in 358 term live births (68.6%), 30 preterm deliveries (5.8%), 6 ectopic pregnancies (1.1%), 8 stillbirths (1.5%), and 6 repeat molar pregnancies (1.1%) ([57](#)). First- and second-trimester spontaneous abortions occurred in 81 (15.5%) and 7 (1.4%) pregnancies, respectively. Major and minor congenital malformations were detected in 10 infants (2.5%). Primary cesarean delivery was performed in 57 (19.4%) of 294 subsequent term and preterm births from 1979 to 1999. It is particularly reassuring that the frequency of congenital anomalies is not increased, although chemotherapeutic agents are known to have teratogenic and mutagenic potential.

[References](#)

Breast cancer accounts for approximately one-third of all cancers in women and is second only to lung cancer as the leading cause of cancer deaths in women. Breast cancer, however, has the highest incidence rate of all cancers. According to estimates from the American Cancer Society, in the United States during 2002 there will be 203,500 new cases of breast cancer and 39,600 deaths from this disease in women ([1](#)). During the past 50 years, the incidence of breast cancer in this country has increased significantly; nearly one in every eight women in the United States will develop breast cancer. Fortunately, the mortality rate actually declined between 1993 and 1997, implying an increased success in earlier diagnosis and treatment.

Predisposing Factors

Less than 1% of all breast cancers occur in women less than 25 years of age. After 30 years of age, however, there is a sharp increase in the incidence of breast cancer. Except for a short plateau between the ages of 45 and 50 years, the incidence increases steadily with age ([2](#)).

Family History

Only 20% of women who develop breast cancer have a family history of the disease. **Any family history of breast cancer increases the overall relative risk ([3](#)).** However, the risk is not increased significantly in women whose mothers or sisters had breast cancer after menopause, whereas women whose mothers or sisters had bilateral breast cancer premenopausally have at least a 40% to 50% lifetime risk. If the patient's mother or sister had unilateral breast cancer premenopausally, her lifetime risk of developing breast cancer is approximately 30%. The increased incidence in this group is probably due to inherited oncogenes.

Approximately 5% to 10% of all breast cancers have an inherited basis. All inherited genes are autosomal dominant but have variable penetrance. Males can carry the gene 50% of the time. Carriers of these germline mutations have up to a 4%-per-year risk of developing breast cancer and a lifetime risk of up to 85% ([4](#)). The most common gene mutations are the *BRCA1* (chromosome 17q21) and *BRCA2* (chromosome 13q12–13) gene deletions. These mutations are rare in the general public (0.1%) but are more commonly identified in Jews of Ashkenazi descent (1% to 2%) ([5](#)). Testing should be performed only if there is a high likelihood that results will be positive, can be interpreted accurately, and will be used to influence decisions regarding medical management of the patient and family.

Diet, Obesity, and Alcohol

Marked geographic differences in the incidence of breast cancer may be related to diet, in particular with regard to variations in fat intake ([6](#)). It is not clear, however, that a high-fat diet is a specific risk factor, because most studies have not clearly separated obesity from other known risk factors ([7](#)). Alcohol consumption may increase the risk of breast cancer, but again this relationship is not clear ([8](#)).

Reproductive and Hormonal Factors

The risk of breast cancer increases with the length of a woman's reproductive phase ([9](#)). Thus, the median age at menarche is lower for women who develop breast cancer, and either natural or artificial early menopause protects against the development of breast cancer ([10](#)). Artificial menopause as a result of oophorectomy lowers the risk of breast cancer farther than does early natural menopause. There is no clear association between the risk of breast cancer and menstrual irregularity and duration of menses. There is some evidence that these reproductive factors, although decreasing the risk of developing breast cancer, may adversely affect a patient's prognosis ([11](#)).

Lactation does not affect the incidence of breast cancer, but women who have never been pregnant have a higher risk of breast cancer than those who are multiparous. Also, women who bear their first child later in life have a higher incidence of breast cancer than do younger primigravida females ([12](#)).

A well-controlled study from the Centers for Disease Control and Prevention showed that oral contraceptive use does not increase the risk of breast cancer, regardless of duration of use, family history, or coexistence of benign breast disease ([13](#)). However, a recent pooled analysis from 54 epidemiologic studies showed

current users of oral contraceptives had a small, but real, increased risk when compared with nonusers. Ten years after discontinuation, the risk of past users declined to that of the normal population (14).

Although short-term estrogen treatment for menopausal symptoms probably does not increase the risk of breast cancer, prolonged use (longer than 10 years) or higher dosages of estrogen may increase the risk. Current data suggest that postmenopausal estrogen administration is a risk factor (15). The current consensus is that, postmenopausally, estrogen should be given in a relatively low dose either cyclically or in combination with progestins when the uterus is present. Although estrogens may slightly increase the incidence of breast cancer, this risk should be weighed against the possible benefits in preventing osteoporosis and heart disease.

History of Cancer

Women with a history of breast cancer have an approximately 50% risk of developing microscopic breast cancer and about a 20% risk of developing clinically apparent cancer in the contralateral breast, which occurs at a rate of 1% to 2% per year (16). Lobular carcinoma has a higher incidence of bilaterality than does ductal carcinoma. A history of endometrial carcinoma, ovarian carcinoma, or colon cancer has also been associated with an increased risk of breast cancer.

Diagnosis

Breast cancer most commonly arises in the upper outer quadrant, where there is more breast tissue. Breast masses are most often discovered by the patient and less frequently by the physician during routine breast examination. The increasing use of screening mammography has expanded the ability to detect nonpalpable abnormalities. Rarely metastatic breast cancer may be found as an axillary mass without obvious malignancy.

Mammography and physical examination, the standard screening modalities, are complementary. In the past, most cases of breast cancer were discovered as a palpable mass. However, **10% to 50% of cancers detected mammographically are not palpable. Conversely, physical examination detects 10% to 20% of cancers not seen on mammography (17).** The purpose of screening is to detect cancers when they are small (<1 cm) and have the highest potential for surgical cure. Most trials have shown a 20% to 30% reduction in breast cancer mortality for women age 50 and older who undergo annual screening mammography. Data for screening of women under 40 have been more controversial. However, recent data from the Gothenburg screening trial showed a 45% reduction in mortality for women screened between the ages 40 and 49 (18). Because of these findings, it is recommended that all women undergo screening mammography starting at age 40, along with clinical breast examination and breast self-examination. No other tests, such as ultrasonography, magnetic resonance imaging (MRI), computed tomography (CT) scans, sestamibi scans, positron emission tomography (PET) scans, or serum blood markers, are effective screening modalities, and these tests should be used only when indicated. Screening guidelines recommended by the American College of Radiology and the American Cancer Society are presented in [Table 35.1](#).

Bilateral mammograms: By age 40: baseline mammogram Age 40-49: every 1-2 years Age >50: every year If family history of breast cancer, may consider baseline mammogram age 35, or 10 years younger than earliest family member was diagnosed, whichever is younger.
Self-examination: Premenopausal: 5-7 days after menstrual period monthly Postmenopausal: same day every month
Clinical breast examination: Age 20-40: exam by physician every 3 years Age > 40: exam by physician every 2-3 years (May do annually if there is a positive family history) Tumor markers (CA27-29, CA15-3): not recommended as screening tests

Table 35.1. Official Screening Recommendations

Masses are easier to palpate in older women with fatty breasts than in younger women with dense, often nodular breasts. An area of thickening amid normal nodularity may be the only clue to an underlying malignancy. Skin dimpling, nipple retraction, or skin erosion is usually obvious, but these are later-stage disease signs. Algorithms for the evaluation of breast masses in premenopausal and postmenopausal women are presented in [Chapter 18](#).

A dominant breast mass must be considered a possible carcinoma, and biopsy is essential for diagnosis. **About 30% to 40% of lesions believed clinically to be malignant will be benign on histologic examination (19).** Conversely, 20% to 25% of clinically benign-appearing lesions will be proven malignant by biopsy (20).

Biopsy Techniques

For patients with obvious malignancy, it may be reasonable to obtain a biopsy specimen and a frozen section immediately before mastectomy or other definitive treatment. It is preferable for the patient to be involved in the planning of her therapy. Initial biopsy is better followed by subsequent definitive treatment in the two-step approach. This approach allows the physician to discuss alternative forms of therapy with the patient who has a malignancy, and it gives the patient an opportunity to obtain a second opinion before undergoing definitive treatment.

Fine-needle Aspiration Cytology

Fine-needle aspiration (FNA) cytology is performed with a 20- or 22-gauge needle. The technique has a high level of diagnostic accuracy, with a 10% to 15% false-negative rate and rare, but persistent, false-positive results (21). If a mass appears to be malignant on physical examination or mammography or both, FNA cytology results can be useful in discussing alternatives with the patient. Negative FNA cytologic results do not exclude malignancy and usually are followed by excisional biopsy or careful observation. In young women, it is prudent to follow a benign-appearing mass for one or two menstrual cycles. Furthermore, confirmation of a clinically apparent fibroadenoma with FNA can serve as the basis for observational follow-up without excision.

Open Biopsy

Open biopsy may be performed if FNA cytology has not been performed or if the results are negative or equivocal. **An unequivocal histologic diagnosis of cancer should be obtained before treatment of breast cancer is undertaken.** Cytologic diagnosis may be relied on if the mass clinically or mammographically appears to be malignant. In equivocal cases, a partial mastectomy can be performed, and a frozen section can be obtained to confirm the diagnosis of cancer before the axillary dissection is started. An alternative to open biopsy is removal of a core of tissue through a Vim-Silverman-type cutting needle. If a definitive diagnosis is not obtained, these procedures must also be followed by open biopsy.

Open biopsy can usually be performed in an outpatient setting with the patient under light sedation, in conjunction with the use of local anesthesia, in the following manner:

1. The patient is positioned and the location of the mass confirmed.
2. Local anesthesia is used to infiltrate the skin and subcutaneous tissue surrounding the palpable mass.
3. An incision is made directly over the mass. Planning should include an ellipse of skin to be either excised with the mastectomy or placed cosmetically so that partial mastectomy can be performed through the same incision. Paraareolar incisions are appropriate only for lesions in proximity to the nipple-areolar complex.
4. After the skin and underlying tissue are incised, the mass is gently grasped with Allis forceps or with a stay suture and moved into the operative field.

5. The mass should be excised completely whenever possible. Large masses that are difficult to excise totally with local anesthesia can be incised. When an incisional biopsy is used, a frozen section should be obtained to confirm that tissue is malignant. Such masses, however, are preferably sampled with FNA or core biopsy.
6. Once the mass is removed, adequate hemostasis is achieved and the incision is closed. A cosmetically superior result will be achieved if the breast parenchyma is not reapproximated deeply. The most superficial subcutaneous fat can be reapproximated with fine absorbable sutures. The skin should be closed with a subcuticular suture and adhesive strips to achieve the most cosmetically pleasing result. Usually a drain is not necessary.

Mammographic Localization Biopsy

Biopsy of nonpalpable lesions is a potentially difficult procedure that requires close cooperation between the surgeon and the mammographer. The mammographer places a needle or specialized wire into the breast parenchyma at or near the site of the suspected abnormality. Many mammographers will also inject a biologic dye to assist localization further. The surgeon then reviews the films with the mammographer and localizes the abnormality with respect to the tip of the wire or needle. An incision is made directly over this area, and a small portion of the breast that is suspected of containing the abnormality is excised. A mammogram of the surgical specimen is obtained to ensure that the abnormality has been excised. Often, the mammographer can place a needle in the specimen at the site of the abnormality to facilitate histologic evaluation and ensure that the pathologist examines the site of the abnormality.

Stereotactic Core Biopsy

Mammographic units with computerized stereotactic modifications can be used to localize abnormalities and perform needle biopsy without surgery. Under mammographic guidance, a biopsy needle is inserted into the lesion and a core of tissue is removed for histologic examination. Ultrasonography may also be used to obtain a core biopsy of a nonpalpable lesion. Because it is less invasive and less expensive than mammographic localization biopsy, core biopsy is preferred for accessible lesions.

Pathology and Natural History

Breast cancer may arise in the intermediate-sized ducts or terminal ducts and lobules. In most cases, the diagnosis of lobular and intraductal carcinoma is based more on histologic appearance than site of origin. The cancer may be either invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma) or *in situ* (ductal carcinoma *in situ* or lobular carcinoma *in situ*). Morphologic subtypes of infiltrating ductal carcinoma can be described as scirrhous, tubular, medullary, and mucinous.

Infiltrating ductal carcinoma of unspecified type accounts for 60% to 70% of the breast cancers in the United States (22). Mammographically, it is characterized by a stellate density or by microcalcifications. Macroscopically, there are gritty, chalky streaks within the tumor that most likely represent a desmoplastic response; microscopically, there is invasion of the surrounding stroma and fat. There is often a fibrotic response surrounding the invasive carcinoma.

Other types of infiltrating ductal carcinoma are far less common. Medullary carcinoma, which accounts for approximately 5% to 8% of breast carcinomas, arises from larger ducts within the breast and has a dense lymphocytic infiltrate. The tumor appears to be a slow-growing, less aggressive malignancy than the infiltrating ductal carcinoma.

Mucinous (colloid) carcinoma accounts for 5% of all breast cancers. Grossly, the tumor may have areas that appear mucinous or gelatinous. Infiltrating comedo carcinoma accounts for 1% of breast malignancies. It is an invasive cancer characterized by foci of necrosis that exude a comedonecrosis-like substance when biopsied. Usually, comedocarcinomas are *in situ* malignancies. Papillary carcinoma is predominantly a noninvasive ductal carcinoma; when invasive components are present, it should be specified as invasive papillary carcinoma. Tubular carcinoma is a well-differentiated breast cancer that accounts for 1% of all breast malignancies. Tubular carcinomas tend to have a better prognosis than infiltrating ductal carcinomas and rarely metastasize to axillary lymph nodes. Adenoid cystic carcinomas are extremely rare and are similar histologically to those seen in the salivary glands. They tend to be well differentiated and slow to metastasize.

Growth Patterns

The growth potential of breast cancer and the patient's resistance to malignancy vary widely with the individual and the stage of disease. The doubling time of breast cancer can range from several weeks for rapidly growing tumors to months or years for slowly growing ones. If the doubling time of a breast tumor was constant and a tumor originated from one cell, a doubling time of 100 weeks would result in a 1-cm tumor in about 8 years (Fig. 35.1) (23). During the preclinical phase, tumor cells may be circulating throughout the body.

Figure 35.1 Growth rate of breast cancer indicating long preclinical phase. (From Gullino PM. Natural history of breast cancer: progression from hyperplasia to neoplasia as predicted by angiogenesis. *Cancer* 1977;39:2697–2703, with permission.)

Because of the long preclinical tumor growth phase and the tendency of infiltrating lesions to metastasize early, many clinicians view breast cancer as a systemic disease at the time of diagnosis. Although cancer cells may be released from the tumor prior to diagnosis, variations in the tumor's ability to grow in other organs and the host's response to the tumor may inhibit dissemination of the disease. Many women with breast cancer can be treated successfully with surgery alone, and some women have been cured even in the presence of palpable axillary disease. Thus, a pessimistic attitude that breast cancer is systemic and incurable at the time of diagnosis is unwarranted. A more realistic approach may be to view breast cancer as a two-component disease: one is the primary tumor in the breast, with all the inherent problems of local and regional extension and primary tumor control, and the other consists of the systemic metastases with their life-threatening consequences.

Although the natural history of breast cancer can involve metastases to any organ, involvement of bone, lungs, or liver occurs in 85% of women with metastatic breast cancer (24,25 and 26). If any of these sites is involved, metastases to other organs are highly likely. The use of systemic chemotherapy affects the sites of metastases, and currently metastases are occurring in more unusual sites with greater frequency.

Staging

After the diagnosis of breast cancer has been established, either cytologically or histologically, the clinical stage of disease should be determined. The Columbia Clinical Staging System was widely used for many years (27) but has been replaced by the tumor–nodes–metastases (TNM) system recommended by the International Union Against Cancer (UICC) and the American Joint Committee on Cancer (28). This system allows both preoperative clinical staging and postoperative pathologic staging (Table 35.2 and Table 35.3).

Primary Site	Secondary Site
Bladder	Bladder
Breast	Breast
Colon	Colon
Esophagus	Esophagus
Endometrium	Endometrium
Stomach	Stomach
Prostate	Prostate
Rectum	Rectum
Small Intestine	Small Intestine
Spleen	Spleen
Testis	Testis
Uterus	Uterus
Vagina	Vagina
Vulva	Vulva
Salivary Gland	Salivary Gland
Soft Tissue	Soft Tissue
Thyroid	Thyroid
Uterine Cervix	Uterine Cervix

Table 35.3. Staging of Breast Carcinoma

Preoperative Evaluation

The extent of preoperative workup varies with the initial stage of the disease (29). For most patients with small tumors, no palpable lymph nodes (TNM stage I), and no symptoms of metastasis, the preoperative evaluation should consist of bilateral mammography, chest radiograph, complete blood count, and screening blood chemistry tests. Bone, CT, and MRI scanning are not necessary unless symptoms or abnormal blood chemistry suggest bone or liver metastasis. For patients with clinical stage II disease, a bone scan should be obtained, but a CT scan of the liver is not necessary unless symptoms or liver function tests suggest liver metastasis. Patients with clinical stage III or IV disease should undergo both bone and liver scanning. A bone marrow biopsy should be performed if there is obvious bone marrow dysfunction but metastases are not evident on a bone scan.

Treatment

Mastectomy

Traditionally, treatment of breast cancer has been surgical, but the type of operation employed has remained a controversial and highly emotional issue. During the nineteenth century, surgical treatment of breast cancer was haphazard, varying from local excision alone to total mastectomy. Halsted devised the radical mastectomy in an attempt to treat carcinoma of the breast as a local infiltrative process (30). Thus, radical mastectomy removes the entire breast, the underlying pectoral muscles, and the contiguous axillary lymph nodes in continuity (31) (Fig. 35.2A). Haagensen and Bodian reported a 51-year experience with radical mastectomy. Their data, which included 1,036 patients with a follow-up of 47 years, remain unequalled in evaluating any single method of treating breast cancer (32).

Figure 35.2 Appearance of breast after radical mastectomy (A) versus modified mastectomy (B). (From Haigh PI, Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000:660, with permission.)

During the twentieth century, extensions and modifications of the radical mastectomy procedure were devised that involved removal of more local and regional tissue. Supraclavicular node dissections were added to the radical mastectomy (33). In addition, supraclavicular, mediastinal, and internal mammary lymph node dissections were performed (34).

Urban added *en bloc* internal mammary lymph node dissection to the standard radical mastectomy (35). This technique became popular and is the operation commonly referred to as the *extended radical mastectomy*. The extended radical mastectomy did not enhance overall survival rates (36). About 5% to 10% of patients in whom axillary lymph nodes are not involved will have involvement of internal mammary nodes. Locally destructive surgery is not justified, however, based on current understanding of the biologic behavior of breast cancer.

Modified Radical Mastectomy

Modified radical mastectomy preserves the pectoralis major muscle (37,38) (Fig. 35.2B). The breast is removed in a manner similar to that of the radical mastectomy; however, removal of the skin and the axillary lymph node dissection are not as extensive, and there is no need for skin grafting. There is no difference in survival rates between radical mastectomy and modified radical mastectomy, but the latter procedure has a better functional and cosmetic result (39). Modified radical mastectomy has replaced radical mastectomy and remains the procedure most often performed for breast cancer despite the proven equivalence of breast conservation therapy.

Total Mastectomy

Total mastectomy is the removal of the entire breast, nipple, and areolar complex without the underlying muscles or axillary lymph nodes. Axillary nodes are not

removed intentionally. However, low-lying lymph nodes in the upper outer portion of the breast and low axilla usually are included in the specimen. Total mastectomy has local control rates comparable with those of radical or modified radical mastectomy but has a higher risk of axillary recurrence. Because the axillary lymph nodes are not examined microscopically, this operation generally is less desirable than modified radical mastectomy. Regional recurrence will occur in at least 15% to 20% of patients treated with total mastectomy alone.

Adjuvant Radiation Therapy

McWhirther developed the combination of total mastectomy with radiation therapy (40). Many have advocated adjuvant radiation therapy in combination with various operative procedures. Studies claiming improvements in overall survival usually are flawed by the use of historical controls and inaccurate preoperative staging. Earlier trials, both prospective randomized studies and historical control studies, show that adjuvant radiation therapy improves local control but not survival rates (41,42,43 and 44). In contrast, a recent randomized control study demonstrated a 9% absolute increase in 10-year overall survival (45). The researchers concluded that the addition of postoperative radiation to mastectomy and chemotherapy prolongs survival in high-risk premenopausal women with breast cancer.

In a prospective randomized trial performed by the National Surgical Adjuvant Breast Project (NSABP), the roles of postoperative radiation therapy and axillary treatment were examined (46). Patients were randomly assigned to therapy consisting of total mastectomy, radical mastectomy, or total mastectomy with radiation therapy. This trial showed no difference in survival rates among the three groups of patients, whereas radiation therapy and axillary treatment improved local and regional control.

Conservative Therapy with or without Radiation Therapy

Radiation therapy alone, without excision of the tumor, is associated with a high local failure rate (47,48,49 and 50). Similarly, local excision without radiation has a high local failure rate. A major prospective randomized trial compared radical surgery with a combination of conservative surgery and modern radiotherapeutic techniques (51,52). Patients were randomly assigned to treatment with either standard Halsted radical mastectomy or a combination of quadrantectomy, axillary lymph node dissection, and postoperative radiation therapy. Only patients in whom tumors were smaller than 2 cm and not centrally located and who had no clinical evidence of axillary lymph node disease ($T_1 N_0 M_0$) were considered for this trial. All 701 women in the study were comparable in age, tumor size, menopausal status, and histologic involvement of the axillary lymph nodes (52). After more than 15 years of follow-up, there has been no statistically significant difference between the two groups in either local control or overall survival rates.

The NSABP conducted a trial that extended these observations and provided further information (53). Eligible patients could have a primary tumor ≤ 4 cm, with or without palpable axillary lymph nodes, provided that the lymph nodes were not fixed (i.e., stage I or stage II, T_1 or T_2 , and N_0 or N_1). Patients were assigned randomly to one of three groups: (a) modified radical mastectomy; (b) segmental mastectomy (lumpectomy) and axillary lymph node dissection; or (c) segmental mastectomy, axillary lymph node dissection, and postoperative radiation therapy. Unlike the quadrantectomy, segmental mastectomy or "lumpectomy" consists of removing only the tumor and a small rim of normal surrounding tissue and is cosmetically superior (Fig. 35.3). Patients were considered ineligible if they were found to have microscopic involvement of the margins. A total of 1,843 women were randomized among the three treatment arms, and the groups were comparable. The lowest local recurrence rate was seen among patients treated with segmental mastectomy and postoperative radiation therapy. Of these patients, 90% were free of local recurrence after 8 years of observation, whereas 39% of the patients undergoing segmental mastectomy without radiation therapy had a local recurrence. Although the addition of radiation therapy clearly improved the local control rate, no significant difference in overall survival rates or disease-free survival could be seen among the three treatment arms; there was a trend, however, in favor of patients who received radiation. **This NSABP study clearly shows that the combination of segmental mastectomy, axillary lymph node dissection, and postoperative radiation therapy was as effective as modified radical mastectomy for the management of patients with stage I and II breast cancer.** These findings have since been updated; after 12 years of follow-up, no difference was seen in survival among the three groups (54). The high local recurrence rate without radiation therapy makes limited surgery alone generally unacceptable except in unusual circumstances.

Figure 35.3 Appearance of breast after lumpectomy, axillary dissection, and radiation therapy. (From Haigh PI, Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*, 3rd ed. Philadelphia: Williams & Wilkins, 2000:662, with permission.)

Axillary lymph node status and the number of involved nodes is the most important prognostic indicator for patients with primary breast cancer (55,56 and 57). For these reasons, axillary lymphadenectomy is used to detect and quantify the extent of nodal metastasis (58). Axillary lymph node dissection (ALND) is performed routinely on all patients with breast cancer for the purposes of staging and the planning of adjuvant chemotherapy. Axillary dissection is associated with a very low risk of regional recurrence (1% to 3%) but at the cost of significant morbidity (59). The rate of acute complication is 20% to 30%. Similarly, the risk of chronic lymphedema is reportedly as high as 20% to 30% (60). Limiting the dissection to level I nodes or random sampling is associated with unacceptably high false-negative rates (61).

Only one-third of patients with a clinically negative axilla will be found to have nodal metastasis after histopathologic examination of all lymph nodes (62). This means that two-thirds of patients will undergo the morbidity of ALND without proven benefit.

In 1991, intraoperative lymphatic mapping and selective lymph node sampling was introduced in an effort to address these problems (63). The concept behind sentinel lymph node dissection (SLND) is best described by the definition of a sentinel node (SN). The SN is the lymph node that has the greatest potential to harbor metastasis if present. The SLND accurately predicts the status of the entire nodal basin by removing only one or two lymph nodes with minimal morbidity. If the SN is found to be negative, this directed approach can be used to distinguish patients who would not benefit from ALND and its morbidity. **In a study of 107 patients with T1 and T2 breast cancer who underwent SLND followed by ALND, the SLN was successfully identified in 100 patients (93.5%). There were no false-negative results and the sentinel node accurately predicted axillary status in all 100 patients.**

The technique of SLND has been validated by a number of authors using a variety of techniques (64,65). The information obtained from SLND appears to be equivalent to that of ALND in the few small trials conducted to date. Furthermore, a recent prospective study demonstrated that in node-negative patients undergoing SLND only, the recurrence rate in the axilla was zero at a median follow up of 39 months (66). The degree of accuracy in predicting axillary metastasis, combined with a very low morbidity rate, makes SLND an attractive alternative to ALND.

Adjuvant Systemic Therapy

For many patients, local and regional control of breast cancer is achieved readily with surgery and radiation therapy alone. About 90% of patients will never experience a local recurrence; however, patients may still develop metastatic disease. The goal of adjuvant systemic therapy is to eliminate occult metastases during the early postoperative period while theoretically they are most vulnerable to anticancer agents (67). This approach, in turn, reduces the risk of local and distant recurrence.

It is currently well accepted that adjuvant systemic therapy will prolong survival in selected breast cancer patients. However, in patients with favorable tumors

and a low risk of recurrence and subsequent death, such as those who have node-negative cancers smaller than 1 cm or node-negative cancers smaller than 2 cm with grade 1 histology, this benefit is small and may not justify the risks of systemic therapy. **Adjuvant systemic therapy reduces the odds of death by about 25% per year in both node-negative and node-positive patients** (68). Because this risk reduction is relatively constant, patients with favorable, node-negative disease have a much smaller absolute benefit as compared with patients who have node-positive disease and a high risk of recurrence. For patients with node-negative disease, the absolute benefit may only be a few percent versus 10% to 20% for those with node-positive disease.

Cytotoxic chemotherapy and hormonal therapy have inherent risks that must be considered when choosing which patients should receive them. Not only are there known acute side effects with current standard regimens, but also there is growing evidence that patients who undergo chemotherapy more frequently report chronic neurocognitive deficits (69). The impact of these deficits remains undefined. Similarly, systemic therapy with tamoxifen has an appreciable long-term morbidity. Adverse effects include an increased incidence of uterine cancer, vaginal dryness, and hot flashes. Choosing the patients who should receive adjuvant therapy can be a difficult decision. This decision entails analyzing a variety of prognostic and predictive factors, identifying patients at risk for recurrence, and quantifying that risk. **In general, adjuvant chemotherapy is currently recommended for women with a greater than 10% chance of relapse within 10 years.** In practice, systemic adjuvant therapy is offered to many patients with early-stage breast cancer. The choice of therapy generally depends on an evaluation of specific risk factors.

Factors that determine the patient's risk of recurrence are nodal involvement, tumor size, estrogen and progesterone receptor status, nuclear grade, histologic type, proliferative rate, and a variety of biologic markers. These prognostic factors and their effects on recurrence are summarized in [Table 35.4](#). The assumption is made that patients with high-risk prognostic factors are more likely to benefit from adjuvant cytotoxic or hormonal therapy; thus, these patients are generally offered such treatment.

Factor	Increased Risk of Recurrence
Size	Larger tumors
Histologic grade	High-grade tumors
DNA ploidy	Aneuploid tumors
Labeling index	High index (>3%)
S phase fraction	High fraction (>5%)
Lymphatic-vascular invasion	Present
Cathepsin D	High levels
HER-2/neu oncogene expression	High expression
Epidermal growth factor	High levels

Table 35.4. Prognostic Factors in Node-negative Breast Carcinoma

It is generally accepted that patients with lymph node metastasis have a higher risk of recurrence than patients with node-negative disease. The 10-year survival rate for women with palpable metastatic axillary lymph nodes who receive no systemic therapy is only about 50% to 60%. Even when they are not clinically palpable, lymph node metastases portend an unfavorable course. The number of lymph nodes involved and the presence of extracapsular invasion are important indicators of poor prognosis.

Another important prognostic indicator of relapse is tumor size. In an evaluation of 767 patients with node-negative disease who underwent radical or modified radical mastectomy without adjuvant chemotherapy, the relapse rate in patients with tumors larger than 1 cm or special tumor types larger than 3 cm (tubular, mucinous or papillary) was 27% at 10 years (70). For tumors smaller than 1 cm, the relapse rate was only 9% at 10 years.

Hormone receptor status is an important predictor not only of prognosis but also of response to hormonal therapy. Several studies demonstrated that patients who are estrogen and progesterone positive have overall improved survival (71,72). The status of these receptors should be known when determining the need for and choice of adjuvant therapy.

Histologic grade appears to predict overall survival as well. Those patients with favorable, well-differentiated tumors tend to fare better than those with poorly differentiated ones ([Table 35.5](#)). In a British study of 1,168 women, histologic grade was an independent predictor of overall survival at 10 years. Among multiple factors analyzed, only tumor size, lymph node status, and histologic grade had independent significance (73).

AJCC Stage	Breast Cancer Cases (%)	5-Year Survival (%)
0	9.4	99
I	40.9	82
II	36.6	73
III	8.9	55

Table 35.5. Year Survival According to Stage of Breast Cancer

Specific tumor biologic markers are now gaining research interest because of their possible role in predicting which patients will respond to chemotherapy regimens. The most research has been performed with HER-2/*neu*. In an NSABP study, patients with HER-2/*neu* overexpression fared worse if they were not treated with anthracycline-based regimens (74). Another study showed that the addition of *trastuzumab* (*Herceptin*), an antibody directed against the HER-2/*neu* receptor, significantly increased the response rate to therapy over standard chemotherapy alone in the presence of metastases (75). Current research is focusing on the role of *trastuzumab* as adjuvant therapy. Other prognostic indicators such as *p53*, Ki-67, and S-phase fraction are also being investigated.

Over the course of several decades, more than 100 prospective, randomized trials have been conducted examining the role of adjuvant chemotherapy in breast cancer (76). From this work, a variety of systemic regimens have emerged. Systemic therapy includes cytotoxic agents and hormonal agents, used alone or in combination. Following is a brief description of the more commonly used regimens. A comprehensive review of all available modalities is beyond the scope of this chapter but is readily available in standard medical oncology texts.

Initially, trials involved a single perioperative course of chemotherapy in an attempt to eradicate circulating tumor cells. The Nissen-Meyer study from Norway showed that a single course of *cyclophosphamide* improved overall survival rates (77). Subsequently, numerous trials have shown the benefit of adjuvant chemotherapy for certain subgroups of patients (78). In the initial NSABP adjuvant trial, a 2-year course of *melphalan* was shown to be superior to no treatment (79). Subsequent trials have shown the enhanced beneficial effect of multiple drugs and a combination of hormonal manipulation with chemotherapy (80).

Historically, the most frequently used adjuvant combination chemotherapy has been CMF: *cyclophosphamide*, *methotrexate*, and *5-fluorouracil* (*5-FU*). In the original study by Bonadonna and associates, patients with positive axillary lymph nodes were randomized to receive either 12 monthly cycles of CMF or no therapy after radical mastectomy (81). A statistically significant benefit was found with CMF for premenopausal patients, especially those with one to three positive nodes. A subsequent study showed six cycles of CMF to be as effective as 12 cycles (82). However, no significant effect was seen for postmenopausal women. This was thought to be because postmenopausal women were less likely to tolerate the full course of CMF (83). **After 20 years of follow-up, this trial demonstrated a**

persistent survival advantage for premenopausal women receiving CMF adjuvant therapy (84). In a later study of node-negative, estrogen receptor–negative breast cancer patients, adjuvant CMF also had a beneficial effect. After 12 years of follow-up, 71% of treated patients remained disease free in comparison with 48% in the control group. Both premenopausal and postmenopausal women benefited from adjuvant CMF (85).

Today, anthracyclines (A) are commonly used more often than in the adjuvant and metastatic treatment of breast cancer. They are among the most active drugs and have been used in the adjuvant setting since 1973 (86). A large randomized NSABP study compared CMF versus AC regimens in node-positive patients. This study demonstrated similar treatment outcomes in the AC and CMF treatment groups. However, the AC regimen was preferred because of the shorter duration (four cycles for 3 months versus six cycles for 6 months) and better reported tolerance (87).

Taxanes are also being used frequently in a variety of multiple-agent chemotherapy regimens because of their demonstrated activity in metastatic breast cancer patients (88). In a randomized trial of 3,170 node-positive patients who received AC 4 times followed by *paclitaxel* 4 times for 4 weeks or no additional therapy, there was an absolute improvement in survival from 84% to 87% at 36 months of follow-up. Benefits were similar in both premenopausal and postmenopausal women (89). In contrast, no benefits were seen in large studies conducted elsewhere (90,91). Currently, there are no definitive data that demonstrate any benefit to the addition of taxanes over CMF or AC in node-negative patients. Ongoing clinical studies are under way in an attempt to define the role of taxanes in the adjuvant setting.

Hormonal Therapies

Hormonal manipulation used alone and in combination with cytotoxic regimens is beneficial in select groups of women. *Tamoxifen*, an estrogen analogue, offers substantial benefits in both premenopausal and postmenopausal women. **Taken at a dose of 20 mg per day for 5 years, *tamoxifen* reduces the annual odds of recurrence by about 50% and the annual odds of death by about 25%. These benefits were seen in women with estrogen receptor–positive disease despite the presence or absence of chemotherapy (92).** The possibility of substituting *tamoxifen* for radiotherapy in patients with small (<1 cm) tumors is also being evaluated prospectively.

There are data to suggest that *tamoxifen*, when used in combination with cytotoxic chemotherapy, improves survival in women with positive axillary lymph nodes and positive estrogen receptor expression (93). In patients with node-negative, estrogen receptor–positive disease, the addition of *tamoxifen* to chemotherapy improved disease-free survival after 5 years of follow-up (94). In NSABP study B-14, 2,644 patients with estrogen receptor–positive tumors and no axillary metastases were randomized, double blinded to either *tamoxifen* (10 mg orally twice daily for 5 years) or a placebo control. After a 4-year median follow-up, the disease-free survival rate for the 1,318 patients treated with *tamoxifen* was 82% compared with 77% for the 1,326 patients treated with placebo ($p = 0.00001$). An advantage existed for both premenopausal and postmenopausal women.

The Early Breast Cancer Trialists' Collaborative Group performed a metaanalysis of adjuvant systemic therapy for breast cancer. They analyzed randomized trials involving adjuvant systemic hormonal, cytotoxic, or immune therapy administered to more than 75,000 women with stage I or II carcinoma. The investigators concluded that, for postmenopausal women with estrogen receptor–positive tumors, *tamoxifen* in a dose of 20 mg daily for at least 2 years had a significant beneficial effect on disease-free survival rates. This beneficial effect lasted up to 10 years. Data demonstrated a decreased incidence of carcinoma in the contralateral breast and a decreased death rate from heart disease.

General Recommendations

Adjuvant systemic therapy, either with *tamoxifen* or multiple-chemotherapy agents, lowers the incidence of recurrence by about 30%. It is important to understand that the proportional reduction in risk of relapse is relatively constant regardless of absolute risk (95) (Table 35.6). As mentioned earlier, adjuvant cytotoxic chemotherapy appears to affect the natural history of patients with axillary node–negative breast cancer. A 2000 consensus statement from the National Institutes of Health on early-stage breast cancer advised that all patients be considered for clinical trials and offered the opportunity to participate (96). Furthermore, node-negative patients who are not candidates for clinical trials should be made aware of the benefits and potential risks of adjuvant systemic therapy. Most high-risk patients with node-negative disease are now being treated with adjuvant cytotoxic therapy.

Age	Therapy	Reduction in Annual Odds of Recurrence %	Reduction in Annual Odds of Death %
<50	Tamoxifen × Sys	45 ± 8	32 ± 10
50–59	Tamoxifen × Sys	37 ± 6	11 ± 8
60–69	Tamoxifen × Sys	54 ± 5	33 ± 6
<40	Polychemotherapy	37 ± 7	27 ± 8
40–49	Polychemotherapy	35 ± 5	27 ± 5
50–59	Polychemotherapy	22 ± 4	14 ± 4
60–69	Polychemotherapy	19 ± 4	8 ± 4

Table 35.6. Effect of Systemic Therapy on Recurrence and Survival from Breast Cancer

In postmenopausal women, chemotherapy is about one-half as effective as *tamoxifen* in the adjuvant setting (97). For most postmenopausal women with hormone-responsive disease (estrogen- and progesterone-responsive positivity), including node-positive patients, *tamoxifen* alone may be adequate therapy. High-risk patients with hormone-resistant disease may benefit from cytotoxic systemic therapy. In patients over age 70 years, there are little data available regarding the benefits of adjuvant cytotoxic therapy because of the eligibility criteria of many large trials. Because of the inherent toxicity of chemotherapeutic regimens, patients in this age group must be carefully selected with regard to treatment.

Caution should be exercised when using chemotherapeutic agents. Patients in whom the risk of recurrence is low are likely to derive little overall benefit from the use of adjuvant systemic therapy, whereas those with an overall high risk of recurrence are likely to receive the greatest benefit. When the risk of recurrence is extremely low, as would be expected for tumors smaller than 1 cm with no lymph node metastasis, the reduction in the risk of recurrence may not justify the side effects of the drugs. Current studies are under way to investigate whether this assumption is true.

The current recommendations for adjuvant systemic therapy in breast cancer are summarized as follows:

1. **Premenopausal women with lymph node involvement should be treated with adjuvant combination chemotherapy. *Tamoxifen* may be added to the regimen for patients with estrogen receptor–positive tumors following cytotoxic therapy.**
2. **Premenopausal women without evidence of axillary lymph node involvement but with risk factors such as large (>1 cm), aneuploid, or estrogen receptor–negative tumors should be treated with combination chemotherapy. *Tamoxifen* should be added for patients with estrogen receptor–positive tumors.**
3. **Postmenopausal patients who have negative lymph nodes and positive hormone receptor levels should receive adjuvant *tamoxifen* therapy. Those with positive lymph nodes may receive *tamoxifen* alone, multidrug cytotoxic therapy, or a combination thereof.**
4. **Postmenopausal women who have lymph node metastasis and negative hormone receptor levels may be treated with adjuvant chemotherapy.**
5. **Adjuvant systemic therapy is not recommended for patients with favorable, small nonpalpable tumors or palpable tumors smaller than 1 cm. The toxicity of chemotherapy and its effect on quality of life must be carefully evaluated, especially in older postmenopausal women.**

Prognosis

The treatment of advanced, metastatic breast cancer is largely palliative. For most physicians who treat this disease, quality of life issues are paramount when

choosing which type of therapy is offered. In patients with locally advanced disease in conjunction with distant metastasis, palliative radiotherapy may be advised. Palliative radiotherapy is most widely used in the treatment of certain soft tissue or bony metastases to control pain or avoid fracture. This approach is best exemplified in the treatment of isolated bone metastases, chest wall recurrences, brain metastases, and spinal cord compression.

Systemic disease may be controlled by hormonal or cytotoxic therapy. Because the quality of life during a remission induced by endocrine manipulation usually is superior to a remission following cytotoxic chemotherapy, it usually is preferable to try endocrine manipulation first. Disseminated disease may respond favorably after endocrine therapy such as functional organ ablation (ovary, pituitary, adrenal glands) or administration of drugs that block hormonal function. A favorable response occurs in about one-third of patients with metastatic disease. For those patients whose tumors express estrogen receptors, this response rate may be as high as 60%. Because only 5% to 10% of women whose tumors do not contain estrogen receptors respond to treatment, they should not receive hormonal therapy except in unusual cases such as elderly patients who are unable to tolerate cytotoxic therapy ([98](#)).

Cytotoxic chemotherapy should be considered for the treatment of metastatic breast cancer in the following instances: (a) if organ involvement is potentially life-threatening (brain, lung, or liver) (b) if hormonal treatment is unsuccessful or the disease has progressed after an initial response to hormonal manipulation, or (c) if the tumor is estrogen receptor–negative. The most useful single chemotherapeutic agent is an anthracycline such as *doxorubicin*, which has an estimated response rate of 40% to 50%. Combination therapy using multiple agents has proved to be more effective, with response rates as high as 60% to 80% ([99](#)). Clinical trials are under way to examine a variety of combinations for stage IV disease. The side effects of nausea and vomiting, which can be devastating, are now well controlled with central-acting antiemetics. The importance of controlling these side effects cannot be overemphasized.

Special Breast Cancers

Paget's Disease

Sir James Paget described a nipple lesion similar to eczema and recognized that this nipple change was associated with an underlying breast malignancy ([100](#)). The erosion results from invasion of the nipple and surrounding areola by characteristic large cells with irregular nuclei, now called Paget cells. The origin of these cells has been much debated by pathologists. However, they are probably extensions of an underlying carcinoma into the major ducts of the nipple–areolar complex. There may be no visible changes associated with the initial invasion of the nipple. Often, the patient will notice a nipple discharge, which is actually a combination of serum and blood from the involved ducts.

The overall prognosis for patients with Paget's disease depends on the underlying malignancy. In patients who have an intraductal carcinoma alone, the prognosis is favorable, whereas in those with infiltrating ductal carcinoma metastatic to the regional lymph nodes, the prognosis is poor. Traditionally, treatment has almost always been total mastectomy and lymph node dissection, although radiotherapy with resection of the tumor and nipple–areolar complex is being performed ([101](#)).

Inflammatory Carcinoma

Inflammatory carcinoma of the breast initially appears to be an acute inflammation with redness and edema. Inflammatory cancer, rather than infiltrating ductal carcinoma, should be diagnosed when more than one-third of the breast is involved with erythema and edema and when biopsy of this area shows metastatic cancer in the subdermal lymphatics. There may be no distinct palpable mass, because the tumor infiltrates through the breast with ill-defined margins, or there may be a dominant mass. There may even be satellite nodules within the parenchyma. Most of the tumors are poorly differentiated, and mammographically the breast shows skin thickening with an infiltrative process.

Except for biopsy of the lesion, surgery usually should not be used in the initial management of inflammatory carcinoma. Mastectomy in the face of inflammatory carcinoma usually fails locally and does not improve survival rates. The best results are achieved with a combination of chemotherapy and radiation therapy. Mastectomy may be indicated for patients who remain free of distant metastatic disease after initial chemotherapy and radiation ([102,103](#)).

In Situ Carcinomas

Both lobular carcinoma and ductal carcinoma may be confined by the basement membrane of the ducts. These carcinomas do not invade the surrounding tissue and, theoretically, lack the ability to spread. Indeed, lobular carcinoma *in situ* is not a malignancy. Untreated it may not become a new cancer, whereas ductal carcinoma *in situ* will. A more appropriate nomenclature for lobular carcinoma *in situ* is lobular neoplasia, and it should be considered a risk factor for the development of cancer in either breast ([104](#)). Because of their unusual natural history, they represent a special form of breast cancer. If treated by biopsy alone, 25% to 30% of patients with lobular carcinoma *in situ* will subsequently develop invasive cancer.

Lobular Carcinoma *In Situ*

Most women with lobular carcinoma *in situ* are premenopausal. The tumor typically is not a discrete mass, but rather it is a multifocal lesion within one or both breasts found incidentally at biopsy of a mass or mammographic assessment of an abnormality not related to the lobular carcinoma *in situ*. Lobular carcinoma *in situ* usually is managed with excisional biopsy followed by careful observation and mammography. It should not be considered a malignancy but rather a risk factor for malignancy. Patients should be informed that they have a higher risk of developing invasive breast cancer. Occasionally, a patient may request bilateral prophylactic mastectomy.

Ductal Carcinoma *In Situ*

Ductal carcinoma *in situ* is more common in postmenopausal women. It may manifest as a palpable mass with features typical of an invasive ductal carcinoma but usually is detected mammographically as a cluster of branched or Y-shaped microcalcifications. By definition, the intraductal disease does not invade beyond the basement membrane. Unlike patients with lobular carcinoma *in situ*, however, at least 30% to 50% of patients with ductal carcinoma *in situ* will develop invasive cancer within the same breast when treated by excisional biopsy alone ([105](#)).

Although modified radical mastectomy has been standard treatment for intraductal carcinoma, more conservative surgery, with or without radiation therapy, can yield good results ([106](#)). In NSABP trial B17, 818 patients were randomly assigned to treatment with excision alone or excision followed by radiation therapy ([107](#)). The mean extent of ductal carcinoma *in situ* lesions was 13 mm, and 88% were larger than 20 mm. All lesions were completely resected with negative margins. After a median follow-up of 43 months, the actuarial 5-year local recurrence rate was 10.4% without radiation versus 7.5% with radiation ($p = 0.055$) for noninvasive cancers, and 10.5% without radiation versus 2.9% with radiation ($p > 0.001$) for invasive cancers. Of 83 recurrences, only 9 (11%) were not in the index quadrant. A recent reanalysis with a mean follow up of 90 months confirmed these results ([108](#)). These data suggest that segmental mastectomy offers excellent local control.

Axillary metastases occur in fewer than 5% of patients, indicating that an invasive component has been missed during biopsy. For small, true ductal carcinoma *in situ*, axillary dissection is not indicated. About 5% of patients whose initial biopsy results show intraductal carcinoma will be found to have infiltrating ductal carcinoma when treated with mastectomy. The incidence of contralateral breast cancer in women with intraductal carcinoma is the same as in those with invasive ductal carcinoma (5% to 8%) ([109](#)).

Breast Cancer in Pregnancy

Breast cancer complicates approximately one in 3,000 pregnancies ([110,111](#) and [112](#)). It is the second most common malignancy seen in association with pregnancy, surpassed only by cervical cancer ([113](#)). Initial studies suggested a significantly worse prognosis for patients with breast cancer diagnosed during pregnancy, but more recent data indicate that the hormonal changes associated with pregnancy seem to have little, if any, influence on prognosis. **When pregnant patients are matched stage for stage with nonpregnant patients, survival rates seem equivalent ([114](#)).**

The treatment of breast cancer in pregnant women must be highly individualized. Considerations include the patient's age and desire to have the child. The overall prognosis should be considered, especially when axillary lymph nodes are involved, because adjuvant chemotherapy can be teratogenic or lethal, particularly during the first trimester, but may be given later in the pregnancy. It is not known whether interruption of pregnancy alters the prognosis for patients with potentially curable

breast cancer.

Following are recommendations for treatment of pregnant women with breast cancer:

1. Localized disease found during the first or second trimester of pregnancy is probably best treated with definitive surgery and radiation therapy similar to that done for nonpregnant patients. Radiation therapy is relatively safe to give provided the abdomen is shielded. Adjuvant chemotherapy can be given after the first trimester. However, most oncologists prefer not to give it to pregnant women.
2. Localized tumors found during the third trimester of pregnancy must be managed on an individual basis. Initially, tumors should be excised early in the third trimester using local anesthesia. If delivery is imminent, standard therapy can be performed immediately postpartum.
3. If the breast cancer is diagnosed during lactation, lactation should be suppressed and the cancer should be treated definitively.
4. Advanced, incurable cancer should be treated with palliative therapy, and the pregnancy may be continued or interrupted depending on the therapy necessary and the desires of the mother.

Counseling regarding future childbearing is important for women who have had carcinoma of the breast. Although it generally has been assumed that subsequent pregnancies are detrimental because of the high levels of circulating estrogens, **there is no clear difference in survival for women who become pregnant after the diagnosis of breast cancer.** A recent study evaluated the effect of subsequent pregnancy on overall survival after the diagnosis of early-stage breast cancer. Although approximately 40% of the women in the study had node-positive disease, 5- and 10-year survival rates were better in women who became pregnant than in matched pair controls who did not. This study suggests that subsequent pregnancy does not adversely affect the prognosis of early-stage breast cancer ([115](#)). Theoretically, it may be that only women with estrogen receptor–positive or progesterone-positive tumors would be affected deleteriously by subsequent pregnancy, but this possibility has not been studied. Because recurrences are most frequent within the first 2 to 3 years after diagnosis, patients with receptor-positive tumors and advanced-stage disease probably should wait before becoming pregnant again (if ever).

Appendix: Reference Values

<i>Measure</i>	<i>SI</i>	<i>Conventional (C)</i>	<i>Conversion Factor (CF)</i> <i>C × CF = SI</i>
Acetoacetate , plasman	<100 µmol/l	<1.0 mg/dl	97 . 95
Adrenal steroids , plasman			
Aldosterone, supine, saline suppression	<200 pmol/l	<8 ng/dl	27 . 74
Cortisol			
8:00 AM	220–660 nmol/l	8–24 µg/dl	27 . 59
4:00 PM	50–410 nmol/l	2–15 µg/dl	27 . 59
Overnight dexamethasone suppression	<140 nmol/l	<5 µg/dl	27 . 59
Dehydroepiandrosterone (DHEA)	0.6–70 nmol/l	0.2–20 µg/l	3 . 467
Dehydroepiandrosterone sulfate (DHEAS)	5.4–9.2 µmol/l	820–3380 ng/ml	0 . 002714
11-Deoxycortisol (compound S)	<60 nmol/l	<2 µg/dl	28 . 86
17a-Hydroxyprogesterone, women	1–13 nmol/l	0.3–4.2 µg/l	3 . 026
Adrenal steroids , urinary excretion			
Aldosterone	15–70 nmol/d	5–26 µg/d	2 . 774
Cortisol, free	30–300 nmol/d	10–100 µg/d	2 . 759
17-Hydroxycorticosteroids	5.5–28 µmol/d	2–10 mg/d	2 . 759
17-Ketosteroids, women	14–52 µmol/d	4–15 mg/d	3 . 467
Ammonia (as NH ₃), venous whole blood	6–45 µmol/l	10–80 µg/dl	0 . 5872
Angiotensin II , plasma, 8 AM	10–30 ng/l	10–30 pg/ml	1 . 0
Arginine vasopressin (AVP), plasma, random fluid intake	2.3–7.4 pmol/l	2.5–8 ng/l	0 . 92
Bicarbonate , serum	18–23 mmol/l	18–23 meq/l	1 . 0
Calciferols (see vitamin D)			
Calcitonin , serum	<50 ng/l	<50 pg/ml	1 . 0
Calcium			
Ionized serum	1–1.5 mmol/l	4–4.6 mg/dl	0 . 2495
Total serum	2.2–2.6 mmol/l	9–10.5 mg/dl	0 . 2495
b-Carotene , serum	0.9–4.6 µmol/l	50–250 µg/dl	0 . 01863
Catecholamines , plasma			
Epinephrine, basal supine	170–520 pmol/l	30–95 pg/ml	5 . 458
Norepinephrine, basal supine	0.3–2.8 nmol/l	15–475 pg/ml	0 . 005911
Catecholamines , urinary			
Epinephrine	<275 nmol/d	<50 µg/d	5 . 458
Normetanephrine	0–11 µmol/d	0–2.0 mg/d	5 . 458
Total catecholamines (as norepinephrine)	<675 nmol/d	<120 µg/d	5 . 911
Vanillylmandelic acid (VMA)	<35 µmol/d	<68 mg/d	5 . 046
Chloride , serum	98–106 mmol/l	98–106 meq/l	1 . 0
Cholesterol , plasma			
Total cholesterol			
Desirable	<5.20 mmol/l	<200 mg/dl	0 . 02586
Borderline high	5.2–6.18 mmol/l	200–239 mg/dl	0 . 02586
High	≥6.21 mmol/l	≥240 mg/dl	0 . 02586
High-density lipoprotein (HDL) cholesterol			
Desirable	≥1.29 mmol/l	≥50 mg/dl	0 . 02586
Borderline high	0.9–1.27 mmol/l	36–49 mg/dl	0 . 02586
High	£0.91 mmol/l	£35 mg/dl	0 . 02586
Low-density lipoprotein (LDL) cholesterol			
Desirable	<3.36 mmol/l	<130 mg/dl	0 . 02586
Borderline high	3.39–4.11 mmol/l	131–159 mg/dl	0 . 02586
High	≥4.14 mmol/l	≥160 mg/dl	0 . 02586
Corticotropin (ACTH), plasma	4–22 pmol/l	20–100 pg/ml	0 . 2202
C peptide , plasma	0.5–2 µg/l	0.5–2 ng/ml	1 . 0
Creatinine , serum	<133 µmol/l	<1.5 mg/dl	88 . 40
Fatty acids , nonesterified or free (FFA), plasma	<0.7 mmol/l	<18 mg/dl	0 . 03906
Gastrin , serum	<120 ng/l	<120 pg/ml	1 . 0
Glucagon , plasma	50–100 ng/l	50–100 pg/ml	1 . 0
Glucose , plasma			
Overnight fast, normal	4.2–6.4 mmol/l	75–115 mg/dl	0 . 05551
Overnight fast, diabetes mellitus	7.8 mmol/l	>140 mg/dl	0 . 05551
72-hour fast, normal women	>2.2 mmol/l	>40 mg/dl	0 . 05551
Glucose tolerance test , 2-hour postprandial plasma glucose			
Normal	<7.8 mmol/l	<140 mg/dl	0 . 05551
Impaired glucose tolerance	7.8–11.1 mmol/l	140–200 mg/dl	0 . 05551
Diabetes mellitus	>11.1 mmol/l	>200 mg/dl	0 . 05551
<i>Measure</i>	<i>SI</i>	<i>Conventional (C)</i>	<i>Conversion Factor (CF)</i> <i>C × CF = SI</i>
Gonadal steroids , plasma			
Androstenedione, women	3.5–7.0 nmol/l	1–2 ng/ml	3 . 492
Estradiol, women			
Basal	70–220 pmol/l	20–60 pg/ml	3 . 671
Ovulatory surge	>740 pmol/l	>200 pg/ml	3 . 671
Dihydrotestosterone, women	0.17–1.0 nmol/l	0.05–3 ng/ml	3 . 467
Progesterone, women			
Luteal phase	6–64 nmol/l	2–20 ng/ml	3 . 180
Follicular phase	<6 nmol/l	<2 ng/ml	3 . 180
Testosterone			
Women	<3.5 nmol/l	<1 ng/ml	3 . 467
Prepubertal boys and girls	0.2–0.7 nmol/l	0.05–0.2 ng/ml	3 . 467
Gonadotropins , plasma			
Women, basal			
Follicle-stimulating hormone	5–20 IU/l	5–20 mIU/ml	1 . 0
Luteinizing hormone	5–25 IU/l	5–25 mIU/ml	1 . 0
Women, ovulatory peak			
Follicle-stimulating hormone	12–30 IU/l	12–30 mIU/ml	1 . 0
Luteinizing hormone	25–100 IU/l	25–100 mIU/ml	1 . 0

Prepubertal boys and girls				
Follicle-stimulating hormone	<5 IU/l	<5 mIU/ml	1	. 0
Luteinizing hormone	<5 IU/l	<5 mIU/ml	1	. 0
Growth hormone , plasma				
After 100 g glucose orally	<5 µg/l	<5 ng/ml	1	. 0
After insulin-induced hypoglycemia	>9 µg/l	>9 ng/ml	1	. 0
Human chorionic gonadotropin , beta subunit, plasma; nonpregnant women	<3 IU/l	<3 mIU/ml	1	. 0
b-Hydroxybutyrate , plasma	<300 nmol/l	<3.0 mg/dl	96	. 05
Insulin , plasma				
Fasting	35–145 pmol/l	5–20 µU/ml	7	. 175
During hypoglycemia (plasma glucose <2.8 nmol/l [<50 mg/dl])	<35 pmol/l	<5 µU/ml	7	. 175
Insulin-like growth factor I (IGF I, somatomedin-C), women	0.45–2.2 kU/l	0.45–2.2 U/ml	1	. 0
Lactate , plasma	0.56–2.2 mmol/l	5–20 mg/dl	0	. 111
Magnesium , serum	0.8–1.20 mmol/l	1.8–3.0 mg/dl	0	. 4114
Osmolality , plasma	285–295 mmol/kg	285–295 mosm/kg	1	. 0
Oxytocin , plasma				
Random	1–4 pmol/l	1.25–5 ng/l	0	. 80
Ovulatory peak in women	408 pmol/l	5–10 ng/l	0	. 80
Parathyroid hormone , serum (intact PTH using immunoradiometric assay [IRMA])	10–65 ng/l	10–65 pg/ml	1	. 0
Phosphorus , inorganic, serum	1–1.5 mmol/l	3.0–4.5 mg/dl	0	. 3229
Potassium , serum	3.5–5.0 mmol/l	3.5–5.0 meq/l	1	. 0
Prolactin , serum	2–15 µg/l	2–15 ng/ml	1	. 0
Pyruvate , blood	39–102 µmol/l	0.3–0.9 mg/dl	0	. 01129
Renin activity , plasma, normal-sodium diet				
Supine	3.2 ± 1 µg/l/h	3.2 ± 1.1 ng/ml/h	1	. 0
Standing	9.3 ± 4.3 µg/l/h	9.3 ± 4.3 ng/ml/h	1	. 0
Sodium , serum	136–145 mmol/l	136–145 meq/l	1	. 0
Thyroid function tests				
Radioactive iodine uptake, 24 hours	0.05–0.30	5–30%		—
Reverse triiodothyronine (rT ₃), serum	0.15–0.61 nmol/l	10–4 ng/dl	0	. 01536
Thyrotropin (TSH), highly sensitive assay, serum	0.6–4.6 mU/l	0.6–4.6 µU/ml	1	. 0
Thyroxine (T ₄), serum	51–42 nmol/l	4–11 µg/dl	12	. 87
Thyroxine-binding globulin, serum (as thyroxine)	150–360 nmol/l	12–28 µg/ml	12	. 87
Triiodothyronine (T ₃), serum	1.2–3.4 nmol/l	75–220 ng/dl	0	. 01536
Triiodothyronine resin uptake, serum	0.25–0.35	25–35%		—
Triglycerides , plasma (as Triolein)	<1.80 mmol/l	<160 mg/dl	0	. 01129
Uric acid , serum	120–420 µmol/l	2–7 mg/dl	59	. 48
Vitamin D (as vitamin D ₃ , cholecalciferol), plasma				
1,25-Dihydroxycholecalciferol (1,25(OH) ₂ D)	36–144 pmol/l	15–60 pg/ml	2	. 400
25-Hydroxycholecalciferol (25-OHD)	20–100 nmol/l	8–40 ng/ml	2	. 496
