Postresuscitation neurologic prognostication and declaration of brain death

Romergryko G. Geocadin, Daniel F. Hanley, Scott M. Eleff

Department of Neurology, Neurosurgery and Anesthesiology-Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD and Department of Anesthesiology, University of Illinois, Chicago, IL, USA

Introduction

The ability to prognosticate or predict accurately the eventual neurologic outcome following successful restoration of native cardiac function has profound clinical, ethical, and financial consequences. Although this chapter focuses on the overall prognosis of the patient who has successfully returned to spontaneous circulation after cardiac arrest, most of the recommendations based on existing data focus on poor or unfavorable outcome. Salient points of recent important studies, focused review, meta-analyses of the existing literature on this topic are included. This chapter provides a sequential approach to evaluating the neurologic status of patients resuscitated from cardiac arrest leading to the ability to predict early trends, especially during the first 72 hours postarrest. The key concepts and discussion of neurologic prognostication are based on intra-arrest factors, clinical examination, and laboratory tests such as electroencephalography (EEG), evoked potentials, analysis of cerebrospinal fluid (CSF) brain enzymes, and brain imaging. A detailed description of how to perform bedside neurologic examination and brain death clinical examinations is provided. A more comprehensive review on brain injury after cardiac arrest, including an expanded discussion of prognostication was recently published.[1]

Consideration in prognostication of neurologic outcomes

Study design

Since the last edition of this book, several new studies, structured reviews, and rigorous meta-analyses have been undertaken specifically to clarify prognostication of neurologic outcome after cardiac arrest. We focus on the quality of study design of data collection, length of follow-up, methods of analysis, and an understanding of the power of the statistical analysis.[1] Despite guidelines for uniform reporting of data and the follow-up period from out-of-hospital cardiac arrest [2] and in-hospital cardiac arrest[3], significant research problems persist, such as considerable variability in outcome and less than 60% compliance to guidelines[4,5]. The use of the Glasgow–Pittsburgh cerebral performance and overall performance categories as outcome measures has received some degree of acceptance, but many studies still vary significantly in their use of other outcome measures. Therefore, a collective definition for poor outcome encompasses any of the following states: death, persistent vegetative state, or a severe neurological disability requiring full nursing care.

The studies on prognostication in comatose patients after cardiac arrest are obviously, biased towards patients who will have a poor outcome. For this reason, most of the observations relating to the neurologic examination of postcardiac arrest victims and the prognostication of outcome for comatose cardiac arrest victims are skewed toward patients with longer arrest times. Moreover, in studies designed to predict poor outcome there is a tendency to provide less than optimal care to patients thought to have a poor prognosis.

Prognostication and extracerebral complications

The cause of death in the majority of patients after resuscitation is largely extracerebral, which is an important consideration in attempting to assess prognostication of outcome. From the Brain Resuscitation Clinical Trial
Fig. 50.1. Percentage mortality in the placebo groups of clinical trials for brain injury after cardiac arrest (1986–2002).

(BRCT) 1 study, non-neurologic causes of death accounted for 63.6%, while cerebral causes accounted for 36.4%.[6] A similar proportion was observed in BRCT 2, with extracerebral causes noted in 72.2% of patients and cerebral cause of death in 27.8%.[7] Consequently, a significant number of patients with excellent initial neurologic examination may not have a good outcome, because the patient died of a second cardiac arrest. Management during the postresuscitation period is provided in chapter 47; management of extracerebral or systemic complications in these patients, particularly cardiac injury, is essential for survival and the functional outcome of these patients. We thus examined the placebo arm of controlled human clinical trials over the last three decades. There has been a general overall trend towards a reduction in the percentage mortality of the placebo-treated patients in 8 clinical trials (see Fig. 50.1). With the exception of Roine *et al.* in 1990,[8] who reported a percentage mortality of less than 80%, three of the BRCT from 1986 to 1991[6,7,9] and Longstreth *et al.* in 1993 reported a percentage mortality of 80% or greater. Whereas the BRCT and the Longstreth studies represented a wider spectrum of cardiac arrest severity, the study by Roine *et al.* selected patients with lesser injury by limiting the duration of

cardiac arrest time and resuscitation time.[8] The succeeding trials starting with Thel *et al.* in 1997[10] reported a declining trend, with percentage mortality of those treated with placebo below 80%. An even lower percentage mortality was reported by Longstreth *et al.* in 2002[11] and two recent studies on therapeutic hyothermia.[12,13] Whereas the wide variability in trial design does not allow the precise determination of the factors that lead to the reduction in mortality, two key factors may have changed in the clinical practice during the time these trials were undertaken. First, inclusion of a focused population that will have higher chances of survival after cardiac arrest and thus allow the assessment of functional outcome. Second is the continued improvement in overall standard critical care in patients treated with placebo. As we attempt to define the neurologic injury and its relation to functional outcome, we must also recognize the potential impact of the continued development in critical care therapies provided to these patients.

Prognostication in the era of therapeutic hypothermia

The recent introduction of therapeutic hypothermia,[12,13] which has improved survival and functional outcome, may

well alter the current practice of prognostication. Almost all of the data and analysis presented in this chapter were derived from studies conducted in patients before the introduction of therapeutic hypothermia. As the use of therapeutic hypothermia becomes more widespread, factors determining prognostication will need to be redefined. Furthermore, for the first time, a therapy actually shows that brain injury after cardiac arrest can be ameliorated and therefore outcome can be influenced by therapy. In the absence of effective therapies, the detection of irreversible loss of a specific brain function led to prediction of an unfavorable outcome, which often led to the cessation or de-escalation of care. We suggest considering two periods: the early period where the injury can still be ameliorated and effective therapies can be provided, and development of novel markers to assess and perhaps treat patients, and a late period where the significant injury is irreversible and unfavorable outcome almost certain.

The ideal study

As indicated in the first edition, the ideal study should also be prospective and focused on neurologic outcome, both normothermia- and hypothermia-treated patients. To avoid unpredictable biases, all levels of neurologic injury must be included and standardized management is required. The optimal study should have strict intensive care protocols over a long period of time to prevent a model from becoming self-fulfilling. Finally, no study can ever guarantee that the proposed model is definitive in stating that a patient who is not brain-dead will never recover. Therefore, except for the diagnosis of brain death, it is not possible to predict outcome in an individual patient with 100% accuracy. This uncertainty has profound ethical consequences, as well as implications concerning the large financial and personal emotional investment in what, in all likelihood, may be a futile situation. Nonetheless, it is clear that many neurologic findings are highly predictive of outcome and are useful in family counseling and for suggesting ways of assessing the success of therapy.

Prognostication of neurologic outcome

Intracardiac arrest factors

The duration of cardiac arrest as the clinical marker of global ischemia has been correlated with brain injury.[14–17] Several studies have associated some variables relating cardiac arrest and resuscitation to poor outcome, such as increased time[14–15] between collapse and initiation of

CPR[14–15] (anoxia time) and the increased duration of CPR. The impact of other characteristics of cardiac arrest (i.e., cardiac rhythm, etiology) and resuscitation (in-hospital and out-of-hospital) are discussed in detail in other chapters of this book.

The BRCT indicated that a cardiac arrest duration of 6 minutes or longer and a resuscitation time to achieve ROSC of 28 minutes or longer predicted poor neurologic recovery[15] whereas shorter cardiac arrest times and resuscitation times, indicating lesser injury were associated with favorable outcome. A similar observation in a European study reported that patients had unfavorable outcome with cardiac arrest time longer than 6 minutes and with resuscitation time longer than 21 minutes.[14]

While most of these variables are associated with poor outcome, the correlations are not sufficient reliably to discriminate patients with poor prognosis from those with a good outcome. The reliability of the CPR as a factor to predict outcome was further placed in doubt after some studies were conducted on the ability of care givers to adhere to resuscitation protocols. In a prospective study of in-hospital CPR quality and compliance with published American Heart Association and international guidelines, it was found that multiple characteristics of CPR were inconsistent and often did not meet published guideline recommendations, even when performed by well-trained hospital staff. These included inadequate chest compression rates, shallow compression depth, and high ventilation rates.[18–19] In an out-of-hospital cardiac arrest resuscitation study in Europe, significant deviations from international CPR guidelines were noted in that chest compressions were not delivered half of the time, and most compressions were too shallow.[20]

Postcardiac arrest factors

Evaluation of the postresuscitation comatose patient

The clinical findings derived from the bedside neurologic evaluation of patients resuscitated from cardiac arrest remain one of the most reliable means of establishing prognosis.[21–22] Therefore, a detailed approach to the bedside neurologic examination is provided below.

Neurologic evaluation is separated into two distinct tasks: first, assessment of the level of consciousness; and second, determination of the integrity of the brain stem and cerebral hemispheres. The overall approach is based on the conventional structure of the neurologic examination which comprises evaluation of mental status, cranial nerve function, and sensorimotor and other reflexes.

Several methods have been developed to standardize the assessment of neurologic function in these patients.

The most widely accepted scale is the Glasgow Coma Scale,[23] which is universally accepted and has been validated for both physicians and nurses. It can be replicated with little interobserver error, performed rapidly, and is easy to learn. This scale is divided into three major components: eye-opening, motor response, and verbal response. Eye-opening is scored as follows: spontaneous to verbal command (3), spontaneous to pain (2), or no opening (1). Motor response is scored as follows: obeys verbal command (6), localizes to pain (5), withdraws to pain (4), flexes to pain (3), extension to pain (2), or no response (1). Verbal response is scored as follows: oriented (5), appropriate words (4), disoriented (3), incomprehensible sounds (2), and no response (1). The addition of the three component scores results in a scale value from 3 to 15. Patients with a GCS score of 3 to 9 have significant impairment of consciousness; 10 to 13 is moderate impairment; and above 13 is mild impairment. Although multiple attempts have been made to define level of consciousness in a stratified manner, there is no uniform agreement on how to describe differences among coma, obtundation, stupor, and such states as delirium or confusion. Significant prognostic value has, however, been attached to the GCS and to the neurologic examination of the brainstem.

A recent method developed to evaluate a comatose patient is the FOUR (Full Outline of UnResponsiveness) score.[24] This consists of four components (eye, motor, brainstem, and respiration), and each component has a maximal score of 4. The Four score provides assessment of critical variables that are important in coma assessment and excludes the verbal response, which has been a major limiting factor in the GCS. Although this is a promising development in coma assessment, the application of this scoring system needs to be established in the postcardiac arrest patient population.

Bedside neurological examination

Level of arousal

To determine the patient's level of arousal, it is necessary to know the patient's best response to specific stimuli. If possible the patient should be informed verbally of the procedure or examination. If noxious stimulation is necessary to get the best response, the least noxious stimulation should be used at the start and the intensity increased until the best response is elicited. Start by calling the patient's name and asking the patient to follow simple commands. If no response is noted, the patient can be tapped or shaken gently, and finally painful pressure such as rubbing the sternum or pinching the trapezius should be applied. Record the specific stimulus that causes a specific response (i.e., eye-opening with voice or extensor posturing of the right side with sternal rub).

If the patient is arousable, he or she should be assessed for ability to follow commands and answer questions. First, have the patient follow simple commands such as "open and close your eyes" or "stick out your tongue", followed by commands involving the extremities, such as "show me two fingers". Next ask questions about orientation: "What's your name? Where are you? What's the date? How did you get here?"

Rapid fluctuation in the level of consciousness, associated with changes in cognition and impaired attention span, should alert the examiner to metabolic dysfunction or even seizures. Serial evaluations must be performed, the trend in level of consciousness is more significant than any specific level of consciousness. Moreover, the findings must be taken in the context of the other significant findings on examination. Intervention must be undertaken to address a rapid or persistent decline in the level of consciousness.

Brainstem evaluation

For the unresponsive patient, the brainstem examination is crucial in assessing the degree of brain injury and the findings are key in prognostication, especially within the first 3 days after cardiac arrest. With the absence of voluntary response in the comatose patient, cranial nerves may be tested by eliciting cranial nerve-based reflexes, such as pupillary light reflex, corneal reflex, grimace, oculovestibular response, caloric response, gag reflex, and cough reflex. By assessing these responses to specified cranial nerves, the pertinent brainstem structures can be evaluated, especially the central portion of the brainstem including the tegmental area, which contains the reticular activating system. An intact reticular activating system is important for neurophysiologic arousal or recovery.

Pupillary response (cranial nerves 2 and 3)

Evaluation of cranial nerves 2 and 3 requires assessment of both responses to light and conjugate eye movements. Reaction of each eye to light is the function of afferent pathways from the retina to the Edinger–Westphal nucleus at the level of the midbrain via the optic nerve. Parasympathetic efferents exit this nucleus via the third nerve. Monocular activation of this reflex with light produces bilateral pupillary constriction. The normal resting pupil size is 4 to 6 mm. Most pupils will constrict to about 2 mm with illumination from a bright flashlight. Normal resting pupillary size is altered by drugs, surgery, and aging. The ability of the pupils to dilate is mediated by sympathetic neurons that travel from the hypothalamus in a longitudinal manner to the cervical cord where they exit and pass rostrally along the

carotid vascular system to the eye. Dilation occurs when ambient light is excluded from the patient's retina. The motor aspects of these cranial nerves are assessed with the vestibular system.

Blink reflex (cranial nerves 5 and 7)
The corneal response is a blink reflex when the corneal is touched with a wisp of cotton. This response is activated by sensory afferents of the face that travel via cranial nerve 5 from the face to the trigeminal ganglia and then to the fifth nerve nucleus in the pons. These neurons form synapses with the seventh nerve nucleus in the pons. The seventh nerve nucleus projections innervate the facial muscula-ture, including the orbicularus oculi. Activation of this reflex leads to constriction of the orbicularis oculi and closure of the eye or a blink. In severely obtunded patients, this reflex may be slightly depressed. The most vigorous stimulus is one of direct corneal pressure, which is applied with a clean cotton swab. Gentle pressure on the cornea produces at least a trace constriction of the orbicularis oculi and in many individuals a brisk blink. This reflex is lost with deep general anesthesia but tends to be preserved with moderate sedation. To study the lower facial muscula-ture in a variant of this response, the nasal tickle or grimace reflex is used. This reflex is elicited by either light or deep pressure to the nares and nasal septum area. Pressure here produces a facial grimace often slightly greater on the side of the stimulus. Comparison of the right and left responses allows evaluation of the nasolabial fold and symmetry of lower facial musculature.

Vestibulo-ocular response (cranial nerves 3, 4, 6, and 8)
Cranial nerves 3, 4, 6, and 8 are grouped together, and their evaluation represents oculomotor reflex testing. This reflex involves vestibular afferents that can be activated by either head-turning (doll's eyes) or thermal inputs (caloric response). These stimuli travel to the ponto-medullary junction via cranial nerve 8. Inputs from synapses with the oculomotor system produce coordinated eye movement via brainstem gaze centers, including the parapontine reticular formation and the medial longitudinal fasciculus. These synapses allow coordinated conjugate eye movement. During normal conscious behavior, this system allows sta-bilization of visual fixation with head movement. In an unconsciousness person, volitional eye movements are lost. Such eye movements tend to be rapid in comparison to those evoked by the vestibulo-ocular response. Thus, in the unconsciousness individual, head-turning provokes a slow eye deviation in the direction opposite to head motion. Similarly, cold water irrigation in one ear provokes a slow tonic deviation of eyes in the opposite direction. The pres-ence of both a slow and a fast phase of eye movement after cold water irrigation suggest a conscious state with active visual perception at the cortical level, and is thus associated with behavioral rather than structural etiologies of coma. In a manner similar to the corneal response, sedative drugs will depress this reflex. During low level sedation, however, a vestibulo-ocular response can usually be elicited. If it cannot be elicited, caloric testing, which represents a stronger stimulus to this system, should be used. The caloric test is suppressed by deep general anesthesia. When doll's eyes or caloric testing provokes a response, it is nor-mally the conjugate or equal motion of both eyes in one direction. If individual eyes have either a horizontal or ver-tical asymmetry to their fixation point, damage to an indi-vidual oculomotor nerve should be considered. This is best evaluated by repeating the doll's eye maneuver for both hor-izontal and vertical planes. Each eye should be evaluated individually; if a full range of motion is noted for each eye, the absence of conjugate eye movement is clinically diag-nosed as strabismus rather than as oculomotor palsy.

Gag response (cranial nerves 9 and 10)
The gag response is best tested with both a tongue depres-sor and a cotton swab. While the tongue is depressed, the right and left retropharyngeal areas are stimulated with the cotton swab. This reflex involves the sensory afferents of cranial nerve 9 and a diverse set of motor efferents, includ-ing those of cranial nerves 9 and 10. A normal response includes symmetric elevation of the soft palate and closure of the pharyngeal space from the nasal space. This pha-ryngeal reflex is often lost in individuals who have had pro-longed oral tracheal or nasotracheal intubation. A variant of this reflex is the cough response to deep tracheal suction. Cough reflex involves cranial nerve 10 sensory afferents, and abdominal, chest wall, and cranial nerve 10 efferents. The reflex is best produced in individuals with endotracheal intubation, whereby a suction catheter is inserted via this endotracheal route into the carina. Rapid to-and-fro motion produces a gasp and then one to three rapid coughs. A positive response suggests that medullary afferent and efferent centers are intact.

An intact brainstem evaluation suggests the potential for normal arousal. An intact brainstem may be found in comatose patients after cardiac arrest, drug overdose, or closed head injury. An examination demonstrating incom-plete function or asymmetric cranial nerve dysfunction is most often associated with cerebrovascular disease in the vertebrobasilar arterial system or a posterior fossa mass. An alternative explanation for incomplete or asymmetric cranial nerve function is a herniation syndrome secondary to a supratentorial mass. The evaluation of conscious

motor behavior is important in cardiac arrest patients because of the high frequency of diffuse cortical injury. Another system that is closely associated with the brainstem is the autonomic system, which may be affected in cardiac arrest. Autonomic manifestations such as an abnormal pattern of breathing, erratic and extreme temperature, arrhythmia and blood pressure lability may be a manifestation of brainstem injury.

Response to pain (motor evaluation)

Conscious behavior requires both an intact reticular activating system and bilateral hemispheric function; therefore, it is important to access hemispheric function as well as brainstem function. The most reproducible assessments of hemispheric functions in unresponsive patients are the motor responses to pain. These responses are elicited individually in each limb, and although they vary with level of consciousness, they should be symmetric. For the unconscious patient, strength cannot be graded objectively so a qualitative description and whether it is reproducible must be provided. The GCS provides a standardized and universal classification system defining five levels of motor response. A conscious individual will obey commands with a defined motor performance. Stuporous or unconsciousness individuals without hemispheric dysfunction will demonstrate purposeful pain avoidance behavior, characterized by rapid attempted withdrawal of the limb from painful stimuli, usually with abducting movements. This is particularly true if painful stimuli are elicited with pinch or deep pressure to the medial aspects of limbs, such as the upper arm triceps area or the adductor region of the thigh, or deep pressure to the medial malleolus at the ankle. A second common behavior is the use of the contralateral limb to remove the noxious stimulus. Deeply comatose individuals do not show this behavior, but rather show simple flexion to painful stimuli. Similarly, individuals with hemispheric lesions may demonstrate brisk and monotonously replicable upper extremity flexion at the shoulder, elbow, wrist, and fingers. When this flexion is asymmetric, a contralateral hemispheric injury or mass is likely. Bihemispheric lesions may demonstrate bilateral flexion. The extension response is present when an injury impairs both cortical and deep basal ganglia and thalamic function. This response is a characteristic extension at the elbow and internal rotation of the forearm with flexion of the fingers. Simultaneous lower extremity extension and adduction are noted. The response represents the unopposed activation of postural extensor muscles by the vestibulospinal system. This response may be asymmetric, suggesting severe cortical and deep hemispheric dysfunction, or bilateral with bilat-

eral hemispheric dysfunction. A final pattern of response to pain is one of no response or minimal flicker of muscles without movement. These findings occur with deep general anesthesia or with bilateral cervical medullary lesions. Taken together, evaluation of the brain stem and the motor response assess the integrity of both sites necessary for conscious behavior, namely, the reticular activating system and the cerebral hemispheres. When the examination suggests that the hemispheres and the reticular activating system are intact, awakening from coma is possible and most likely depends on the underlying disease causing coma. This chapter does not attempt to address the issue of differential diagnosis of coma. With the detailed medical history, laboratory testing, and imaging, a diagnosis is usually possible. Current data provide support that the clinical evaluation of the nervous system and data on the duration of global ischemia are of value in predicting the eventual outcome. Because many cardiac arrests are unwitnessed, the exact duration of ischemia is unknown. For this reason, significant clinical emphasis is placed on the repeated evaluation of the patient at the bedside.

Bedside neurologic examination and prognostication

Numerous studies have reported the importance of specific components of the bedside neurologic examination to functional outcome after in-patient resuscitation from cardiac arrest without therapeutic hypothermia. Studies by Levy and colleagues[25] in 1985 followed by the studies by Rogove and colleagues,[15] and Edgren and colleagues[21] from the Brain Resuscitation Clinical Trials (BRCT) have been largely responsible for defining the key factors in the neurologic examination that are clearly associated with poor functional outcome. Many other studies provide additional support for use of these clinical characteristics in prognostication.[26–30] In 2006, the American Academy of Neurology published an evidence-based review on the predictors of outcome in comatose patients after resuscitation from cardiac arrest.[98] It is important to emphasize that almost all these studies indicate the absence rather than the presence of a specific clinical finding that is best associated with unfavorable outcome after cardiac arrest. This highlights the need for research to provide an early clinical finding that has the ability to determine which patients will have a good recovery postresuscitation.

Of all the clinical findings in the neurologic assessment, a meta-analysis found two clinical findings had 100% specificity at 3 days: absence of pupillary light reflexes (positive likelihood ratio = 10.5 (95% CI 2.1–52.4), and absent motor response to pain (positive likelihood ratio = 16.8 (95% CI 3.4–84.1)).[22] A recent study by Booth and

Table 50.1. Clinical, electrophysiological, and laboratory markers of poor outcome (death or persistent vegetative state, severe disability requiring full nursing care) after cardiac arrest[a]

Based on the current literature, the predictive markers are summarized as follows:

Markers of poor outcome

1. **Clinical markers**

   The absence of pupillary light responses and absence of motor responses to pain in medically stable comatose survivors 3 days after CPR are the most studied and reliable markers.

2. **Electrophysiological markers**

   Bilateral absent cortical responses (N20) on Somatosensory Evoked Potentials recorded > 24 hours is most objective, but expertise and availability limits its widespread use.

   Persisting burst suppression pattern on electroencephalogram recorded > 24 hours after CPR is useful, but less specific than SSEP.

3. **Biochemical markers**

   Serum and cerebrospinal fluid (neuron-specific enolase, S100, creatinine kinase isoenzyme BB) are very useful in prognostication, but variability in cut-off and inability of test in many hospital laboratories limits application.

4. **Neuroimaging markers**

   MR imaging and CT scanning are promising, but data are still insufficient to support or refute use for prognostication.

5. **Multimodality markers**

   The combination of several prognostic markers, such as clinical, electrophysiologic, and biochemical markers, promises to improve the ability predict both poor and good outcome. More studies are needed to validate the used of multimodality markers.

[a] *Prognostic markers may not be reliable in patients receiving sedatives or neuromuscular blocking agents, in patients with severe metabolic derangement, or medically unstable or cardiogenic shock. These prognostic markers were not studied in patients who received therapeutic hypothermia.*

colleagues suggested that similar clinical findings as early as 24 hours can adequately predict poor neurologic outcome: absent response to pain (positive likelihood ratio 4.9 (95% CI 1.6–13.0)), absent pupillary light reflexes (positive likelihood ratio = 10.2 (95% CI 1.8–48.6)), and absent corneal reflexes (positive likelihood ratio = 12.9 (95% CI 2.0–68.7)). With the findings, Booth *et al.* suggest that cessation of life-sustaining therapies may be justifiable. While the 24-hour period may be encouraging in some cases, several studies have reported 18%–36% false positive rates for the absence of pupillary light responses during the first 24 hours after resuscitation.[25,31,32]

The Glasgow Coma Scale which provides a more objective framework for neurologic prognostication, and shows a total aggregate and low component score (especially in the motor response). In a study by Mullie *et al.* of patients who died or were still comatose at 2 weeks, 98% had a GCS score of 4 or less, while only 18% had a GCS-score ≥ 10.[30] Other studies have also used the GCS as a predictive tool[27,33] or as a predominant factor that determines outcome in a more comprehensive score such as the Acute Physiology and Chronic Health Evaluation Score (APACHE) II (Table 50.1).[26,34]

As two of the strongest findings of poor outcome in comatose patients untreated with hypothermia, the absence of pupillary light reflex and absence of motor responses 72 hours after resuscitation may be used to guide the decisions made by clinicians about the intensity and duration of care provided after cardiac arrest. As indicators for poor outcome at 72 hours, these findings have little direct impact on the decision to provide therapies that are currently focused on the first 24 hours. Therefore, there is still a need for research to identify early (within minutes or few hours of injury) neurological markers of brain injury and recovery. Such clinical markers may aid in the development of more effective therapies.

Neuroimaging

Neuroimaging has been used to define brain injury related to cardiac arrest. No large prospective studies have been performed to date. With some limitations, retrospective studies described the brain injury and attempted to define its relation to poor outcome after cardiac arrest. Non-contrast head computerized tomography (CT) is one of the most common screening tools that can rule out a structural abnormality in patients with neurologic dysfunction. An abnormality on CT scan is generally associated with worse outcomes when compared to patients with no CT abnormalities. As global ischemia to the brain leads to cerebral edema, non-contrast head CT will be able to show that edema that leads to effacement of sulci and cisterns also causes a decrease in gray matter density, leading to loss of the gray matter to white matter differentiation. This is pronounced in the basal ganglia and watershed areas.[35]

Quantitatively, the loss of the distinction between gray and white matter on CT, even when normal to the naked eye, has been shown to correspond to neuronal necrosis, watershed infarcts, and periventricular leukomalacia. Torbey and colleagues used CT Housefield units to quantify the loss of gray and white matter (GM/WM) demarcation in association with global cerebral ischemia and found that a lower GM/WM ratio of <1.18 is associated with poor outcome or death after cardiac arrest.[36] The loss of the GM/WM demarcation in a CT scan performed at 48 hours, when combined with the clinical status of the patients such as the GCS and the duration of cardiac arrest, increased the ability of the measure to predict poor functional outcome.[37]

Many retrospective studies on the use of MRI in prognostication have been reported. As an imaging technique, the use of MRI is limited in critically ill patients because of patient safety and possibly lack of compatibility of supportive equipment. A retrospective study defined the role of MRI in prognostication and noted poor prognosis in patients with diffuse cortical signal changes on diffusion-weighted imaging (DWI) or fluid-attenuated inversion recovery (FLAIR).[38] In this study of 10 patients, 8 who remained comatose with no indicator of poor prognosis, such as myoclonic status epilepticus, fixed dilated pupils, absence of SSEP, and burst suppression on EEG, were found to have diffuse and extensive abnormalities in the cortex, thalamus, and cerebellum. The two remaining patients who awoke had normal or localized MRI findings. The study also noted that the DWI abnormalities eventually improved, but the FLAIR abnormalities persisted on follow-up.

Several studies with functional neuroimaging have documented brain injury, but the limited number of patients hamper its reliable application to prognostication. The use of Positron Emission Tomography (PET) has been undertaken in defining the brain injury and prognostication. As in cases of ischemia, changes in lactate and NAA are associated with a specific outcome. However, one study with 8 patients and the other with 7 patients[40] did not find any significant PET index that differentiated between survivors and non-survivors.

Evoked potentials

Somatosensory evoked potentials (SSEP) is a neurophysiological test that measures the integrity of the neuronal pathways from a peripheral nerve, spinal cord, brain stem, and cerebral cortex.[41,42] In the evaluation of brain injury after cardiac arrest, disruption of the neural pathways manifested as slowing or absence of waveforms that are generated by the brain stem and cortex are most important in prognostication. The absence of early cortical SSEPs

(N20/P25) after stimulation of the median nerve has been shown to be a reliable predictor of poor outcome (with persistent coma or death) in several studies of patient series in coma after cardiac arrest.[42–45] The absence of N20 during the first week after cardiac arrest and poor neurologic outcome showed a positive likelihood ratio of 12 (95% CI 5.3–27.6).[22] This ability of SSEP to prognosticate a poor neurologic outcome was also supported by other reviews and large patient series.[42,46] Although the absence of the N20 signal is strongly associated with poor outcome, a normal N20 is only associated with about 60% of those who awake from coma, and a delayed N20 is associated with arousal in only 20% of subjects. (See Fig. 50.2).[42]

Most of these studies report the use of SSEP from several hours to a few days after resuscitation from cardiac arrest, most commonly within 3–4 days. But no studies have established its use earlier than 24 hours. With no reported return of a previous absent N20 in a comatose patient, the absence of the N20 is one of the most significant predictors of poor outcome. Repeated testing must be considered, however, when the N20 responses are present early in the course of postcardiac arrest coma, especially in patients who remain unresponsive. The use of SSEPs in determining a poor prognosis is preferred over other tests, such as EEG and other types of evoked responses, because it is less susceptible to the effect of drugs, metabolic derangements, and temperature. Nevertheless, it may be susceptible to muscle artifact and occasionally the use of muscle relaxants may improve the test quality.

Other evoked response tests, such as brain stem auditory and visual and event-related potential tests, have been used for prognostication but their definitive use still needs to be established. The use of brainstem auditory response is limited by the reversible dysfunction of the cochlear which may lead to the initial absence of brainstem auditory signals that may return over subsequent days.[47] In some studies normal brainstem auditory evoked potential (BAEP) have been seen in patients with poor outcome, including PVS.[48,49] The presence of the late component of the SSEP waveform such as the N70 response was reported to be associated with favorable outcome,[48] but more studies are needed to validate its prognostic ability in these patients.

Electroencephalography (EEG)

EEG is useful for evaluating depth of coma and extent of damage after cardiac arrest. EEG is widely available, easy to perform even in unstable patients, and non-invasive.[41] The widespread application of EEG in prognostication is hampered by several factors, including lack of a unified classification system, which is confounded by the variability of the
Fig. 50.2. Median nerve SSEP after cardiac arrest demonstrating bilateral absence of the cortical N20 peak (arrows). (From Koenig, M.A., Kaplan, P.W. and Thakor, N.V., Clinical Neurophysiologic Monitoring and Brain Injury from Cardiac Arrest. In Brain Injury after Cardiac Arrest, Neurologic Clinics vol 24 issue 1, Editor: Geocadin, R.G, Publisher – Elsevier 2006, with permission.)

types of EEG patterns in a given category, lack of consistency in the intervals of EEG after resuscitation, and bias toward evaluation of severely injured patients. The numerous EEG studies reviewed for this chapter[41,43,50–54] showed significant variability in the time intervals from CPR to EEG, but the majority seem to be performed around 3 days or later. The key patterns of EEG that provide the basic classification include: presence or absence of EEG activity; reactivity of EEG to specific stimuli; different EEG frequencies (i.e.,

alpha, theta, and delta); certain specific patterns, such as burst suppression or low voltage or isoelectric EEG. These patterns were grouped into five grades in an older classification, which has been consolidated by more recent classifications into three categories for prognostication: malignant, uncertain, and benign. Many classifications of "malignant" EEGs include a combination of suppression, burst-suppression, non-reactive alpha and theta pattern, and generalized periodic complexes.[43,51,52,55,56] The patterns

most often associated with poor outcome are generalized suppression to 20 μV, burst-suppression pattern with generalized epileptiform activity, or generalized periodic complexes on a flat background.[57] In a meta-analysis of several relevant studies, EEG recordings with an isoelectric or burst-suppression pattern had a specificity of 100% for poor outcome with a pooled positive-likelihood ratio = 9.0 (95% CI 2.5–33.1) (see Fig. 50.3).

As an early indicator of brain recovery after resuscitation, the early return of continuous and reactive EEG activity may predict good outcomes.[41,58,59] Novel EEG analyses and applications are still being actively investigated as potential objective markers for brain injury, with the ability to track recovery, such as quantitative EEG analysis focusing on real-time changes of EEG, or limited channel recording in order to follow general trends to track recov-

ery or injury processes or development of anoxic encephalopathy, or in detecting sudden changes (such as seizures). EEG may provide potential monitoring for brain recovery during therapeutic hypothermia after cardiac arrest. EEG changes have been described during hypothermia in a limited clinical study.[60] With the exception of a case report detecting seizure activity[61] to date no clinical studies have described a postcardiac arrest population in terms of relating therapeutic hypothermia and EEG.

Biochemical markers

Biochemical markers that can reflect neurologic injury can be measured both in the serum and the CSF. Ideally, a chosen marker should be shown to be released from neurons or glial cells as a result of damage to that cell, and should be easy to obtain.[62] A meta-analysis of published

Fig. 50.3. Burst-suppression EEG pattern after cardiac arrest demonstrating periodic generalized bursts of sharply contoured electrical activity separated by periods of EEG suppression (from Koenig, M.A., Kaplan, P.W. and Thaker, N.V., Clinical Neurophysiologic Monitering and Brain Injury from Cardiac Arrest. In Brain Injury after Cardiac Arrest, Neurologic clinics vol 24 issue 1, Editor: Geocadin, R.G., Publisher – Elsevier 2006, with permission).

biochemical tests used to prognosticate outcome after cardiac arrest has been published,[45] as well as several other studies on biochemical tests in serum and CSF.[62–65] While specific cut-off levels are associated with poor outcome, these values vary considerably between studies, even for the same biochemical test (Table 50.1). This significant variability limits the universal translation of these tests into widespread clinical practice. While biochemical markers can detect brain injury and provide prognostication, more controlled clinical studies are required to define precisely their role in prognosticating functional outcome after cardiac arrest.

CSF creatine kinase BB (CKBB)

When the brain is injured, the CKBB in the brain will leak from the cytoplasm of the destroyed cells into the extracellular fluid.[66] CKBB levels in the CSF reach a peak between 48 and 72 hours after cardiac arrest.[67] Several studies investigated the prognostic value of CSF CKBB. The cut-off value higher than 204 units/l predicted poor outcome in these studies.[63,66] In a meta-analysis of 28 studies that included 802 patients,[45] CKBB >204 U/l showed no false-positives for poor outcome. Nevertheless, because of the small numbers of patients studied and methodological limitations, no reliable recommendation can be made for non-treatment decisions. Some concerns have been raised about the safety of CSF sampling as well as the risk of cerebral herniation.

Neuron specific enolase (NSE)

NSE is the neuronal form of the intracytoplasmic glycolytic enzyme enolase, which was first found in extracts of brain tissue (neuronal bodies and axons) and later in neuroendocrine cells (APUD) and neuroendocrine tumors (including small cell lung cancer).[68] It has a relatively high molecular weight, and is therefore unlikely to cross cell membranes unless the cell is damaged. It reaches a peak in the serum and CSF at 72 hours following the ischemic insult.[69] Many studies have investigated the value of increased serum and CSF NSE in patients who remained comatose after cardiac arrest. There is significant variability in the cutoff points for 100% positive predictive value for poor outcome. Some of the larger studies such as that performed by Fogel et al. in 50 patients used a cutoff value of serum NSE of 33 ng/ml and found 80% sensitivity and 100% specificity. Importantly, almost all of these studies were done in normothermic patients.

S-100

This is a dimeric acidic calcium-binding protein present in high concentrations in glial and Schwann cells.[68] It is eliminated by the kidneys, and is also found in certain tumors (including glioma, melanoma, schwannoma, and highly differentiated neuroblastoma).[68] It has a lower molecular weight than NSE and is highly soluble, and therefore more likely to cross the cell membrane.[68] S-100 is a sensitive marker for glial cell damage. The highest levels are usually observed during the first 24 hours after the anoxic insult, and usually decline over the next 48 hours, probably due to ease of permeability.[69] Several studies have used S-100 for prognostication: one used a cutoff value of 0.2 mcg/L, and found a positive predictive value of 79% of S100 2 hours after cardiac arrest, 87% of S-100 24 hours after cardiac arrest, and 75% at 48 hours after cardiac arrest.[70]

NSE, S-100 and hypothermia

Since the positive findings related to therapeutic hypothermia after cardiac arrest, a study by Tiainen et al. of 70 patients to evaluate the effect of therapeutic hypothermia on levels of serum NSE and S-100B protein found that the levels of NSE ($P = 0.007$), but not S-100B, were lower in hypothermia-treated patients than in normothermia-treated patients.[64] A decrease in NSE values between 24 and 48 hours was observed in 88% of the hypothermia group and only 50% in the normothermia group ($P < 0.001$). This decrease in NSE values was associated with good outcome at 6 months after cardiac arrest ($P = 0.005$), recovery of consciousness ($P < 0.001$), and survival > 6 months after cardiac arrest ($P = 0.012$).[64]

Associated manifestations

Elevation of intracranial pressure

Cellular injury and neuronal death from global brain ischemia may lead to cerebral edema. Commonly, increased intracranial pressure is attributed to significant cerebral edema. A study of head CT 3 days after cardiac arrest showed that brain edema was more common in patients who had cardiac arrest due to respiratory distress, and of those patients diagnosed with brain edema, more developed brain death compared to those without brain edema.[71] A study with 10 patients suggests that intracranial pressure elevation (ICP) following CPR does not necessarily increase in the absence of primary intracranial pathology or seizures,[72] but when ICP is elevated, the presence of ICP > 20 mmHg in comatose patients has been associated with poor outcome.[39, 73] Although this is a promising indicator of brain injury after cardiac arrest, more studies are needed to establish the usefulness of elevated ICP for prognostication.

Myoclonus status epilepticus

As many as one-third of comatose CPR survivors experience seizure activity at some time during the hospital course,

most commonly within the first 24 hours.[74,75] A detailed discussion of seizures, diagnosis, and management, and impact on outcome after cardiac arrest is provided in a comprehensive review by Koenig and Geocadin.[76]

The prognostic significance of seizure needs to be clarified. Although studies focus on the occurrence of myoclonus status epilepticus as a predictor of poor outcome in selected patients with severe injury,[77,78] other types of seizures may be less ominous, as shown in a general population study by Levy *et al.*[25] which failed to demonstrate poorer outcomes in the subpopulation with seizures of any type.

Episodic jerking in postcardiac arrest patients must be carefully characterized prior to proposing prognosis. The classical syndrome of postanoxic myoclonus (also known as the Lance–Adams syndrome), which occurs more frequently after respiratory arrest, was previously regarded as a predictor of poor outcome. But a recent report of survivors with postanoxic myoclonus indicates that the myoclonus may improve as neurologic status improves.[79] Nevertheless, myoclonic status epilepticus which presents as repetitive, unrelenting, generalized multifocal myoclonus in the face, limbs, and axial musculature,[74] which is often associated with burst suppression on EEG, is considered to be an indicator of extremely poor prognosis, and it does not respond to anticonvulsants.[74,78]

Multimodality prognostication

Most of the studies on the prognostic markers in cardiac arrest have been made by considering single variables. Few studies have looked at combining the values of the above tests to increase the reliability of predicting outcomes.[43,53,66] Bassetti *et al.* assessed the value of combining clinical examination, EEG, SSEP, and two serum biochemical markers (ionized calcium and neuron-specific enolase). Individually, clinical examination correctly predicted outcome in 58%, SSEP in 59%, EEG in 41%, and in combination, all three factors (clinical exam, SSEP, and EEG) improved the predictions to 82%. No false poor prediction was observed using the combination.

To improve further the ability of SSEP in predicting poor outcome, Sherman *et al.* added CSF creatine kinase BB isoenzyme activity (CKBB). As individual tests, they found that poor outcome was predicted with a CKBB ≥ 205 U/l with a sensitivity of 49% and a specificity of 100%, whereas the bilateral absence of the N1 peak had a sensitivity of 53% and a specificity of 100%. The combined presence of CKBB ≥ 205 U/l and bilaterally absent SEP N1 peaks, improved the sensitivity to 69%, while the specificity remained at 100% in predicting a poor outcome.

While novel injury and recovery parameters for prognostication and real-time tracking and application are being developed through research,[80,81] multimodality prognostication provides an opportunity for further enhancement of the ability of clinicians to predict the outcome after cardiac arrest. Although this is a very promising direction, better designed prospective studies with adequate statistical power are needed for real advances in this area.

Withdrawal of life-sustaining therapies

Advances in resuscitation and critical care have allowed the prolongation of life in resuscitated patients, but the desired quality of life is not attained in most of these cases. The practice of withdrawal of life-sustaining therapies is currently widespread in ICUs. Several major organizations, including the American Medical Association,[82–84] the American Academy of Neurology,[85] and the Society of Critical Care Medicine-American College of Chest Physicians,[86] have recognized the right of patients in specific situations to forgo treatment, even if refusal may lead to death. Indeed, research demonstrates widespread support among critical care physicians and nurses for withdrawal of life-sustaining therapies in cases of devastating injury and expected poor outcome.[87–89] The clinical findings in patients with persisting coma presented above, such as the absence of pupillary light flex and motor response on day 3, with or without the SSEP test showing the absence of the N20 wave during the first week, may be used to define the high likelihood of poor outcome.

The actual process leading to the decision to withdraw life-sustaining therapies has not been studied in detail. This is a clinical decision that is based on the clinical condition of the patients in conjunction with treatment and outcome preference of the patients, and clinical expertise of the treating team.[90] A study found that advanced ICU care is provided to treat morbidity and delay mortality, and at the same time to orchestrate the dying process.[91] They also found that the decisions to withhold, provide, continue, or withdraw life support were "socially" negotiated leading to a common decision among family members and clinicians.[91] A survey study showed that 73% of the general public respondents and 70% of nurse respondents advocated a joint decision made by the family and the physician.

A recent report of patients withdrawn from life-sustaining therapies after resuscitation from cardiac arrest indicated that patients with absence of bilateral N20 on SSEP and poor neurologic examination had a shorter period of

observation before withdrawal of life support compared to those with poor neurologic examination and indeterminate or present N20 on SSEP.[93] The ICU team and the families decided sooner if the poor neurological examination result was supported by an objective measure like the SSEP.[93] More studies are needed to understand this process and how to apply the information to improve the experience of patients' families and physicians. While the process of withdrawal of life support is widely practiced and discussed, it is still not well known how the clinicians and the families actually process the clinical characteristics used in neurologic prognostication to reach a specific decision.

Evaluation of brain death

Despite the advances in resuscitation techniques and therapies for patients after cardiac arrest, the progression of injury to death is very common. The progression of brain injury after resuscitation from cardiac arrest leading to the irreversible loss of function of the brain and the brain stem underlies the condition of brain death.[94] The practice of declaring brain death has defined criteria that were first established by an ad hoc committee of Harvard Medical School in 1968;[95] the criteria were further developed to be more relevant to clinical practice through a set of guidelines published by the Quality Standards Subcommittee of the American Academy of Neurology (AAN) in 1995.[94] These guidelines are presented below with some additional suggestions pertinent to a patient suspected of brain death following cardiac arrest. It is also strongly advised that the physician performing the brain death examination consults and applies the practice guidelines of the hospital, as well as any established laws of the state or country where the test is performed.

The AAN prerequisites for the declaration of brain death include a known proximate cause for the irreversible absence of brain function;[94] this may be demonstrated by neuroimaging. In patients with global brain ischemia from cardiac arrest, neuroimaging may not be necessary unless other complicating etiologies are considered. For example, medical conditions that may mimic clinical manifestations of brain death or confound the clinical assessment of brain death should be ruled out. These include a severe electrolyte, acid-base, or endocrine disturbance, drug intoxication, use of paralytic and sedative agents, and poisoning. Additionally, significant hypotension must to be corrected, and the patient's core temperature must be greater than or equal to 32 °C (90 °F). In efforts to demonstrate irreversibility and consistency of findings, the determination of brain death requires that two neurological examinations be performed at least more than 6 hours apart. Once all these prerequisites are met, the examination can proceed to establish the presence of the three cardinal findings in brain death: (1) coma or unresponsiveness; (2) absence of brainstem function; and (3) apnea.[94]

Determination of coma

After resuscitation from cardiac arrest, a comatose patient will display no purposeful or spontaneous movements, or response to stimuli of any kind. The depth of the patient's coma may be assessed by the neurological examination. A detailed approach to the determination of the depth of coma was presented above in the section on neurologic assessment. In unresponsive patients, significant noxious stimulation must be used to avoid an erroneous coma diagnosis. If noxious stimulation is to be used, it must be applied first in the midline areas (sternum), and then in the limbs, and in the facial areas as supraorbital ridge pressure. Responses generated by noxious stimulation should not elicit any activity that can be attributable to the brain or brainstem. Not infrequently, reflexive movements generated from the level of the spine may suggest brain or brainstem function.[96] Some of these movements include a minor reflexive flexion in the limb with the application of a noxious stimulant, a slow flexion at the waist, arms raised independently or together, stepping movements, slow turning of the head, movement of toes, facial twitching, or the Babinski reflex.[96] If all the clinical prerequisites are met and the reflexive activity is localized to the spine, the diagnosis of brain death persists.

Examination of brainstem reflexes

Together with the determination of coma, the absence of all clinical functions of the brainstem must also be established. Again, a detailed approach to specific cranial nerves was provided above; the key findings included total absence of the pupillary light reflex (cranial nerve 2) and the persistence of a midpositioned (4 mm) to dilated pupils (9 mm). The absence any ocular response (cranial nerves 3, 4, and 6) with oculocephalic maneuver is consistent with brain death. For patients with known or suspected cervical spine injury, head-turning should not be attempted. All patients undergoing brain death determination should receive cold caloric testing (cranial nerve 8).[94,96,97] During this test, eyes should not deviate while each ear is irrigated with 50 ml of cold water. The patient should be observed for a response for 1 minute following injection, and a period of 5 minutes should be maintained before testing in the patient's other ear. The absence of the cranial nerve 5

and 7 functions can be documented with the absence of the corneal reflex and facial grimace to pain. Finally, pharyngeal and tracheal reflexes (cranial nerve 9 and 10) should be evaluated. The absence of the gag reflex can be documented by the lack of response to tongue depressor placed in the posterior pharynx and the absence of the tracheal cough when tracheal suctioning is applied in intubated patients. The absence of spontaneous respirations or the need for a full ventilatory support also strengthens the diagnosis of brainstem injury in brain death.

The apnea test

The apnea test is performed to determine if the patient's brainstem can trigger a spontaneous breath given an adequate stimulation of carbon dioxide. To perform the test adequately, some prerequisites must be met: a core temperature of 36.5 ºC or higher; systolic blood pressure greater than or equal to 90 mmHg; euvolemia; normal pCO_2 (> 40 mmHg), and normal arterial PO_2 with the option to pre-oxygenate to $pO_2 > 200$ mmHg.[94] Close hemodynamic and respiratory monitoring is required because the procedure is closely associated with hypotension and cardiac arrhythmias,[94] especially with the occurrence of systolic blood pressure ≤ 90 mmHg, and significant O_2 desaturation.

The apnea test should begin with a baseline arterial blood gas measurement with the patient connected to a pulse oximeter. The ventilator may then be disconnected, and 100% O_2 should be delivered into the trachea at 6 liters/minute. Oxygen should be delivered using a cannula placed at the level of the carina. The patient should be observed for respiratory movements. Respiration-like movements or abdominal movements may be observed, but a spirometer may be used to confirm the absence of tidal volumes. Arterial PO_2, PCO_2, and pH should be measured every 3–4 minutes.

The test is positive if respiratory movements are absent and PCO_2 reaches a critical level (i.e., ≥ 60 mm Hg, or increase is ≥ 20 mmHg over baseline).[94] The test is negative if respiratory movements are observed. The test may be repeated if negative.[19] The test result is indeterminate if PCO_2 is < 60 mmHg, or increase is < 20 mm Hg over baseline normal level,[94] after which an additional confirmatory test may be considered.

Confirmatory tests

If the determination of brain death cannot be made with certainty on clinical grounds, such as in cases of severe facial trauma, pre-existing pupillary abnormality, toxic drug levels, and severe chronic CO_2 retention, confirmatory testing may be necessary. Confirmatory laboratory testing findings that may help establish the diagnosis of brain death include: (1) absence of cerebral filling at the level of the carotid bifurcation or circle of Willis on conventional angiography; (2) no uptake of isotope in brain parenchyma with technetium-99m hexamethylpropyleneamineoxime brain scan; (3) no electrical activity for at least 30 minutes on the EEG Brain Death protocol by the American Electroencephalographic Society; (4) absence of blood flow on adequate studies with transcranial Doppler; and (5) absence of bilateral N20–P22 response with median nerve stimulation on SSEP based on the protocol adopted by the American Electroencephalographic Society. A detailed discussion of these tests and procedures is provided in AAN guidelines.[94]

Multiple brain-damaging processes occur both during cardiac arrest and after return of spontaneous circulation (ROSC). The first aspect, the actual arrest, is best treated by rapid institution of artificial circulation/ventilation and early ROSC. The details and physiologic background for these procedures are discussed in previous chapters. This chapter will focus on the early period after restoration of spontaneous circulation and treatment aimed to prevent or minimize postischemic brain damage after restoration of spontaneous circulation. The ultimate importance of the postreperfusion (after ROSC) phase for long-term outcome is often underestimated. Currently it is believed that the majority of brain-injuring processes occur not during the no-flow state (cardiac arrest) but during resuscitative reperfusion. This latter stage includes a trickle-, a low-, and a temporary high-flow period. Since significant injury occurs during the resuscitation period, there is a window of opportunity to intervene and affect outcome. Nevertheless, the development of treatments for the multifactorial postresuscitation syndrome is complex and time-consuming and has thus far led to disappointing results. Numerous treatments effective in the laboratory have failed or been shown to have an almost undetectable benefit in clinical studies. Large multicenter studies – the only way to detect small(er) benefits – are extremely expensive and time-consuming and require an enormous administrative and financial investment. Sometimes ethical concerns about obtaining informed consent make clinical resuscitation research increasingly difficult. Nevertheless, definitive clinical studies are the only way to prove the effectiveness of resuscitation and postresuscitation treatment; clinically relevant laboratory studies may only help to select those that are most promising.

Reperfusion

The regulation of cerebral perfusion is complex and only partially understood. Loss of perfusion or insufficient perfusion also results in loss of regulation. Reperfusion but not autoregulation is regained with the initiation of cardiopulmonary resuscitation (CPR). Safar and Bircher have summarized three steps that occur in the failure of early post-ROSC perfusion: (a) immediate multifocal no-flow; (b) transient global "reactive" hyperemia; and (c) delayed, prolonged global, and multifocal hypoperfusion. Later, blood flow either normalizes or hypoperfusion continues, depending on the progress of recovery. Many treatments after ROSC aim to optimize reperfusion and restore autoregulation.[1]

Animal studies have demonstrated that cerebral perfusion early after ROSC is marked by an initial transient period of hyperemia.[2] Although overall cerebral blood flow at this time is greater than normal, however, it is unevenly distributed and the needs of the microcirculation are probably not satisfied. After 15 to 30 minutes of reperfusion, global cerebral blood flow decreases and generalized hypoperfusion develops. This inability to sustain cerebral blood flow after a significant period of flow interruption is part of the no-reflow phenomenon.[3–5] Postischemic blood flow may be impaired for 18 to 24 hours, after which regional cerebral blood flow may either improve, correlating with functional recovery, or decline, correlating

with progressive ischemic damage and cell death.[3,4,6] Physiologic mechanisms proposed to explain persistent postischemic hypoperfusion include vasoconstriction,[7,8] decreased red blood cell deformability,[7,9] increased platelet aggregation,[4,6,10] pericapillary cellular edema,[11] and abnormal calcium ion fluxes.[12,13] Intracranial pressure generally does not increase immediately after ROSC and therefore is not a major influence on early cerebral perfusion pressure and consequent cerebral blood flow.[14–18]

Maintenance of adequate cerebral perfusion pressure (dependent on the individual patient's baseline blood pressure before arrest) is a mainstay of postresuscitation care. In normal circumstances, cerebral blood flow is autoregulated such that it is independent of perfusion pressure over a wide range of blood pressures (between approximately 50 and 150 torr mean arterial pressure (MAP)).[19] After global brain ischemia, however, autoregulation is lost, and perfusion becomes dependent on arterial pressure.[20–23] Consequently, the occurrence of postischemic hypotension can severely compromise cerebral blood flow and may result in additional brain damage.[24] Therefore, after restoration of spontaneous circulation, arterial pressure should at least be rapidly normalized, based on prearrest blood pressure levels, by administering intravascular fluids and vasopressors as needed.[8,25]

Experimental evidence indicates that, after a prolonged insult, a transient period of moderate hypertension (MAP at 130 mm Hg) improves postischemic brain reperfusion and neurologic recovery.[8,26–28] Such transient hypertensive reperfusion may occur after resuscitation because of epinephrine loading during resuscitation, or may be induced by administration of vasopressors after ROSC. In dogs an induced brief period of hypertension (MAP 150 to 200 mm Hg for 1 to 5 minutes), followed by controlled normotensive blood pressure levels, abolished evidence of the immediate no-flow state[29,30] and correlated with improved outcome.[8,26,27] Nevertheless, there are potential risks to such an aggressive therapeutic approach: pharmacologically induced hypertension may not be tolerated by the ischemic heart,[11,31] and volume replacement therapy should optimally be guided by monitoring central venous pressure and pulmonary artery pressure. In animal studies, mildly elevated blood pressure (MAP 130 mm Hg) prolonged over the first 4 hours after resuscitation was well tolerated.[27] Although induced hypertension has not been tested in a formal clinical trial, early postarrest hypertension was found to correlate with good cerebral outcome in patients, whereas hypotension correlated with poor cerebral outcome.[32]

For control of early postresuscitation blood pressure, a titrated intravenous infusion of adrenaline or noradrenaline may be more effective than phenylephrine or dopamine. There is also some evidence that noradrenaline may be less arrhythmogenic.[1] Dobutamine may be preferred later for improvement of cardiac output and indirect blood pressure support.[1,33,34] Further, mechanical approaches can also support reperfusion. A spectrum of experimental possibilities, including assisted circulation with cardiopulmonary bypass or aortic balloon pumping, is under development and available for trial.

Emergency cardiopulmonary bypass seems to be a promising approach to accomplish all of the previously described blood flow-promoting treatments. Animal experiment work strongly suggests a beneficial effect of cardiopulmonary bypass after prolonged cardiac arrest.[35–38] Increased ability to resuscitate the heart and improved postresuscitation cardiac and neurologic function have been demonstrated in dogs when cardiopulmonary bypass was instituted after prolonged ischemic insults.[39,40] Use of this technique on an emergency basis via access to femoral vessels may allow restoration of spontaneous circulation in patients refractory to standard CPR and advanced cardiac life support, especially in cardiac arrest secondary to intoxication with central nervous system (CNS) depressant drugs. It may also improve reperfusion of the brain, thereby significantly ameliorating postischemic brain damage. Further, it may assist in the delivery of cerebral resuscitative medications that have cardiodepressant properties. Cardiopulmonary bypass appears to be one of the most effective techniques for rapid induction of therapeutic hypothermia (see discussion of hypothermia). Taken together, the beneficial effects of cardiopulmonary bypass are: (a) to help establish ROSC by optimizing coronary reperfusion; (b) to reduce cardiac work during the early period after ROSC; (c) to reduce the use of catecholamines and in turn reduce myocardial oxygen demand; (d) to allow safe delivery of treatments after ROSC; and (e) to be a potential bridge to heart surgery and heart transplant, if needed. Unfortunately, the practicality of initiating cardiopulmonary bypass during CPR has thus far been limited by the time required for vessel cannulation. Clinical feasibility studies have had limited success in improving outcome.[41] Nevertheless, selective clinical use of this technique may hold promise for future cardiac and cerebral resuscitation.[1,38,41–43]

During the last 10 years several other invasive flow-promoting resuscitation techniques were reevaluated. These include a cup-like direct mechanical ventricular assist device,[44] which requires a relatively large thoracotomy for placement, and a mini-plunger MID-CPR (minimally invasive CPR) placed directly on the pericardium inserted via a small thoracic incision.[45–47] This latter device was developed for actual resuscitation and not for promotion

of postresuscitative blood flow. For several reasons, none of these modified CPR techniques has reached clinical acceptance or has been proven to be sufficiently effective in general use. Techniques to improve postischemic organ perfusion by modifying the rheologic characteristics of blood have also been studied.[48] Therapies tested in experimental models include hemodilution with crystalloids, colloids, and fluorocarbons;[49] anticoagulation and/or fibrinolysis with heparin and/or streptokinase;[49–51] blocking of platelet aggregation with prostaglandin inhibitors, such as indomethacin;[52] and the use of calcium entry-blocking drugs to improve deformability[7,9] of red blood cells and microcirculatory flow. The potential benefit of thrombolytic agents remains speculative. In a study of VF in pigs, however, application of hypertonic saline as well as hypertonic HES saline during CPR improved myocardial blood flow, ROSC rate, and survival rate significantly;[53] further studies are planned. New stroma-free hemoglobin (SFH) solutions, currently under development, have so far failed to improve outcome.[54,55] Nonetheless, diaspirin crosslinked hemoglobin (DCLHb) treatment in a 5-min VF, 10 min-CPR pig study increased the ROSC rate, and provided better myocardial O_2 delivery, venous blood O_2 content, and myocardial and cerebral perfusion pressure.[56] The author concluded that this effect was most likely related to improved coronary perfusion and myocardial oxygen delivery. The problem of maximizing blood flow by decreasing viscosity with hemodilution while avoiding a compromise of blood oxygen-carrying capacity has not been resolved. At present, none of these experimental therapies are ready for clinical trials.

Tissue oxygenation

Adequate oxygenation and ventilation of tissues are necessary to preserve cellular function and to allow postischemic reparative processes to occur. Normal arterial PO_2 levels should be maintained by using the lowest FIO_2 possible. Some controversy currently exists concerning the possible role of high arterial oxygen levels in the generation of postischemic, reperfusion-induced free radicals. In recent dog studies,[57] prolonged maximal O_2 administration (before and after arrest) worsened outcome. This was thought to be caused by a triggering of reoxygenation injury cascades induced by free radicals.[57–60] Nevertheless, hippocampal damage in rats resuscitated from cardiac arrest either with hyperoxia (FiO_2 1.0) or normoxia (FiO_2 0.21) did not differ.[61] Therefore, at this time no changes in current clinical practice are recommended.

Ventilation and acid–base balance

Although hyperventilation is still practiced, controversy as to its benefit has developed.[62,63] In pigs hyperventilated during resuscitation, coronary perfusion pressure and postresuscitative survival dropped significantly with higher ventilation rates.[64,65] It has been hypothesized that after prolonged cardiac arrest, early hyperventilation may create a reverse-steal phenomenon that would improve blood flow to the most severely insulted areas of the brain. In these areas, blood vessels lose CO_2-mediated vasomotor responsiveness, whereas vessels in less injured areas may maintain the ability to constrict as CO_2 is lowered. Thus, with hyperventilation, blood may be shunted to the worst areas. Although this modulation of blood flow has been shown to occur, improved outcome has not.[66] Data from patients with head injury suggest that hypocapnia, induced by hyperventilation, may decrease cerebral blood flow and increase differences in cerebral arteriovenous oxygen content, which may worsen neurologic outcome.[67] In brain trauma patients with Glasgow Coma Scale scores below 8, neurologic outcome was worse when $PaCO_2$ was controlled to 24 mm Hg compared to normocapnia (35 mm Hg).[68] With prolonged hyperventilation, cerebrospinal fluid and renal transport mechanisms attempt to compensate by retaining HCO_3.[69] After approximately 4 hours, the effectiveness of hyperventilation may gradually decline.[70] Currently, evidence is insufficient to recommend an optimal $PaCO_2$ level to be maintained.[71–75]

During the early postresuscitation period, washout of elevated tissue PCO_2 into the systemic circulation occurs. In this phase, hyperventilation may help correct postischemic tissue acidosis by enhancing excretion of the CO_2 load generated during ischemia and by the administration of CO_2-generating buffers during CPR.

If hypoperfusion is prolonged after ROSC, the increased tissue CO_2 and the associated acidemia may require pharmacologic treatment. Several buffer solutions are currently in clinical use and are under investigation. Sodium bicarbonate, used during CPR since the early 1960s, is now subjected to critical investigation because CO_2 is produced during a reaction with hydrogen ions. Beside other potential side effects, this additional hypercarbic load may theoretically depress myocardial resuscitability, although animal studies of HCO_3 administration after 5 or 10 minutes of ventricular fibrillation found no harm to the heart and possible benefit to the brain.[76–78] Bicarbonate may only be advantageous when combined with epinephrine; this possibility may not have received enough attention in past studies.[76,78] Other potential buffer agents, such as Tribonate ($NaHCO_3$ + THAM + phosphate acetate) and

Carbicarb ($Na_2CO_3 + NaHCO_3$), are available. In animal studies, low dose Carbicarb (3 ml/kg) administered during resuscitation from asphyxial cardiac arrest attenuated acidosis, improved resuscitation, and reduced neurologic deficits and the number of dead hippocampal neurons.[79] Currently, clinical data are insufficient to support the effectiveness of the use of these drugs during CPR.

In general, buffer solutions should be withheld as an initial intervention during CPR, especially after short arrest periods. When arrest or CPR duration is prolonged, buffer administration may be useful and should be tested in a clinical trial.

After restoration of spontaneous circulation, buffer therapy may be beneficial. Bicarbonate deficit can be estimated by the following formula:

$$\text{bicarbonate deficit} = 0.3 \times \text{body weight (kg)} \times \text{base deficit}$$

Moderate acidemia should be treated initially with an amount of bicarbonate that is only half of the calculated deficit, after which the acid–base status should be corrected over the next few hours. Profound metabolic acidemias should be treated with a bicarbonate bolus of about 1 meq/kg (50 to 150 meq) followed by closely controlled titration. Outcome studies testing the benefit of postresuscitation buffer treatment are needed.

Immobilization and sedation

In the comatose patient the brain responds to external stimuli such as physical examination or airway suctioning with increases in cerebral metabolism and intracranial pressure. This elevated regional brain metabolism requires increased regional cerebral blood flow at a time when oxygen supply and demand may be precariously balanced. Protection from afferent sensory stimuli with administration of titrated doses of sedative-anesthetic drugs and (carefully titrated) muscle relaxants may protect this balance and improve the chance for neuronal recovery, although clinical trials are needed to support this hypothesis.

Anticonvulsant therapy

Seizure activity can increase brain metabolism 300 to 400%.[80–82] This extreme increase in metabolic demand may tip the tissue oxygen supply : demand balance, causing unfavorable neurologic consequences. Clinical evidence confirms this effect after cardiac arrest (Brain Resuscitation Clinical Trial I, unpublished data). Outcome is worse if convulsions occur at any time within the first 3 days after resuscitation. Not surprisingly, the number of seizures correlates with poor outcome. Although controversy exists about the prophylactic use of anticonvulsant drugs, it is generally agreed that after any signs of seizure activity, anticonvulsive therapy should be administered immediately. Commonly used drugs include barbiturates, phenytoin, and benzodiazepines. Phenytoin has been reported to improve neurologic recovery after experimental global brain ischemia through postulated mechanisms independent of its anticonvulsant effect, such as membrane stabilization.[83,84] Potential beneficial effects of barbiturates are discussed later in this chapter.[55]

Other metabolic factors

Hyperglycemia (observed or experimentally induced) before cardiac arrest has detrimental effects on neurologic outcome.[85] The higher glucose supply available during ischemia and low-flow states serves as a reservoir for continued anaerobic metabolism and results in increased lactate production.[86] Although control of hyperglycemia before arrest is not feasible, blood glucose levels after ROSC can be controlled. In experimental models of forebrain ischemia, hyperglycemia after insult was shown to exacerbate ischemic brain dysfunction.[87–89] In a rat study of asphyxial cardiac arrest, however, administration of glucose during reperfusion did not worsen neurological outcome, most likely because glucose is required for recovery of cellular metabolism after ROSC.[90] Frequently, blood glucose levels observed immediately after resuscitation are elevated, probably because of severe stress and catecholamine release. Reports of detrimental neurologic outcomes in patients with hyperglycemia after ROSC probably reflect the correlation with prolonged resuscitation time rather than a primary effect of the hyperglycemia.[91] Although human studies have not clearly demonstrated a correlation between elevated glucose levels and the effect on neurologic outcome, some clinicians now recommend that at least highly elevated blood glucose levels should be treated aggressively with insulin.

Interestingly, experiments in rats have shown that postischemic high dose insulin treatment may reduce neurologic damage[89,92,93] independent of its glucose-lowering effect. Insulin may also be beneficial for normalization of cerebral blood flow, metabolism, and cardiac function, as well as postulated reparative effects. It seems rational to combine glucose (metabolic substrate for tissue repair) with insulin, to support transport mechanisms and to

avoid hypoglycemic side effects. Recently, it has been demonstrated in rats that postresuscitation treatment with a combination of glucose, 1 g/kg, and insulin, 1.2 μg/kg, improved outcome significantly as compared to treatment with placebo, low dose insulin only, or glucose only.[90]

In contrast to the uncertainty concerning the effect of elevated blood glucose levels after cardiac arrest, prolonged hypoglycemia is detrimental.[90,94,95] Hypoglycemia interrupts the autoregulation of cerebral blood flow, disturbs cerebral metabolism, and compromises membrane stability. Thus hypoglycemia after resuscitation must be avoided.

Neurologic protection, preservation, and resuscitation barbiturates

Among the first potential neuroprotective agents to be tested, barbiturates appeared promising because of their ability to reduce cerebral metabolism,[96] edema,[97] intracranial pressure,[26] seizure activity,[98] and damage induced by focal and incomplete ischemia.[99–101] Barbiturates also seemed to improve postischemic brain oxygen supply:demand ratios,[102] cell energy charge,[103] and cyclic adenosine monophosphate (AMP) stores,[104,105] and to lower accumulation of free fatty acids.[106,107] The most influential experimental work indicating that barbiturate administration after complete global brain ischemia ameliorated neurologic damage was performed on rhesus monkeys in the mid 1970s. Even though these studies had methodological problems with blood pressure control, they stimulated studies of clinical feasibility[108] and pilot trials of thiopental loading in comatose CPR survivors,[109] which indicated that high doses of this drug might be administered safely, and also suggested a beneficial effect. A randomized clinical trial of thiopental loading (with up to 30 mg/kg[5,110–112]) between 1979 and 1983 did not show statistically significant differences in neurologic outcome between control and treatment groups.[113–115] On the basis of these data, high-dose thiopental loading has not been recommended for routine clinical use after cardiac arrest. The story may not be completely closed, however, because several studies in dogs have shown a significant improvement in histological outcome with high-dose barbiturate loading (90 mg/kg) after cardiac arrest.[55,116]

Steroids

Commonly administered to patients with intracranial pathologic conditions, steroids may stabilize lysosomal membranes and prevent release of lytic enzymes,[48,117] stabilize mitochondria and preserve adenosine triphosphate (ATP) synthesis,[8,118] inhibit release of free fatty acids from cell membranes,[119,120] and scavenge free radicals generated during postischemic reperfusion.[120] All of these proposed mechanisms contribute to the rationale supporting the use of steroids. Although there is evidence that steroids are beneficial for patients with intracranial tumor-related cerebral edema,[119,121] no clinical evidence documents their efficacy for treatment of brain ischemia.[121]

Methylprednisolone, one of the most widely used steroids, has been shown potentially to improve functional and histological outcome after blunt spinal injuries,[122–127] and when used in dogs after cardiac arrest (as part of a multicomponent treatment) it improved outcome slightly (see discussion of combination treatment).

The effectiveness of 21-aminosteroids ("lazaroids") after global ischemia is still under investigation. Animal models of trauma and focal brain ischemia treated with aminosteroids showed improved outcome.[128–130] After cardiac arrest, however, 21-aminosteroids improved neurologic outcome only when given as a pretreatment.[131,132] New 21-aminosteroids are currently under investigation, but sufficient data are not yet available.[133,134]

Calcium channel-blocking drugs

The potential beneficial effect of calcium channel blockers after cardiac arrest has been demonstrated in (at least) four organ systems:

1. Blood: decreased platelet aggregation, increased red blood cell (RBC) deformability, and decreased blood viscosity[7,9,90]
2. Vessels: decreased vasoconstriction[135,136]
3. Neurons: decreased calcium entry resulting in improved ATP production and decreased production of cytotoxic chemicals[12,137–140]
4. Systemic circulation: improved oxygen supply:demand ratio in myocardium and other tissues.[141]

Postischemic cerebral blood flow may be improved through amelioration of cerebral vasospasm and redistribution of regional flow.[142] It appears that certain calcium channel blockers have a greater effect on cerebral vessels than on peripheral vessels because cerebral vascular muscle tone is more dependent on the entry of extra-cellular calcium.[143] In controlled, blinded animal studies, lidoflazine improved neurologic recovery in dogs when administered after cardiac arrest.[18,144] Nimodipine had the same result in monkeys after cerebral ischemia caused by hypotension and neck tourniquet compression.[135]

Nevertheless, well-conducted clinical trials did not confirm these promising animal experimental findings. No difference was found between patients treated with lidoflazine or standard therapy after cardiac arrest.[145] The reason for these disparities in clinical trials is uncertain, but the beneficial neuroresuscitative properties of these drugs may be neutralized by their deleterious cardiovascular effects. Clinical trials of nimodipine and flunarizine, two other experimental calcium channel blockers, also failed to show evidence of improvement.[96,146]

Temperature control

It is well established that brain temperature before, during, and after cerebral ischemia has a major influence on cerebral outcome.[147–149] Extensive animal experimentation, as well as clinical case reports (especially of drowning victims) as early as the 1970s have shown that hypothermia improves neurological functional outcome after cardiac arrest. The effectiveness and safety of hypothermia after cardiac arrest seems to be maximal between 32 and 34°C, a level termed mild hypothermia.[22,148,150] Temperatures below 32 °C do not seem to increase neuroprotection, but are known to increase the side effects of hypothermia, including increased blood viscosity, decreased cardiac output, and increased susceptibility to infection. The beneficial laboratory data on mild hypothermia was so impressive that a push to have mild hypothermia used as a treatment for cardiac arrest has been advocated for years.[151] Two well-controlled, prospective clinical trials demonstrated that mild (32–34 °C) hypothermia induced as early as possible during cardiac arrest and resuscitation improved neurological outcome.[152–154] Although hypothermia is an effective method of suppressing cerebral metabolic activity, its beneficial effects on cerebral ischemia are believed to differ from CNS depressant drugs. Mild hypothermia not only attenuates the deleterious effects of reperfusion disease,[155–157] but it may have an active role in improving cerebral blood flow and increasing expression and production of brain-derived neurotrophic factor (BDNF).[158,159]

Unfortunately, the beneficial effect of hypothermia on eurological outcome after cardiac arrest is time-dependent. The earlier that hypothermia is induced during cardiac arrest, the more effective it will be in improving neurological outcome.[160] Interestingly, patients early after cardiac arrest have a slight decrease in body temperature, so the magnitude of temperature decrease to reach therapeutic mild hypothermia is relatively small.[161] Normal counter-regulatory mechanisms, such as shivering,

however, can slow the process of reaching a therapeutic level.[162] Recent research suggests that the brain's thermostat can be pharmacologically reset to a lower control temperature to speed the rate of attaining therapeutic hypothermia.[163,164] In addition, current therapies are available to overwhelm these counter-regulatory mechanisms and achieve therapeutic hypothermia.[165,166] The precise duration of hypothermia necessary to attain its maximal benefit on neurological outcome has not been established; however, it appears that a minimum of 24 hours of forced mild hypothermia is required to assure that the benefit of therapy is long lasting.[167,168] The optimal method and rate of rewarming after hypothermia has also not been well studied; it is apparent, however, that rapid rewarming (greater than 0.5 °C/hour) may be deleterious to neurological outcome).[169,170] Rewarming is a critical component of therapeutic hypothermia, as several animal studies have documented that even modest hyperthermia worsens histological outcome after an ischemic insult and may negate many of its beneficial properties.[149] Since cerebral metabolic rate changes by about 8% per degree Celsius change in body temperature,[171–173] and regional cerebral metabolic rate determines regional blood flow requirements, elevation of temperature above normal creates the possibility for a significant imbalance between oxygen supply and demand. In addition, the denaturing effect of hyperthermia on proteins may exacerbate structural and biochemical damage. In general, hyperthermia in the postischemic period must be treated aggressively to reduce secondary brain injury.

Cerebral regeneration

The focus of cardiac arrest research has been on reducing brain injury during reperfusion, a field of study referred to as cerebral resuscitation.[174,175] Nevertheless, until recently there has been no research on developing therapies once brain damage has occurred, a phenomenon referred to as cerebral regeneration. The potential to utilize stem cells to repair or replace an injured region of the brain is an area of intense research. Stem cells are broadly categorized as being either embryonic or organ-specific in origin. Oncological research on cell differentiation led to the consideration that embryonic tissue may have therapeutic value for organ repair.[176] The brain is a particularly attractive organ for transplant experiments, because it is historically and clinically considered to have minimal regenerative capabilities after structural damage.[177,178] Experiments with fetal tissue have contributed immensely to the understanding of embryonic stem cell physiology and the potential for tissue repair, especially in the

brain.[179,180] However, in addition to ethical concerns and mechanical limitations of transplantation, fetal tissue is composed of heterogeneous embryonic stem cells, making interpretation of transplant experiments complex. Identification of neural stem cells and neurogenesis in the adult brain has allowed for detailed in vitro analysis of neuronal stem cell development and differentiation as well as in vivo transplant experiments.[181] The advances resulting from studying neurogenesis have brought stem cell transplantation closer to reality as a therapy for tissue repair in the brain. The recognized multipotential of adult stem cells has raised enthusiasm for the notion that stem cells from adult organs aside from the brain may provide unique mechanistic information and therapies for a variety of disease processes, including brain injury.[182–185]

Combination therapies

All novel treatments described in this chapter have shown promise of improvement in outcome in laboratory studies but, except for mild hypothermia, have failed to bring a breakthrough in clinical practice. The complexity of pathologic mechanisms before and after cardiac arrest makes it unreasonable to believe that the treatment of an isolated mechanism could bring a therapeutic breakthrough. Perhaps future research on clinical treatment approaches should simultaneously target at least several of the mechanisms in the postresuscitation syndrome by combining the most promising and clinically relevant results from mechanism-oriented research. Intensive animal research – preferably with outcome models in

large animals – should be performed before initiating clinical trials. An example of this is the research strategy at the International Resuscitation Research Center. In a recently performed series of dog outcome studies[54,55,186] the effects of various combination treatments aimed at treating numerous physical and pharmacologic components of the postresuscitation syndrome were tested by using an established intensive care model (Table 51.1). All components included were previously reported as significantly beneficial for improving outcome in other models. A stepwise combination of physical (hemodilution, hypothermia, normocapnia, initial hypertension) as well as pharmacologic (steroid, barbiturate, anticonvulsive, antimetabolic) interventions was used. Combining these treatments improved outcome only to a limited extent. Drug interactions and combination side effects may be the reason for the plateau in improvement and partially worsened outcome in these highly complex treatment groups.

Hemodynamic support

The eventual outcome of cardiac arrest has only recently been shown to be influenced by complex postresuscitation hemodynamic derangements.[187,188] Several issues may explain why promising therapies from animal studies have not translated into significant improvement in neurologic outcome in humans. First, downtimes in humans may be underestimated so that the total ischemia time, including the low-flow state of CPR, may be outside the effective window for neuronal recovery. This can only be solved by

increasing access to and response by emergency medical services. Second, in contrast to laboratory studies of cardiac arrest where animals receive immediate and aggressive postresuscitation care, hemodynamic support for initial survivors of cardiac arrest is often much more variable and less aggressive. Because of the historically poor neurologic prognosis of patients resuscitated from cardiac arrest, many clinicians do not provide these individuals with aggressive care. Nevertheless, because it is not possible immediately after resuscitation to predict definitively what the ultimate neurologic outcome will be, patients should initially be subjected to aggressive postresuscitation management for at least 24 hours. This should include attention to management in global terms; that is, to consider effects on other organ systems that may ultimately affect the heart and brain.

As already stated, the heterogeneous underlying causes of cardiac arrest in humans present a tremendous challenge: their treatment clearly influences the outcome of this insult. Since cardiac arrest is a symptom rather than a disorder *per se*, it is essential to identify and treat any underlying disease (e.g., respiratory diseases, pulmonary embolus, myocardial ischemia, toxic agents, and metabolic abnormalities) after ROSC in order to prevent rearrest.

In terms of oxygen delivery (DO_2), oxygen consumption (VO_2), and oxygen debt, most patients are in a state of shock after ROSC.[187–190] Postresuscitation shock differs from primary cardiogenic shock, however, because of two important events: (a) it is preceded by a period of systemic no-flow and/or extremely low flow during cardiac arrest and CPR; and (b) large doses of catecholamines are usually administered during CPR, which, together with increased output of endogenous catecholamines, may result in further global oxygen debt, impaired myocardial function, and impaired ability to extract oxygen.[187,188] To what extent these abnormalities are reversible is apparently related to the events just described. In studies of other forms of shock, survival and degree of multiorgan failure are found to be related to the cumulative oxygen debt.[190] For a 70-kg man, an oxygen debt of less than $4100 \, ml/m^2$ is rarely if ever fatal; 50% mortality occurs at an oxygen debt of $4900 \, ml/m^2$; and mortality reaches 95% when oxygen debt exceeds $5800 \, ml/m^2$. Oxygen debt is difficult to calculate in humans after cardiac arrest since baseline VO_2 is unknown and the duration of cardiac arrest and prearrest events is also often not known. Assuming a baseline VO_2 of $120 \, ml/min/m^2$, however, a 30-minute cardiac arrest will result in an oxygen debt of $3600 \, ml/m^2$, which is not likely to present a serious problem with dysfunction of many extracerebral organs. Nevertheless, Rivers *et al.* have shown that additional oxygen debt accumulates during the postresuscitation period, which may lead to multiorgan dysfunction.[187,188] Some problems may be due to inappropriate use of catecholamines and reliance on inadequate monitoring (i.e., blood pressure and pulse rate) to guide therapy, as well as insufficient attention to ensuring adequate oxygen transport to the rest of the body.

After ROSC, it is important to determine whether the patient is evolving a myocardial infarction. Standard 12-lead and right-sided electrocardiograms (ECGs) should be obtained as soon as possible to search for ongoing ischemia. Without an appropriate history, it may be difficult to determine whether ischemia showing on the ECG is the cause or result of the cardiac arrest. Treatment for the post-arrest patient evolving a myocardial infarction is obviously optimized if a well-thought out multidisciplinary approach is in place. Patients who have had less than 10 minutes of CPR without evidence of CPR-induced trauma and who are not in vasopressor cardiogenic shock should be considered for thrombolytic therapy.[191] Patients who have had more than 10 minutes of CPR or significant CPR trauma should be considered for immediate angioplasty. Without effective revascularization strategies, myocardial dysfunction is likely to worsen and lead to hypoperfusion of many organs, including the brain. If ischemia is continuing, use of vasopressors to maintain perfusion pressures may increase myocardial oxygen demand above supply, which might result in extension of the infarct or promote dysrhythmias and lead to rearrest. Other hemodynamic supporting measures, such as intraaortic balloon pumping or percutaneous cardiopulmonary bypass, should be considered to increase oxygen delivery and utilization without placing a further burden on the ischemic heart. Heparin and aspirin may be given if there is no evidence of hemorrhage or profound prolonged hypertension. Nitrates and β-blockers as adjunctive therapy are best used when guided by invasive hemodynamic monitoring.

Defects in oxygen utilization, which are observed to various degrees after ROSC, will alter the relationship between VO_2 and DO_2.[187,188] Many patients have venous hyperoxia at lower ranges of DO_2, indicating impaired extraction.[187] Thus, mixed venous oxygen saturation (S_vO_2) will be higher and VO_2 will be lower than values predicted at any given DO_2 under normal conditions. This state indicates ongoing ischemia, shown by continued production of lactic acid, and decreased survival. Notably, these abnormalities cannot be predicted by simple measurements of blood pressure, heart rate, central venous pressure, or initial lactate levels.[187–189,192]

Even though oxygen debt after ROSC cannot be calculated accurately, the debt can be repaid with variable success if the abnormalities described above are taken into

consideration. Because of possible decreases in metabolic demand after resuscitation, the debt may be repaid at VO_2 values that are lower than those at baseline. VO_2 values below 90 ml/min/m² are associated with 100% mortality at 24 hours after arrest.[187,188] Inadequate VO_2 during the postresuscitation period may be due largely to insufficient DO_2 and to microcirculatory defects. Critically ill patients with DO_2 below 330 ml/min/m² show progressive lactic acidosis.[189,193] In a specific study of initial survivors of cardiac arrest, those who did not survive to hospital discharge had a maximal DO_2 of 165 ml/min/m², whereas survivors had a DO_2 of 495 ml/min/m².[187,188]

Derangements in oxygen transport are best detected and treated by appropriate hemodynamic monitoring. Pulmonary artery catheter monitoring, particularly with oximetric capabilities, provides the most useful information, including calculations of DO_2, VO_2, and oxygen extraction ratios. If this technique is not available, central venous pressure (CVP) monitoring at the level of the right atrium with continuous or intermittent monitoring of central venous oxygen saturation ($S_{cv}o_2$) is appropriate, even though cardiac output cannot be measured directly. Changes in output may be estimated from changes in S_Vo_2, blood pressure, heart rate, CVP, and lactic acid. In the future, non-invasive bioimpedance equipment[194] and gastric tonometry to monitor DO_2 to the visceral organs[195] may aid recognition of decompensation or inadequate resuscitation.

$S_{cv}O_2$ and S_VO_2 have been helpful in monitoring patients, because patients may show normal vital signs even with diminished tissue oxygenation.[196–199] Many of these patients will show abnormally low S_VO_2, which is correlated with increasing lactic acidosis and continuing shock.[192] S_VO_2 decreases when DO_2 has been compromised by declines in hemoglobin, cardiac output, or oxygen saturation or if VO_2 has exceeded supply. As already stated, however, S_VO_2 and $S_{cv}O_2$ alone should not be the sole therapeutic guide, because patients with normal or elevated values may have optimal or suboptimal DO_2 with a low VO_2 because of gross impairments of oxygen extraction. Sequential monitoring of lactate is helpful, with a goal of clearance of 2.5%/hour, which has been associated with improved survival.[193,200]

In postresuscitation cardiogenic shock, it may be difficult to increase DO_2 levels to above normal values (greater than 600 ml O_2/min per m²) as suggested in other shock states.[201,202] Nevertheless, in studies in acute myocardial infarction with cardiogenic shock, carefully monitored aggressive dobutamine and fluid administration can increase DO_2 to about 400 ml/min per m², which increases VO_2 above 100 ml/min/m² and improves survival.[189] When delivery-independent VO_2 is reached in this manner, further increases in DO_2 will not result in further significant changes in VO_2. Large increases in S_VO_2 will be seen, however, indicating improved oxygen availability.

Increasing catecholamines in patients with limited cardiac reserve may be problematic because they may adversely affect myocardial oxygen demand and exacerbate defects in oxygen utilization. When catecholamines are the only option, volume status should be optimized with a combination of crystalloids and colloids, guided by pulmonary artery or central venous pressures. With volume status optimized, dobutamine and/or noradrenaline may be more effective than dopamine in enhancing oxygen delivery and utilization.[189,203] Supplemental cortisol may also be beneficial and decrease the need for vasopressors, given the significant impairment of adrenal function found in the postresuscitation period.[204,205]

Vasodilators may be required in the postresuscitation state to control hypertension or improve flow by reducing afterload. Since hypertension may occur when volume is depleted, preload should be optimized before vasodilator therapy is instituted.[206,207] Figure 51.1 provides a postresuscitation hemodynamic algorithm based on goal-directed therapy, taking into account that pulmonary artery monitoring may not be available. Until routine monitoring of cerebral arteriovenous oxygen and lactate gradients can be made via such methods as jugular venous bulb catheterization, this goal-directed therapy may be the best readily available alternative to promote adequate cerebral oxygen delivery.[208] Therefore, the algorithm may be viewed as a neuronal salvaging strategy and should help provide adequate oxygen delivery to both cerebral and extracerebral organs and repay oxygen debt, thus potentially preventing development of systemic inflammatory response syndrome and multiorgan dysfunction and failure. The effect of any additional salvaging agents or strategies on these hemodynamic goals should be taken into account. Notably, no therapy will be successful if it is administered outside the effective window.

Summary

For more than 40 years the multifactorial cerebral postresuscitation syndrome has been intensely investigated experimentally and clinically; nevertheless, the mechanisms and interactions underlying this syndrome remain poorly understood. Treatment trials have focused on only one or a few components of the complex of reactions. Hemodynamic resuscitation guided by oxygen transport measures has been largely neglected, although attention to

Postresuscitation Goals

MAP	70-90 mmHg	SaO$_2$	94–99%
CVP/PCWP	10–15/15–18 mmHg	S$_{cv}$O$_2$/S$_v$O$_2$	65–75%
Hemoglobin	≥10 g/dl	DO$_2$	400–500 ml/min/m^2
Lactate	< 2.0 mM	VO$_2$	> 90 ml/min/m^2
Temperature	32–34.0 °C for 12–24 hrs then consider 36–37.0 °C	Avoid VO$_2$ dependent on DO$_2$	

ECG: If evolving MI then prepare for PTCA or immediate thrombolysis while meeting postresuscitation goals

Not meeting goals

MAP < 70 mmHg   **MAP 70–90 mmHg**   **MAP > 90 mmHg**

CVP or PCWP < 15 mmHg

CVP or PCWP > 15 mmHg

1. **Assure CVP or PCWP ≥15 mmHg**
2. **Decrease afterload** Nitroprusside or NTG

Increase pre-load
(a) IV crystalloid or colloid
(b) Transfuse if Hb <10 g/dl

Increase contractility and/or afterload
(a) Norepinephrine
(b) Dobutamine
(c) Consider IABP

S$_{cv}$O$_2$ or S$_v$O$_2$ < 65%
or
Lactate clearance < 5%/h

S$_{cv}$O$_2$ or S$_v$O$_2$ > 65%

VO$_2$ < 90 ml/min per m^2
or
Lactate clearance < 5%/h

Optimize DO$_2$
(a) Optimize CO
    Optimize pre-load
    Optimize contractility
    Consider IABP or CPB
(b) Optimize arterial O$_2$ content

S$_{cv}$O$_2$ or S$_v$O$_2$ < 65% or lactate clearance < 5%/h
and
VO$_2$ > 120 ml/min per m^2

Decrease VO$_2$
(a) Decrease temperature
(b) Sedation and paralysis

Fig. 51.1. Postresuscitation goal-directed treatment algorithm. These suggested targets and means of achieving them should begin to be instituted as soon as possible after ROSC to prevent further oxygen debt and the development of multiorgan system dysfunction and failure. This should be viewed as a neuronal salvaging strategy in itself. All other neuronal salvaging agents or strategies should take into account how they will affect oxygen transport and utilization characteristics of the body as a whole. PCWP, pulmonary capillary wedge pressure; PTCA, percutaneous transluminal coronary angioplasty; NTG, nitroglycerin; IABP, intraaortic balloon pumping; CPB, cardiopulmonary bypass.[25,209] (From ref. 25 and 209.)

these variables alone might reduce the number of deaths in the immediate postresuscitation period and the frequency of multiorgan dysfunction later in the course, and also improve neurologic outcome in some individuals. For fully effective neuronal salvaging, early attention to the consequence of treatment on oxygen transport to all other organ systems is critical. In addition, mild induced hypothermia should become the standard of care for the neurological treatment of patients who remain comatose after resuscitation from cardiac arrest as long as cardiovascular function is stabilized. Since it is unlikely that a single pharmacologic "magic bullet" will ever be found to relieve this complex syndrome, current research focuses on combination treatments. With the combination of treatments reviewed in this chapter, improvement in neurologic outcome may be possible (Table 51.1).

Special resuscitation circumstances

Prevention of sudden death in patients at risk: channelopathies and arrhythmic syndromes in the structurally normal heart

Alan Cheng, Gordon F. Tomaselli, and Ronald D. Berger

Johns Hopkins University, Baltimore, MD, USA

Introduction

Despite an overall reduction in death caused by cardiovascular diseases, the percentage of death due to arrhythmia-related sudden cardiac death (SCD) has remained high (Fig. 52.1) and is largely accounted for by an increase of death in women over 65 years old (described in detail in Chapter 23).[1] Due in part to its unpredictability and the logistical limitations of immediate access to medical care, the likelihood of surviving an SCD event is estimated between 1% and 5% both in the United States and abroad. Commonly, these events occur in individuals with known cardiac disease (Table 52.1) and can be the initial manifestation of an underlying structural abnormality in 33%–50% of all SCD cases. Although the two most important risk factors for SCD are left ventricular systolic dysfunction[2] and the presence of decompensated heart failure,[3] SCD has also occurred in otherwise healthy individuals with structurally normal hearts and accounts for the bimodal distribution of its incidence with age, particularly in those less than 45 years old.[4] This chapter highlights the syndromes with increased risk of sudden death due to ventricular tachyarrhythmias in the otherwise structurally normal heart. Classic conditions such as right ventricular outflow tract tachycardia and idiopathic ventricular tachycardia are beyond the scope of this chapter because of their low propensity toward sudden death.

Electrophysiologic processes underlying sudden cardiac death

Electrical impulses conducted through myocardial tissue can be fundamentally described by the cardiac action
Fig. 52.1 Magnitude of SCA in the USA.[1] SCA claims more lives each year than these other diseases combined.
Source: [1] U.S. Census Bureau, *Statistical Abstract of the United States* 2001. [2] American Cancer Society, Inc., Surveillance Research, Cancer Facts and Figures 2001. [3] 2002 *Heart and Stroke Statistical Update*, American Heart Association. [4] *Circulation*, 2001:104:2158–2163.

potential, which is composed of four different phases of activity (Fig. 52.2). Cardiac action potentials are typically longer than those of other excitable tissues such as neural or striated skeletal muscle cells and range between 200 and 400 msec (in contrast to the latter type of tissue in which the range is between 1 and 5 ms). The action potential profile is governed by the orchestrated activity of multiple ionic currents, each with distinctive time- and voltage-dependent amplitudes as a result of several ion-specific transmembrane channels and transporters. Some are involved with passive flow of ions along electrical and concentration gradients, whereas others are energy-dependent processes that drive ion movements against electrochemical gradients. Depending on the type (e.g., sodium, potassium, calcium)

Table 52.1. Abnormalities associated with sudden cardiac death

Coronary artery abnormalities
    Atherosclerotic
    Non-atherosclerotic (arteritis, embolism, dissection, congenital malformations, anomalous origin of left coronary artery from
    pulmonary artery or right or non-coronary aortic sinus of Valsalva [artery passing between the aortic and pulmonary artery roots])
Myocardial abnormalities
    Hypertrophic cardiomyopathy
    Idiopathic dilated cardiomyopathy
    Arrhythmogenic right ventricular dysplasia (congenital right ventricular cardiomyopathy)
    Myocarditis
    Sarcoidosis or other infiltrative diseases
    Left ventricular hypertrophy
    Valvular and congenital heart disease
Other conditions
    Aortic dissection
    Acute cardiac tamponade
    Rapid exsanguination
    Pheochromocytoma
    Subarachnoid hemorrhage
    Café coronary (acute glottis obstruction by food)
    Holiday heart syndrome
    Acute alcoholic states
    Massive pulmonary embolism
    Severe asthmatic attacks
    Peripartum air or amnionic fluid embolism
Proarrhythmic effects[a]
    Antiarrhythmic drugs
    Psychotropic agents, phenothiazines, antihistamines, antibiotics, gastrointestinal drugs
    Anorexia nervosa
    Toxic substances
    Electrolyte abnormalities

[a] Often (but not always) associated with QT prolongation (acquired long QT). Classic proarrhythmia usually occurs within days after initiation of treatment but may extend over one year of exposure.[4]

and number of specific ion channels, regional disparities in the action potential profile can be seen within the heart. The activity of these ion channels (and therefore the action potential) can be affected by a number of factors including electrolyte abnormalities, medications, profound bradycardia, and even mutations or variants in the channel gene. In the proper milieu, arrhythmic triggers such as ventricular extrasystoles and afterdepolarizations can develop, resulting in the initiation of sustained, life-threatening arrhythmias.

Long QT syndrome

The long QT syndrome (LQTS) is an inherited entity, originally described in 1957,[5] that encompasses individuals with a high propensity for sudden cardiac death in the setting of an abnormally prolonged QT interval. All individuals are described to have structurally normal hearts, although early echocardiographic observations have been made suggesting the presence of small ventricular wall motion abnormalities.[6] Initially, two clinical variants were recognized, one of which is associated with congenital deafness and autosomal recessive inheritance (Jervell and Lange–Nielsen syndrome) and the other is dominantly inherited without hearing deficits (Romano–Ward syndrome).[7,8] LQTS is genetically heterogeneous with mutations described in six different genes. Andersen and Timothy syndromes are multisystem inherited diseases associated with deficient ventricular repolarization and QT interval prolongation produced by mutations in *KCNJ2* and *CANC2*, respectively. *KCNJ2* and *CANC2* encode the inward
Fig. 52.2 Cardiac action potential: various phases of the cardiac action potential and their respective ionic currents involved in depolarization and repolarization.[96]
Fig. 52.3 T wave morphologic abnormalities seen in long QT syndrome.[11]

Table 52.2. Different LQT syndromes and their respective genetic abnormalities[97]

Disease	Gene (alternative names)	Protein
LQT-1	*KVLQTI (KCNQ1)*	I_{Ks} K$^+$ channel α subunit
LQT-2	*HERG (KCNH2)*	I_{Kr} K$^+$ channel α subunit
LQT-3	SCN5A	I_{Na} K$^+$ channel α subunit
LQT-4	ANKB	ANKRIN-β
LQT-5	*minK (KCNE1)*	I_{Ks} K$^+$ channel β subunit
LQT-6	*MiRP1 (KCNE2)*	I_{Kr} K$^+$ channel β subunit
LQT-7	KCNJ2	I_{Kr} K$^+$ channel α subunit

rectifier potassium channel (I_{K1}) and dihydropyridine-sensitive calcium channels ($Ca_V1.2$), respectively (Table 52.2). To date, approximately 300 mutations in 6 different ion channels have been associated with this syndrome.[9,10]

The QT interval is a summative representation of myocardial ventricular repolarization, a process that is governed by the interplay of a number of different ion channels. Hence, phenotypic characteristics of the T wave morphology exist based on the specific channel mutated. Although LQT1 patients tend to have considerable variation in their T wave morphologies, LQT2 T waves present with the classic bifid pattern, while LQT3 T waves tend to have late peaks (Fig. 52.3).[11,12] Some variation exists in these observations due in part to variable degrees of penetrance, variations in the genetic background even among

members of the same affected families, environmental factors, or even the severity of the specific mutation.

Since the absolute QT interval measured on the ECG can vary by changes in heart rate, many have employed the Bazett's correction formula to standardize the QT interval (QTc). Classically, QTc intervals in excess of 440 ms and 460 ms are considered prolonged in males and females, respectively. Although extremely prolonged QTc intervals (>600 ms) predict a higher risk for sudden death, it is unclear whether the *degree* of QTc interval prolongation predicts an individual's risk for episodes of ventricular tachyarrhythmias. In normal individuals, QTc intervals vary to some degree with age and gender. Women tend to have slightly longer QTc intervals after puberty when compared to age-matched men,[13] an observation suggesting a hormonal effect on ventricular repolarization. This may explain in part the propensity of this syndrome to affect more women than men, unlike most other diseases

of the cardiovascular system. One fascinating feature of this syndrome is the marked variability in phenotypic penetrance.[14] The variability has been described in members within the same family and even among those carrying the same genetic mutation.[15] This is thought to be due in part to the interplay between genetics and environmental factors, as well as the presence of multiple polymorphisms occurring in related genes.[16]

Diagnostics

Most individuals with LQTS have abnormally prolonged QTc intervals at baseline, but approximately 6%–10% of these patients do not.[17,18] Because of this finding and the variability in phenotypic penetrance, the diagnosis of LQTS may need to be made based on the presence of major and minor diagnostic criteria and a point-scoring system (Fig. 52.4)[19]. There have also been reports of individuals who have normal QTc intervals at baseline, but who have an exaggerated prolongation of the QTc interval in the presence of certain pharmacologic agents or environmental stressors (Table 52.3). The underlying mechanisms of this form of long QT syndrome, also known as "acquired long QT syndrome," may be due in part to several genetic polymorphisms resulting in a reduction of what has been described as "repolarization reserve."[20] On the basis of this concept, individuals with acquired long QT syndrome have no evidence of QT abnormalities at baseline, but in the presence of a stressor (e.g., drugs, heart block, hypokalemia, ischemia), they lack the physiologic mechanisms to accom-

modate for these insults. Acquired long QT syndrome is not a milder form of congenital long QT syndrome, as evidenced by the observation that the former group of individuals also have an increased risk for torsades de pointes.[21] Identifying individuals at risk for acquired long QT syndrome can often be difficult and many have suggested a number of clinical characteristics that should alert the clinician to the possibility of this risk.[22]

Classically, patients with LQTS are young and present with tachyarrhythmia-associated syncope in the setting of emotional stress, physical exertion, sudden awakening, or menses.[23] Earlier reports have demonstrated ventricular arrhythmias occurring during sleep primarily in individuals with LQT3 with documented mutations in SCN5A.[24] The risk of ventricular arrhythmias also appears to depend on the ion channel mutated. LQT1 and LQT2 patients have the highest risk for ventricular arrhythmias compared to those with LQT3. Although the frequency of events is lower for LQT3 patients, the events occurring in this group are more often fatal. In the end, the cumulative mortality of these three variants is approximately the same.[25]

The surface ECG typically exhibits abnormalities of T wave morphology (as described above) and a prolonged QTc. It is not uncommon for individuals to describe a history of repeated episodes of syncope. The syncopal episodes are invariably due to torsades de pointes that typically terminate spontaneously but may degenerate into ventricular fibrillation. Imaging modalities to assess cardiac function do not help in the diagnosis, as most individuals display grossly normal ventricular systolic function. Diagnosis is based largely on a detailed personal and family history and the ECG.

Risk stratification for sudden cardiac death

The QTc interval on a surface ECG in excess of 500 msec is generally regarded as high risk for sudden cardiac death; however, daily variations in the QTc interval occur even within the same individual. Hence, relying solely on the surface ECG is limited in its scope. Signal-averaged ECGs have been utilized in a number of different conditions for risk assessment of sudden death. Their role in LQTS is limited and not described well enough to warrant routine use.[26] Graded exercise stress testing and other non-invasive tests have been assessed for their ability to aid in risk stratification.[27,28] These early observations suggest that individuals who display prolongation of the QTc at peak exercise are at particularly high risk of arrhythmic events when compared to their age-matched counterparts.[29] The role of invasive electrophysiologic testing has been limited by its lack of robust sensitivity and specificity[30] and is generally

not recommended in these individuals, despite isolated reports of a higher incidence of resting bradycardia[31] or inducibility of ventricular tachyarrhythmias with ventricular burst pacing[32] in this patient population. Universal recommendations for genetic testing in familial cases of long QT syndrome remain equivocal, although a recent article demonstrated that this may be both feasible and cost-effective in certain individuals.[33,34]

Because of the limitations in objective measures for sudden death, a patient's symptoms play a significant role in risk stratification. Individuals with a prior history of syncope (often mistaken for seizure events) or sudden death are naturally at higher risk of a future fatal event, whereas those who are asymptomatic tend to be at lesser risk. Nevertheless, exceptions exist in this observation, especially in asymptomatic individuals with a strong family history of sudden death. Priori *et al.* suggested a method of risk stratification based on gender and genotype analysis and suggest that individuals with LQT1 have a lower risk of arrhythmic events when compared to those with LQT2 and LQT3.[35] Current efforts are underway to make this method widely accessible to the general public.[36]

Preventative strategies

In all patients with LQTS, a careful review of both prescription and non-prescription medications is paramount to identifying agents that may increase the QT interval. Identifying other reversible causes such as ischemia or electrolyte abnormalities is also critical. LQTS patients deemed at high risk for sudden death (e.g., markedly prolonged QTc intervals, history of sudden cardiac death, or recurrent episodes of syncope) are typically managed with β-adrenergic blockers and are recommended to undergo implantation of an ICD. Pharmacotherapy alone does not provide a degree of protection similar to that of an ICD, but may be appropriate in individuals with low–moderate risk for SCD. Since prolongation of the QTc interval in these individuals can result from a number of different ion channelopathies, no single drug should be expected to reduce risk in everyone with LQTS. Beta-blockers are thought to be more effective in LQT1 patients, whereas sodium channel blockers may be more effective in individuals with LQT2 and LQT3.[37] Nevertheless, beta-blockers are recommended in all individuals with LQTS when the genotype is unknown, because a majority of arrhythmic events occur in the setting of heightened adrenergic tone.[38]

Recommendations on physical exertion in patients with LQTS have been addressed by an international panel of experts appointed by the American Heart Association.[39] In this treatise, the type of exercise is graded on the basis of

intensity and specific recommendations are made. The reader is referred to this article for specific recommendations on patient management.

Acute management strategies

Tachyarrhythmic syndromes in patients with LQTS are often due to torsades de pointes, polymorphic ventricular tachycardia occurring in the setting of a prolonged QT interval. The acute management of these episodes is heavily based on the degree of hemodynamic instability associated with these arrhythmias. Individuals with asymptomatic episodes of unsustained ventricular tachycardia seen on a cardiac monitor seldom require emergent intervention beyond a careful review of reversible causes of QT prolongation and observation. Individuals presenting acutely with syncope or sudden cardiac death should be promptly managed by the recently revised cardiopulmonary resuscitation treatment recommendations.[40] Once sinus rhythm has been restored, acute secondary preventative measures should be considered. These include infusion of 2–4 g of magnesium intravenously, regardless of the current serum magnesium levels.[41] Magnesium is primarily excreted by the kidneys so individuals with renal insufficiency should be treated cautiously, but this is rarely an absolute contraindication to use. If magnesium proves ineffective in preventing subsequent episodes of sustained ventricular tachyarrhythmias, lidocaine has been demonstrated to be effective in some animal models by blocking sodium channels responsible for rapid depolarizing currents initiated by early afterdepolarizations.[42] Its efficacy in clinical practice has been mixed. Individuals who continue to have episodes of tachyarrhythmias and who fail these initial measures can often be treated with temporary pacing.

In cases of acquired LQTS, temporary rapid atrial pacing should be initiated. This can effectively suppress subsequent episodes of ventricular tachyarrhythmia by reducing the time of myocardial repolarization based on the properties of electrical restitution. If transvenous pacing is unavailable, isoproterenol can be used to increase the heart rate since this agent has a greater chronotropic effect per microgram than other adrenergic agents. Use of isoproterenol is contraindicated in individuals with uncontrolled hypertension, acute coronary syndromes, or a documented history of congenital long QT syndrome.

Short QT syndrome

Recognized as a distinct clinical entity since its discovery in 1999, the short QT syndrome (SQTS) encompasses individuals with QTc intervals <300 ms and clinically presenting with syncope, palpitations, and an increased propensity toward atrial fibrillation, sudden death, or both.[43] Although rare, the true prevalence of this condition is unknown since the brevity of the QT interval is often only recognized with heart rates below 80 bpm. Thus far, mutations in two ion channel genes (HERG and KvLQTI) have been linked to this clinical syndrome, both of which result in a gain of function and increased repolarizing current, presumably I_{Kr} and I_{Ks}, respectively, in the ventricle. On a cellular level, these mutations are thought to contribute to an increase in the heterogeneous dispersion of repolarization between the ventricular M cells and the epicardial cells. Clinically, most individuals have easily inducible ventricular tachycardia during electrophysiologic testing. To date, only 22 confirmed cases of short QT syndrome have been described.[44] Hence, recommendations on management are less well defined. Acute management of these individuals presenting with cardiac arrest should be guided by standard advanced cardiopulmonary life support (ACLS) recommendations; longer term management for those with the most severe presentations should include ICD implantation. The role of drugs that prolong the AP and QT interval in SQTS is not yet defined.

Brugada syndrome

The Brugada syndrome, also referred to as Sudden Unexplained Nocturnal Death syndrome,[45] was described in 1992 after a series of otherwise healthy individuals with structurally normal hearts presented with a high propensity for sudden cardiac death.[46] Classically, this entity is marked by characteristic ECG abnormalities, including the presence of a right bundle branch block pattern and ST segment elevations along V1-V3 (Fig. 52.5). The ECG abnormalities are not pathognomonic for this condition and may be caused by other factors, such as well-conditioned athletic hearts or a variety of drugs (Table 52.4). Although the syndrome has been diagnosed in individuals between 2 and 84 years of age, the mean age of sudden death is 41 ± 15 years and it appears to have an 8:1 predilection for males.[47] Many of the ECG abnormalities seen with this entity are dynamic and occasionally can be accentuated by a febrile state, ischemia, hypotension, or the administration of beta-blockers or sodium channel blockers (e.g., procainamide, flecainide). Often, exercise or adrenergic agents such as isoproterenol can make the ST-segment abnormalities disappear.[48] Hence, the true prevalence of this condition is unknown, although it is estimated to be 5 in 10 000 individuals worldwide. It is
Fig. 52.5 Brugada ECG abnormalities (Type I–III).[100]

generally recognized that individuals from Europe and the United States[49] are less commonly affected while those from Japan[50] and Southeast Asia have higher rates of prevalence for this syndrome. Current estimates (based in large part on epidemiological experiences in Asian populations) report that the Brugada syndrome accounts for 4% of all sudden cardiac deaths and 20% of all sudden cardiac deaths occurring in individuals with structurally normal hearts.[51] In addition to the increased risk for sudden death, 20% of individuals with the Brugada syndrome have recently been described to develop atrial fibrillation as well.[52]

Early work in understanding the molecular pathogenesis of this condition identified loss-of-function mutations in the SCN5A gene,[53] the alpha subunit of the voltage-gated sodium channel originally cloned in 1992.[54] This has also been implicated in a number of other clinical syndromes including progressive familial heart block syndrome[55] and chromosome 3-linked long QT syndrome.[56] More than 80 different mutations[57] in SCN5A have been associated with this condition. Interestingly, only 18%–42% of subjects carrying a clinical diagnosis of Brugada syndrome harbor these mutations;[58] the remaining subjects are thought to

carry mutations in the non-coding portions (e.g., introns) of the gene. How loss-of-function mutations in SCN5A result in the classic ECG abnormalities has been a subject of experimental investigation. It has long been recognized that ventricular myocardium is composed of three functionally distinct layers, the epicardium, the M cell layer, and the endocardium. Normally during Phase I of myocardial repolarization, a gradient exists between the epicardial and endocardial cells that results from a difference in I_{to} current. In the presence of a loss of function mutation such as the Brugada syndrome, this difference is further accentuated whereby an abnormally steep voltage gradient is generated that causes exaggerated J point and ST-segment elevations. The same steep voltage gradient predisposes the myocardium to reentry during the plateau phase of the action potential, thereby initiating rapid ventricular tachycardia.

Diagnostics

The diagnosis of Brugada syndrome is suggested by the presence of distinct repolarization abnormalities noted on the surface ECG marked by the presence of an incomplete right bundle branch block pattern of conduction with coved ST-segment elevations (>2 mm) followed by inverted T waves primarily in leads V1-V3 (Type I pattern). The diagnosis of Brugada is made with Type I ECG abnormalities in addition to one or more clinical features suggestive of an increased propensity toward sudden cardiac death (Table 52.5). Often these abnormalities may be intermittent and are concealed except in the presence of a sodium channel-blocking agent. The absence of these abnormalities by no means excludes this diagnosis. Variations in ECG abnormalities have also been recognized. Type II ECG abnormalities are characterized by the presence of an incomplete right bundle branch block pattern of conduction with "saddleback-like" ST segment elevations (>2 mm) in leads V1-V3. Type III abnormalities are characterized as any Type I or Type II abnormality with minimal ST segment elevation (<2 mm). Type II and Type III abnormalities (in the presence of a clinical feature from Table 52.5) are not diagnostic of Brugada syndrome unless there is conversion of either pattern type to a Type I abnormality in the presence of a sodium channel-blocking agent.

Risk stratification for sudden cardiac death

Not all individuals with Brugada syndrome share the same risk for sudden cardiac death. Hence, developing a strategy to identify those at highest risk permits an economically sound approach to provide aggressive treatment to

Table 52.4. Drug-induced Brugada-like ECG patterns

I. Antiarrhythmic drugs
1. Na$^+$ channel blockers
   Class IC drugs (flecainide, pilsicainide, propafenone)

Inducibility of VT with ventricular programmed stimulation
Syncope
Nocturnal agonal respirations

those who need it the most. Much of the early work in identifying sudden cardiac death markers relied on the surface ECG. On the basis of studies of Japanese patients with Brugada syndrome, individuals with a prior episode of ventricular fibrillation arrest had ECGs with widened S waves in V$_1$ and more pronounced ST segment elevation in V$_2$ when compared to those without a prior history of cardiac arrest.[59] Other studies have found predictive power in the presence of signal-averaged ECG late potentials or an increase in the body surface area of right precordial ST segments.[60] Despite these reports, no one marker has been found to be particularly more predictive for development of sudden cardiac death than others. Extensive work has also been done regarding the role of electrophysiologic testing in predicting future events.[61–63] Currently, evidence is inconclusive with respect to the role of programmed stimulation in determining whether inducibility of ventricular tachyarrhythmias provides useful prognostic information.

Recent data based on a large cohort of individuals with Brugada syndrome suggest that the risk for sudden death depends on the degree of symptomatology.[64] Eckardt *et al.* followed 212 patients with Type I ECG abnormalities for an average of 3.3 years. Individuals with the highest risk for sudden cardiac death were those who had a history of syncope or a prior history of resuscitation due to ventricular tachyarrhythmias. Asymptomatic individuals had the lowest risk for sudden death. Indeed, only 0.8% of the asymptomatic individuals developed an arrhythmic event (Fig. 52.6). It was also suggested that individuals with spontaneous Type I ECG pattern abnormalities were more likely to develop syncope or sustained ventricular tachyarrhythmias when compared to those whose ECG abnormalities were only noted in the presence of a sodium channel-blocking agent. Genetic testing in Brugada syndrome remains an area of intense research and is currently not recommended for screening of asymptomatic individuals.[65]

Preventative strategies

The classic ECG findings in patients with Brugada syndrome stem from an imbalance of currents, specifically I$_{to}$ and I$_{Ca}$, during Phase I and Phase II of the action potential (Fig. 52.2).[66,67] Hence, factors affecting these currents can alter the degree of ST-segment elevation seen. Vagal maneuvers (via suppression of I$_{Ca}$ and/or augmentation of potassium currents) and administration of Class IC sodium channel blockers (via its effects on I$_{to}$) enhance the ST-segment abnormalities seen on the ECG, while beta-adrenergic agonists, through their effects in augmenting I$_{Ca}$, normalize them. These observations suggest that pharmacologic agents that can augment I$_{Ca}$ or inhibit I$_{to}$ may be pivotal in mitigating the arrhythmogenicity of this condition. Examples include quinidine and 4-aminopyridine, both of which inhibit I$_{to}$. Commonly used agents, such as tricyclic antidepressants, phenothiazine, selective sero-

tonin reuptake inhibitors, calcium channel blockers, β-blockers, and histaminic H_1 receptor antagonists can all accentuate the ST-segment abnormalities seen in patients with Brugada syndrome.[68] It is not clear whether patients with Brugada syndrome are more susceptible to ventricular tachyarrhythmias with the use of these medications, but avoidance of these drugs seems generally prudent in patients with suspected Brugada syndrome, except as noted in the management of acute manifestations of the syndrome.

Current practice guidelines recommend implantation of an ICD in patients with Brugada syndrome with a history of sudden cardiac arrest or syncope. The indications for implanting an ICD in asymptomatic patients remain controversial. Although pharmacologic therapy is less effective than ICDs in preventing SCD, a number of case reports have described the efficacy of quinidine in preventing ventricular fibrillation (VF).[69] Other agents have also been described, including cilostazol, sotalol, and mexiletine.[70] These agents,[71] however, should only be considered as an adjunct to an ICD.

Acute management strategies

Individuals who present with ventricular fibrillatory storm should be treated with β-adrenergic agonists such as isoproterenol and titrated to achieve a 20% increase in the baseline heart rate. Atropine may also be considered, although the effects are ephemeral. Both of these agents act by augmenting I_{Ca}. The use of quinidine in ventricular fibrillatory storm has also been described.[70] Additional acute management strategies for this condition should follow current ACLS guidelines.

Catecholamine-induced polymorphic ventricular tachycardia

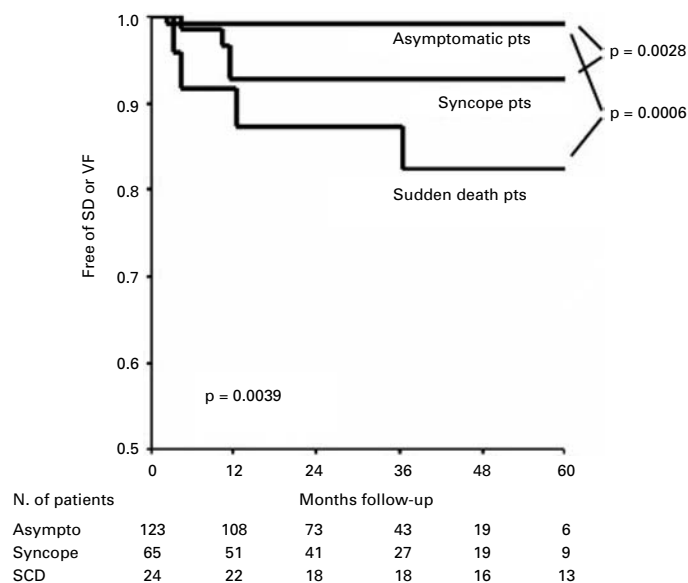
Catecholamine-induced polymorphic ventricular tachycardia (CPVT) is a rare autosomal disorder originally reported in 1975 to describe children without a history of structural heart disease who were at increased risk for syncope, seizures, or sudden cardiac death.[72] Often these individuals present in the prepubescent period with arrhythmic episodes of bidirectional or polymorphic ventricular tachycardia occurring almost exclusively during physical activity or extreme emotional states. Approximately 72% of these episodes are self-limiting; however, up to 7% may degenerate to ventricular fibrillation.[73] Baseline ECGs, echocardiograms, and histologic cardiac examination of affected individuals are all normal.[74] Estimated risks of sudden death


Fig. 52.6 Outcomes of patients with Brugada syndrome risk stratified based on history of syncope or resuscitated sudden death.[64]

range between 30% and 50% in untreated individuals in their second and third decades of life,[75] with approximately 30% of cases having a family history of childhood syncope or sudden death. In a series of 21 children with this condition, Leenhardt *et al.* described the natural history of this condition over a 7-year follow-up period.[76] Most children experienced their first episode of syncope by age 7. In severe cases, these arrhythmia-associated episodes would often be misdiagnosed as manifestations of epilepsy since they were usually associated with a period of hypertonia marked by convulsions and loss of bladder or bowel control. A useful distinction between epilepsy and CPVT is the observation that arrhythmic episodes of CPVT almost always occur in the setting of increased physical or emotional states.

Genetic analyses aimed at elucidating the mechanisms behind this disorder have identified two inherited forms, an autosomal dominant variant and a less common autosomal recessive type. Autosomal dominant CPVT is caused by mutations in the type 2 ryanodine receptor (RyR2), a major transmembrane protein responsible for intracellular calcium transport.[77] Autosomal recessive CPVT is due to mutations in calsequestrin.[78] As such, the initiation of many arrhythmic episodes is due to the development of delayed afterdepolarizations.

Diagnostics and risk stratification for sudden cardiac death

Information obtained from baseline electrocardiograms typically demonstrates sinus bradycardia without evidence of intraventricular conduction delays or prolongation of the QTc interval. Priori *et al.* evaluated 118 individuals with CPVT and assessed current diagnostic modalities in predicting their risk for sudden death.[79] Electrophysiologic testing has little role in risk stratification, with a majority of individuals displaying no inducible arrhythmias during programmed stimulation. Exercise stress testing and ambulatory cardiac monitoring during periods of exercise have often helped in the diagnosis of this condition. During exercise, individuals with this condition elicit a normal increase in the sinus rate. When the rate reaches approximately 120 beats per minute, frequent premature ventricular complexes are seen. With continued exercise, these degenerate into runs of polymorphic ventricular tachycardia.[80] Although these observations appear readily reproducible with physical activity, the role of exercise testing in risk stratification has not been validated. The strongest risk factor for sudden death in this condition appears to be gender, with an increased risk for arrhythmic syncope in males. The presence or absence of symptoms does not appear to predict future risk for sudden death.

Preventative strategies

If left untreated, an individual's risk for sudden death reaches 30%–50% by early adulthood. Hence, proper diagnosis and screening of family members with an affected proband is essential. The use of long-acting beta-blockers without sympathomimetic activity has previously been shown to be highly effective in preventing future episodes of syncope.[73] Recent data from Priori *et al.*,[79] however, demonstrate that beta-blockers are only effective in approximately 50% of individuals. In subjects who underwent ICD implantation, 50% of these patients experienced appropriate ICD firings for ventricular tachyarrhythmias, despite the concomitant use of beta-blockers. The use of calcium channel blockers has limited utility, but recent evidence supports their use in individuals intolerant of beta-blocker therapy.[81] Current recommendations include the use of beta-blockers at the time of diagnosis. The indications for ICD implantation are less clearly defined, but as with any heritable arrhythmia syndrome with a life-threatening presentation, it is prudent in any individual with a history of syncope or resuscitated sudden cardiac death.

Acute management strategies

Individuals presenting with ventricular tachycardia should be treated by currently accepted ACLS guidelines. Since many of these arrhythmias occur in the setting of increased adrenergic tone, the use of intravenous propranolol has been advocated.[82]

Wolff–Parkinson–White syndrome

Wolff, Parkinson, and White (WPW) are credited with describing this syndrome based on their initial experiences of 12 individuals with recurrent episodes of tachycardia and a baseline ECG displaying bundle branch block-like patterns of conduction and a short PR interval.[83] Individuals with these "pre-excited" ECG abnormalities (Fig. 52.7) are diagnosed with the WPW *syndrome* in the presence of paroxysms of tachycardia. Often the tachycardia is regular with a narrow QRS complex (orthodromic reciprocating tachycardia), but it may occasionally present with irregular wide QRS complexes as a result of pre-excited atrial arrhythmias (e.g., atrial fibrillation, atrial tachycardia) or antidromic reciprocating tachycardia. The mechanism for the pre-excitation is a result of a congenital accessory pathway supporting atrioventricular conduction that can manifest in a number of different variations (Fig. 52.8). Normally, the atrioventricular (AV) node serves as the sole means of electrical conduction from the atrium to the ventricles. In patients with WPW, an additional pathway exists composed of working myocardial tissue that allows for activation of the ventricles without the need for the AV node. Unlike the AV node, which has the ability to limit the rate at which impulses are conducted from the atrium to the ventricle, the accessory pathway can often sustain very rapid electrical conduction. Therefore, individuals are at increased risk for sudden death in the setting of pre-excited atrial arrhythmias, such as atrial fibrillation that can rapidly degenerate into ventricular fibrillation.[84] The degree of pre-excitation (i.e., prominence of the delta wave) on a baseline ECG is dependent on the conduction velocity of the AV node and the location of the accessory pathway. Hence, the presence and orientation of the delta wave can provide clues to the location of the pathway (Fig. 52.9).

Clinically, the incidence of WPW syndrome is 1.5 per 1000 persons, with a small predilection toward males.[85] Although most individuals with WPW syndrome have structurally normal hearts, an association with Ebstein's anomaly has been described.[86] Interestingly, patients with Ebstein's anomaly often have multiple accessory pathways. Despite the presence of an accessory pathway,

Fig. 52.7 WPW ECG with delta wave and the three classic features (1) short PR<120 ms, (2) QRS >120 ms, (3) ST–T wave changes directed in an opposite direction of the delta and QRS vectors.[87]

episodes of tachyarrhythmias do not occur in all affected individuals. Current estimates of the frequency of paroxysms of tachycardia range between 10% and 36% of patients with a WPW ECG depending on the individual's age.[87] A vast majority (80%) of these tachycardias are atrioventricular reciprocating tachycardias, while the remaining 20% include atrial arrhythmias such as atrial tachycardia, atrial flutter, or atrial fibrillation. The risk of sudden death is small and is estimated to be 0.02%–0.1%.[88]

The natural history of patients with WPW syndrome suggests that the frequency of tachyarrhythmias and the risk of sudden death decreases with age, based on age-related changes in the accessory pathway's conduction velocities.[89] Patients with WPW ECG features but who are otherwise asymptomatic do very well with a low arrhythmic event rate of approximately 1.7 per 100 patient-years.[90]

Diagnostics and risk stratification for sudden cardiac death

The diagnosis of WPW can often be made by the presence of a delta wave on a baseline ECG especially if the pathway is located on the right side of the heart. The absence of a delta wave, however, does not exclude the presence of an accessory pathway, but in these individuals there is no increased risk of sudden death. Individuals with WPW syndrome are often referred for additional testing, including exercise stress testing and/or electrophysiologic testing with ablation. Although the predictive value of ST-T wave changes during exercise testing is poor,[91] the conduction

properties of the accessory pathway can be elucidated in an effort to risk-stratify patients for the development of sudden death. In the presence of pre-excitation at baseline, sudden loss of the delta wave during peak exercise suggests that conduction via the accessory pathway has been blocked and that the patient's risk for sudden death is low.[92] Electrophysiologic testing remains an integral part of the assessment and management of patients with WPW syndrome and should be considered in the absence of known contraindications. Individuals with WPW ECG who are otherwise asymptomatic, however, may not benefit from electrophysiologic testing in light of their low risk for sudden death or tachyarrhythmias. Controversy remains on the optimal management of individuals with asymptomatic WPW ECG patterns.[93,94]

Acute management strategies

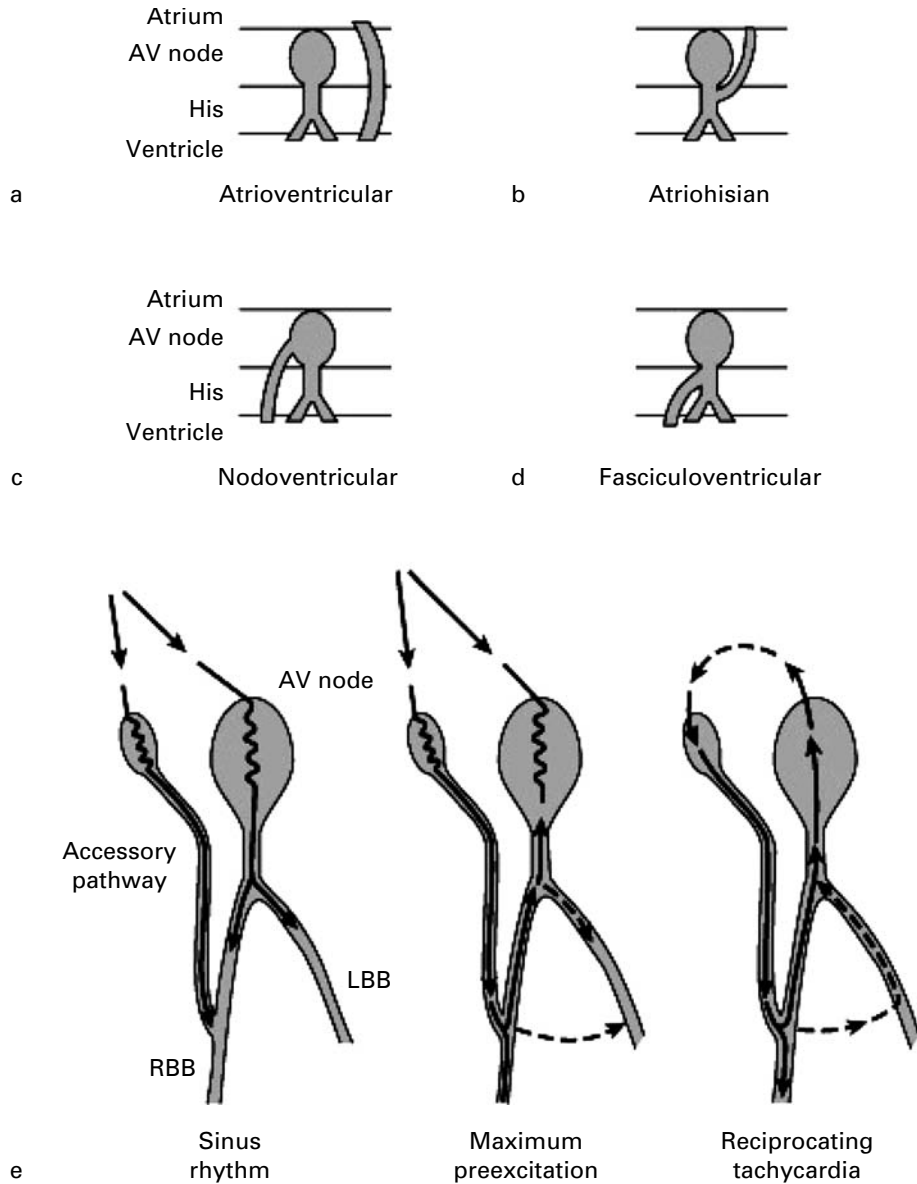
Individuals with WPW can present to the emergency department with a variety of tachyarrhythmias. Management of individuals presenting with narrow complex tachycardias should be focused on use of pharmacologic agents that impair AV node conduction, such as adenosine, beta-blockers, or calcium-channel blockers. Individuals presenting with irregular wide complex tachycardias, however, do not rely on the AV node for antegrade conduction. Hence, targeting the AV node will have little effect on the arrhythmia. Antiarrhythmic agents such as procainamide remain the first choice in the acute management of these arrhythmias. Other agents such as disopyramide, dofetilide, and amiodarone have also been described with


Fig. 52.8 Various types of accessory pathways.[87]
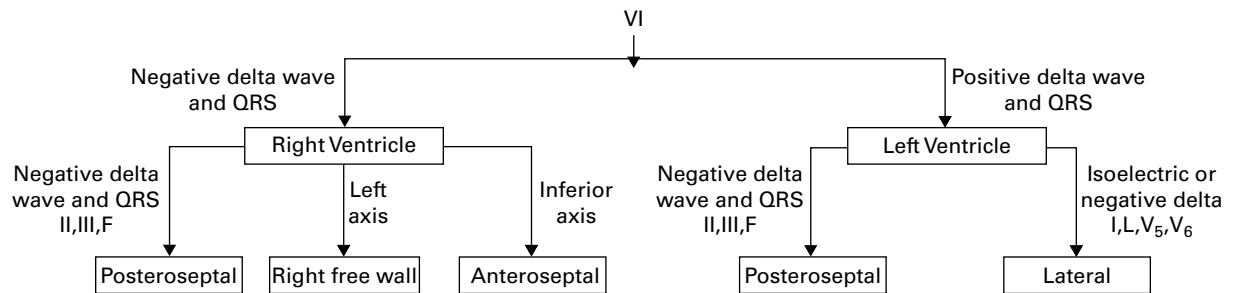

Fig. 52.9 Algorithm to determine location of accessory pathway based on the surface ECG.[87]

moderate degrees of efficacy.[95] Individuals with any degree of hemodynamic compromise should be considered for urgent electrical cardioversion to restore sinus rhythm as described in the ACLS guidelines.

Summary

Sudden cardiac death is typically associated with individuals having structural heart disease. Nevertheless, a number of individuals without structural heart disease but with an increased risk for sudden death have been identified in recent years. Through a series of experimental investigations in both animal models and humans, we have gained a greater understanding of the pathophysiologic mechanisms underlying each of these conditions and consequently realize that pharmacologic therapy is limited in its efficacy. Hence, the ICD remains the standard of care in the primary prevention of SCD for those at increased risk. What is less clear now is determining who is at increased risk. Current efforts aimed at better defining this cohort are now under way and will significantly improve our ability to deliver better care.

Pediatric cardiopulmonary resuscitation

Robert A. Berg and Vinay M. Nadkarni

Department of Pediatrics, The University of Arizona College of Medicine
Departments of Anesthesia and Pediatrics
University of Pennsylvania School of Medicine
Department of Anesthesia and Critical Care Medicine
The Children's Hospital of Philadelphia, PA, USA

Appropriate pediatric CPR differs from that in adults, because children are anatomically and physiologically different from adults. In addition, the pathogenesis of the cardiac arrests and the most common rhythm disturbances are different in children. In contrast to adults, children rarely suffer sudden ventricular fibrillation (VF) cardiac arrest from coronary artery disease. The causes of pediatric arrests are more diverse and are usually secondary to profound hypoxia or asphyxia due to respiratory failure or circulatory shock. Prolonged hypoxia and acidosis impair cardiac function and ultimately lead to cardiac arrest. By the time the arrest occurs, all organs of the body have generally suffered significant hypoxic-ischemic insults.

Importantly, children of various ages exhibit developmental changes that affect cardiac and respiratory physiology before, during, and after cardiac arrest. For example, newborns undergoing transitional physiological changes during emergence from an environment of amniotic fluid to a gaseous environment certainly differ from adolescents. Similarly, newborns and infants have much less cardiac and respiratory reserve, and higher pulmonary vascular resistance than do older children. Moreover, many children who experience in-hospital cardiac arrest have pre-existing developmental challenges and other organ dysfunction. Finally, pediatrics is developmental medicine, and pediatric neurological tools that are appropriate at one age may not be accurate or valid at another age.

Perhaps the most profound difference between child and adult cardiac arrest is the devastating effect of the death of a child on a family. Coping with a sudden unexpected death is always difficult. When the victim is a child, the loss tends to be even more oppressive. We do not expect children to die before their parents and thus are not prepared for it. Therefore, families and friends are typically overwhelmed. Even "hardened" healthcare providers often become very emotional, and occasionally dysfunctional, when faced with a dying child.

Epidemiology

Our knowledge of the epidemiology and appropriate treatment of pediatric cardiac arrest has been limited, in part, because investigators have categorized diverse diseases and pathophysiologies into general categories. Pediatric studies tend to include all pediatric cardiac arrests, such as those secondary to sudden respiratory failure (e.g., drowning, foreign body aspiration), progressive respiratory failure from infections and/or neuromuscular diseases, trauma, Sudden Infant Death Syndrome (SIDS), septic shock, hypovolemic shock, anaphylaxis, primary cardiomyopathy, primary arrhythmia (e.g., VF or VT), drug intoxications, and others. Some pediatric studies have not clearly differentiated respiratory arrests from cardiac arrests, or CPR episodes from pulseless cardiac arrests, and many have included both pre-hospital and in-hospital cardiac arrests in their data. Moreover, many of the cardiac arrest victims in these studies had been dead for a prolonged period of time (e.g., those with Sudden Infant Death Syndrome) and, therefore, data such as initial cardiac rhythm of asystole and lack of response to therapy are not helpful in terms of understanding the etiology, pathophysiology, or appropriate therapy. The quality of CPR is generally poor, and this is not generally taken into account in most of these studies. Finally, most pediatric arrest studies have inadequate and non-uniform data collection.

Table 53.1. Summary of representative studies of outcome following in-hospital pediatric cardiac arrest

Author, year	Setting[a]	# of patients	ROSC	Survival to discharge	Good neurological survival
Nadkarni 2005 NRCPR[b]	In-hospital CA	880	459 (52%)	236 (27%)	154 (18%)
Reis 2002	In-hospital CA	129	83 (64%)	21 (16%)	19 (15%)
Extracorporeal Life Support Organization, 2002	In-hospital CA resuscitation by ECMO	232	N/A All needed ECMO	88 (38%)	not reported
Suominen 2000	In-hospital CA	118	74 (63%)	1-year survival 21 (18%)	not reported
Parra 2000	Ped CICU CA	32	24 (63%)	14 (44%)	8 (25%)
Chamnanvanakij 2000	In-hospital intubated NICU pts with chest compressions for bradycardia	39	33 (85%)	CPR 20 (51%) CA 10%	CPR 5 (13%) (6 lost to follow-up)
Slonim 1997	In-hospital PICU CA	205	not reported	28 (14%)	not reported
Torres 1997	In-hospital CA	92	not reported	1-year survival 9 (10%)	7 (8%)
Zaritsky A 1987	In-hospital CA	CA 53	not reported	CA 5 (9%)	not reported
Young 1999	Meta-analysis In-hospital CA	544	not reported	129 (24%)	not reported
Lopez-Herce 2005	Mixed in-hospital and OOH CA	213	110 (52%)	45 (21%)	34 (16%)
Tunstall-Pedoe 1992	Mixed in-hospital and OOH CA	3765	1411 (38%)	706 (19%)	not reported

[a] CA = cardiac arrest.

[b] NRCPR = National Registry of CPR.

Characterization of the process of care and outcomes following pediatric cardiac arrest events has been limited by this lack of consistent data collection and analysis. In particular, pediatric reports often have not clearly differentiated between respiratory arrest, near-arrests (bradycardia with pulses) treated with CPR, and pulseless cardiac arrest. In the early 1990s, international experts developed guidelines for uniform data reporting of out-of-hospital cardiac arrests and in-hospital resuscitation, the so-called Utstein style. Nevertheless, epidemiological information about pediatric cardiac arrests is dominated by retrospective chart reviews with small numbers and inconsistent definitions of cardiac arrest and cardiopulmonary resuscitation, and a few small prospective single-center studies.

Pediatric in-hospital arrests

The true incidence of pediatric pulseless arrest is difficult to estimate because of inconsistent terminology in the literature and difficulty in assessing pulselessness in children. Cardiac arrests were reported in 3% of children admitted to one children's hospital, in 1.8% of all children admitted to pediatric intensive care units in the USA, in 6% of children admitted to one PICU in Finland, and in 4% of children admitted to a pediatric cardiac intensive care unit.

Several well-designed in-hospital pediatric CPR investigations with long-term follow-up have established that pediatric CPR and advanced life support can be remarkably effective (Table 53.1). Typically, one-half to two thirds of these patients were initially successfully resuscitated (i.e., attained sustained ROSC). Survival progressively decreased with time, in large part due to the underlying disease processes. Indeed, most of these arrests/events occurred in pediatric intensive care units because of progressive life-threatening illnesses that had not responded to treatment despite critical care monitoring and supportive care. The 1-year survival rates of 10%–44% are superior

to outcomes from out-of-hospital pediatric CPR, and substantially superior to the certain 0% survival rate if CPR and advanced life support were not provided.

Only a few studies have used the more rigorous Utstein-style reporting for exclusively in-hospital pediatric cardiac arrests and CPR. Two describe all CPR events at children's hospitals in Brazil and Finland. The most common causes of the events were progressive respiratory failure and progressive shock: approximately two thirds of the children attained sustained ROSC, and 1-year survival was 15% and 18%, respectively.

A recently published Utstein-style report of in-hospital pediatric cardiac arrests is derived from the American Heart Association's multi-center National Registry of Cardiopulmonary Resuscitation (NRCPR). The NRCPR is a prospective, multicenter observational registry of in-hospital cardiac arrests and resuscitations. The first description of children (<18 years old) from this registry included 880 patients whose arrests occurred between January 1, 2000 and March 30, 2004 in 10 pediatric facilities and 136 mixed pediatric–adult facilities. Because of the size and scope of the NRPCR, and the rigorous data collection, these data are further highlighted in Tables 53.2 and 53.3.

In the NRCPR, a cardiac arrest was defined as cessation of cardiac mechanical activity, determined by the absence of a palpable central pulse, unresponsiveness, and apnea. Events were excluded if the cardiac arrest began out-of-hospital, involved a newborn in a delivery room or neonatal intensive care unit, or was limited to a shock by an implanted cardioverter-defibrillator. Most of these arrests occurred in children with progressive respiratory insufficiency and/or progressive circulatory shock. These children were often succumbing to their critical illnesses despite aggressive critical care monitoring and therapy. Therefore, 95% of these arrests were witnessed and/or monitored, and only 14% occurred on a general pediatric ward. Before the arrest, 57% of these children were mechanically ventilated, 38% had continuous vasoactive infusions, and 29% had continuous direct arterial blood pressure monitoring.

Despite the dire clinical circumstances leading to their arrests, 52% attained sustained ROSC, 36% survived for 24 hours, and 27% survived to hospital discharge. Outcomes for these children were substantially superior to outcomes for adults in this registry (27% survival to discharge versus 18%, respectively; adjusted odds ratio, 2.3 [95%CI, 2.0–2.7]). Importantly, 65% of these children had relatively good neurological outcome, defined as: (1) Pediatric Cerebral Performance Category of 1, 2 or 3; or (2) no change from baseline Pediatric Cerebral Performance Category.

Interestingly, 200 children who received chest compressions for any reason during this time period were excluded from the NRPCR cardiac arrest analysis because they initially had bradycardia with pulses and did not lose their pulse during the event. Similar to the two previous Utstein-style pediatric in-hospital studies, only 82% of children who received chest compressions fit the definition of

pulseless cardiac arrest. Of note, and as expected, children who received chest compressions for bradycardia with pulses had a much higher survival to hospital discharge rate (60%) than did those with pulseless cardiac arrest (27%, $P < 0.001$).

Are outcomes from in-hospital cardiac arrest improving? The rate of survival to discharge following pulseless cardiac arrest in the NRCPR database, 27%, is substantially higher compared with the two previous studies that used Utstein-style reporting, 15% and 18%, even though the rate of sustained ROSC was not higher (52% versus 63% and 64%). The better postresuscitation outcomes are especially impressive because these two previous single-center studies reported on all children who received CPR, including many for bradycardia with palpable pulses. It is not clear whether the superior longer term survival after initially successful resuscitation in the present study is due to differences in patient population characteristics, resuscitation performance, reporting bias, or improvements in patient care during the postresuscitation phase (e.g., superior hemodynamic support). The authors believe that better postresuscitation care is probably a major contributor to the apparent improvements in outcome.

Pediatric out-of-hospital arrests

Outcomes following pediatric out-of-hospital arrests appear to be much worse than those from in-hospital arrests (Table 53.4). In particular, the neurological outcomes appear to be much worse among children surviving out-of-hospital arrests. Two diseases have especially poor outcomes: traumatic arrests and SIDS. Traumatic cardiac arrests are typically due to exsanguination resulting in profound circulatory shock; not surprisingly, chest compressions with an empty heart are not likely to provide adequate coronary and cerebral perfusion. SIDS patients have typically been dead for quite a long time before resuscitation is attempted. In most series of out-of-hospital pediatric cardiac arrests, 1/3–1/2 of the children have the diagnosis of SIDS. For other pediatric cardiac arrests in the pre-hospital setting, CPR and advanced life support from EMS providers may be too little, too late (see below). As might be expected, these poor outcomes after pediatric out-of-hospital cardiac arrests are similar to the poor outcomes after adult non-VF out-of-hospital cardiac arrests.

Is CPR in the pre-hospital setting effective for children?

As noted above, the outcomes from pediatric pre-hospital cardiac arrests are frequently dismal. In contrast, outcomes from in-hospital pediatric asphyxial cardiac arrests are much better. For example, in the seminal report from Kouwenhoven and colleagues of successful resuscitation with closed chest cardiac massage, the initial patients were asphyxiated children in the operating room who received immediate effective resuscitation and attained excellent outcomes. Furthermore, our clinical experience suggests

Table 53.4. Summary of representative studies of outcome following out-of-hospital pediatric cardiac arrest

Author, year	Setting	# of patients	ROSC	Survival to discharge	Good neurological survival

that excellent outcomes can occur after various types of bystander CPR, including mouth-to-mouth rescue breathing alone (MTM), chest compressions alone (CC), or standard chest compressions and mouth-to-mouth rescue breathing (CC + MTM). Nevertheless, some reports question the effectiveness and advisability of pre-hospital pediatric CPR.

In order to characterize these issues further, pre-hospital pediatric asphyxial arrests were simulated in animal models. In the first study, asphyxia was induced by clamping the tracheal tubes of piglets until cardiac arrest occurred, defined by loss of aortic pulsation. The mean time until loss of aortic pulsations was 8.9 ± 0.4 minutes. After loss of aortic pulsations, animals were randomized to simulated bystander CPR (MTM, CC, or MTM + CC) or no CPR until simulated EMS arrival 8 minutes later. A similar study was performed with intervention at a slightly earlier point in the asphyxial process, when the pulse was "no longer palpable," as defined by systolic pressure <50 mmHg. The mean tracheal tube clamp time to induce this severe hypotension was 6.8 ± 0.3 minutes, clearly a severe asphyxial insult. Not surprisingly, after a complete cardiac arrest, 24-hour survival was clearly superior in the CC + MTM group compared to the other groups (Fig. 53.1). When intervention was provided earlier in the process (i.e., after severe hypotension but before complete loss of aortic pulsation), even though cardiac arrest would have been the clinical diagnosis, 24-hour survival was best with MTM + CC, but was better with MTM or CC than no "bystander CPR" (Fig. 53.2) Interestingly, most of the animals with 24-hour survival had return of spontaneous

Fig. 53.1. Asphyxial Cardiac Arrest – Outcome (Loss of aortic pulsations)

circulation (ROSC) before the simulated EMS arrival. CPR was not futile in these models of pre-hospital pediatric cardiac arrest; excellent CPR was remarkably effective when provided early enough.

In a large prospective study in Houston over 3½ years, Sirbaugh and colleagues found that the outcomes from pediatric pre-hospital cardiac arrests were dismal. Only 6 of the 300 children (2%) survived to hospital discharge, and only 1 of the 300 survived without significant neurological deficits. As in most such studies, the diagnosis of cardiac arrest was determined by EMS providers when they arrived at the scene. Of note, children in cardiac arrest who attained ROSC after bystander CPR before EMS arrival

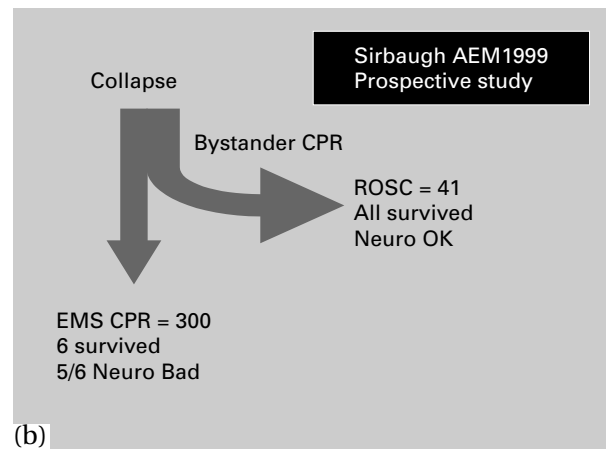
Fig. 53.2. "Pulseless" Arrest – Outcome (Syst BP<50 mmHg)

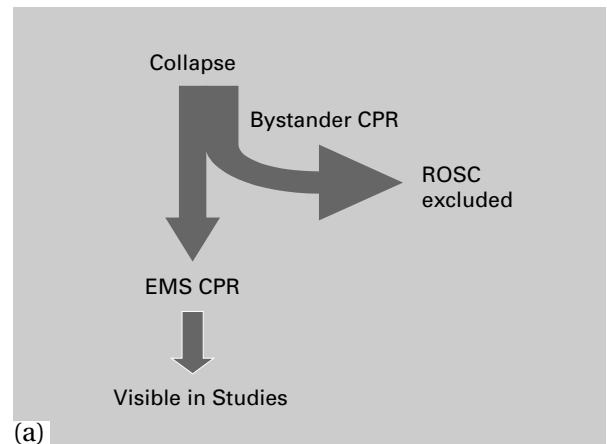
Fig. 53.3. (a), (b)

were excluded from analysis (Fig. 53.3(a)). Importantly, 41 children who had received bystander CPR were not in cardiac arrest at the time of EMS arrival; all 41 presumably had drowning-related cardiac arrests, and all survived with good neurological outcomes (Fig. 53.3(b)). Most were quite ill when they arrived at a hospital emergency department. In contrast, none of the other 24 children with drowning-related cardiac arrests who were still in cardiac arrest when the EMS personnel arrived survived with a good neurological outcome.

These data and similar data from Hickey *et al.* are consistent with the animal data, reported clinical experience, and in-hospital pediatric CPR data: that is, CPR can be quite effective for asphyxial cardiac arrests, but timing of interventions is critically important.

Recent prospective evaluation of a decade-long, population-based study of pediatric drowning-related events in Houston found 421 children with drowning events in a population of ~2 million total and ~400 000 children (annual incidence of 10.0 per 100 000 children), and 234 required resuscitation. Of these resuscitated children, 193 (82%) received bystander CPR and 72% of these children were long-term survivors. Moreover, 99% of the long-term survivors were neurologically intact. If the child was still apneic and pulseless when EMS personnel arrived, however, less than 5% were revived, and none of these subsequent survivors were ultimately neurologically intact. These data are further evidence that pre-hospital CPR can be quite effective for drowning-associated acute asphyxial cardiac arrests, if provided promptly.

In summary, animal and human data both indicate that CPR for children can be quite effective. In addition, these data support the notion that BLS early is more important than ALS late. Contrary to popular opinion, prompt action by a citizen bystander in the pre-hospital setting or a provider in the in-hospital setting is generally more effective than late heroic efforts in our intensive care units.




Pediatric ventricular fibrillation

Ventricular fibrillation (VF) is an uncommon, but not rare, electrocardiographic rhythm during out-of-hospital pediatric cardiac arrests. Two studies reported VF as the initial rhythm in 19%–24% of out-of-hospital pediatric cardiac arrests after SIDS deaths were excluded. In studies that include SIDS victims, however, the frequency drops to the range of 6%–10%. The exclusion of SIDS patients can be justified by the rationale that most SIDS patients have been "long dead" by the time emergency medical personnel arrive; therefore, the ECG rhythms when the children were potentially salvageable are not known. Of note, ECG rhythms are often not attained as promptly in children as in

adults and VF converts into asystole over time. Therefore, the frequency of VF may have been higher among the children in these studies, but some of the VF may have been undocumented.

The incidence of VF varies by setting and age. In special circumstances, such as tricyclic antidepressant overdose, cardiomyopathy, postcardiac surgery, and prolonged QT syndromes, VF is a more likely rhythm during cardiac arrest. Another special circumstance is commotio cordis, or mechanically initiated VF due to relatively low-energy chest wall impact during a narrow window of repolarization (10–30 ms before the T wave peak in swine models). These tragic events predominantly occur in children, 4 to 16 years old.

VF during an out-of-hospital cardiac arrest is uncommon in infants, but occurs more frequently in children and adolescents. The variance of VF by age was highlighted in a study documenting VF/VT in only 3% of children in cardiac arrest 0–8 years old versus 17% of children 8–19 years old.

Although VF is often associated with underlying heart disease and generally considered the "immediate cause" of cardiac arrest, VF can also occur secondary to asphyxia. In two studies of VF among asphyxiated piglets, the incidence of VF was 28% and 33% at some time during the cardiac arrest. This phenomenon, asphyxia-associated VF, is also well documented among pediatric near-drowning patients. Furthermore, as noted below, VF occurs commonly during in-hospital cardiac arrests, often during resuscitation.

In-hospital pediatric cardiac arrests are uncommon, but not rare. Cardiac arrests occur in ~2% of PICU patients. Although the rhythms during most in-hospital cardiac arrests (both in children and adults) are asystole and pulseless electrical activity (PEA), in a considerable number of arrests the rhythms are VF or pulseless VT. Among the first 1,005 pediatric in-hospital cardiac arrests in the American Heart Association's National Registry of CPR, 10% had an initial rhythm of VF/VT, an additional 15% had subsequent VF/VT (i.e., some time later during the resuscitation efforts), and another 2% had VF/VT but the timing of the arrhythmia was not clear. Therefore, 27% of children with in-hospital cardiac arrests had VF/VT.

In this NRCPR cohort of pediatric in-hospital arrests, survival to discharge was much more common among children with an arrhythmogenic arrest (i.e., initial VF/VT) than among children with VF/VT occurring later during the resuscitation (i.e., subsequent VF/VT): 35% with initial VF/VT vs. 11% subsequent VF/VT (adjusted odds ratio 2.9 [95% CI, 1.2–5.8]). This novel observation is not surprising because children with subsequent VF/VT had hypoxic-ischemic processes before the arrest (i.e., the arrests were

generally precipitated by progressive respiratory failure or shock). In addition, the children with subsequent VF/VT had further hypoxic-ischemic insults during resuscitation for asystole or PEA before VF/VT occurred. This is supported by the observation that only 14% of the subsequent VF/VT group had CPR for <15 minutes compared with 44% of the initial VF/VT group.

Surprisingly, the subsequent VF/VT group had worse outcomes than did children with asystole/PEA who never developed VF/VT during the resuscitation: 11% with subsequent VF/VT during resuscitation from asystole/PEA vs. 27% with asystole/PEA alone. Why was the outcome so poor in the subsequent VF/VT group? Rescuers may have been led astray by the initial non-shockable rhythm, so that recognition of VF/VT and defibrillation were delayed. If so, consideration of subsequent VF/VT could have led to earlier recognition, earlier defibrillation, and better outcomes. Another possibility is that subsequent VF/VT was a marker of more severe myocardial pathology. For example, patients with non-shockable rhythms who were most likely to respond promptly to CPR may have attained ROSC before they could develop subsequent VF/VT. Alternatively, resuscitators may have induced VF/VT in some patients by their interventions during the more prolonged CPR for the subsequent VF/VT group (e.g., greater amounts of epinephrine administration).

Traditionally, VF and VT have been considered "good" cardiac arrest rhythms, resulting in better outcomes than asystole and PEA. These NRCPR pediatric VF/VT data suggest a new paradigm: outcomes after *initial* VF/VT are "good," but outcomes after *subsequent* VF/VT are substantially worse than after asystole/PEA without subsequent VF/VT.

Finally, these NRCPR data emphasize the importance of early and repeated electrocardiographic monitoring during resuscitation, because the shockable rhythms of VF/VT occurred in >25% of these children. Even in the setting of progressive respiratory failure and shock with an initial ECG of asystole or PEA, a substantial number of these children developed subsequent shockable VF/VT during CPR.

Treatment of choice: defibrillation

Defibrillation, termination of VF, is necessary for successful resuscitation from VF cardiac arrest. When prompt defibrillation is provided soon after the onset of VF in a cardiac catheterization laboratory, the rates of successful defibrillation and survival approach 100%. When automated external defibrillators are used within 3 minutes of

witnessed VF in casinos, long-term survival occurs in ~75%. In general, the mortality increases by 7%–10% per minute of delay to defibrillation. Provision of CPR can improve outcome (i.e., shift the mortality curve).

Because pediatric cardiac arrests are commonly due to progressive asphyxia and/or shock, the treatment of choice is prompt CPR. Therefore, rhythm recognition is relatively less emphasized compared with adult cardiac arrests. Nevertheless, successful resuscitation from VF requires defibrillation. First, we must consider VF, and then diagnose it before we can treat it successfully.

Determinants of defibrillation (termination of VF)

Defibrillation is achieved by attaining current flow adequate to depolarize a critical mass of myocardium. Current flow (amperes) is primarily determined by the shock energy (joules), which is selected by the operator, and the patient's transthoracic impedance (ohms).

Animal studies in the 1970s established that adequate electrical current flow through the myocardium led to successful defibrillation, and too much current flow resulted in postresuscitation myocardial damage (including histopathological evidence of myocardial necrosis). In addition, various extraneous sources of impedance were determined, including paddle size, thoracic gas volume, electrode/paddle contact, and conducting paste. Small paddle size increases resistance, and thereby decreases current through the myocardium. On the other hand, paddles/pads larger than the heart result in current flow through extramyocardial pathways, and thereby less current through the heart (consequently less flow for effective defibrillation). These studies established that current density, i.e., current flow through the myocardium, determines both effectiveness of the shock and myocardial damage.

Further studies established that both poor electrode paddle contact and increased thoracic gas resulted in greater impedance, whereas both conducting paste and increased pressure with the paddle against the skin decreased impedance. Moreover, transthoracic impedance decreased with subsequent shocks, partly due to increased skin blood flow after electrical shocks.

Pediatric defibrillation doses

In the mid-1970s authoritative sources recommended initial defibrillation doses as high as 200 joules for all children. Despite clinical experience indicating that such doses were effective, providing an adult dose to infants seemed potentially dangerous. Because of animal data demonstrating histopathological myocardial damage

with dosages >10 J/kg and further animal data suggesting that 0.5–10 J/kg were generally adequate for defibrillation in a variety of species, some experts recommended a pediatric dose of 2 J/kg.

Gutgesell and colleagues retrospectively evaluated the efficacy of the 2 J/kg pediatric defibrillation strategy. Seventy-one transthoracic defibrillation attempts on 27 children were evaluated. These children were 3 days to 15 years old, and weighed from 2.1 to 50 kg. Fifty-seven of 71 shocks were within 10 joules of the 2 J/kg pediatric dose. Ninety-one percent (52/57) of these shocks effectively terminated VF. The authors did not report any other outcome measures (e.g., successful resuscitation to a perfusing rhythm, 24-hour survival, survival to discharge). Subsequent clinical usage suggests that the 2 J/kg dose is effective for short duration in-hospital defibrillation, although this conclusion has not been rigorously evaluated.

As noted above, current density determines the effectiveness and harm of the shock. Moreover, differences in paddle size, defibrillation energy dose, and the individual's transthoracic impedance are the main determinants of current density. Therefore, Atkins and colleagues investigated the effects of paddle size, age, and weight on transthoracic impedance in children (Fig. 53.4). As expected, transthoracic impedance increased substantially with pediatric paddles. On the basis of those data, the AHA recommends that "pediatric" paddles only be used in infants.

More important, they established that the relationship between transthoracic impedance and weight is not linear. The mean transthoracic impedance in their children was ~50 Ω with 83 cm² adult paddles, and varied three-fold among children. With "pediatric" pads (44 cm²), the mean impedance was ~70 Ω in 3.8–36 kg children. The impedances of their infants were slightly lower than those of their older children, but the range of each was wide and the overlap substantial. Interestingly, the mean transthoracic impedance in adults is typically ~60–80 Ω and it also varies by more than three-fold, yet we shock all adults with the same doses. These data suggest that the pediatric dosage should not vary in a linear manner based on weight. Nevertheless, the pediatric 2 J/kg dose has apparently withstood the test of time over the last 30 years.

Pediatric defibrillation doses for prolonged VF

As noted above, ~16 000 American children suffer a cardiac arrest each year, ~10%–20% with VF as the initial rhythm. There are minimal published data on pediatric defibrillation doses for prolonged VF. Therefore, the approach to pediatric prolonged VF is extrapolated from adult recommendations. For adults, the same defibrillation dose is rec-
Fig. 53.4. Effect of paddle electrode size on transthoracic impedance (TTI). •, pediatric paddles; ○, adult paddles; *P<.001 *v.* adult paddles; bar indicates standard deviation.

ommended after brief duration or prolonged duration VF, even though the monophasic 200-J dose is often ineffective at terminating prolonged VF (~60% termination of prolonged VF compared with >90% for short duration VF). Adult defibrillation differs from pediatric defibrillation in many ways. First, the adult defibrillation dose is much higher in absolute joules or joules/kg. For example, a 70-kg man would receive 200 J (~3 J/kg), whereas a 70-kg 11-year-old boy may be treated with a pediatric dose of 140 J. Secondly, adult defibrillation from prolonged VF is now typically performed with biphasic defibrillators, and the 150 J or 200 J biphasic AED dosage is nearly 90% successful at terminating prolonged VF (much better than the ~60% effectiveness with 200 J monophasic defibrillation).

Is the currently recommended pediatric VF dose of 2 J/kg by monophasic waveform safe and effective for prolonged VF? A recently published animal study of defibrillation after 7 minutes of untreated VF in 4 to 24 kg piglets suggests that 2 J/kg may be an inadequate dose. Twenty-four piglets were shocked with 2 J/kg, followed by 4 J/kg. The pediatric dose of 2 J/kg monophasic shocks was uniformly unsuccessful at terminating fibrillation in all 24 piglets. This should not be overinterpreted; there could be interspecies differences in defibrillation thresholds.

A small clinical study of pediatric defibrillation attempts, however, also suggests that the 2 J/kg defibrillation dose is often inadequate. Eleven children received 14 pediatric dose shocks of brief duration for VF in the Tucson EMS over a 5-year period, by using the criteria described by Gutgesell in his pediatric in-hospital defibrillation study (2 J/kg ±

10 J). Only 7/14 shocks (50%) terminated out-of-hospital (prolonged) VF vs. 52/57 shocks (91%) in their 27 in-hospital patients (*P*< 0.01). Although this small series does not determine what dose we should use, it raises doubts about the efficacy of 2 J/kg monophasic shocks for prolonged VF.

Because standard weight-based dosing strategy for pediatric defibrillation is not easily implemented in automated external defibrillators (AEDs), manufacturers developed an alternative pediatric AED dose of 50–86 J biphasic shocks by attenuating the adult defibrillation dose with pediatric pads/cable systems, thereby delivering 50–86 J rather than 150–360 J. This dose is safe and effective in piglets after either brief or prolonged VF. In addition, the 50 J/75 J/86 J shocks were more effective than the 2 J/kg dose at initial termination of fibrillation after prolonged VF. In another piglet study modelling prolonged out-of-hospital pediatric VF (7 minutes of untreated VF), adult biphasic shocks of 200 J/300 J/360 J were compared with a "pediatric" biphasic AED dose of 50 J/75 J/86 J. Pediatric dosing resulted in fewer elevations of cardiac troponin T levels, less postresuscitation myocardial dysfunction (i.e., smaller decreases in left ventricular ejection fraction 1–4 hours postresuscitation), and superior 24-hour survival with good neurological outcome. These data suggest that adult defibrillation dosing may be harmful to pediatric patients with prolonged VF and support the use of attenuating electrodes with adult automated external defibrillators for pediatric defibrillation. Although human data are certainly needed, these animal data support the

AHA/ILCOR pediatric AED guidelines: "Ideally, the device should deliver a pediatric dose."

It is important to remember that the pediatric defibrillation LD_{100} is O joules. The patient uniformly dies if defibrillation is not attempted. Therefore, adult defibrillation doses are preferable to no defibrillation. A single case report in the literature demonstrated that an adult AED dose saved the life of a 3-year-old boy in VF. That child was defibrillated with a biphasic shock of 150 J (9 J/kg) and survived without any apparent adverse effects. In particular, neither serum creatine kinase nor cardiac troponin was elevated, and postresuscitation ventricular function was normal on echocardiogram.

Pediatric AEDs

VF is prolonged in nearly all children with out-of-hospital VF by the time EMS personnel and defibrillators arrive. Until recently, AEDs were not recommended for children <8 years old. Therefore, young children in VF had to wait for a trained operator with a manual defibrillator. Too often, this delay precluded survival. Current international guidelines recommend AED usage for children 1–8 years old. Two issues had to be considered before such recommendations: (1) the safety and efficacy of the AED diagnostic rhythm analysis program in children; and (2) the safety and efficacy of the AED shock dosage.

An important concern was that babies and small children with sinus tachycardia or supraventricular tachycardia can have very high heart rates that might be misinterpreted as "shockable" by AEDs with diagnostic programs developed for adult arrhythmias. Fortunately, published studies of rhythm analysis programs from two leading manufacturers (Philips and Medtronics) have established that they are quite sensitive and specific in detecting the shockable rhythm of VF. Both algorithms were less sensitive at detecting the very uncommon shockable rhythm of VT, but were quite specific (i.e., the algorithm did not misinterpret other rhythms as VT, and therefore did not recommend shocking a "non-shockable" rhythm"). On the basis of these two rhythm analysis program studies and the defibrillation dose information noted above, the AHA/ILCOR PALS Task Force recommended that "AEDs may be used for children 1 to 8 years of age with no signs of circulation. Ideally the device should demonstrate high specificity for pediatric shockable rhythms, i.e., the device will not recommend a shock for non-shockable rhythms." Because of the relative rarity of out-of-hospital VF in infants and the limited rhythm analysis program information in infants with VF, the Task Force concluded that "Currently the evidence is insufficient to

support a recommendation for or against the use of AEDs in children >1 year of age."

Finally, pediatric AEDs with shock doses are now available. Technological developments have enabled these AEDs to deliver a pediatric dose by attenuating the adult biphasic defibrillation dose with pediatric pads/cable system, thereby delivering 1/4 to 1/3 (50–86 J) of the standard adult energy. As noted above, animal studies and extrapolations from adult defibrillation studies suggest that this pediatric biphasic AED dosage is at least as safe and effective as the 2 J/kg monophasic dose. Although there are theoretical concerns and animal data suggesting that adult AED doses may be less safe than pediatric AED doses, an adult AED dose can terminate VF and save a child's life.

The four phases of cardiac arrest and CPR

There are at least four phases of cardiac arrest: (1) **pre-arrest**, (2) **no-flow** (untreated cardiac arrest), (3) **low-flow** (CPR), and (4) **postresuscitation**. Interventions to improve outcome from pediatric cardiac arrest should optimize therapies targeted to the phase of resuscitation as suggested in Table 53.5. The pre-arrest phase provides the opportunity to have the largest impact on patient survival by preventing cardiopulmonary arrest. Interventions during the pre-arrest phase focus on prevention. Infant safety seats and safe driving to prevent traumatic arrests, water safety programs to prevent drowning arrests, medication safety caps to prevent drug poisoning arrests are well known highly effective efforts to prevent cardiac arrests. Because many pediatric cardiac arrests are due to progressive respiratory failure and shock, the main focus of the Pediatric Advanced Life Support (PALS) is the early recognition and treatment of respiratory failure and shock in children (i.e., prevention of cardiac arrest in the pre-arrest phase). This issue has been popularized as the main focus of medical emergency response teams or rapid response teams.

Interventions during the **no-flow** phase of untreated cardiac arrest focus on early recognition of cardiac arrest and rapid initiation of basic and advanced life support. When there is insufficient oxygen delivery to the brain or heart, CPR should be started. The goal of effective CPR is to optimize coronary perfusion pressure and blood flow to critical organs during the **low-flow** phase. Basic life support with continuous effective chest compressions (i.e., push hard, push fast, allow full chest recoil, minimize interruptions, and do not overventilate) is the emphasis in this phase.

The **postresuscitation** phase is a high-risk period for continuing brain injury, ventricular arrhythmias, and other reperfusion injuries. Injured cells can hibernate, die,

Table 53.5. Phases of cardiac arrest and resuscitation

Phase	Interventions
Pre-arrest phase (**protect**)	• Optimize community education regarding child safety • Optimize patient monitoring and rapid emergency response • Recognize and treat respiratory failure and/or shock to prevent cardiac arrest
Arrest (no-flow) phase (**preserve**)	• Minimize interval to BLS and ACLS (organized response) • Minimize interval to defibrillation, when indicated
Low-flow (CPR) phase (**resuscitate**)	• Push Hard, Push Fast • Allow full chest recoil • Minimize interruptions in compressions • Avoid overventilation • Titrate CPR to optimize myocardial blood flow (coronary perfusion pressures and exhaled CO_2) • Consider adjuncts to improve vital organ perfusion during CPR • Consider ECMO if standard CPR/ALS not promptly successful
Postresuscitation phase: short-term	• Optimize cardiac output and cerebral perfusion • Treat arrhythmias, if indicated • Avoid hyperglycemia, hyperthermia, hyperventilation • Consider mild postresuscitation systemic hypothermia • Debrief to improve future responses to emergencies
Postresuscitation phase: longer-term rehabilitation (**regenerate**)	• Early intervention with occupational and physical therapy • Bioengineering and technology interface • Possible future role for stem cell transplantation

or partially or fully recover function. Interventions such as systemic hypothermia during the immediate postresuscitation phase strive to minimize reperfusion injury and support cellular recovery. Overventilation is frequent and can have adverse effects during and after CPR. The postarrest phase may have the most potential for innovative advances in the understanding of cell injury and death, inflammation, apoptosis, and hibernation, ultimately leading to novel interventions. Thoughtful attention to management of temperature, glucose, blood pressures, coagulation, and optimal ventilation may be particularly important in this phase. The rehabilitation stage of postresuscitation concentrates on salvage of injured cells, recruitment of hibernating cells, and re-engineering of reflex and voluntary communications of these cell and organ systems to improve functional outcome.

The specific phase of resuscitation should dictate the timing, intensity, duration, and focus of interventions. Emerging data suggest that interventions that can improve short-term outcome during one phase may be deleterious during another. For instance, intense vasoconstriction during the low flow phase of cardiac arrest may improve coronary perfusion pressure and probability of ROSC.[2] The same intense vasoconstriction during the postresuscitation phase may increase left ventricular afterload and worsen myocardial strain and dysfunction. Current understanding of the physiology of cardiac arrest and recovery only enables the crude titration of blood pressure, global oxygen delivery and consumption, body temperature, inflammation, coagulation, and other physiologic parameters to attempt to optimize outcome. Future strategies will likely take advantage of emerging discoveries and knowledge of cellular inflammation, thrombosis, reperfusion, mediator cascades, cellular markers of injury and recovery, and transplantation technology.

Definition of pulseless cardiac arrest

Pulseless cardiac arrest is typically defined as the documented cessation of cardiac mechanical activity, determined by the absence of a palpable central pulse, unresponsiveness, and apnea. As simple as this definition appears, separation of severe hypoxic–ischemic shock from the non-pulsatile state of cardiac arrest can be challenging at any age. This separation can be especially difficult in babies because of their anatomic and physiologic differences.

A rescuer's ability to determine cardiac arrest by a pulse check is neither sensitive nor specific in adults. Not surprisingly, the pulse check is even more problematic in children. In adults, pulses can typically be palpated until the

systolic pressure is <50 mmHg. Because the systolic blood pressure in neonates is generally in the 60s, a decrease in blood pressure to "non-palpable pulse" may occur earlier in the continuum from hypoxic–ischemic shock to non-pulsatile cardiac standstill. Furthermore, the best arterial pulse to palpate in an adult is the carotid pulse; however, the short, chunky neck of a baby limits the effectiveness of carotid pulse palpation in babies. Moreover, attempts to palpate the carotid pulse can compress the airway and impede respiration. Therefore, the recommended sites for palpation of pulses in an infant are the brachial, axillary and/or femoral pulses.

Interventions during the low flow phase: CPR

Airway and breathing

As noted above, one of the most common precipitating events for cardiac arrests in children is respiratory insufficiency. Therefore, providing adequate ventilation and oxygenation must remain a high priority. Effective ventilation does not necessarily require a tracheal tube. In one randomized, controlled study of children with out-of-hospital respiratory arrest, those who were treated with bag-mask ventilation did as well as children treated with pre-hospital endotracheal intubation. Effective bag-mask ventilation skills remain the cornerstone of providing effective emergency ventilation. Emergency airway techniques such as transtracheal jet ventilation and emergency cricothyroidotomy are rarely, if ever, required during CPR.

Provision of adequate oxygen delivery to meet metabolic demand and removal of carbon dioxide is the goal of initial assisted ventilation. During CPR, cardiac output and pulmonary blood flow are about 10%–25% of that during normal sinus rhythm. Consequently, much less ventilation is necessary for adequate gas exchange from the blood traversing the pulmonary circulation during CPR. Animal and adult data indicate that rapid rate assisted ventilation (overexuberant rescue breathing) during CPR is common and can substantially compromise venous return and cardiac output. Of most concern, these adverse hemodynamic effects during CPR plus interruptions in chest compressions typically necessary for airway management and rescue breathing can be a lethal combination.

Although **A**irway and **B**reathing hold places of honor in the **ABC** algorithm, that priority has been challenged in certain circumstances. In animal models of sudden VF

cardiac arrest, acceptable PaO_2 and $PaCO_2$ persist for 4 to 8 minutes during chest compressions without rescue breathing. Moreover, many animal studies indicate that outcomes from sudden VF cardiac arrests are at least as good with chest compressions alone as with chest compressions plus rescue breathing. In addition, several retrospective studies of adults also suggest that outcomes are similar after bystander-initiated CPR with either chest compressions alone or chest compressions plus rescue breathing. A randomized, controlled study of dispatcher-assisted bystander CPR in adults found a trend toward improved survival in the patients who received chest compressions alone compared to those who received dispatcher-instructed ventilation and chest compressions. In contrast, animal studies of asphyxia-precipitated cardiac arrests have established that rescue breathing is a critical component of successful CPR.

Since oxygenation and ventilation are clearly important for survival from any cardiac arrest, why is rescue breathing not initially necessary for VF, yet quite important in asphyxia? Immediately after an acute fibrillatory cardiac arrest, aortic oxygen and carbon dioxide concentrations do not vary from the pre-arrest state because there is no blood flow and aortic oxygen consumption is minimal. Therefore, when chest compressions are initiated, the blood flowing from the aorta to the coronary and cerebral circulations provides adequate oxygenation at an acceptable pH. At that time, myocardial oxygen delivery is limited more by blood flow than oxygen content. Adequate oxygenation and ventilation can continue without rescue breathing because the lungs serve as a relatively high oxygen/low carbon dioxide reservoir during the low-flow state of CPR. In addition, ventilation can occur due to chest compression-induced gas exchange and spontaneous gasping during CPR in victims of sudden cardiac arrest. Therefore, arterial oxygenation and pH can be adequate with chest compressions alone for VF arrests.

Forgoing ventilation in the pediatric patient is not prudent, because respiratory arrest and asphyxia generally precede pediatric cardiac arrest. During asphyxia, blood continues to flow to tissues; therefore, arterial and venous oxygen saturations decrease while carbon dioxide and lactate continue to increase for many minutes before progression to cardiac arrest. Furthermore, continued pulmonary blood flow before the cardiac arrest depletes the pulmonary oxygen reservoir. Therefore, in contrast to VF, asphyxia results in significant arterial hypoxemia and acidemia prior to resuscitation. In this circumstance, rescue breathing can be life-saving.

Circulation

Basic life support with continuous effective chest compressions is generally the best way to provide circulation during cardiac arrest. As noted in previous chapters of this book, basic life support is often provided poorly or not provided at all. The most critical elements are to Push Hard and Push Fast. Because there is no flow without chest compressions, it is important to minimize interruptions in chest compressions. To allow good venous return in the decompression phase of external cardiac massage, it is important to allow full chest recoil, and to avoid overventilation. The latter can prevent venous return because of increased intrathoracic pressure.

The use of closed-chest cardiac massage to provide adequate circulation during cardiac arrest was initially demonstrated in small dogs with compliant chest walls. Based on reasonable extrapolation, these investigators thought that closed chest cardiac massage would be effective with children, but might not be effective with adults. Therefore, the first patients successfully treated with closed-chest cardiac massage were children. The presumed mechanism of blood flow was direct compression of the heart between the sternum and the spine in these children with compliant chest walls. Later investigations indicated that blood can also be circulated during CPR by the thoracic pump mechanism. That is, increases in intrathoracic pressure induced by chest compression can generate a gradient for blood to flow from the pulmonary vasculature, through the heart, and into the peripheral circulation. Regardless of mechanism, cardiac output during CPR seems to be greater in children (and immature animals) with compliant chest walls than in adults with less compliant chest walls.

Circumferential vs. focal sternal compressions

In adults and animal models of cardiac arrest, circumferential (Vest) CPR improves CPR hemodynamics dramatically. In smaller infants, it is often possible to encircle the chest with both hands and depress the sternum with the thumbs, while compressing the thorax circumferentially. In an infant model of CPR, this "two-thumb" method of compression resulted in higher systolic and diastolic blood pressures and a higher pulse pressure than did traditional two-finger compression of the sternum.

Duty cycle

Duty cycle is the ratio of time of compression phase to the entire compression-relaxation cycle. In a model of human adult cardiac arrest, cardiac output and coronary blood flow are optimized when chest compressions last for 30% of the total cycle time. As the duration of CPR increases, the optimal duty cycle may increase to 50%. In a juvenile swine model, a relaxation period of 250–300 ms (a duty cycle of 40%–50% if 120 compressions are delivered per minute) correlates with improved cerebral perfusion pressure when compared to shorter duty cycles of 30%.

Open chest CPR

Excellent standard closed chest CPR generates a cerebral blood flow that is approximately 50% of normal. By contrast, open chest CPR can generate a cerebral blood flow that approaches normal. While open chest massage improves coronary perfusion pressure and increases the chance of successful defibrillation in animals and humans, performing a thoracotomy to allow open chest CPR is impractical in many situations. A retrospective review of 27 cases of CPR following pediatric blunt trauma (15 with open chest CPR and 12 with closed chest CPR) demonstrated that open chest CPR increased hospital cost without altering rates of ROSC or survival to discharge[4][10a]. No patient in either group survived, however, indicating that the population may have been too severely injured or were treated too late in the process to benefit from this aggressive therapy. Open chest CPR is often provided to children after open heart cardiac surgery status-post sternotomy. Earlier institution of open chest CPR may warrant reconsideration in selected special resuscitation circumstances.

Ratio of compressions to ventilation

Ideal compression–ventilation ratios for pediatric patients are unknown. Current compression–ventilation ratios and tidal volumes recommended during CPR are based upon rational conjecture, tradition, and educational retention theory. Recent physiologic estimates suggest that the amount of ventilation needed during CPR is much less than the amount needed during a normal perfusing rhythm, because the cardiac output during CPR is only 10%–25% of that during normal sinus rhythm. The benefits of positive pressure ventilation (increased arterial content of oxygen and carbon dioxide elimination) must be balanced against the adverse consequence of decreased circulation.

Maximizing systemic oxygen delivery during single rescuer CPR requires a trade-off between time spent doing chest compressions and time spent doing mouth-to-mouth ventilations. Theoretically, neither compression-only nor ventilation-only CPR can sustain systemic oxygen delivery. Some intermediate value of the compression to ventilation ratio is probably optimal. The best intermediate value depends upon many factors including the compression rate, the tidal volume, the blood flow generated by compressions,
Fig. 53.5. Scaling rules for optimum C/V ratios in pediatric basic life support. Open symbols represent theoretical compression–ventilation ratios for optimal oxygen delivery, scaled for persons having a wide range of body weight. Lay rescuers (lay) are assumed to take 8 seconds to deliver one rescue breath in an adult size individual, in keeping with the observations of Chamberlain and coworkers. Professional rescuers (pros) are assumed to take 2.5 seconds to deliver one rescue breath. Solid symbols indicate approximations to the theoretical curves, based upon average body weights of children ages 1 to 18, according to the rules "5 + patient age in years" for lay rescuers and "5 + one-half patient age in years" for professional rescuers.

and the time that compressions are interrupted to perform ventilations. A chest compression to ventilation ratio of 15:2 delivered the same minute ventilation as CPR with a chest compression to ventilation ratio of 5:1 in a mannequin model of pediatric CPR, but the number of chest compressions delivered was 48% higher with the 15:2 ratio.

In adults, mathematical models of oxygen delivery during CPR performed with variable ratios of healthcare provider chest compressions to ventilations suggest that the optimal compression to ventilation ratio is approximately 30:2 in adults. When the model is adjusted to simulate lay rescuer ability to provide chest compressions and ventilations, the optimal compression to ventilation ratio ranges from 50 to 100:2. Mathematical models of
Fig. 53.6. Sensitivity analysis for scaling rules for optimal C/V ratios in pediatric basic life support. The general effect of body size upon the optimal C/V ratio is insensitive to changes in the exponent of body weight. (A) calculations for professional rescuers, (B) calculations for lay rescuers.

compression–ventilation ratios suggest that matching of the amount of ventilation to the amount of reduced pulmonary blood flow during closed chest cardiac compressions should favor high compression to ventilation ratios. Babbs and Kern suggest that the best way to determine optimal compression to ventilation ratios by using simulation is to choose ratios that maximize oxygen delivery to peripheral tissues. Maximizing oxygen delivery to peripheral tissues during single rescuer CPR requires a trade-off between the time required to compress the chest and time required to provide rescue breathing. If one ignores the relatively small amount of ventilation provided by chest compressions alone, neither compression-only nor ventilation-only CPR can sustain oxygen delivery to the periphery for prolonged periods of CPR. The best ratio depends upon many factors including the compression rate, the tidal volume, the blood flow generated by compressions, and the time that compressions are interrupted to perform ventilations. These factors can be related in a simple mathematical formula based upon classical physiology. These variables necessarily change as a function of the size of the patient. Such considerations may help to refine the amount of ventilation recommended for both adults and children. The ratio of chest compressions to ventilations during "no-flow" and "low-flow" phases of cardiopulmonary-cerebral resuscitation remains an area of high interest, controversy, and future research. These formulas adjusted to the known physiologic variables in children have suggested the potential to simplify the compression: ventilation ratio to 15 chest compressions and 2 ventilations in all children.

Intraosseous vascular access

In infants and children requiring emergent access for resuscitation from cardiac arrest, intraosseous vascular access should be established if reliable venous access cannot be achieved rapidly. Because of the difficulty in establishing vascular access in pediatric cardiac arrest victims, it may be preferable to attempt intraosseous (IO) access immediately. A practical approach is to pursue IO and peripheral or central venous access simultaneously.

Intraosseous vascular access provides access to a non-collapsible marrow venous plexus, which serves as a rapid, safe, and reliable route for administration of drugs, crystalloids, colloids, and blood during resuscitation. Intraosseous vascular access often can be achieved in 30 to 60 seconds. Although a specially designed intraosseous or Jamshidi-type bone marrow stylet needle is preferred to prevent obstruction of the needle with cortical bone, butterfly needles and standard hypodermic needles have

been used successfully. The intraosseous needle is typically inserted into the anterior tibial bone marrow; alternative sites include the distal femur, medial malleolus or the anterior superior iliac spine, and the distal tibia. In adults and older children, the medial malleolus, distal radius, and distal ulna are other options.

This intraosseous vascular access technique can be used in all age groups, from pre-term neonates through adulthood. The needle should be twisted into, rather than shoved through, the bone marrow. Evidence for successful entry into the bone marrow includes: (1) the sudden decrease in resistance after the needle passes through the bony cortex, (2) the needle remains upright without support, (3) aspiration of the bone marrow into a syringe (this is not consistently achieved), and (4) the fluid infuses freely without evidence of subcutaneous infiltration.

Resuscitation drugs, fluids, and blood products can be safely administered by the intraosseous route, as well as continuous catecholamine infusions. Onset of action and drug levels following intraosseous infusion during CPR are comparable to those achieved following vascular administration, including central venous administration. Intraosseous vascular access may also be used to obtain blood specimens for chemistry, blood gas analysis, and type and crossmatch, although administration of sodium bicarbonate through the intraosseous cannula eliminates the close correlation with mixed venous blood gases.

Complications have been reported in less than 1% of patients following intraosseous infusion. Such complications include tibial fracture, lower extremity compartment syndrome, severe extravasation of drugs, and osteomyelitis. Most of these complications may be avoided by careful technique. Although microscopic pulmonary fat and bone marrow emboli have been demonstrated in animal models, they have never been reported clinically and appear to occur just as frequently during cardiac arrest without intraosseous drug administration. Animal data and one human follow-up study indicate that local effects of intraosseous infusion on the bone marrow and bone growth are minimal.

Endotracheal drug administration

Before the intraosseous route became commonly used for vascular access during CPR, endotracheal intubation was often easier to attain than vascular access during pediatric CPR. Important lipid-soluble drugs could be administered via the endotracheal tube before vascular access was achieved. In particular, lidocaine, atropine, naloxone, and epinephrine were commonly administered via the endotracheal route. Sodium bicarbonate and calcium are not lipid-soluble, however, and may be very irritating to the

airways and lung parenchyma, so they were not recommended for endotracheal administration.

Absorption of drugs into the circulation after endotracheal administration depends on dispersion over the respiratory mucosa, pulmonary blood flow, and matching of the ventilation (drug dispersal) to perfusion. The small volumes of drug that remain as droplets in the tracheal tube are obviously not effective. Inadequate chest compressions resulting in poor pulmonary blood flow will also limit absorption of the drug and prevent its delivery to the heart and systemic circulation. Pre-existing pathophysiologic conditions such as pulmonary edema, pneumonitis, and airway disease also affect the pharmacokinetics of endotracheally administered drugs. Another confounding factor is that the vasoconstrictive effects of epinephrine may limit local pulmonary blood flow, thereby diminishing drug uptake and delivery. It is therefore not surprising that drug absorption varies greatly and that optimal drug doses have not been determined (and probably never can be).

Case reports and our personal experiences suggest that endotracheal epinephrine can be effective and life-saving. Animal studies, however, reveal a wide variability in plasma epinephrine levels and physiological effects after endotracheal administration. On average, 10 times as much endotracheal epinephrine is needed to attain peak plasma levels comparable to intravenous administration. Moreover, a prolonged depot effect typically occurs after endotracheal administration of epinephrine, which can lead to postresuscitation hypertension, tachycardia, and ventricular arrhythmias.

Quinton and associates randomly treated five asystolic adults with 1 mg of endotracheal epinephrine versus seven patients with 1 mg of intravenous epinephrine. Arterial epinephrine levels only increased in the group treated intravenously. They concluded that health care providers should not rely on the endotracheal route.

Endotracheal epinephrine has been considered more important for infants and children than for adults because of vascular access issues. Nevertheless, intraosseous drug administration is more reliable than endotracheal administration because of the inherent problems with the pharmacokinetics of endotracheally administered drugs.

Medication use during cardiac arrest

Although animal studies indicate that epinephrine can improve initial resuscitation success after both asphyxial and VF cardiac arrests, no medication has been shown to improve survival outcome from pediatric cardiac arrest. Because of the dearth of pediatric CPR medication studies, this fact should not be overinterpreted.

Vasopressors

During CPR, the α-adrenergic effect of epinephrine on vascular tone is most important. The α-adrenergic action increases systemic vascular resistance, increasing diastolic blood pressure which, in turn, increases coronary perfusion pressure and blood flow, and improves the likelihood of ROSC. Epinephrine also increases cerebral blood flow during CPR because peripheral vasoconstriction directs a greater proportion of flow to the cerebral circulation. The β-adrenergic effect increases myocardial contractility and heart rate and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi, although this effect of less important. Epinephrine also increases the vigor and intensity of ventricular fibrillation, enhancing the likelihood of successful defibrillation.

High-dose epinephrine (0.05–0.2 mg/kg) improves myocardial and cerebral blood flow during CPR more than does standard-dose epinephrine (0.01–0.02 mg/kg), and may increase the incidence of initial ROSC. Administration of high-dose epinephrine, however, can worsen a patient's postresuscitation hemodynamic condition, with increased myocardial oxygen demand, ventricular ectopy, hypertension, and myocardial necrosis. Retrospective studies indicate that use of high-dose epinephrine in adults or children does not improve survival and may be associated with a worse neurological outcome.

A randomized, controlled trial of rescue high-dose epinephrine vs. standard-dose epinephrine after failed initial standard-dose epinephrine for pediatric in-hospital cardiac arrest indicated a worse 24-hour survival in the high-dose epinephrine group (1/27 vs. 6/23, $P < 0.05$). In particular, high-dose epinephrine seemed to worsen the outcome of patients with asphyxia-precipitated cardiac arrest. High-dose epinephrine cannot be recommended routinely for initial therapy or rescue therapy.

Wide variability in catecholamine pharmacokinetics and pharmacodynamics dictates individual titration of therapy in non-cardiac arrest situations. Therefore, it is likely that a life-saving dose during CPR for one patient may be life-threatening to another. Therefore, high-dose epinephrine should perhaps be considered as an alternative to standard-dose epinephrine in special circumstances of refractory pediatric cardiac arrest (e.g., for a patient on high-dose epinephrine infusion before cardiac arrest) and/or when continuous direct arterial blood pressure monitoring allows titration of the epinephrine dosage to diastolic (relaxation phase) arterial pressure during CPR. Nevertheless, high-dose epinephrine has not been shown to improve outcome and should only be used with caution.

Vasopressin is a long-acting endogenous hormone that acts at specific receptors to mediate systemic vasoconstriction (V_1 receptor) and reabsorption of water in the renal tubule (V_2 receptor). In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long-term survival compared to epinephrine. Vasopressin may decrease splanchnic blood flow during and after CPR. In randomized controlled trials of in-hospital and out-of-hospital arrests in adults, vasopressin had comparable efficacy to epinephrine. Vasopressin did not improve outcome compared with epinephrine.

In a pediatric porcine model of prolonged *ventricular fibrillation*, the use of vasopressin and epinephrine in combination resulted in higher left ventricular blood flow than either pressor alone, and both vasopressin alone and vasopressin plus epinephrine resulted in superior cerebral blood flow than epinephrine alone.[7] By contrast, in a pediatric porcine model of *asphyxial* cardiac arrest, return of spontaneous circulation was more likely in piglets treated with epinephrine than in those treated with vasopressin. A case series of four children who received vasopressin during six prolonged cardiac arrest events suggests that the use of bolus vasopressin may result in return of spontaneous circulation when standard medications have failed. Vasopressin has also been reported to be useful in low cardiac output states associated with sepsis syndrome and organ recovery in children. While vasopressin will not likely replace epinephrine as a first-line agent in pediatric cardiac arrest, there are preliminary data to suggest that its use in conjunction with epinephrine in pediatric cardiac arrest deserves further investigation.

Calcium

For in-hospital pediatric cardiac arrests, hypocalcemia is not uncommon. Although calcium administration is only recommended during cardiac arrest for hypocalcemia, hyperkalemia, hypermagnesemia, and overdose of calcium channel blockers, it is commonly used for in-hospital pediatric cardiac arrests, especially those occurring after cardiac surgery. Administration of calcium has not been found to improve outcome in cardiac arrest. Animal studies suggest that calcium administration may worsen reperfusion injury.

Buffer solutions

Cardiac arrest results in lactic acidosis from inadequate organ blood flow and poor oxygenation. Acidosis depresses myocardial function, reduces systemic vascular resistance, and inhibits defibrillation. Nevertheless, the routine use of sodium bicarbonate for a child in cardiac arrest is not recommended. Clinical trials involving critically ill adults with severe metabolic acidosis did not disclose a beneficial effect of sodium bicarbonate. The presence of acidosis may depress the action of catecholamines, however, so that the use of sodium bicarbonate seems rational in an acidemic child who is refractory to catecholamine administration. The administration of sodium bicarbonate is more clearly indicated in the patient with a tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia, or sodium channel blocker poisoning.

The buffering action of bicarbonate occurs when a hydrogen cation and a bicarbonate anion combine to form carbon dioxide and water. If carbon dioxide is not effectively cleared through ventilation, its build-up will counterbalance the buffering effect of bicarbonate. Other side effects with sodium bicarbonate include hypernatremia, hyperosmolarity, and metabolic alkalosis. Excessive alkalosis decreases calcium and potassium concentration and shifts the oxyhemoglobin dissociation curve to the left.

Antiarrhythmic medications: lidocaine and amiodarone

Administration of antiarrhythmic medications should not delay administration of a shock for a patient with ventricular fibrillation. After unsuccessful attempts at electrical defibrillation, however, medications to increase the effectiveness of defibrillation should be considered. In both pediatric and adult patients, the current first line medication in ventricular fibrillation is epinephrine for improved myocardial readiness, because of improved myocardial blood flow. If epinephrine with or without vasopressin and a subsequent repeat attempt to defibrillate are unsuccessful, the antiarrhythmic agents amiodarone or lidocaine should be considered.

Lidocaine has been recommended traditionally for shock-resistant VF in adults and children. Nonetheless, amiodarone is the only antiarrhythmic agent that has been prospectively determined to improve survival to hospital admission in the setting of shock-resistant VF when compared to placebo. Furthermore, patients who received amiodarone for shock-resistant out-of-hospital ventricular fibrillation had a higher rate of survival to hospital admission than those patients who received lidocaine alone. Neither of these randomized controlled trials included children. Although there are no published comparisons of antiarrhythmic medications for pediatric refractory ventricular fibrillation, extrapolation of the adult studies has led to the recommendation of amiodarone as the preferred antiarrhythmic agent for children.

Postresuscitation interventions

Temperature management

Mild induced hypothermia is the most celebrated goal-directed postresuscitation therapy for adults. Two articles published in the *New England Journal of Medicine* on February 21, 2002 established that mild induced hypothermia could improve outcome for comatose adults after resuscitation from ventricular fibrillation cardiac arrest. In both randomized controlled trials, the inclusion criteria were patients older than 18 years who were persistently comatose after successful resuscitation from non-traumatic ventricular fibrillation. The multicenter European study led by Fritz Sterz and Michel Holzer had a goal of 32–34°C for the first 24 hours post-arrest. The mean time until attainment of this temperature goal was ~8 hours. Six-month survival with good neurological outcome was superior in the hypothermic group (75/136 vs. 54/137 with RR of 1.40 [CI,1.08–1.81]). Similarly, death at 6 months after the event occurred less often in the hypothermic group (56/137 vs. 76/138; RR of 0.74 [CI, 0.58–0.95]). In the same issue of *NEJM*, Bernard reported good outcomes in 21/43(49%) of the hypothermic group vs. 9/34 (26%) of the control group, $P = 0.046$, OR 5.25 (CI, 1.47–18.76).

Importantly, hypotension occurred among over half of the patients in both groups and was aggressively treated with vasoactive infusion in the European study. Similarly, more than half of Bernard's patients received epinephrine infusions during the first 24 hours post-resuscitation.

How should these data affect postresuscitation treatment after pediatric arrests? Fever following cardiac arrest is associated with poor neurological outcome. Hyperthermia following cardiac arrest is common in children. Although it is reasonable to believe that mild induced systemic hypothermia may benefit children resuscitated from cardiac arrest, benefit from this treatment has not been rigorously studied and reported in children or in any patients with non-VF arrests. At a minimum, it is advisable to avoid even mild hyperthermia in children following CPR. Scheduled administration of antipyretic medications *and* use of external cooling devices are often necessary to avoid hyperthermia in this population.

Postresuscitation myocardial support

Postarrest myocardial stunning occurs commonly after successful resuscitation in animals, adults, and children. Moreover, most adults who survive to hospital admission after an out-of-hospital cardiac arrest die in the postresuscitation phase, many due to progressive myocardial dysfunction. Animal studies have demonstrated that postarrest myocardial stunning is a global phenomenon with biventricular systolic and diastolic dysfunction, that typically resolves after 1 or 2 days. This postarrest myocardial stunning is pathophysiologically and physiologically similar to sepsis-related myocardial dysfunction and postcardiopulmonary bypass myocardial dysfunction, including increases in inflammatory mediator and nitric oxide production. Postarrest myocardial stunning is worse after a more prolonged untreated cardiac arrest, after more prolonged CPR, after defibrillation with higher energy shocks and after a larger number of shocks.

In 1998, Mullner and colleagues demonstrated poor LV function in all 20 adults surviving to ICU admission after out-of-hospital cardiac arrest. Similar to the data from the induced hypothermia studies noted above, 17 of these 20 adults were treated with vasoactive infusions (epinephrine, dopamine, and/or dobutamine) during the first 24 hours after resuscitation.

Optimal treatment of postarrest myocardial dysfunction has not been established. As noted above, such myocardial dysfunction has been treated with various continuous inotropic/vasoactive agents, including dopamine, dobutamine, and epinephrine, in both children and adults. Prospective, controlled animal studies have documented amelioration of myocardial dysfunction with post-resuscitation intravenous dobutamine infusions. In addition, milrinone improves the hemodynamic status of children with postcardiopulmonary bypass myocardial dysfunction and septic shock. Milrinone has also improved postarrest myocardial function in a swine investigation. Finally, the new inotropic agent levosimenden has also been effective in animal models of postresuscitation myocardial dysfunction.

Although prospective controlled trials in animals have demonstrated that the myocardial dysfunction can be effectively treated with vasoactive agents, there are no data demonstrating improvements in outcome. Nevertheless, because myocardial dysfunction is common and can lead to secondary ischemic injuries to other organ systems or even cardiovascular collapse, treatment with vasoactive medications is a rational therapeutic choice that may improve outcome. The hemodynamic benefits in animal studies of postarrest myocardial dysfunction, pediatric studies of postcardiopulmonary bypass myocardial dysfunction, and pediatric sepsis-related myocardial dysfunction support the use of inotropic/vasoactive agents in this setting. Furthermore, adult studies document the common occurrence of postarrest hypotension and/or poor myocardial function "requiring" inotropic/vasoactive agents. In summary, because treatment of postarrest myocardial

dysfunction with inotropic/vasoactive infusions can improve the patient's hemodynamic status, such treatment should be considered routinely.

Assuming treatment of postresuscitation myocardial dysfunction is appropriate, what should be our therapeutic goal? Should we aim for a normal echocardiographic ejection fraction? Normal cardiac output? Normal blood pressure? Normal mixed venous oxygen saturation? The answers to these questions are not currently available. This is a potentially rich area for further investigation.

Blood pressure management

As noted above, postresuscitation myocardial dysfunction is common and has many similarities to sepsis-associated myocardial dysfunction. Therefore, it should not be surprising that Laurent and colleagues (2002) found that 55% of adults surviving out-of-hospital cardiac arrests required in-hospital vasoactive infusions for hypotension unresponsive to volume boluses.

Compared to healthy volunteers, adults resuscitated from cardiac arrest have impaired autoregulation of cerebral blood flow. Hence, they may not maintain cerebral perfusion pressure when systemic hypotension is present and likewise may not be able to protect the brain from acutely increased blood flow due to systemic hypertension. It is reasonable to presume that blood pressure variability should be minimized as much as possible following resuscitation from cardiac arrest.

Nonetheless, a brief period of hypertension following resuscitation from cardiac arrest may diminish the no-reflow phenomenon. In animal models, brief induced hypertension following resuscitation results in improved neurological outcome compared to normotension. In a retrospective human study, postresuscitative hypertension was associated with a better neurological outcome after controlling for age, gender, duration of cardiac arrest, duration of CPR, and pre-existing diseases.

Given these limited data, what should be our postresuscitation blood pressure goals for children? It seems reasonable to treat aggressively and prevent hypotension, Moreover, it seems unlikely that severe hypertension is desirable. Any further assertions are difficult to support.

Glucose control

Hyperglycemia following adult cardiac arrest is associated with worse neurological outcome, after controlling for duration of arrest and presence of cardiogenic shock. In an animal model of asphyxial cardiac arrest, administration of insulin and glucose, but not administration of glucose alone, improved neurological outcome compared to administration of normal saline. Data are not available to clarify whether clinicians should target tight glucose control to avoid hyperglycemia and hypoglycemia following pediatric cardiac arrests.

Extracorporeal membrane oxygenation CPR

Perhaps the ultimate technology to control postresuscitation temperature and hemodynamic parameters is extracorporeal membrane oxygenation (ECMO). In addition, the concomitant administration of heparin may optimize microcirculatory flow.

The use of veno-arterial ECMO to re-establish circulation and provide controlled reperfusion following cardiac arrest has been published, but prospective, controlled studies are lacking. Nevertheless, these series have reported extraordinary results with the use of ECMO as a rescue therapy for pediatric cardiac arrests, especially from potentially reversible acute postoperative myocardial dysfunction or arrhythmias. In one study, 11 children who suffered cardiac arrest in the PICU after cardiac surgery were placed on ECMO during CPR after 20–110 minutes of CPR. Prolonged CPR was continued until ECMO cannulae, circuits, and personnel were available. Six of these 11 children were long-term survivors without apparent neurological sequelae. More recently, two centers have reported an additional remarkable 8 pediatric cardiac patients provided with mechanical cardiopulmonary support during CPR within 20 minutes of the initiation of CPR. All 8 survived to hospital discharge. Nevertheless, CPR and ECMO are not curative treatments; they are simply cardiopulmonary supportive measures that may allow tissue perfusion and viability until recovery from the precipitating disease process. As such, they can be powerful tools.

Most remarkably, Morris and Nadkarni reported 66 children who were placed on ECMO during CPR at the Children's Hospital of Philadelphia over 7 years. The median duration of CPR before establishment of ECMO was 50 minutes, and 35% (23/66) of these children survived to hospital discharge. We emphasize that these children had brief periods of "no-flow," excellent CPR during the "low-flow" period, and a well-controlled post-resuscitation phase.

What does this ECMO-CPR experience mean? Potential advantages of ECMO come from its ability to maintain tight control of physiologic parameters after resuscitation. For example, blood flow rates, oxygenation, ventilation, and body temperature can be manipulated precisely through the ECMO circuit. As we learn more about the processes of secondary injury after cardiac arrest, ECMO might enable controlled perfusion and temperature management to minimize reperfusion injury and maximize cell recovery.

Conversely, perhaps we should imitate ECMO goals for children successfully resuscitated from cardiac arrest (e.g., maintain adequate SvO_2).

Neuropsychological issues

Information about neurological outcomes and predictors of neurological outcome after both adult and pediatric cardiac arrests is quite limited. Two other pediatric issues create barriers in assessing neurological outcomes of children after cardiac arrests. First, pediatrics is developmental medicine. Prediction of future neuro-psychological status is a complex task for any child, especially babies. This issue is particularly complex after an acute neurological insult like a cardiac arrest. In addition, the need to consider the prearrest neurological potential of a child adds another dimension/barrier to the assessment and prediction of postarrest neurological status. Second, many children who suffer a cardiac arrest have substantial pre-existing neurological problems. For example, 17% of the children with in-hospital cardiac arrests from the NRCPR were neurologically abnormal before the arrest.

Our present knowledge about factors predicting neurological outcome from pediatric cardiac arrest is quite limited. There is little information about the predictive value of clinical neurological examinations, neurophysiological diagnostic studies (e.g., EEG, or somatosensory evoked potentials), biomarkers, or imaging (CT , MRI, or PET) on eventual outcome following cardiac arrest or other global hypoxic–ischemic insults in children.

There are some data indicating that burst-suppression pattern on postarrest EEG is sensitive and specific for poor neurological outcome. One study showed somatosensory evoked potential (SSEP) was highly sensitive and specific in pediatric patients after cardiac arrest. Nevertheless, SSEP is not standardized in the pediatric population and is difficult to interpret.

Biomarkers are emerging tools to predict neurological outcome. In an adult study, serum level of neuron-specific enolase (NSE) and S100b protein showed prognostic value. NSE >33 mcg/liter and S100b >0.7 mcg/liter were highly sensitive and specific for poor neurological outcome (death or persisting unconsciousness). The validation of those biomarkers in pediatric postarrest patients requires further study.

CT scans are not sensitive in detecting early neurological injury. The value of MRI studies following pediatric cardiac arrest is not yet clear. MRI with diffusion weighting, however, should provide valuable information about hypoxic–ischemic injury in the subacute and recovery phases.

Most outcome studies of pediatric cardiac arrest have not included neurological outcomes. Investigations that include neurological outcomes have generally used the Pediatric Cerebral Performance Category, a gross outcome scale. Many neuropsychological tests can detect more subtle, clinically important neuropsychological sequelae from neurological insults. Neuropsychological outcomes are important issues for future studies of outcome after pediatric cardiac arrest.

Conclusions

Outcomes from pediatric cardiac arrest and CPR appear to be improving. It seems likely that the evolving understanding of pathophysiologic events during and after pediatric cardiac arrest and the developing fields of pediatric critical care and pediatric emergency medicine have contributed to these apparent improvements. In addition, there are exciting breakthroughs in basic and applied science laboratories that are on the immediate horizon for study in specific subpopulations of cardiac arrest victims. By strategically focusing therapies to specific phases of cardiac arrest and resuscitation and to evolving pathophysiology, there is great promise that critical care interventions will lead the way to more successful cardiopulmonary and cerebral resuscitation in children.

To shed the "therapeutic orphan" status of treatment for pediatric sudden cardiac arrest and improve outcome for children, the following are necessary: a large pediatric sudden death registry; more and better pediatric sudden arrest and asphyxial arrest animal studies; and multicenter therapeutic trials in pediatric sudden arrest populations. Treatment of sudden death in children in the future needs to be more evidence-based and less anecdotal. Timing of therapeutic interventions to prevent arrest, and protect, preserve, and promote restoration of intact neurological survival is of high priority.

Resuscitation in elder persons

Arthur B. Sanders

Department of Emergency Medicine, University of Arizona College of Medicine
Tucson, AZ, USA

The percentage of elder persons throughout the developed world is rapidly increasing. In the USA, for example, the percentage of the population 65 years and older has increased from 4% in 1900 to 13% in 1990 and is projected to be 22% by 2030. The fastest growing segment of the elderly population is the oldest persons who are 85 years or older and made up about 1% of the population in 1990 but will increase to more than 5% over the next 30 years.[1–9]

Similarly in developed countries worldwide (including Japan, Australia, New Zealand, and countries in Europe and North America) the elderly segment of the population is increasing significantly. The highest proportion of elderly people in the world is in Sweden, with 18% of the population 65 years or older.[7] This demographic change with increasing numbers of elder persons in the population is expected to continue over the next 30 to 50 years. By the year 2025, 5%–9% of the population in the developed nations will be 80 years or older.[1–9]

This graying of the population in the developed world is largely due to several demographic factors. This includes a decline in the mortality rate especially from cardiovascular diseases and decreased fertility rates in much of the developed world. The post-World War II baby boom generation in the USA consists of 75 million persons born between 1946 and 1964. These people will be entering the geriatric population over the next 20 years.[1–9]

This increased population of elder persons will have a major impact on the delivery of healthcare. The majority of elder patients suffer from chronic medical conditions and many have limitations on daily activities. Persons over 75 years of age require the greatest amount of medical care per capita of any age group. In addition, the social support systems of the elderly are often less than optimal, with many elderly persons living alone.[1–9]

The number of ED visits in the USA has increased by 26% in the past decade. Elder persons are the most frequent users of the emergency healthcare system. Each year, in the USA there are 64 emergency department visits for each 100 persons over 75 years of age. Heart disease is the most frequent ED diagnosis for elder patients.[10] In 1995, approximately 16% of emergency department visits in the USA were made by patients 65 years or older. Of the 100 million emergency department visits in 1995, it is estimated that 15.7 million patients were 65 years or older, with the most common symptoms related to ischemic heart disease or cardiac dysrhythmias. More than 300 000 elderly patients are treated for cardiac arrest in emergency departments in the USA each year.[1,5] Of patients seen in the emergency department, elderly patients are seven times more likely to be admitted to the hospital, five times more likely to be admitted to an intensive care bed and five times more likely to use ambulance transport compared to younger adult patients.[11] Elder patients seen in the ED are generally sicker than younger patients. Approximately 47% of older patients seen in the ED receive comprehensive ED care, 46% are admitted to the hospital and 39% arrive by ambulance.[11] As the number of elder persons increases over the next four decades and medical resources come under scrutiny, it will be a challenge to ensure that the emergency care needs of elder patients are met.

Aging and the cardiovascular system

The functional reserve of the cardiovascular system and the ability to tolerate stresses such as cardiac arrest or

acute myocardial infarction decline with age. Although elder persons constitute a heterogeneous group, coronary artery disease, valvular heart disease, hypertension, and myocardial infarction all increase with age.[1–7,12–14] It is difficult to sort out whether it is age itself or accompanying cardiovascular diseases that are responsible for cardiac problems in the elderly. As people age, their arteries stiffen, resulting in increased systolic blood pressure.[1–7,12–14] Left ventricular hypertrophy may accompany the rise in arterial systolic pressure. There is no change in resting heart rate. Nevertheless, maximal heart rate and aerobic capacity decrease with age. The lack of heart rate response to exercise or stress means that cardiac output must be maintained by increases in stroke volume and cardiac dilation.[14] As people age there is increased myocardial stiffness which impairs left ventricular filling increasing the risk for heart failure and arrythmias. About 50% of elder patients have abnormalities in their resting electrocardiogram. With advanced age, there is also an attenuation of responsiveness to beta-adrenergic stimulation.[1–9,12–14]

About 60% of acute myocardial infarctions occur in patients 65 years of age or greater. All of the physiologic changes associated with aging, and particularly the lack of cardiovascular reserve, contribute to the high mortality after acute myocardial infarction in elder persons.[1–7,15–20] Patients over 75 years have a much higher mortality from acute myocardial infarction compared to younger patients. In the GUSTO trial patients 75 years and greater had more than a fourfold increase in mortality compared to those under 65 years. This is thought to be due to comorbid diseases, physiologic dysfunction and lack of physiologic reserve.[21]

Older patients also have a higher mortality some time after myocardial infarction compared to younger patients. Rich *et al.* found the 1-year postdischarge mortality following an acute myocardial infarction was 6.8% in patients under 70 years and 19.1% in those 70 years or older. Hospital mortality was 5.6% in patients under 70 years and 16.1% in patients 70 years or older. Even after adjusting for multiple baseline and therapeutic differences in elder persons, age remained a strong predictor of worsened in-hospital and 1-year mortality.[15] Posthospital mortality is also increased three- to fourfold in elder patients.

The presentation of acute myocardial infarction changes with age. Elderly patients present with atypical symptoms such as shortness of breath, syncope, or confusion. This fact may contribute to a delay in treatment and increased mortality of older persons with acute myocardial infarction. Fewer than half of patients 85 years or older with acute myocardial infarction present with chest pain.[1–5,22]

Ironically, elder patients who are at greater risk for death following acute myocardial infarction are less likely to receive aggressive treatment such as emergent reperfusion.[15,19,23] Even though this observation is partially explained by the atypical presentations and contraindications for some treatments, many elderly patients who are eligible for aggressive treatment do not receive them. In a recent study of more than 2000 older patients with acute myocardial infarction, Magid *et al.* found that older patients were less likely to receive standard treatments even when treatments are controlled for contraindications and atypical presentations. Only 81% of eligible elder patients received aspirin, 60% received beta-blockers, and 78% received acute reperfusion therapy.[23] Weaver *et al.* found that only 25% of potential candidates 75 years or older who would have been eligible to receive thrombolytics were given this therapy.[19] Some healthcare professionals are hesitant to administer key treatments to elder patients; this is unfortunate because older patients with acute myocardial infarction are at the highest risk and have the most to gain in mortality and morbidity benefits.

Outcomes of cardiopulmonary resuscitation in elder persons

The outcome of resuscitation attempts for cardiac arrest in elder persons has been a subject of debate and conflicting recommendations in the medical literature. Comparing different studies in the medical literature is often difficult. Many of the studies looked only at specific populations, such as elderly patients in a nursing home or geriatric unit. Other studies do not differentiate the effects of age from those of other factors such as comorbid diseases, which have a profound effect on survival from cardiac arrest. In some studies of out-of-hospital cardiac arrest, resuscitation rates of elderly and non-elderly patients were not compared. This is important because successful resuscitation of all patients depends highly on the efficiency of the emergency medical services (EMS) system (bystander CPR, time to defibrillation, and other factors). Consequently, without studying a broad population including both older and younger patients, it may be unclear whether poor survival is due to age or an inefficient EMS system. Finally, studies define the elderly population differently: ages above 60, 65, 70, 75 or 80 years have all been used to define an elderly population.

One of the issues in dealing with the special needs of elder patients is understanding societal attitudes about aging. Many misperceptions, even among healthcare professionals, result in stereotyping. For example, some people

believe that elder persons who are resuscitated have severe neurologic impairments; therefore some healthcare professionals treat elderly patients less aggressively than they treat younger patients with the same disease. Words in the medical literature are indicative of attitudes. For example, the following titles appeared in prestigious journals: "Should the Elderly be Resuscitated Following Out-of-Hospital Cardiac Arrest?" and "Resuscitation of the Elderly: a Blessing or a Curse?"[24,25] Particular care should be taken in distinguishing attitudes from scientific data and policy recommendations.

Murphy *et al.* studied 503 patients who suffered cardiac arrest in five Boston health care institutions.[26] Only two of the institutions were acute care hospitals, one was a long-term care institution, and two were chronic care hospitals. Of 503 cases reviewed, 112 (22%) had return of spontaneous circulation, but only 19 (3.8%) survived to hospital discharge.[26] Poor outcomes were noted for patients who had unwitnessed or out-of-hospital arrests or arrests associated with an initial rhythm of asystole or pulseless electrical activity. The prognosis was also very poor in patients who had two or more acute diseases or a severe underlying chronic disorder.

This article was accompanied by an editorial in the *Annals of Internal Medicine* by Podrid, who used these data to demonstrate the futility of resuscitating elderly patients in a cost-conscious environment with a shortage of critical care beds.[25] The editorial states:

When a person is an in-patient, resuscitation should not be attempted even in the absence of a "do not resuscitate" order. . . . In view of the findings of this study, it is perhaps time to establish meaningful guidelines for do not resuscitate orders in the elderly hospitalized patient in order to spare them costly, artificial, and uncomfortable measures that only serve to delay death. . . . Is it reasonable or fair to use critical care beds, which are costly and in short supply, to provide intensive care for those patients who are unlikely to recover or even survive the hospitalization? In this cost conscious environment our resources must be more efficiently allocated to those who are most likely to benefit from them.

This editorial is particularly interesting in light of the significant flaws in the study by Murphy *et al.*[26] Although the data are interesting and provide a basis for discussion, they are far from convincing and are contradicted by subsequent studies. Murphy *et al.* describe resuscitation success in an elderly population in the Boston area without comparing it to a control group of non-elder persons in the same area. Out-of-hospital resuscitation success depends highly on an effective EMS system. What was the level of EMS provided in the Boston area at the time of the study? Becker *et al.* had shown that, while some cities have developed highly sophisticated EMS systems that produced

significant resuscitation and survival rates, other cities such as Chicago have dismal resuscitation rates for all patients in cardiac arrest.[27] In a more recent study, survival rates for all patients suffering cardiac arrest in Los Angeles were less than 2%.[28] Is the observation of poor survival in the elderly population the result of age or of a poor EMS system? Another concern is that Murphy *et al.* mixed populations from a number of healthcare institutions including two acute care hospitals, two chronic care hospitals, and one long-term care institution; yet the conclusions and implications do not clearly distinguish these populations. Is it fair to lump these populations together when many patients in the database were in chronic care facilities? Are there enough data to make conclusions about all elderly patients? Patients, especially in chronic care facilities, have significant comorbid diseases, a fact that was demonstrated in the article by Murphy *et al.* Patients who had two or more acute problems or one chronic disease had a poor prognosis for long-term survival. Were the poor outcomes the result of age itself or the comorbid diseases that may occur at any age?

Out-of-hospital arrest

The Belgian cerebral resuscitation study group analyzed 2776 out-of-hospital cardiac arrests to determine the effect of age on outcome and neurologic deficit.[28] Overall, 23% of patients were admitted to the hospital and 8% were discharged alive. Age had no effect on hospital admission or discharge rates. Seven percent of patients under 40 years survived to discharge, compared to 7% of patients aged 70 to 79 years and 6% of patients older than 80 years. After cardiac arrest, age had no effect on subsequent death from neurologic causes. There was, however, a significant difference in non-neurologic deaths across the age groups. After resuscitation, more elderly patients died in the hospital from non-neurologic causes than did non-elderly patients. The investigators also compared the effect of age on outcome according to prearrest health status. Although elderly patients more frequently had a dependent lifestyle before the arrest, there was no effect of age on outcome adjusted for prearrest health state. Pulseless electrical activity occurred more frequently in patients 70 years or older (12% vs. 9%). The authors concluded that decision making in cardiac arrest should not be based on age and that age was not associated with overall poor survival or neurologic disability.[29]

Longstreth *et al.* reviewed the relation between age and outcome in patients treated for out-of-hospital cardiac arrest in Seattle over a 5-year period.[30] Outcomes of 1405 patients 70 years and older were compared to 1624

younger patients. There was no difference in elderly vs. non-elderly patients with regard to resuscitation success (27% vs. 29%) or discharge rate from the hospital (10% vs. 14%). Twenty-four percent of elderly patients with ventricular fibrillation were discharged from the hospital alive. The authors concluded that elderly patients can benefit from attempted resuscitation from out-of-hospital cardiac arrest.[30]

In a series of important studies, Tresch *et al.* provided further insight into the etiology of cardiac arrest in elder persons. They studied 1345 adult victims of out-of-hospital cardiac arrest,[31] and found that ventricular fibrillation as the initial rhythm in cardiac arrest decreased as the age of the patient increased, whereas pulseless electrical activity progressively increased (Fig. 54.1). Fifty-eight percent of patients under 70 years of age demonstrated ventricular fibrillation, compared to 44% of patients over 70 years. Overall, 16% of patients under 70 years of age survived to hospital discharge compared with 9% of patients older than 70 years.

In another study, Tresch *et al.* analyzed 381 patients who had out-of-hospital cardiac arrest witnessed by paramedics.[32] Elderly patients were significantly more likely to have a past history of congestive heart failure (25% vs. 10%) and were more commonly taking digoxin (40% vs. 20%) and diuretics (35% vs. 25%). Before the cardiac arrests, elderly patients were more likely to complain of dyspnea

Fig. 54.1. Difference in initial rhythm by age group for patients with out-of-hospital cardiac arrest. Note greater prevalence of electromechanical dissociation (*EMD*) (pulseless electrical activity) and lower prevalence of ventricular fibrillation (*VF*) in older age groups. (From ref. 31. Reprinted with permission from *American Journal of Cardiology.*)

(53% vs. 40%), whereas younger patients were more likely to complain of chest pain (23% vs. 13%). Ventricular fibrillation was more likely to occur as the initial rhythm in cardiac arrest in younger than in older patients (42% vs. 22%). There was no difference in successful resuscitation rate between younger and elderly patients; however, 24% of younger patients survived to hospital discharge compared to 10% of elder patients. Survival to hospital discharge depended on the patient's age, presenting complaint, and initial cardiac rhythm associated with the arrest. In elder patients, 58% survived if their complaint was chest pain and if ventricular fibrillation was their initial arrest rhythm.[32] This study gives us insight into the etiology of cardiac arrest in elderly patients. It reinforces the concept that chest pain is less common in elder patients as a presenting symptom and that in elder patients congestive heart failure and dyspnea are more common symptoms (and possibly etiologies) of their arrest. Even though resuscitation rates are similar in elderly and younger patients, more elderly patients die postresuscitation in the hospital. This is consistent with the concept that elderly patients have less cardiovascular reserve to withstand the insult of a cardiac arrest and postarrest complications.

Herlitz *et al.* reviewed factors associated with resuscitation in more than 8000 patients in Sweden. The proportion of patients with a cardiac etiology of the arrest increased with age. Fewer patients over 75 years presented with ventricular fibrillation as their initial rhythm. Overall, 1-month survival was worse in older patients, 4.5% for those less than 65 years, 3.2% between 65 and 75 years and 2.5% over 75 years of age. The authors noted that they did not control for comorbid diseases and their effect on outcome in older persons.[33]

Swor *et al.* investigated whether age was a factor in the survival to hospital discharge for more than 2500 patients suffering cardiac arrest over a four year period. Patients 80 years or older were more likely to arrest at home and more likely to have a bradyasystolic initial rhythm than younger patients. Ventricular fibrillation was the initial rhythm in 64% of patients age 40–49 years, but found in only 40% of patients 80 years and older. Survival to hospital discharge was significantly decreased in patients 80 years and older. Only 3.3% of patients over 80 years survived compared to 7.1% of patients age 70–79 and 8.1% for age 60–69. Though the prognosis was not dismal for patients over 80 years, age was an independent factor for decreased survival. In this study, comorbid disease was not taken into account as a variable affecting outcome.[34]

Iwami *et al.* reviewed out-of-hospital cardiac arrest in Osaka, Japan over 2 years. They found that the annual
incidence of arrest increased with increasing age. This was due to an increase in cardiac causes of arrest with age, while non-cardiac etiologies of arrest decreased with age. The incidence of witnessed ventricular fibrillation also decreased with age. Overall survival decreased with age. However, some of the decreased survival may have been due to other factors including comorbid diseases.[35]

In summary, the studies on the effect of age on out-of-hospital cardiac arrest show a consistent pattern. Resuscitation of older patients in cardiac arrest is not futile. Many studies show that the overall prognosis for survival is worse for patients age 80 or greater. This observation holds when other emergency medical service factors are accounted for such as bystander CPR, witnessed arrest, time to defibrillation and initial rhythm. Most studies of out-of-hospital arrest, however, do not take into account the important prognostic factors of comorbid diseases and baseline health status. Since older people generally have more comorbid diseases than younger adults, it is unknown whether it is age itself or the comorbid diseases that are responsible for the worse prognosis after age 80. It is also clear from multiple studies that the pattern of cardiac arrest in older persons is different from that in younger adults. Arrests are less frequently witnessed, more frequently of a cardiac etiology and most importantly, less frequently presenting with ventricular fibrillation as an initial rhythm.

In-hospital arrest

Bedell *et al.* studied prognostic factors that determine outcome after in-hospital CPR in 294 patients at a university hospital in Boston.[36] Overall, 14% of patients were discharged alive, with 11% of the 294 patients alive at 6 months. A multivariate analysis showed that pneumonia, hypotension, renal failure, cancer, and a home-bound lifestyle before hospitalization were associated with poor survival. None of the patients in whom the resuscitation attempts took more than 30 minutes survived to hospital discharge. Age did not appear to influence prognosis for survival after CPR or adjustment to illness after discharge from the hospital.[36]

Taffet *et al.* reviewed in-hospital CPR efforts for 77 patients 70 years or older in a Veterans Administration hospital in Houston.[37] Thirty-one percent of patients had return of spontaneous circulation, and 22% were alive after 24 hours, but none survived to hospital discharge. In contrast, 16% of younger patients suffering cardiac arrest were discharged alive. A multivariate analysis indicated that the presence of sepsis, cancer, increased age, number of medications, and absence of witnessed arrest were statistically

predictive of a poor outcome.[37] In another study that took place over many years, Gordon and Cheung retrospectively reviewed cardiac arrests in a frail elderly population in a multilevel geriatric care institution.[38] Forty-one patients underwent CPR, and four long-term survivors lived for 60 days or longer. No patient with unwitnessed arrest survived for 60 days. Notably, three of the four survivors were not chronically ill.[38]

Bayer *et al.* reviewed 106 cardiac arrests in a geriatric unit: 39% were successfully resuscitated, 17% were discharged from the hospital, and 15% were alive at 3 months. These survival rates were comparable to those of younger patients. The authors thought that age had no influence on outcome and concluded that resuscitation attempts on geriatric units can benefit a significant minority of patients.[39]

Parish *et al.* assessed the records of more than 2000 patients who suffered in-hospital arrest. The overall survival to hospital discharge was 27%. Geriatric patients had a 24% survival to discharge while other adult patients had a 29% survival rate. Younger age and initial rhythm were correlated with survival. The researchers did not control for comorbid diseases.[40]

De Vos *et al.* reviewed the charts of 553 patients who received in-hospital CPR to determine risk factors for poor survival. Overall, survival to hospital discharge was 22%. Independent risk factors for non-survival were an age of 70 years or older, renal failure before admission and congestive heart failure during hospitalization. Patients with risk factors had a projected survival of less than 10%.[41]

Di Bari *et al.* did a retrospective review of 245 cardiac arrests in a geriatric unit. Overall, long-term survival was 17%. The investigators compared patients above and below 70 years of age. Independent predictors of short-term survival were the initial rhythm in arrest, acute myocardial infarction, heart failure and hypotension. Long-term survival was negatively associated with heart failure. Age was not an independent risk factor when the researchers controlled for comorbid diseases.[42]

Hajbaghery *et al.* reported on factors influencing survival after 206 patients with in-hospital cardiac arrest in Kashan, Iran. Predictors of survival to hospital discharge were CPR duration, time of cardiac arrest, time from cardiac arrest to CPR and defibrillation. Age was not an independent prognostic factor.[43]

Sandroni *et al.* evaluated factors affecting the outcome of 114 patients with in-hospital cardiac arrest over 2 years. The key factor determining survival to hospital discharge was the time to arrival of the cardiac arrest team. Age was not a factor in the survival outcome.[44]

In summary, studies on in-hospital cardiac arrest consistently demonstrate the importance of comorbid

diseases and systemic factors in responding to the arrest. In some studies age was an independent factor and in others age was not a factor. It is clear that clinicians should not consider it futile to resuscitate elder patients in cardiac arrest.

Prognosis after return of spontaneous circulation

The hospital course and long-term survival in elderly and younger patients who were successfully resuscitated after out-of-hospital cardiac arrest was also investigated by Tresch *et al.*[24] The investigations were designed to determine whether elderly patients had worse neurologic outcome and utilized more hospital resources than did non-elderly patients. Although hospital deaths were more common in elderly patients resuscitated from cardiac arrest compared to non-elderly patients, the lengths of hospitalization and stay in intensive care units were not significantly different between the age groups. The number of neurologic deaths and residual neurologic impairments were similar in both age groups. Long-term survival curves demonstrated similar survival in both

patient groups after hospital discharge, with approximately 65% of hospital survivors alive at 24 months after discharge (Fig. 54.2).[24] In this important study the authors concluded that resuscitation of elderly patients who suffer out-of-hospital cardiac arrest is appropriate. Although elderly patients are more likely to die during hospitalization, the hospital stay and residual neurologic deficits are no different from those in younger patients.

Studies seem to reinforce the concept that resuscitation of the elderly in cardiac arrest will benefit a significant minority of patients. Elder patients often have more comorbid diseases, and their cardiovascular systems have less reserve. These factors may influence the etiology of the arrest; congestive heart failure and respiratory problems may be more important etiologies in elder persons who suffer cardiac arrest than they are in younger adult patients. We have a similar concept regarding the importance of respiratory compromise as an etiologic factor in children suffering cardiac arrest. Ventricular fibrillation appears to be less common as the initial rhythm, whereas pulseless electrical activity is more common. Since our treatment for the latter condition is much less satisfactory than for ventricular
Fig. 54.2. Comparison of long-term survival curves for elderly (70 years and greater) and non-elderly patients. (From ref. 24.)

fibrillation, this may account for some of the observed differences in outcome.

It is also clear that many laypersons as well as healthcare professionals fear that by attempting to resuscitate elderly patients, they risk the possibility of resuscitating patients who are severely neurologically compromised and consume much of society's health care resources. In fact, all the data in the literature indicate that neurologic disability, neurologic deaths, and even hospital resource use are similar for elderly and younger patients following resuscitation from cardiac arrest.

Ethical issues

Ethical issues concerning resuscitation of elder persons are not unique to this population. The same concerns should be relevant to any patient suffering cardiac arrest or in a critical condition. Advance directives have become common in the USA's healthcare system and are particularly relevant where decisions concerning resuscitation must be made immediately. Advance directives convey the wishes of the patient with respect to specific treatment, including resuscitation from cardiac arrest. Written directives in the form of living wills or other recognized documents that specifically direct healthcare providers how to treat patients are particularly useful. Directives that specify "do not attempt resuscitation" (DNAR) are one form of advance directive. These can be portable and used out of the hospital as well as in healthcare institutions. Many EMS systems throughout the USA have standardized portable DNAR forms that a relative can present to the emergency healthcare personnel. Emergency healthcare professionals should respect the wishes of the patient when presented with valid advance directives not to attempt resuscitation.

In effect, advance directives allow patients to make decisions about their healthcare even if they are unconscious or incapacitated. The underlying assumption, however, is that it is the patient who makes the decision about resuscitation. A more thorough discussion of ethical issues in resuscitation can be found in Chapter 66.

Therapeutic considerations

Most studies in the medical literature have focused on the outcome of cardiac arrest in the elderly population. There are few data to modify the existing recommendations for the treatment of older patients in cardiac arrest. Recommendations regarding therapy are therefore based on consideration of the etiology of cardiac arrest. During the cardiac arrest sequence it is important to realize that ventricular fibrillation is less common in elder persons and pulseless electrical activity is more common compared to other adult cardiac arrests. Aggressive anticipation of extracardiac causes of pulseless electrical activity such as hypovolemia from a ruptured aneurysm or dehydration is especially important. Attention to hypoxia is also important, particularly since so many patients present with dyspnea and congestive heart failure.

Recognition that acute myocardial infarction in elder persons can present with atypical symptoms is probably the most important factor preventing cardiac arrest in these patients. Symptoms include dyspnea, dizziness, syncope, and weakness, as well as chest discomfort. Elder persons have a high mortality following an acute myocardial infarction. Therefore, it is most important to treat myocardial infarction in such patients aggressively. Early use of reperfusion strategies as well as other treatments that may limit infarct size is more important in the elderly than in a younger population.

Future directions

In the future it will be important for research to focus on the special etiology and therapeutic needs of the elderly in cardiac arrest. Academicians must do a better job of teaching emergency healthcare personnel about the special needs of elderly patients and the importance of aggressive management of cardiovascular diseases.

Asphyxial cardiac arrest

Peter Safar, Norman A. Paradis[1] and Max Harry Weil[2]

[1]University of Colorado Health Sciences Center
[2]Weil Institute of Critical Care Medicine

There is no malice in this burning coal;
The breath of heaven has blown his spirit out . . .
But with my breath I can revive it, . . .

William Shakespeare

Although asphyxia literally means no pulse (in Greek), it represents an inability to breathe and therefore suffocation. Failure of gas exchange is characterized by hypoxemia and hypercarbia, as originally defined by J.B.S. Haldane.[1] A mechanistic classification of asphyxia (Table 55.1) includes a diversity of pathophysiological processes that preclude movement of gas from the upper airway to the alveoli and ultimately to the tissues, the cells, and then to the mitochondria, thereby sustaining oxidative metabolism in vital organs.

Asphyxia is a cause of sudden death,[1–3] but in contrast to primary cardiac causes, it more often presents with bradycardia and asystole rather than ventricular fibrillation (VF).[4–8] In children, normothermic cardiac arrest is predominantly due to asphyxia. Asphyxia is also the predominant mechanism of cardiac arrest in neonates[9,10] and in infants due to the so-called sudden infant death syndrome,[11,12] Status asthmaticus is an important cause of asphyxia.[13] The most frequent cause is failure of respiratory muscle function.[1–3] Outcomes are worse when VF evolves during asphyxial cardiac arrest than after primary VF in adults.[9–14]

Anoxia or *hypoxia* is defined by critical reductions in arterial oxygen saturation (SaO_2) or arterial oxygen tension (PaO_2). *Hypercarbia* is defined by increases in arterial carbon dioxide tension ($PaCO_2$) in settings of inadequate alveolar ventilation and usually in association with hypoxia.

The more recent and large focus on sudden cardiac death predominantly due to VF followed the introduction and

Table 55.1. Mechanisms of asphyxia

- Impaired alveolar ventilation of neuromuscular cause including impairment of spinal cord, peripheral nerve, in end-plate functions such as myasthenia gravis, neuromuscular blockade
- Obstruction of the airway by foreign particulates, aspiration, blood clots
- Obstruction of the upper airway by soft tissue, especially the tongue, epiglottis
- Mechanical constraints of chest expansion, tension pneumothorax, flail chest
- Tracheobronchial disruption due to trauma, tumor
- Drowning, laryngospasm
- Allergic or inflammatory disease of the airways (tracheitis, asthma, chronic obstructive pulmonary disease)
- Drug-induced apnea caused by sedatives, narcotics, anesthetic agents, neuromuscular blockade
- Generalized seizures (e.g., status epilepticus)
- Cardiogenic and permeability pulmonary edema
- Pulmonary thromboembolism
- Interstitial lung diseases
- Impaired oxygen availability, altitude, confined spaces
- Anemia, including acute hemorrhage, hemodilution
- Hemoglobinopathies, carboxy- and methemoglobinemia, cyanide intoxication
- Neonatal uteroplacental dysfunction, umbilical cord compression
- Sudden infant death syndrome

routine use of defibrillators. Historically, however, resuscitation first focused on patients who had stopped breathing. Indeed, drowning was the first to receive attention and the management of victims of drowning predominated in the

evolution of out-of-hospital resuscitation medicine.[1] The "humane societies" of London and Copenhagen were organized for that purpose (see Chapter 1).[1] There is usually opportunity for distinguishing between dysrhythmic cardiac arrest of primary cardiac cause and asphyxia in settings of witnessed cardiac arrest. The time course of asphyxial cardiac arrest is typically prolonged and preceded by overt signs, in contrast to dysrhythmic arrest and sudden death.[3,14–17]

Asphyxia also terminates life either at the beginning or at the end of natural life. Intrauterine asphyxiation and peripartum asphyxiation are major causes of perinatal injury and death.[9,10]

Mouth-to-mouth ventilation was described in the old testament.[18] The earliest implementation of mouth-to-mouth artificial ventilation of asphyxiated newborn infants was by midwives.[1] Before the advent of vaccines and antibiotics, diphtheria- or "croup"-induced laryngeal obstruction or bronchiolitis in the young and pneumonia in the elderly were common causes of fatal asphyxia. Today, increased immune suppression for treatment of autoimmune diseases, chemotherapy for malignancies, and prevention of transplant rejection, as well as the increasing problem of antimicrobial resistance, the incidence of infectious diseases may once again increase. Asphyxia also occurs as a complication of permeability pulmonary edema including the adult respiratory distress syndrome (ARDS). ARDS remains one of the most intractable problems in critical care medicine. Asphyxia therefore remains a major cause of fatalities over the entire age spectrum.

Unlike sudden cardiac arrest, cardiopulmonary dysfunction during asphyxiation is progressive.[19–23] Claude Beck, a famed cardiac surgeon who is credited with electrically defibrillating the heart during surgery,[4,5] observed that the asphyxiated heart became cyanotic. This contrasted with regional ischemia which he described as pink as it advanced to cell death due to myocardial infarction.

Asphyxial cardiac arrest progresses from initial tachycardia to progressive bradycardia terminating in electromechanical dissociation (EMD), now more appropriately described as pulseless rhythm. Cardiac arrest terminates in electrical asystole.[3,20] Prompt reversal of asphyxia minimizes cellular injury and irreversibility.

Complete airway obstruction is typically followed by apnea based on studies in experimental animals (Fig. 55.1).[14–17,19,21–36] Anatomical differences between animal models and patients have been cited by the late Professor Peter Safar as important. Humans and some primates have a kinked upper airway, with greater likelihood of obstruction in comatose patients.[37–43] In contrast, dogs

and pigs have a relatively straight upper airway that is more likely to remain open even in the absence of tracheal intubation. Intermittent chest compression may produce adequate tidal volumes in animals without airway obstruction, but not necessarily in comatose human victims and this was ascribed by Professor Safar to differences in anatomy and therefore airway patency.[6,45,48]

Asphyxia has also been documented in patients caused by extravasation of blood during jugular vein cannulation, tracheobronchial thrombus, and esophageal polyps.[41–44]

Pathophysiology

During cardiac arrest, the heart and the brain become the most vulnerable organs.[2,3] This applies to both asphyxial and dysrhythmic cardiac arrest. Current techniques of cardiopulmonary-cerebral resuscitation (CPCR) for re-establishment of spontaneous circulation differ contingent on either asphyxial or dysrhythmic cause. In both instances, however, global brain ischemia is followed by cerebral ischemic injury. Its pathophysiology is more specifically reviewed in Chapters 5 and 13.

Haldane regarded asphyxia as a combination of hypercarbia and hypoxemia in which hypercarbia may make the machine malfunction, but it is hypoxemia that not only stops the machine but also wrecks the machinery.[1] Henderson[9] differentiated among apneic asphyxia, acarbic asphyxia as in carbon monoxide poisoning, and chronic asphyxia as in anemia. Alveolar anoxia alone, without hypercarbia, stops the heart in systole. Hypercarbia without hypoxemia produces hypercarbic acidosis and may impair cardiac function but does not stop the heart beat.[49–56]

Dysrhythmic cardiac arrest represents perfusion failure of the myocardium and therefore failure of oxygen delivery to sustain myocardial metabolism. When patients are maintained on total cardiopulmonary bypass (CPB), no ventilation is required because gas exchange is supplied by the extracorporeal circuit. This contrasts with patients who have supranormal minute ventilation but impaired alveolar ventilation characteristic of respiratory distress syndromes. Accordingly, *processes that critically reduce cellular availability and use of oxygen in the absence of circulatory failure* are appropriately defined under the umbrella of asphyxia (Fig. 55.2).

The asphyxial syndromes are categorized in Table 55.1 and Fig. 55.2. Asphyxia may interfere with energy metabolism at multiple sites between *mouth* and *mitochondria*. Airway obstruction is selectively asphyxial. Impediments to ventilation, such as tension pneumothorax, may impair
Fig. 55.1. Experimental asphyxiation to cardiac arrest and resuscitation by standard external CPR with intravenous epinephrine and NaHCO3. Electrocardiogram (ECG) and mean and cyclic arterial pressure (MABP) in lightly anesthetized rat before, during, and after apneic asphyxiation. (From Katz L, Ebmeyer U, Safar P, Radovsky A, Neumar R. Outcome model of asphyxial cardiac arrest in rats for functional and morphologic evaluation of cerebral resuscitation. *J Cereb Blood Flow Metab* 1995.)

oxygen delivery and therefore organ function through a combination of asphyxial and circulatory mechanisms.

Airway obstruction may produce initial hypoventilation and terminate in apnea after consciousness is reduced.[2,38] Coma, in contradistinction to sleep, is characterized by a loss of muscle function such that the tongue and epiglottis are no longer lifted off the posterior pharyngeal wall.[38] Backward tilt of the head, and in some victims, forward displacement of the mandible lifts the tongue and epiglottis and thereby restores patency of the air passage (Fig. 55.3).[37–43] Approximately one-third of comatose patients require forward displacement of the mandible as part of the so-called triple airway maneuver (Fig. 55.4).[37,38] Intermittent or continuous positive-pressure ventilation

(IPPV, CPPV) minimizes laryngospasm.[57] Nasal obstruction is usually expiratory because of valve-like function of the soft palate.[39,40] If the larynx itself is obstructed, tracheal intubation or cricothyrotomy are life-saving (Fig. 55.5). In settings of asphyxia in a conscious patient, there is a high likelihood of full recovery if ventilation is promptly restored. After cardiac arrest, ventilation and chest compressions have a lesser likelihood of successful outcomes even if spontaneous circulation is restored. Cerebral recovery is likely to be incomplete.[32–34]

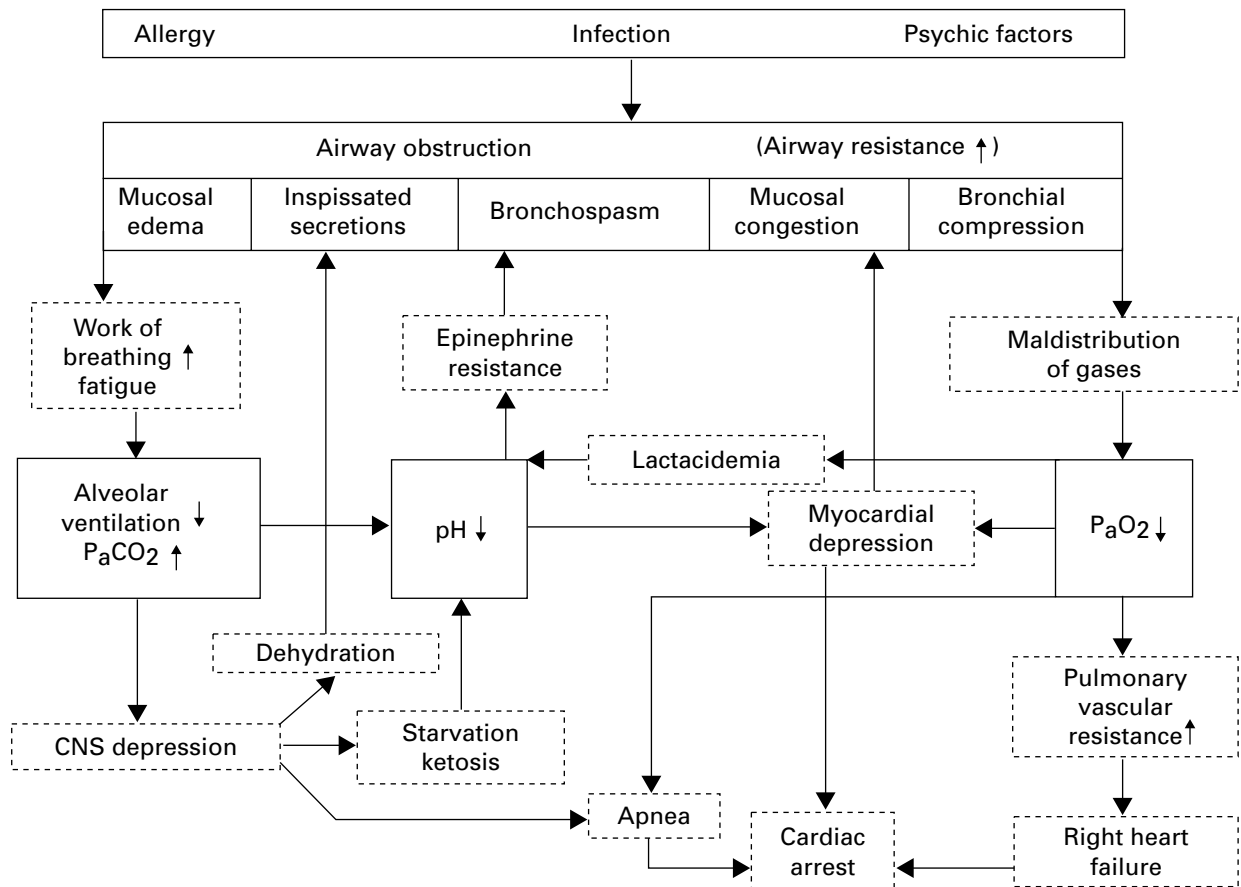
Apnea or complete airway obstruction in adult humans breathing air is followed by critical decreases in arterial O_2 saturation to less than 80% within 60 seconds.[37,58] Without alveolar ventilation, arterial PCO_2 increases by 5 to 7 mm


Fig. 55.2. Pathophysiology of asphyxiation in status asthmaticus. Vicious cycle and progression of asphyxiation. Hypoxemia and acidemia (respiratory plus metabolic) are the focal derangements leading to death. (From Safar P. Recognition and management of airway obstruction. *J. Am. Med. Assoc.* 1969; 208: 1008–1011.)

Hg/min. A small number of effective inflations, even with exhaled air, will rapidly normalize blood gas values.[37,58]

Sudden onset of apnea progresses at a slower rate to asphyxial cardiac arrest than does complete airway obstruction during which spontaneous breathing efforts increase oxygen demands.[59] Sudden apnea may result from traumatic or electrical injury, anesthesia, muscle relaxants, narcotics, or hypnotics, or cerebral injury with a sudden increase in intracranial pressure.

In conscious persons, upper airway obstruction provokes coughing, and this represents a spontaneous attempt to relieve obstructions. Powerful ventilatory efforts may clear the airway. Partial obstruction also provokes vigorous ventilatory efforts, which may reduce rather than increase arterial Pco_2. Hypoxemia can be exacerbated by reflex-induced bronchospasm or laryngospasm.

Airway obstruction that provokes increased ventilatory efforts, including exaggerated intercostal and suprasternal retractions, provokes autonomic discharges and in turn, hypertension and tachycardia. A brief interval of hypertension is then followed by hypotension in part due to myocardial impairment. Vagotonus accounts for nodal rhythms followed by ectopic ventricular beats terminating in ventricular asystole or an agonal rhythm or electric asystole.

If the victim is breathing room air, complete airway obstruction is followed by a fall in arterial Po_2 of 30 mm Hg and arterial O_2 saturation to 60% or less after approximately 2 minutes. The decline is coincident with loss of consciousness. Between 3 and 10 minutes after complete airway obstruction, apnea and pulselessness supervene. When the arterial Po_2 is reduced to approximately 20 mm Hg, apnea begins. The arterial PCO_2 is over 70 mm Hg, and the arterial pH is about 6.8 to 7.0. Pulselessness occurs when the arterial PO_2 is approximately 10 mm Hg and the arterial pH is 6.3 to 6.8.[17] When arterial pressure decreases below 30 mm Hg, pupillary dilation occurs and progresses
Fig. 55.3. Upper airway (hypopharyngeal) soft tissue obstruction in comatose (anesthetized) adult human. (*Top*) Backward tilt of head stretches anterior neck structures and lifts base of tongue off posterior pharyngeal wall and epiglottis of larynx entrance. (*Bottom*) With head in mid position or flexed, there is hypopharyngeal obstruction by the tongue and laryngeal obstruction by the epiglottis. (From Safar P, Escarraga LA, Chang F. Upper airway obstruction in the unconscious patient. J Appl Physiol 1959; 14: 760–764.)

to an isoelectric electroencephalogram (EEG). With systolic pressure below 25 mm Hg, PEA is apparent.[20–36] Eventually the arterial pressure tracing is almost flat, but ECG complexes may continue, possibly for 5 minutes or longer. Thus complete airway obstruction after air breathing causes clinical death (pulselessness) in 5 to 10 minutes.

After resuscitation from asphyxial cardiac arrest, the circulatory and metabolic abnormalities are similar to those of sudden cardiac arrest due to VF.[3,27,44] Asphyxial arrest is more likely than fibrillatory arrest to cause cerebral ischemic injury.[32–34]

Asphyxia disrupts homeostasis through the interruption of O_2 delivery to the mitochondria. Once the balance between O_2 supply and demand is disturbed, cellular

hypoxia occurs and pyruvate produced by anaerobic glycolysis is converted to lactate. Initial respiratory acidosis becomes combined respiratory and metabolic acidosis (Fig. 55.2). Elevated serum lactate and increases in tissue PCO_2 are among the most sensitive indicators of impaired cellular respiration. It has been suggested that elevated tissue lactate and PCO_2 may of themselves mediate brain injury during asphyxia but the evidence is not persuasive.[60–62]

Effects of hypercarbia

During apnea the increase in arterial PCO_2 is approximately 5 to 7 mm Hg/min. In healthy persons, pre-ventilation with 30% O_2 will maintain arterial PO_2 above 75 mm Hg for at least 5 minutes. Pre-ventilation with 100% O_2 and complete denitrogenation can maintain arterial PO_2 above 75 mm Hg for over 30 minutes if there is no impairment in alveolo-capillary diffusion. The arterial PO_2 declines when alveolar O_2 is displaced by CO_2 followed by right-to-left shunting associated with absorption atelectasis of oxygen-filled alveoli. Hypercarbia alone rarely results in death; dogs can tolerate artificial ventilation with up to 70% CO_2 (30% O_2).[53,54] Hypotension begins when the arterial pH decreases to approximately 6.8 and cardiac arrest is likely to occur after arterial pH decreases to 6.5 units. In animals this may require as long as 30 minutes after arterial PCO_2 has risen to about 340 mm Hg provided that arterial PO_2 is maintained above 80 mm Hg. Humans can survive such severe hypercarbia provided that oxygenation is adequately provided so that return to normocarbia is gradual to avoid ventricular arrhythmias attributed to rapid potassium shifts.[50–55]

Neurologic injury and comparison of asphyxia and ventricular fibrillation

VF-induced normothermic cardiac arrest of 3 to 4 minutes' duration can be reversed with complete neurologic recovery and histologically preserved brain. After 5 minutes of VF there may be functional recovery but histological ischemic damage of neurons.[32,63] When the duration of normothermic VF is 7 minutes or longer, some neurologic deficit will be apparent together with permanent histologic brain damage.[44,63,64]

When asphyxiation was reversed just prior to onset of cardiac arrest, complete recovery followed without histologic brain damage. After onset of pulselessness, however, permanent neurologic deficit, with histologic brain damage is observed.[32–34] Neurologic deficit is
Fig. 55.4. Emergency airway control. Triple airway maneuver (backward tilt of head, lips and teeth separated, forward displacement of mandible [jaw thrust]). A. With operator at patient's vertex, for spontaneously breathing patient. B. With operator at side of patient, for direct mouth-to-mouth ventilation. Seal nose with cheek for mouth-to-mouth breathing. Seal mouth with other cheek for mouth-to-nose breathing. C. Modified triple airway maneuver by thumb–jaw lift method (for relaxed patient only). (From Safar P, Bircher NG, Cardiopulmonary cerebral resuscitation. 3rd ed. World Federation of Societies of Anaesthesiologists. London: Saunders, 1988.)

particularly likely in patients in whom pre-existing illness caused tissue hypoxia prior to asphyxiation.

After asphyxial arrest and resuscitation, ischemic neuronal changes "mature" over 3 days or longer; and injury appears more severe and widespread than after VF of the same duration of circulatory arrest.[32–34] After both insults, injured neurons appear shrunken, with eosinophilic cytoplasm and pyknotic nuclei. Selectively vulnerable are the hippocampus, cerebellum, and neocortex. After asphyxia, however, there are also scattered microinfarcts.[32–34] The severity of injury after asphyxial cardiac arrest is increased when hypotension precedes pulselessness.

In summary, asphyxial cardiac arrest appears more injurious to the brain and less injurious to the heart than does VF cardiac arrest of similar duration. Brain recovery also appears less likely after asphyxial arrest than it does after exsanguination cardiac arrest of equal duration.[65]

Therapeutic considerations

If alveolar ventilation with air or O_2 is restored prior to impairment of blood flow manifested by arterial hypotension, resuscitation is usually prompt and complete. When asphyxiation progresses to profound hypotension or pulselessness, basic life support (BLS) measures *may* still restore spontaneous circulation, but both ventilation and

chest compression are needed. After just a brief interval of true cardiac arrest, ROSC may be possible after up to 20 minutes of pulselessness.[16] The brain, however, may not fully recover after as little as 2 minutes of asphyxiation-induced pulselessness.[32–34]

Asphyxial cardiac arrest is the final common pathway for a diverse group of disease processes, and its complete reversal usually requires correction of the underlying disorder. The most important initial interventions are airway control, ventilation, and oxygenation (Table 55.2). The triple airway maneuver, i.e., backward tilt of the head plus forward displacement of the mandible and separation of lips requires no devices (Fig. 55.4). This is often all that is needed to prevent progression of asphyxiation to cardiac arrest. Tracheal intubation or alternate and now less invasive devices are utilized to secure the airway for the longer term. Under immediate life threat, puncture of the cricothyroid membrane may be required (Fig. 55.5).

Asphyxia progressing to pulselessness is often encountered in prehospital settings of cardiac arrest and accounts for PEA and/or asystole.[7] The pathophysiology of asphyxia is fundamentally different from sudden death due to VF. Cardiac arrest is not sudden. Signs of asphyxiation provide opportunities for intervention before the onset of pulselessness. Therapeutic intervention must be rapid, optimally before onset of hypotension.

(From Safar P, Penninckx J. Cricothyroid membrane puncture with special cannula. *Anesthesiology* 1967; 28: 943–948.)

The most common ECG rhythm during asphyxial cardiac arrest is PEA. Defibrillation is indicated only if VF is identified and often follows precordial compression.

The transition from spontaneous circulation to asphyxial cardiac arrest is not easily detected. There are no specific measurements such as blood pressure that would mandate chest compression or alternative circulatory support. Such is also likely to be contingent on the etiology. All patients would best be under the close observation of appropriately skilled clinicians until they are stable and fully awake.

Patients with a potentially reversible etiology of asphyxial arrest who fail to respond to standard BLS-ALS maneuvers may be candidates for open-chest CPR, especially in settings of tension pneumothorax, pericardial tamponade, and other intrathoracic crises.[66,67] Institutions that provide extracorporeal circulation and who have a team prepared to secure the protocol prospectively may utilize extracorporeal circulation.[68]

Airway obstruction

Upper airway soft tissue obstruction during coma of any cause or during general anesthesia is the most common cause of asphyxiation in humans (Fig. 55.3).[2] In an unconscious patient when the head is in the mid or flexed position, the relaxed tongue and epiglottis impinge on the posterior pharyngeal wall and larynx. Such obstruction occurs in diverse body positions: supine, lateral, or prone.[38]

This cause of asphyxia is not only most common but also most easily managed. Simply tilting the head backward or thrusting the jaw forward re-establishes patency of the airway (Fig. 55.3).[37–43] Professor Safar estimated that in 20 to 30% of instances, both techniques are required.[39,40] Airway adjuncts may maintain airway patency (Table 55.2).[2] *Foreign body aspiration* is the second most common cause of life-threatening airway obstruction.

Mouth-to-mouth or mouth-to-nose for BLS advances to mouth-to-adjunct breathing, with or without O_2 and the bag-mask (tube) ventilation with or without O_2.

Airway obstruction may be due to vomitus, blood, or a foreign body or mass lodged in the pharynx or larynx. Obstruction may occur at any level between mouth or nose and bronchioles. In the classic syndrome of sudden solid foreign body obstruction, described as a cafe coronary, food is the obstructing foreign body.[69–75] Altered mental state and especially intoxication by alcohol or drugs and poor dentition are major risk factors. Aspiration, especially in the elderly,[76] may block the airway by direct mechanical obstruction or by triggering laryngospasm and bronchospasm. Laryngospasm reverses after cerebral hypoxia supervenes. Obstruction

may also accompany inflammatory, infectious, or neoplastic diseases.

Complete obstruction of the airway by a "swallowed" foreign body is most commonly due to impaction of the foreign body in the hypopharynx, in the entrance to the larynx, or at the level of the cricoid cartilage.[69] Sudden inability to talk, labored respiratory efforts, and progressive cyanosis constitute the classic signs of foreign body obstruction. The patient may clutch his or her neck. The presence of a high pitched upper airway sound and the capability to vocalize or cough indicate incomplete obstruction. When the obstruction is incomplete and the patient is conscious, the patient should be encouraged to expel the foreign body by himself. Supplementing inspired oxygen is beneficial. Once complete obstruction progresses to unconsciousness, there is impending asphyxial cardiac arrest.

The use of subdiaphragmatic (abdominal) thrusts[70,71] is the primary intervention for relieving the airway obstruction in persons above the age of 1 year and back blows for infants below 1 year. Infants and small children should be placed prone, with the head lowered on the rescuer's hand or knee. Alternatively, back blows may be used in lieu of abdominal thrusts in all age groups. If abdominal thrusts produce only a weak cough-like effect,[73] the chest thrust may be effective and is safer[77] and this is the maneuver

of choice for pregnant women. Abdominal thrusts as described by Heimlich are not without controversy.[2,8,70,72]

Thrusts should best be synchronized with the patient's intrinsic attempts to expel the foreign body. If the victim is conscious, rescuers should be alert to minimize injury to the victim during struggling. Physical attempts to remove the impacted foreign body may result in greater impaction or a human bite to the hand of the rescuer.

Once the patient is unconscious, mouth-to-mouth inflations, digital scooping of the hypopharynx, abdominal or chest thrusts, and back blows are administered and continued until the airway is cleared.[2] When complete obstruction is not relieved, *early* decision to perform cricothyroidotomy is life-saving (Fig. 55.5).

Professional ALS rescuers should be prepared to use airway equipment before unconsciousness occurs. Use of the bag-valve-mask with 100% oxygen is the first option. If the obstruction is complete, the hypopharynx should be visualized with a laryngoscope and attempts made to remove the foreign body with forceps. Blind attempts to remove a foreign body are not advised for they may force the obstructing material to be pushed further in the more distal airway. Endotracheal intubation may be life-saving, yet the risk of advancing the foreign body to the cricothyroid level has grave consequences.

If there is failure to remove the foreign body promptly, cricothyrotomy should not be delayed. One operator should support the triple airway maneuver (Fig. 55.4), with the other person performing cricothyrotomy (Fig. 55.5). Puncture of the trachea or cricothyroid membrane with a catheter needle with insufflation of oxygen distally is another life-saving option.[78–81] Relatively small amounts of oxygen are needed to prevent progression to cardiac arrest. After complete obstruction, care must be taken to prevent overdistending the lungs and causing air trapping. Pressurizing the airway distal to the obstruction in the upper airway may move the foreign body upward, making it easier to remove. If cardiac arrest occurs before patency is established, chest compressions are likely to be futile.

A unique form of sudden and total airway obstruction is hanging,[82–84] but this is not addressed in this chapter.

Stupor and coma

Spontaneous ventilation requires an intact neuraxis and, as stated above, CNS impairment is the most common cause of asphyxial cardiac arrest. Critical loss of innervation between the respiratory center and respiratory muscle fibers impairs ventilation specifically from anesthesia and other drug-induced coma; neurologic diseases, including

poliomyelitis or polyneuritis (Guillain–Barré syndrome); head trauma and other causes of increased intracranial pressure; focal cerebral ischemia; intracranial hemorrhage; and seizures.

Metabolic or toxic causes also impair ventilation. Trauma may impair the respiratory center or disrupt transmission through the spinal cord. Polyneuritis can interfere with peripheral transmission of action potentials. The poliomyelitis virus infects and impairs anterior horn motor neurons. Botulism and neuromuscular blocking agents prevent transmission at the neuromuscular end-plates.

A patient who is not fully alert is at risk of asphyxia. Pulse oximetry is likely to forewarn the clinician of progression to asphyxia. Patients presenting with new onset of coma should be routinely intubated and usually provided with supplemental oxygen. Apneic or hypoventilating patients should be mechanically ventilated. Initiation of these measures, including pulse oximetry and optimally, capnometry, should precede evaluation of the underlying etiology prior to cardiac arrest. Measurement of expired CO_2 ($P_{ET}CO_2$) is less reliable to guide interventions during asphyxial cardiac arrest.[85]

Head trauma as the etiology of CNS dysfunction will usually be obvious on presentation. Intoxication by sedatives, narcotics, alcohol, or cocaine have characteristic presentations and are among the most treatable etiologies of asphyxia and these are addressed in Chapter 58. It is important to identify the underlying cause for purposes of specific interventions; nonetheless, BLS-ALS takes precedence. After spontaneous circulation has been restored, attention should then be directed to the underlying cause.

Traumatic brain injury, blunt or penetrating, may cause so-called impact apnea lasting seconds to minutes.[86,87] Immediate ventilation is indicated to prevent hypoxemia with hypercarbia, most especially if the situation is complicated by seizures. Seizures exacerbate ischemic brain injury and BLS may be life-saving. If both apnea and trismus complicate management, mouth-to-nose breathing is indicated. After initial stabilization, care must be taken to avoid secondary failure of spontaneous ventilation due to intracranial hypertension. Comprehensive ICU monitoring of cardiorespiratory function and repetitive neurologic examinations alert the clinician to early intervention.[88,89]

Acute focal brain ischemia follows cerebrovascular accidents, including intracranial hemorrhage and this may be difficult to distinguish from brain ischemia due to transient apnea resulting from airway obstruction.[90] Even if the patient is initially conscious, secondary brain swelling may impair ventilation, especially if there is progression to brain stem herniation. Measures to counter increases in intracranial pressure and to improve cerebrocortical oxygen delivery are advised.

Generalized convulsions can cause asphyxia from loss of pharyngeal muscle tone, with secondary airway obstruction. The extraordinary increases in metabolic rate and therefore oxygen demands may contribute to the neurologic deterioration that occurs if epilepsy is poorly controlled. Neurologic injury is traced to both hypoxemia during convulsions, and to metabolic failure.

Management of repetitive or prolonged generalized convulsions, so-called status epilepticus, is an indication for mechanical ventilation with oxygen. A muscle relaxant may facilitate external ventilation. A CNS depressant, such as diazepam, or a rapidly acting barbiturate is administered to control the seizures. Seizures themselves lead to death from cardiac causes. Temporal lobe seizures, for example, may cause ventricular arrhythmias and VF by mechanisms that are not fully understood. Electroconvulsive therapy may produce asphyxia due to airway obstruction, apnea, postictal coma, or from anesthetics and relaxants administered in conjunction with such treatments. Appropriate airway management and monitoring, including pulse oximetry, has made asphyxia a rare complication of electroconvulsive therapy.

Lightning stroke[91,92] can cause prolonged apnea and cardiac standstill. The heartbeat may return over minutes. Apnea may account for asphyxial cardiac arrest. Household currents may cause cardiac arrest by producing VF.

Traumatic asphyxia

Crushing injury of the thorax is a distinct cause of asphyxia.[93–102] It can occur during stampedes when large crowds panic and attempt to leave a confined area through a restricted exit. Traumatic crush may then be a mass casualty event. Extrication may be delayed and therefore delay restoration of ventilation. If cardiac arrest precedes extrication, it precludes a good outcome. After national disasters such as earthquakes or in military settings, victims may have parts of their body trapped and crushed, and such patients may become unconscious, apneic, and pulseless after release and extrication. This "acute crush release death" of accidental cause following reperfusion must be differentiated from the late postcrush catabolic syndrome caused by myoglobinemia and renal failure.

Sustained thoracic crush injury (squeeze) may result in a distinct syndrome characterized by cephalad cyanosis and edema and facial and conjunctival petechiae.[96–98] Pressure may be transmitted through the venous system into the cranium, increasing intracranial pressure and exacerbating

neurologic injury.[99–101] Abdominal structures appear to be relatively protected.[98] After crush injuries, it is likely that if victims do not lose spontaneous circulation and are promptly resuscitated, the outcome is favorable.[95,102] The prognosis worsens considerably after prolonged crushing, when patients progress to hypotension and cardiac arrest. If spontaneous circulation is restored, neurologic impairment is common.

In these settings, there is indication for securing the airway. Cephalad edema may make orotracheal intubation difficult. If shock, and especially cardiac arrest, supervene, a surgical airway is indicated. Crush squeeze injury such as to cause traumatic asphyxia should be distinguished from pulmonary compromise due to multiple rib fractures, flail chest, and pulmonary contusion. These require controlled ventilation.[103–105]

Drowning

Submersion produces asphyxia, usually with water in the lungs.[106–110] Hypoxemia and hypercarbia from submersion without loss of pulse represent "near-drowning." After resuscitation, lung damage usually remains. Progression to cardiac arrest is defined as drowning. If ROSC is achieved, brain damage may be the principal deficit. This subject is specifically addressed in Chapter 61.

Sudden death after submersion is attributed to asphyxia caused by impaired alveolo-capillary exchange of oxygen. Struggling, swallowing, and laryngospasm precede asphyxia,[15] followed by hypoxia-associated relaxation and flooding of the tracheobronchial tree. Alveoli remain damaged after aspiration of either sea water[111] or fresh water.[112] Hypertonic sea water draws fluid from the vascular compartment into the alveoli and causes pulmonary edema. Hypotonic fresh water is less damaging but causes atelectasis after pulmonary surfactant is inactivated. In both instances, asphyxia is potentially reversible with restoration of improved pulmonary gas exchange.[110] Pulmonary damage is typically transient with modern methods of assisted or controlled ventilation.[110] Electrolyte abnormalities are less important than earlier suspected.[110,113,114] Water should be allowed to drain passively from the airways during CPR with the victim horizontal or head slightly lowered; abdominal thrusts[70] are not of proven benefit.[115]

The limiting factor to recovery after *drowning* is postischemic-anoxic encephalopathy. This is contingent on immersion (arrest) time and water temperature. After normothermic drowning, cerebral recovery has been poor, particularly in children.[109,116,117] It comes as no surprise that even brief normothermic pulselessness is predictive of brain damage.[32–34] In cold water drowning, however, cerebral hypothermia is protective and circulatory arrest is delayed.[118] That explains why after 45 or even 60 minutes of ice water submersion, complete recovery has been observed following successful CPR and slow rewarming.[117,119] After cold water drowning, standard external CPR after 45 minutes of submersion[119] and in dogs after 1 hour[120] or even 2 hours of cardiac arrest[121] have allowed restoration of spontaneous circulation and neurological recovery.

Pulmonary failure

Critically ill or injured patients develop hypoxemia in consequence of acute or chronic ventilation-perfusion mismatching, including right-to-left shunting of unoxygenated blood through non-ventilated alveoli.[122] Atelectasis from airway obstruction or failure of surfactant, alveolar edema, and pneumonic exudate are primary causes of such shunts. Etiologies include congenital, infectious, neoplastic, traumatic, toxic, immunologic, and thromboembolic causes. In neonates and children, congenital etiologies are particularly common. As antibiotic resistance and immunologic incompetence have become more prevalent, the incidence of sepsis is increasing together with pulmonary infiltrates characteristic of ARDS.[123–125]

Acute pulmonary insufficiency stimulates hyperventilation, largely driven by peripheral chemoreceptors and by mechanical stimulation of pulmonary stretch receptors. As little as 20% of the total lung tissue suffices to keep arterial PCO_2 within normal limits during spontaneous or artificial hyperventilation. Nevertheless, there is progressive hypoxemia.[126] The clinical features are therefore predominantly those of hypoxemia with varying degrees of hypercarbia. Superimposed lactic acidosis represents circulatory failure. Sudden death from asphyxia of primary pulmonary etiology is traced to acute cardiogenic pulmonary edema, aspiration, near-drowning, inhalation of toxic fumes, and rare cases of fulminating hemorrhagic pneumonitis, including viral causes. The key is to prevent critical decreases in arterial oxygen saturation.[127]

Pulmonary failure alone, without reduced blood flow, causes brain damage or cardiac arrest only when arterial PO_2 falls to <25 mm Hg or less. Severe hypoxemia, however, usually compromises cardiac output and peripheral circulation. When combined with acute circulatory failure and shock, even moderate hypoxemia may damage the brain. In the absence of circulatory failure, hypoxemia is associated with stupor and coma only when the arterial

PO_2 has decreased to <30 mm Hg. In patients with a low-flow state, however, unconsciousness may occur when arterial PO_2 declines to between 40 and 60 mm Hg. The brain suffers irreversible damage only when cerebral blood flow is reduced to <20% of normal in the presence of normal levels of oxygen. The mixed cerebral venous PO_2 values are then 20 mm Hg or less.[128]

Clinicians should consider any patient with pulmonary failure at risk of asphyxia and cardiac arrest. Progression to asphyxia can often be prevented with respiratory management if decompensation is recognized early. Patients with rapidly progressing, potentially reversible pulmonary consolidation, as in fulminant pneumonia, would best have arterial PO_2 maintained above 60 mm Hg. If standard ventilatory techniques cannot maintain adequate oxygenation, extracorporeal circulation (ECMO) has been of value for pediatric patients, especially if instituted early, but ultimate benefit has not been proven for adults.[129,130]

Acute exacerbations of chronic obstructive pulmonary disease (COPD) may progress to asphyxia.[122] Oxygen should not be withheld in these settings. Spontaneous hypoventilation in patients with so-called oxygen-dependent ventilatory drive usually occurs only after an acute event. In patients with longstanding hypercarbia, the brain bicarbonate is greatly increased. Rapid reduction of arterial PCO_2 per se is a cause of coma and convulsions[131] presumably due to cerebral alkalosis and consequent cerebral vasospasm,[132] CO_2 but no bicarbonate crosses the blood–brain barrier rapidly.

Acute asthma

Bronchial asthma, chronic bronchitis, and emphysema represent the triad of clinical COPDs.[122] Asthma affects approximately 5% of the United States population. Its prevalence, morbidity, and mortality have been increasing for unclear reasons.[133,134] In 1990 it was estimated that 1.8 million persons with asthma visited emergency departments for treatment of acute exacerbations of their disease. The general management of asthma is outside the scope of this chapter except for acute and severe episodes representing the so-called "asthmatic crises" and asphyxial cardiac arrest.

Pathophysiology

Asthma is an inflammatory condition. The "hyperreactive lungs" of chronic asthma remain poorly understood, although recent focus on immune derangements promises better insight into mechanisms and improved prevention. The disease is chronic, with episodic exacerbations of bronchial obstruction by thick mucus, bronchial spasm, mucosal edema, and mucosal congestion secondary to variable combinations of allergic, environmental, emotional, and infectious factors.[122] During acute exacerbation, diffuse obstruction of small airways is complicated by dehydration, mucous plugging, exhaustion, arrhythmias, and resistance to sympathomimetic bronchodilators. The morphologic changes seen in patients who died in status asthmaticus include widespread mucous plugging of bronchi and bronchioles, abundance and hypertrophy of goblet cells, infiltration and bronchial exudates with eosinophilic leukocytes, thickening of bronchial musculature, and sometimes interstitial fibrosis.

Clinical presentation

The majority of asthma-related deaths occur outside the hospital and the terminal event is not always understood. A study of near-fatal exacerbations, however, has established that asphyxia, rather than cardiac arrhythmias, is the fatal complication. Therefore undertreatment rather than overtreatment is implicated in most near-fatal or fatal exacerbations.[135–139]

Fatal events have onsets with little warning, and advance to asphyxiation over less than 1 hour. Patients should be prepared to treat themselves first and then only with the help of bystanders. Patients at risk for asthma-related sudden death usually have had a history of multiple emergency department visits, intermittent hospitalizations, and even prior intubations and may have recently withdrawn from corticosteroid therapy, changed locales, or had psychological trauma. Appropriate maintenance therapy with inhaled corticosteroids has allowed more patients to remain crisis-free. This includes especially patients previously treated with oral theophylline or with systemic corticosteroid therapy administered orally. It has allowed lesser use of inhaled β-adrenergic agonists and therefore fewer adverse cardiovascular effects.[139,140]

Patients may have a reduced chemosensitivity to hypoxia and blunted perception of the onset of dyspnea.[141] In cases of sudden onset of fatal asthma, pathologic examination sometimes showed more neutrophils than eosinophils in the airway submucosa,[137,139,141,142] suggesting that a mechanism in addition to allergy, including infection or inflammation, was responsible. Patients with a history of sudden asthmatic crises would best be advised to wear an alert bracelet, and to carry a written treatment plan and injectable epinephrine.[137]

At the onset of an asthmatic crisis, patients are likely to be sitting upright, manifest respiratory distress, and be unable to speak except for a few and often unintelligible words. Tachycardia, pulsus paradoxus, diaphoresis, and overt breathing with accessory muscles will be apparent. The absence of these signs, however, does not rule out the existence of major airflow limitations. In less severely distressed patients, the severity of asthma is best quantified with measurements of forced expiratory volume in 1 second, and/or by the maximal expiratory flow rate (MEFR).

Hypoxemia typically precedes hypercarbia. Patients are likely to be resistant to catecholamine. Progressive dyspnea with diffuse wheezing over the lung fields is followed by altered mental status. Aggressive treatment should be instituted before hypercarbia progresses. Mortality is increased if tension pneumothorax or ventricular arrhythmias supervene.[133]

Management of acute severe asthmatic crisis

Prompt intubation and mechanical ventilation should be instituted. In the still conscious patient, a severe, life-threatening broncho-constriction will be identified if the MEFR declines to 25% or less of the predicted value.

Pharmacologic management[142–152]

Oxygen
Maximal inspired O_2 concentrations are recommended to achieve a PaO_2 of 90 mm Hg or greater. High-flow oxygen by mask with high humidity precedes rapid sequence endotracheal intubation.

β-Agonists
(a) Nebulization of a β-adrenergic agonist, preferably with selective β_2 actions, such as albuterol, for inhalation, is a mainstay of initial therapy. Escalating doses of albuterol are advised with 5.0 mg/70-kg increments at 15- to 20-minute intervals or continuous inhalation in amounts of 15 mg/hour[144,145] with an upper limit of 30 mg/hour. Larger doses can exacerbate tachycardia and may provoke VT and VF.[146] Achieving adequate oxygenation takes precedence. Intravenous administration of a β_2-agonist may not be more effective or less adverse than inhaled drugs with respect to their cardiotoxic actions.[147,148]

(b) Isoproterenol by titrated intravenous infusion has been used, beginning with 0.1 μg/kg/minute and increasing doses up to a maximum of 6.0 μg/kg/minute until arterial PCO_2 is reduced to 50 mm Hg or less. This intervention

poses the risk of greater tachycardia and potentially fatal ventricular arrhythmias, however.[147]

(c) The "final" rescue drug is epinephrine by intravenous infusion or injection, but not without risk. Experimentally, epinephrine may increase mortality.[149] The adult intravenous infusion dose is 2 to 10 ml of 1:10 000 administered over an interval of 5 minutes, which may be repeated contingent on response. A continuous infusion of 1 to 20 μg/minute may produce bronchodilation but careful monitoring of the electrocardiogram and blood pressure is important.

Corticosteroids
Corticosteroids reduce the inflammatory mechanisms that accompany acute asthma. Corticosteroid drugs are administered intravenously and may be combined with adrenergic agonists and with increases in inspired oxygen. Methylprednisolone, 2 mg/kg/6 hour, or hydrocortisone, 10 mg/kg/6 hour, are alternatives.

Aminophylline
The use of intravenous aminophylline is no longer routine. Although it may enhance bronchodilation, its adverse effects are significant, including hypotension and cardiac arrhythmias.

Buffer agents
The routine use of buffer agents to reverse acidemia is controversial.[150] Accordingly, normalization of arterial pH with intravenous $NaHCo_3$[151] is of potential but unproven value as an addition to bronchodilation treatment, presumably due to restoring the bronchodilator effects of adrenergic amines. Tris buffer (THAM)[152] has been proposed as a more rational choice, because it is not a CO_2 donor like $NaHCo_3$, but it is also not of proven benefit.

Anticholinergic therapy
This is another option. Nebulized ipratropium bromide may be administered in doses of 0.5 mg/70 kg, and mixed with β-agonist.[150,151]

Magnesium sulfate
Magnesium sulfate has been administered intravenously, but without clear proof of effectiveness, in doses of 2 to 3 g/70 kg, at a rate of 1 g/minute, in conjunction with aggressive β-agonist therapy.[153–155] Excess doses result in hypotension.

Intravenous hydration
This is a priority. Patients are typically dehydrated because of insensible fluid losses. Bronchial mucus is inspissated.

Mechanical ventilation

Mechanical ventilation with 100% oxygen and appropriate prolongation of expiration with the option of pressure and flow assist ventilation is a mainstay of management of potentially fatal bronchoconstriction.[156–158]

Intratracheal artificial ventilation in status asthmaticus

Stupor, coma, and apnea are absolute indications for immediate start of artificial ventilation. Awake intubation after topical anesthesia and intravenous sedation, is preceded by oxygenation by mask. The patient is best managed under light anesthesia and short acting neuromuscular blockade, preferably by an experienced anesthesiologist.[156,157] The almost inevitable "auto-PEEP" is indicative of air trapping and is best managed by maintaining PEEP levels during ventilation that compensate. Typically, there is major benefit when ventilation is adjusted to prolong exhalation, i.e., expiratory retard. Clinical examination, and, specifically lung auscultation, guides adjustments that minimize wheezes, but maintain gas exchange. Complete plugging of bronchi with mucus, however, may account for the absence of wheezes, requiring confirmation that reduced wheezes are accompanied by better gas exchange. Once the patient is intubated and mechanically ventilated, elective hypoventilation may be the only option with which to maintain oxygenation and acceptable inspiratory airway pressure.[158] This results in *permissive hypercarbia*. Although this may lead to relatively high arterial Pco_2 values, there is evidence that it may decrease mortality, but the objective data are not secure, especially in children.[159] Initial ventilator settings may be as follows: FIO_2, 100%; low tidal volumes of 5 to 10 ml/kg, ventilation rate of 10/minute or less to minimize air trapping, PEEP exceeding the measured auto-PEEP, initial inspiratory:expiratory ratio between 1:2 and 1:3, minimize exchange peak inspiratory pressure, and barotraumas. At the time of this writing, the use of high frequency oscillatory ventilation is an option, but without proof of improved survival, including that of newborns.[160]

Volatile anesthetic agents such as halothane, isoflurane, and enflurane, which relax bronchial smooth muscle, have been employed during status asthmaticus unresponsive to initial treatment.[161–164] Nonetheless, technical restraints in delivering these agents in emergency settings to partially "closed" lungs are recognized. The vasodilators and myocardial depressant effects of fluorocarbon anesthetics may be adverse.

Intravenous *ketamine*, in titrated doses, has proven useful for sedation or anesthesia without adverse effects on circulation and with some evidence that it has bron-

chodilation actions.[165–167] It may also have a cerebral protective effect.

During mechanical ventilation when intrathoracic pressure is increased, alveolar distension may lead to deterioration of cardiovascular function and increased risk of barotrauma, including pneumothorax. "Lung massage" has been used for 10 minutes in children with severe asthma undergoing mechanical ventilation. Peak airway pressures decreased and arterial PCO_2 and pH improved. Chest message is applied just after the end of inflation. One operator applies a sustained, firm, bilateral squeeze to the lower chest wall, until the start of the next inflation. There is as yet no proof of survival benefit, however, and it must be regarded as experimental.[168]

If cardiac arrest occurs, the prognosis is very poor. Bilateral tube thoracostomy should be performed simultaneously with other resuscitative measures (Fig. 55.6), because unrecognized *pneumothorax* may contribute to the deterioration.[169] There is no time for confirmation with chest radiography prior to placement of the chest tube. External CPR may be performed after chest tubes are in place. Femorofemoral CPB has been used anecdotally for emergency resuscitation of patients in status asthmaticus, but there is no persuasive proof of better outcomes.

Preload, representing the venous return, may be reduced by the high intrathoracic pressures. Peripherally administered medications may therefore fail to reach the central circulation. Early use of intravascular catheters to monitor blood pressure may aid in differentiating true cardiac arrest from profound hypotension associated with decreased preload.

Pulmonary edema

Pulmonary edema progressing to asphyxia is an extreme form of pulmonary failure. Alveolar spaces are flooded with fluid.[122,170–175] Under normal physiologic conditions, a dynamic equilibrium was described by Starling in his law of capillary–interstitial fluid exchange.[172] The net fluid movement is a function of membrane integrity; capillary, interstitial, and alveolar pressures; plasma and interstitial oncotic pressures; and lymphatic drainage. The net forces change as blood moves through the capillary, and at the venular end of the capillaries, fluid transudes back into the vascular space. Remaining fluid is normally removed via the pulmonary lymphatics.[174]

If the normal forces of fluid movement become deranged by disease, fluid may accumulate in interstitial and alveolar spaces. When interstitial fluid exceeds the capacity of the lymphatic system, it spills into the alveoli, resulting in

Drained fluid

II
One-way valve

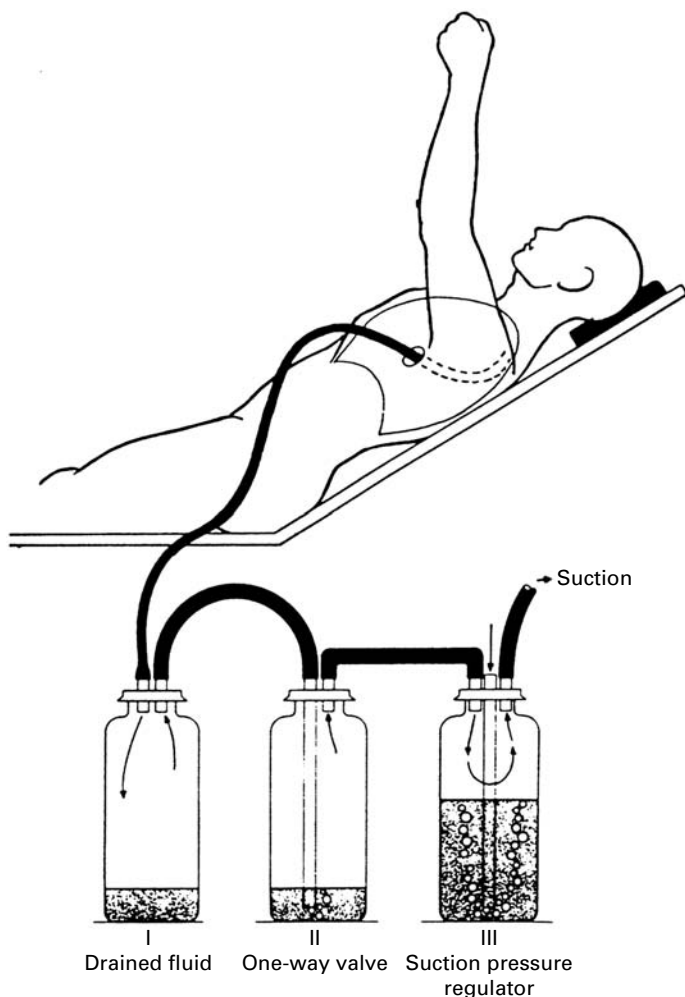
III
Suction pressure
regulator


Fig. 55.6. Technique of pleural drainage. The appropriate size chest tube is inserted through a stab incision in the skin and into the pleural cavity, with the open technique (blunt Kelly clamp pierced through the intercostal space and prised open for tube insertion) or the closed technique (using a trocar). The latter technique requires greater skill to avoid complications. One lateral-to-posterior chest tube, with multiple holes, is usually sufficient. The tube is connected to the bottle system consisting of bottle 1 for collection of fluids; bottle 2, a one-way valve; and bottle 3 to keep a constant controllable negative pressure. For transportation a one-way valve instead of the three-bottle system is used. In hospitals the three-bottle system may be replaced by a chest suction device (e.g., Pleurevac) provided it permits control of negative pressure and high flow rate. (From Safar P, Bircher N. Cardiopulmonary cerebral resuscitation. 3rd ed. World Federation of Societies of Anaesthesiologists. London, WB Saunders, 1988.)

pulmonary edema.[175] Alveolar fluid is a barrier to gas exchange. Pulmonary capillary blood then passes through unventilated alveoli, such as to produce pulmonary arterio-venous shunting with hypoxemia and asphyxia.

Any process that alters the osmotic or hydrostatic forces that maintain alveolar-capillary equilibrium may cause pulmonary edema. Increased pulmonary capillary back pressure is most often due to myocardial failure. Decreased plasma oncotic pressure may follow hepatic disease, or extreme losses of plasma albumin as occurs in protein-losing enteropathies.

There are important non-cardiogenic types of pulmonary edemas that may progress to asphyxia. The most common is capillary–alveolar membrane leakage[175] caused by toxic, chemical, bacterial, viral, thermal, or other insults, presenting as ARDS[124,173] with "progressive pulmonary infiltration".[125] When ARDS progresses to cardiac arrest, it is refractory to therapy, because it usually cannot overcome the block to oxygenation caused by the underlying disease state. Non-cardiac pulmonary edema is also caused by membrane damage due to street drugs and especially cocaine. Loss of interstitial negative pressure may be due to pneumothorax, infection, or carcinoma involving pulmonary lymphatics, fibrotic and inflammatory states, or high altitude.[173]

Pulmonary edema should be treated before it progresses to asphyxia and cardiac arrest. During spontaneous circulation, acute pulmonary edema is treated by administration of 100% oxygen delivered with positive pressure.[122,176] The simplest emergency treatment includes spontaneous breathing of 100% oxygen by continuous positive airway pressure, utilizing a mouthpiece or mask.[177–180] If the patient is stuporous or comatose, or has an arterial PO_2 of <60 mm Hg, or if the arterial PCO_2 increases despite therapy, endotracheal intubation, sedation, paralysis, and 100% oxygen with positive pressure are indicated.[122] Ventilation may be facilitated by administration of a muscle relaxant, but this may delay recovery of spontaneous breathing. Increased airway pressure raises the arterial PO_2 by increasing functional residual capacity through recruitment of fluid-filled alveoli with displacement of edema fluid. After oxygenation, fluid should be removed for management of underlying cause.[175] In left-sided heart failure, standard oxygenation may be combined with administration of morphine, a diuretic, and under extreme conditions, phlebotomy. When pulmonary edema has progressed to asphyxial cardiac arrest, the likelihood of ROSC is remote.

Tension pneumothorax

Venting the pleural space, either through the chest wall or through the lung, results in pneumothorax. The cause may be trauma or disease with destruction of lung tissue.[181–184] When the opening is large enough, pressure in one pleural

space is increased throughout the respiratory cycle and the ipsilateral lung is compressed. Previously healthy patients then manifest hypoxemia because 40% to 50% of blood flow is shunted through non-ventilated alveoli. If the opening to the pleural space operates as a one-way valve, it causes a tension pneumothorax. Breathing, positive-pressure ventilation, or coughing may further increase the pressure of free gas in the pleural space. Alveoli may rupture, admitting air into the pulmonary interstitial spaces, and thereby producing mediastinal and subcutaneous emphysema. Tension pneumothorax may preclude venous return and therefore preload. Mediastinal shift further impairs venous return. Tension pneumothorax therefore progresses to cardiac arrest by a combination of impaired pulmonary and circulatory mechanisms. The initial event is asphyxial, with impaired delivery of oxygenated blood to the left side of the heart. Subsequently, reduced cardiac filling accounts for decreased cardiac output. Ultimately, circulatory arrest is due to the combined effects of hypoxemia, compression atelectasis, compression of the contralateral lung, and elevated intrathoracic pressures that impede venous return. Compression of major vessels and airways and mediastinal emphysema may contribute to the severity of the insult.

Predisposing causes of tension pneumothorax include lung disease, positive-pressure ventilation, and coughing in the presence of valve-like bronchial obstruction, during asthma and in patients with COPD. Patients with connective tissue disorders, and especially Marfan's syndrome, are at increased risk of pneumothorax as are women with endometriosis.[186,187]

Tension pneumothorax should be suspected when a patient presents with sudden onset of chest discomfort or shortness of breath, especially if predisposing factors are present and are identified. The diagnosis may be made presumptively by diminished or absent breath sounds with hyper-resonance to percussion in one lung, progressive difficulty in ventilation, subcutaneous emphysema, mediastinal and/or tracheal shift. Progressive abdominal distension may accompany tension pneumothorax when pleural gas under pressure breaks through serosal membranes at the openings in the diaphragm.[2]

Confirmation by chest roentgenogram is *not* required in life-threatening settings. A high index of suspicion is needed to diagnose this condition before the hemodynamic crisis occurs.

Needle puncture serves only for confirmation; it is insufficient for relief of gas build-up and has a high false-negative rate.[185] Rapid transformation of the closed pneumothorax into an open pneumothorax is imperative. Thoracostomy with use of a large-bore tube or an intercostal incision to

vent the pleural space may be life-saving. Confirmation that the thoracostomy tubes are in the pleural space is made by observation of the characteristic misting with ventilation and subsequent chest radiography. When cardiovascular collapse appears imminent, thoracostomy should proceed without a chest tube tray.[185]

When pulselessness develops, bilateral venting of the pleural space, ventilation, and chest compressions may still restore spontaneous circulation. Open-chest CPR is a final option.

Thromboembolism

Acute pulmonary thromboembolism is among the most common causes of death among old and chronically ill patients.[188,189] It may, however, also occur in persons of seemingly good health. The large list of risk factors includes chronic diseases, especially carcinoma; immobilization, especially in fracture casts; recent surgery; obesity; tobacco abuse; and pregnancy. Deep venous thromboses, predominantly in the veins of the pelvis or a lower extremity, embolize to the pulmonary artery and peripheral pulmonary arteries, impeding pulmonary blood flow.[190] The initial presentation may be circulatory shock or cardiac arrest. Plain chest films in most cases are not helpful but may suggest decreased pulmonary vascularity. If the patient's clinical status permits, a lung scan and arterial blood gas are useful because a normal scan and normal arterial PO_2 virtually rule out significant embolization. If the lung scan is positive and time permits, axial tomography or a pulmonary angiogram confirms the diagnosis.[191,192] The pathogenesis, diagnosis, and management of pulmonary thromboembolism in patients with spontaneous circulation are reviewed elsewhere. The focus of this chapter is on the moribund patient who presents in circulatory shock or cardiac arrest.

The mechanism by which pulmonary thromboembolism progresses to cardiac arrest is a combination of obstructive shock with a low cardiac output together with asphyxia. Acute pulmonary embolism increases not only the physiologic dead space but also right-to-left shunting.[189]

The hypoxemia and a high alveolar–arterial PO_2 gradient are traced to ventilation–perfusion disturbances, including patchy bronchoconstriction and hyperemia, and even scattered pulmonary edema. The severity is contingent on the proportion of the total cross-sectional area of the pulmonary arterial tree that is deprived of blood flow. In patients with previously healthy lungs and heart, more than 30% of the vascular tree is obstructed prior to onset of

shock. In patients with cardiopulmonary disease a smaller proportion of the pulmonary vasculature that is suddenly blocked may produce shock and subsequent cardiac arrest.[193] The thrombus in the pulmonary vascular bed has additional local and systemic effects. The primary treatment, however, is to relieve intravascular mechanical obstructions. In the previously fit person with occlusion of one pulmonary artery, bronchial circulation may allow the lung to survive.

A single embolus or multiple small emboli that occlude approximately 50% of the pulmonary vascular bed result in arterial hypotension, tachycardia, pulmonary artery hypertension, and bronchospasm. Prompt anticoagulation and thrombolysis are indicated. More conservative management of the patient with acute pulmonary thromboembolism for whom thrombolysis or mechanical relief is delayed can support vital functions until spontaneous thrombolysis and recanalization of obstructed vessels occurs, at the same time preventing recurrent embolization with anticoagulation.[194–197] Heparinization prevents secondary thrombus formation.[198]

Diagnosis of pulmonary embolism as the cause of cardiac arrest is difficult. If PaO_2 remains markedly reduced when the patient is ventilated with 100% oxygen, and in the absence of gross signs of pulmonary edema, the presumptive diagnosis of pulmonary embolism is supported. ALS is usually ineffective. A central aortic catheter helps to provide better definition of the hemodynamic state[199] and identifies "pseudo-PEA."

Previously healthy patients presenting with probable pulmonary embolism and cardiac arrest represent a special subgroup of patients who may benefit from open-chest CPR or CPB.[200] The decision that standard therapy may not be effective must be made *early*, while a good outcome remains possible. If open-chest CPR is performed, the pulmonary artery should be identified and massaged to break up the thrombus and allow it to move peripherally. If emergency CPB is performed, thoracotomy and embolectomy are appropriate interventions.

Amniotic fluid embolism

Amniotic fluid embolism is an uncommon but tragic cause of sudden death in that two persons, both potentially healthy, may die. It occurs in approximately 1 in 80 000 deliveries.[201,202] Multiparous women are at increased risk, as are those undergoing uterine manipulation. Amniotic fluid embolism causes a distinct pathophysiologic response, indicating that amniotic fluid itself or secondary mediators are biologically active. The pulmonary vascular

bed constricts, and at least in part explains progression to cor pulmonale. Oxygen delivery is impaired due to hypoxemia and decreased cardiac output in part as a result of septal shift associated with expansion of right ventricular volume and pressure. Consumptive coagulopathy with hypofibrinogenemia accounts for disseminated intravascular coagulation (DIC).

Amniotic fluid embolism should be suspected when sudden pulmonary or cardiovascular compromise occurs in patients with placenta accreta, cesarean delivery, uterine rupture, retention of the products of conception, or premature separation of the placenta.[203] Sudden collapse with signs of shock is accompanied by dyspnea and cyanosis. More frequently, the event occurs during labor and delivery. Early detection by continuous pulse oximetry has been demonstrated.[204] Therapy includes aggressive respiratory support with 100% oxygen and possibly the addition of pulmonary vasodilator drugs. Aggressive therapy of DIC is recommended.

Management of cardiac arrest is similar to that of pulmonary thromboembolism with the exception that massage of the pulmonary outflow tract is not advised. Early initiation of CPB may be life-saving.[205]

Anaphylaxis

Anaphylaxis is an acute, severe, life-threatening hypersensitivity reaction that may progress to asphyxia and cardiac arrest. Antibodies, principally immunoglobulin E (IgE), that were formed in response to a previous exposure to an antigen, trigger a potentially lethal series of immunologic cascades on re-exposure. Although a very large number of antigens may cause anaphylaxis in sensitized individuals, the most common inciting antigens are β-lactam antibiotics, iodinated contrast media, and Hymenoptera stings.[206] In many cases the etiologic agent may be unclear.

Anaphylaxis is a complex event. The antigen–antibody complex is absorbed by mast cells and basophils. Calcium-dependent degranulation results in the release of bioactive substances. Primary mediators include histamine, serotonin, bradykinin, the slow-reacting substance of anaphylaxis (SRS, now known to be leukotrienes C, D, and E4); the eosinophilic chemotactic factor of anaphylaxis, prostaglandins and leukotrienes, metabolites of arachidonic acid (via the cyclooxygenase and lipoxygenase pathways, respectively); and platelet-activating factor. Secondary mediators include complement and the products of polymorphonuclear leukocytes (prostaglandins [PGs], leukotrienes [LTs], fibrinolysin, plasminogen,

elastase); platelets (PGs, LTs, Hageman factor activators, lysosomal enzymes, and serotonin), and eosinophils (collagenase, histaminase, phospholipase D, arylsulfatase D).[207] Most likely, additional mediators will be identified as assays become available.

Anaphylaxis blocks delivery of oxygen in multiple ways. Many of the bioactive substances are smooth muscle and membrane modulators, and their most significant target organs are the airways, lungs, and cardiovascular systems. Pharyngeal and laryngeal edema, bronchospasm, edema of the bronchial mucosa, and vasodilation occur early. Asphyxia is due to upper and lower airway obstructions. Shock develops through a combination of decreased vascular tone and increased capillary permeability. Evidence suggests that the chemical mediators of anaphylaxis may also decrease myocardial function and, together with hypoxemia, exacerbate circulatory shock and cardiac arrest.[208,209] As in all the asphyxial syndromes, aggressive management to prevent progression to cardiac arrest includes airway control, oxygenation, and ventilation. Angioedema and laryngospasm may make orotracheal intubation difficult. Early consideration should be given to transtracheal ventilation or cricothyroidotomy. Early treatment includes relief of bronchospasm.

Epinephrine is life-saving for the treatment of anaphylaxis.[210] Patients known to be at risk should carry an epinephrine auto injector with them and be trained in its use. Epinephrine increases cyclic adenosine monophosphate (cAMP) levels in mast cells and provides inotropic, chronotropic, and pressor support as well as bronchodilation. Anaphylactic shock is treated with intravenous, sublingual, intratracheal, or subcutaneous administration of epinephrine. Intravenous epinephrine is best titrated in 0.1-mg increments. Patients who have received β-blocking drugs may require large doses of epinephrine.

Blood pressure should be closely monitored with an indwelling arterial catheter. Because severe anaphylaxis is associated with hypovolemia,[211,212] fluid challenge is indicated. A corticosteroid may be administered, although its beneficial effect is not immediate. Antihistamines are administered for prophylaxis but are of limited value during resuscitation. In specific situations, antivenoms may be indicated.

Management of anaphylactic shock

Management includes considerations of support for ventilation, circulation, and mitigation of the immunologic response.

Ventilation

1. 100% oxygen by spontaneous breathing or IPPV-CPPV by mask.
2. Endotracheal intubation, transtracheal ventilation, cricothyroidotomy, and IPPV-CPPV.
3. β-Adrenergic agonist, for example, aerosolized albuterol, 0.5 ml in 3 ml saline.
4. Consider neuromuscular blockade (e.g., vecuronium, pancuronium).
5. Consider helium/O_2.
6. Consider general anesthesia (especially intravenous ketamine).

Circulation

1. Crystalloid guided by central venous pressure (fluid challenge).
2. Epinephrine, 5 mg/500 ml ISS, by titrated intravenous infusion. Maintain mean arterial pressure (MAP) at 90 mm Hg or above.

Immunologic support

1. Epinephrine (see above).
2. Antihistamines (diphenhydramine, 50 mg/70 kg); consider cimetidine.
3. Corticosteroid (methylprednisolone, 120 mg/70 kg).
4. Specific antivenom!

A syndrome that combines hypoxemia and hypotension places the patient at high risk for cardiac arrest. Once the pulse is lost, injury to vital organs will occur rapidly. As in all asphyxial syndromes, prevention of cardiac arrest is the primary treatment.[213,214]

Carbon monoxide poisoning

Carbon monoxide (CO) impairs oxygen transport. CO is a colorless, odorless gas that causes more poisoning deaths in the United States than any other single agent.[215] CO has a high affinity for hemoglobin, reversibly displacing oxygen to create carboxyhemoglobin (COHb). Hemoglobin binds carbon monoxide about 200 to 300 times more readily than it binds oxygen. The COHb produced is subsequently not available for oxygen transport. This creates a form of anemic hypoxia without a decrease in plasma hemoglobin.[216] CO toxicity is a more complex process than previously believed. Classically, COHb interferes with O_2 transport. It may also be a cellular poison, interfering with cytochrome function.[217]

CO poisoning does not alter PaO_2 even though available oxygen is reduced. If as little as 0.2% CO is inhaled, COHb will form at a rate of 1.1%/min. If the patient is doing heavy work, the rate will increase to 2.4%/min, and within about 45 minutes CO will saturate 76% of the hemoglobin. Conscious dogs inhaling 1% CO reach 80% CO hemoglobin saturation rapidly followed by sudden death. There is no increase in respiratory drive since the peripheral chemoreceptors sense no decrease in PaO_2.

Most persons who die in fires are asphyxiated. CO intoxication or the effects of other toxic gases are more lethal than decreases in O_2 or increases in CO_2. A key to the early diagnosis is knowledge of the circumstances of intoxication, such as combustion in closed spaces or multiple ill persons within the same family.[218,219]

CO intoxication may manifest itself by headache and variable impairment in mental status and neurologic function. Eventually there is loss of consciousness, followed by hypotension, convulsions, apnea, and cardiac arrest in asystole. IPPV with 100% oxygen delays progression and promotes spontaneous breathing. Permanent cerebral impairment persists even though there is relatively prompt return of spontaneous circulation. Irreversible cerebral damage may occur even in the absence of cardiac arrest.[220]

The initial therapy is to remove the patient from the source of CO. The serum elimination time for COHb is inversely related to the serum partial pressure of oxygen.[218] Administration of 100% oxygen is the primary therapy. Patients with CO poisoning who develop cardiac arrest have a very poor prognosis. Simply intubating these patients and ventilating them with 100% oxygen may not restore an adequate oxygen delivery for favorable neurologic outcomes.

Resuscitation in a hyperbaric chamber has proven effective. Even though the logistics of using such a chamber are daunting, it is the best option.[221]

Cyanide poisoning

Cyanide is the classic cellular asphyxiant; it interrupts the function of oxidative phosphorylation at the mitochondrial level by binding to the ferric (Fe^{3+}) component of cytochrome oxidase. Cells are unable to utilize oxygen as the final electron acceptor, and anaerobic glycolysis results. This is reflected in the early signs of organ dysfunction and increased serum lactate.

Because the block to respiration is at the cellular level, arterial hypoxemia and hypercarbia, the sine qua non of classic asphyxia, will not be present, at least initially. Cyanide asphyxiation presents challenges that are similar to those of CO intoxication. Once cardiac arrest has

occurred, the prognosis is bleak. In laboratory studies, amyl nitrite and sodium thiosulfate have not been effective after onset of cardiac arrest.[222,223] The only present option is to prevent progression to arrest.

Conclusions and recommendations

Asphyxial cardiac arrest may be sudden, but it is not immediate. Whatever the cause, the progression from inciting etiology through shock to cardiac arrest provides an opportunity for effective resuscitation before pulselessness sets in. Airway control and artificial ventilation alone are likely to reverse asphyxiation. After cardiac arrest has occurred, return of spontaneous circulation can often be achieved by conventional ALS. Unfortunately, cerebral recovery is less likely after asphyxial cardiac arrest than after primary cardiac arrest due to VF of the same duration. Of the two components in asphyxiation, hypercarbia may cause transient coma and acidosis but is totally reversible, whereas hypoxia–anoxia can cause permanent unresuscitatable damage, particularly to the brain.

Hemorrhagic shock and hypovolemic cardiac arrest

James L. Atkins, Michael T. Handrigan and David Burris

Uniformed Services University of the Health Sciences, Bethesda, MD, USA

Incidence and current outcomes of post-traumatic cardiopulmonary arrest

Traumatic injury is the leading cause of death among adults under 44 years of age,[1] and it is a worldwide problem. In the year 2000, road traffic injuries were the ninth leading cause of death in the world and this toll is predicted to increase significantly in the next 15 years as road traffic injuries increase in underdeveloped countries.[2] Because traumatic injury has a predilection for the young, it is a major cause of productive life-years lost and it is predicted that by the year 2020, traumatic injury will match or surpass infectious diseases as the leading cause of productive life-years lost world-wide.[3,4] The greatest opportunity to save lives is to improve early care since the majority of traumatic deaths occur within the first few hours after injury.

In the United States as many as 34% of all trauma deaths occur pre-hospital and two major mechanisms predominate as the cause of early death: blood loss and injury to the central nervous system (CNS).[5–7] In a study by Sauaia et al. in 1995,[5] 43% of the overall deaths were due to injury to the central nervous system (CNS), 39% were relegated to exsanguination, and 7% died from multiorgan failure. More recent studies have indicated that the mortality of post-traumatic multi-organ failure is decreasing as a result of improvements in ICU care and now multi-organ failure may account for less than 4% of all traumatic deaths.[8] Multiorgan failure occurs several days after injury while the majority of both CNS and hemorrhage deaths occur within the first 2 hours of injury.[5,9] In the study by Sauaia

et al,[5] exsanguination was the most common cause of death among those found dead at the scene and it was the most frequent cause of early hospital deaths. Interventions that may improve early survival include resuscitation after cardiopulmonary arrest (CPR) and therapies aimed at preventing imminent arrest. To date, the results with CPR after trauma (TCPR) have not been encouraging.

Survival rates of pre-hospital closed-chest cardiopulmonary resuscitation after trauma (TCPR) are quite low.[10] Despite an early encouraging report to the contrary by Copass et al.[11] which demonstrated 23% survival in pre-hospital TCPR, numerous subsequent studies have found dismal results with survival rates varying between 0 and 2.6%.[10,12–18] The reason for this discrepancy is not clear, although the study by Copass et al.[11] had a very high prevalence of penetrating injury in the group of survivors. The group of surviving patients included 60% with penetrating injuries and 40% with blunt injuries, while the non-surviving group included 95% with blunt injury and 5% with penetrating injuries. A more favorable outcome of TCPR in patients with penetrating injuries has been seen in some[17] but not all subsequent studies.[12,14,16] There is one subgroup of patients with penetrating injury that may have a clear survival advantage in TCPR, however; that is, patients with isolated penetrating injury to the thorax who can be rapidly transported to the trauma center to receive open-chest CPR and injury repair.[10] More favorable outcome might also be expected in patients with special conditions such as victims of drowning and lightning strike, victims with significant hypothermia, and patients

in whom the mechanism of injury does not correlate with the clinical condition suggesting a non-traumatic cause of the arrest. The paper by Copass et al.[11] made mention of another special circumstance, the patient with an isolated head injury who is apneic. They proposed that "successful establishment of an endotracheal tube may be lifesaving" in this circumstance. With the increasing frequency of explosive injuries it might be argued that blast-induced apnea[19–22] warrants the same special consideration.

The dire results with TCPR have led several groups to evaluate the risks versus benefits of pre-hospital TCPR. In these considerations the risk-benefit analysis is somewhat unusual, because often the risk evaluated is to the provider while the potential benefit is to the victim. One example of such an evaluation is the consideration of medical care on the battlefield. In a tactical situation when the health care providers are under real risk of receiving fire, the danger to the health care provider administering CPR is quite substantial, and the resources diverted to that likely futile effort might endanger both the security of the team and the ability to provide care to other more salvageable casualties. Under such conditions TCPR is not advised.[23,24] In a peacetime civilian setting the risks to the provider are certainly lower but they may nonetheless be substantial. Recently the National Association of EMS Physicians and the American College of Surgeons Committee on Trauma (NAEMSP/ACSCOTS) have published a position statement proposing guidelines for withholding or terminating resuscitation in prehospital TCPR.[10] In this paper they consider the inherent costs and risks to the community and healthcare providers: (1) "trauma resuscitation consumes significant amounts of ED, operating room, and intensive care unit resources," (2) "there is significant risk for EMS crews and the public associated with emergency transport" and (3) "the chaotic environment of trauma resuscitations may pose a heightened risk of blood-borne pathogen exposure to the involved health care workers." On the basis of these considerations the committee listed specific clinical situations where they believed the likelihood of success is so low that CPR should not be recommended. The debate over these issues is ongoing and recently Pickens et al.[25] have evaluated the guidelines of NAEMO/ACSCOT and concluded that the required clinical assessments could not be obtained reliably in prehospital urban settings. In that study, which had an overall survival to discharge of 7.6%, they concluded that the NAEMO/ACSCOT guidelines might not be applicable to urban systems with rapid transport to a Level 1 Trauma Center. In addition to the consideration that rapid transport to a trauma center may provide improved clinical assessment, rapid transport may also provide the opportunity to have the patient arrive at a Level 1 trauma center before 15 minutes of CPR have elapsed. Both animal[26] and clinical studies indicate a poor outcome is more likely if closed-chest CPR has continued for more than 15 minutes.[14,27] Hence, arrival at a Level 1 center before 15 minutes of closed-chest CPR may provide an opportunity for successful open-chest CPR.

Animal studies have shown that open chest CPR is more effective than closed-chest CPR and produces higher perfusion pressures of the coronaries and brain.[26] Clinical studies seem to confirm better outcomes. A study by Lorenz et al.[28] showed overall 13% survival with open chest CPR, with 2% survival in blunt trauma and 22% survival in penetrating trauma. This confirmed the bias that open chest CPR is more effective in penetrating trauma; however, Fialka et al.[29] have recently found similar survival rates (10%) in open chest CPR in casualties with blunt trauma to the chest or abdomen. In this study all traumatic arrests with severe blunt chest or abdominal trauma isolated or in combination with other injuries were included in the study if the victims were less than 70 years of age and had a documented resuscitation duration of less than 20 minutes. Hachimi-Idrissi et al.[30] studied out-of-hospital open chest CPR and found survival rates of 6%; moreover, they report that the procedure was well accepted by the populace of Belgium.

The NAEMO/ACSCOT guidelines paper emphasizes that their recommendations are based on available research to date and are subject to change as advances are made in the care of the trauma patient.[10] Much of the rest of this chapter will focus on recent research advances that hold promise to improve the treatment of TCPR or to prevent imminent cardiac arrest. We will also explore more basic mechanisms in the body's response to hemorrhage that may account for some of the failures of TCPR and, it is to be hoped, indicate potential new avenues of research.

Research that promises to improve the outcome of TCPR in the future

Emergency preservation and resuscitation (EPR)

Animal studies have examined profound hypothermia as a means to extend the period of time during which surgical repair can be accomplished. Very promising results have been seen in both swine[31–33] and dogs.[34] Following cardiac arrest from hemorrhage, profound hypothermia (core temperature of 10 °C) was induced by rapid cold aortic flush (normal saline at 2 °C at 1.7 l/min in dogs) until core temperature was 10 °C and hypothermia was maintained for 60 minutes. Rewarming was accomplished

by cardiopulmonary bypass. After recovery for 72 hours (dogs) or 6 weeks (swine) brain histology and cognitive function were normal. Recently Nozari *et al.*[35] have extended their large series of studies[34,36] to examine the consequence of adding trauma to the hemorrhage model. Splenic injury was induced prior to the hemorrhage. During the profound hypothermia, the spleen was resected and the animals underwent left thoracotomy. Even though there was still 100% survival in all groups, half of the trauma animals (4) had neurologic deficits and three required prolonged mechanical ventilation. The addition of plasma exchange allowed full neurologic recovery even after a 2-hour period of no-flow.[37] This technology may provide sufficient time for repair of even very severe and otherwise unsalvageable vascular injuries in a controlled manner.

Improved ventilation strategies

Hemorrhage sufficient to lower central volume can severely limit venous return and theoretically make it impossible to attain adequate coronary and cerebral perfusion pressure during CPR. The absolute limit to this is total exsanguination after which external chest compressions would essentially squeeze an "empty heart." Cardiac arrest can occur in hemorrhage before there is true exanguination, however, and methods that redistribute the blood to the central core or improve cardiac return have the potential to improve the outcome of TCPR. One such approach is to limit the duration of positive interthoracic pressure during TCPR.

It has been appreciated for some time that positive pressure ventilation can quickly exacerbate a tension pneumothorax and significantly decrease venous return, but recent studies have focused on a much more subtle and more common event that also decreases cardiac return, albeit to a less but still quite significant degree. Positive pressure ventilation decreases cardiac return by raising interthoracic pressure and this effect may be most critical in hypovolemic states.[38] To demonstrate this point, Pepe *et al.*[39,40] recently studied the effect of changes in the rate of positive pressure ventilation in swine with a moderate degree of hemorrhage. Elevated ventilatory rates of 20 and 30 breaths per minute caused a fall in diastolic blood pressure and decreased coronary perfusion pressure as compared to ventilatory rates of 6 breaths per minute. Based on this evidence, the authors raise the concern that rapid ventilatory rates for trauma resuscitation could significantly impair hemodynamics. Krismer *et al.*[41] have examined the use of positive end expiratory pressure (PEEP) after intubation of hemorrhaged swine that had not received fluid resuscitation. Those treated with PEEP of 5 or 10 cm water had significantly decreased survival compared with those treated with 0 PEEP. Although not directly tested, it might be expected that the same principles apply to animals that arrest as a result of hemorrhage and lower ventilatory rates without PEEP could improve the outcome of TCPR by improving average cardiac return.

A corollary of this concept is that increases in negative interthoracic pressure would improve venous return. It is likely that the body's own compensatory response takes advantage of this concept by the increased ventilatory drive and respiratory alkalosis seen in early hemorrhage and early sepsis. This benefit can be enhanced by the use of a respiratory impedance threshold device (ITD). This valve creates more negative interthoracic pressure during ventilation. It improves blood pressure in hemorrhaged swine with both unassisted ventilation[42] and with ventilation assisted by a phrenic nerve stimulator.[43] In stimulated blood loss in humans accomplished by using lower body negative pressure, the impedance threshold valve improved velocity of cerebral blood flow and preliminary results showed an increase in stroke volume.[44] The ITD coupled to a vacuum source for the generation of controlled – 10 cm water vacuum in the trachea during the decompression phase of CPR, has been shown to improve both cerebral and coronary perfusion pressure during CPR of anesthetized swine in which ventricular fibrillation (VF) cardiac arrest was induced by intracardiac direct electrical current.[45] There was also a remarkable increase in short term survival from 10 to 100% in this group. Hemodynamic parameters were also examined in a group of animals that were subjected to hemorrhage 50% of their estimated blood volume before induction of VF cardiac arrest. These animals also had a significant, but less dramatic, improvement in coronary and cerebral perfusion pressures. Survival was not examined in the hemorrhaged animals.

The results are exciting and provide real hope that changes in pre-hospital ventilatory strategies may prevent arrest in some trauma victims with marginal cardiac return. Moreover, the use of the ITD holds the promise to improve TCPR. Nevertheless, there are still some complexities of CPR after hemorrhage that have not yet been examined with this new methodology. Induction of VF after hemorrhage in propofol-anesthetized animals does not mimic some important features of cardiac arrest after hemorrhage. Cardiac arrest in conscious animals after hemorrhage involves a loss of vasoconstrictor activity and increased vascular compliance. ITD alone may not overcome these additional impediments to venous return and additional therapies may be required to create effective CPR after hemorrhagic arrest. An additive approach to

increased venous return may be the use of vasoconstric-tors to decrease vascular compliance in non-critical vascular beds.

Hemorrhage-induced vascular collapse

At first glance vasoconstrictors would appear to be an unsuitable adjunctive therapy for the treatment of hemorrhage-associated arrest, because total peripheral resistance is normally increased after hemorrhage, sometimes quite remarkably. In cases of limited fluid resuscitation there are anecdotal stories of alert patients presenting with such severe peripheral vasoconstriction that no peripheral pulses were apparent and there was no bleeding from severed brachial arteries or amputated extremities until fluid resuscitation was initiated. There are animal studies, however, that show specific circumstances when these predominantly vasoconstrictor responses fail. In these circumstances, cardiac arrest ensues in part from an apparently inappropriate vasodilatation or loss of vasoconstrictor action. Two distinct mechanisms have been described that would be expected to occur in two very different circumstances. The literature is somewhat confounded because both of these mechanisms are normally referred to as "irreversible shock" and/or "compensatory failure".[46–49] In order to provide perspective we will first describe the normal sequential responses to continued hemorrhage and then discuss how and when "compensatory failure" may occur.

The body's initial response to hemorrhage is a beautifully orchestrated combination of events involving a delicate balance between an intense increase in vasoconstrictor activity[50] and a large increase in the production of the vasodilator nitric oxide.[51] The net balance of these mediators differs among vascular beds and the systemic effect involves both an increase in total peripheral resistance, which tends to preserve sufficient blood pressure to maintain tissue perfusion, and a redistribution of cardiac output, which tends to preserve blood flow to the coronary and cerebral circulations at the expense of other vascular beds.[50]

In conscious animals, the initial compensatory response to hemorrhage involves a baroreflex-mediated increase in sympathetic activity and a decrease in parasympathetic activity that results in a decrease in vascular conductance and an increase in heart rate. The central pathways involved in this response are quite complex. Numerous neurotransmitters have been implicated in the efferent pathways including classical neurotransmitters, vasopressin,[52,53] histamine,[54] neuropeptides, including CRH, opioids,[49,55] serotonin,[56] neuropeptide Y and galanin, and gaseous mediators like nitric oxide and carbon monoxide.[57] In addition to these complex central pathways, descending autonomic visceromotor cells are activated. The net result of this response is that in awake animals blood pressure is maintained during the initial few minutes of hemorrhage. If rapid hemorrhage continues blood pressure will begin to fall.[58] Somewhat surprisingly this fall in blood pressure is caused in part by a decrease in sympathetic tone and in part by a global vasodilation. Sympathetic tone to most organs will decrease and heart rate will fall in a process referred to as hemorrhage-induced sympathoinhibition (HISI). The fall in blood pressure results in increased production of nitric oxide, which compounds the insult and also contributes to the fall in blood pressure.[59] If the hemorrhage continues at a rapid rate, the combination of these two events results in a further fall in blood pressure to low levels, despite the brisk release of renin, epinephrine and vasopressin. Eventually blood pressure will be too low to preserve perfusion to the coronaries and brain, and ventilatory arrest and death will ensue. The cardiac output threshold for the onset of HISI is influenced by differences in PaO_2[60,61] and various drugs such as α_2-adrenergic antagonists, and perhaps vasopressin and renin.[62] Some controversy exists whether naloxone also influences this threshold.[63–65]

If the initial rate of bleeding was not as fast, the animal may exhibit spontaneous recovery of blood pressure.[66] Angiotensin II and vasopressin are important in this recovery,[67] which appears to be adversely affected by combined brain injury.[68,69] The recovery of blood pressure after severe hemorrhage has also been seen in clinical trials in which little or no fluid resuscitation is given in the initial management of the patient.[70] If blood pressure recovery is adequate then it may tend to remain at the recovery level for some period of time. If the total oxygen debt has already been substantial, however, or if moderate hemorrhage continues, the animals may remain hypotensive or fall back to hypotensive levels where they can remain for some period of time. They can maintain sufficient blood pressure to assure perfusion of critical tissues by a continued rise in total peripheral resistance. During this period of time increased plasma and tissue levels of endothelin have been documented along with increased levels of angiotensin II, but after some time, peripheral resistance will gradually start to fall.

This relatively late fall in peripheral resistance is seen in both awake and anesthetized animals and it occurs at the same time that there is a generalized loss of vascular responsiveness to the vasoconstrictors adrenaline and angiotensin II. This decrease in responsiveness is seen as early as 1 hour after the onset of hypotension in some

vascular beds,[71–73] but a systemic decrease in total peripheral resistance can require as long as 2–4 hours of hypotension.[74] The progressive decline in total peripheral resistance likely results from the progressive involvement of more vessels in the phenomenon.

The mechanism of the loss of responsiveness to epinephrine and angiotensin II is not fully explained, but it is associated with increased production of nitric oxide,[71,75] and it may be mediated through an opening of the K-ATP channel in vascular smooth muscle.[74,76] Non-selective nitric oxide synthase inhibition[71,72] and K-ATP channel blockade[76–79] can both return the vascular responsiveness. The continued production of nitric oxide during hemorrhage and the accumulation of nitric oxide adducts like S-nitrosylated proteins[51] may contribute indirectly. It has recently been shown that S-nitrosylation of the RAS/mitogen-activated protein kinase in brain leads to opening of the K-ATP channels.[80] Several other factors in this stage of shock also seem to target this channel, including intercellular acidosis, and decrease in intercellular ATP.[81] The opening of this channel results in hyperpolarization of the vascular smooth muscle, and vasodilation. This process, which also occurs in septic shock, is termed "vasodilatory shock". The net effect may be compounded in hemorrhage by accumulation of extracellular potassium,[82–87] which appears to be mediated in part by loss of transport function of Na-K ATPase.[87] Both uncoupling of the Na-K-ATPase[87] and the presence of an inhibitor[88] have been proposed as the mechanism, but the inhibitor appears to be different from the circulating ouabain-like factor that has recently been shown to be decreased in hemorrhagic shock.[89] The increase in extracellular potassium concentrations to 10–15 mmol[82,84] can contribute to the vasodilation[90] in part by the opening of another related potassium channel, the inward rectified potassium channel (Kir). The importance of these potassium changes has recently been emphasized by the findings of Darlington and Gann who have shown that administration of purine nucleosides[91] especially adenosine[92,93] can increase Na/K ATPase activity, prevent the rise in plasma potassium, and improve survival in hemorrhagic shock. Previous studies have also shown that the protection afforded by modest hypothermia correlates most closely with a slower rise in plasma potassium.[94]

At the late stage of shock there is also a fall in peripheral vasopressin levels perhaps due to depletion of central stores. The hyperpolarization of the vascular smooth muscle and a fall in peripheral vasopressin levels combine to cause a gradual fall in peripheral resistance. At this stage there is also evidence of increased vascular permeability,[95] and although blood pressure can be sustained for some

period of time by continued volume replacement, eventually only massive volume infusions[48] are effective in maintaining a life-sustaining blood pressure.

In summary, there are two different mechanisms of vascular collapse following hemorrhage: (1) HISI, which is seen in awake man and animals very early after the start of rapid hemorrhage; and (2) vasodilatory shock, which is seen in both awake and anesthetized animals after a significant oxygen debt. The timing for onset of HISI is minutes after the start of hemorrhage. The timing for onset of vasodilatory shock is variable and will occur as early as half an hour after injury if the hypotension is severe, and as late as several hours if the hypotension is modest. Both mechanisms of vascular collapse can be averted if blood pressure is restored early after hemorrhage by fluid and/or blood resuscitation, but if cardiac arrest intervenes it is possible that the ability to perfuse the brain and coronaries during cardiac compressions is limited by the same mechanisms that initially caused the vascular collapse. Direct evidence for this hypothesis is lacking, but circumstantial evidence implicates HISI in the events surrounding cardiac arrest: (1) HISI is heralded by a fall in heart rate and this biphasic heart rate response to hemorrhage (increased early and then decreased during HISI) may partially account for the finding that heart rate is an unreliable marker of the severity of hemorrhage; (2) HISI may account for the finding that bradycardic rhythms (heart rate below 40 beats per minute) after TCPR are associated with particularly poor outcomes; and (3) HISI is also associated with a marked reduction in oxygen consumption and a fall in core temperature.[96] Hypothermia after severe hemorrhage has also been associated with dismal outcomes. We consider below therapies that may be effective in reversing hemorrhage-induced vascular collapse. Although the two mechanisms may share some common pathways, more targeted therapy may be required that is specific to the mechanism of vascular decompensation.

Therapies to reverse the systemic vasodilation that occurs during rapid hemorrhage

Although HISI is heralded by a fall in heart rate, atropine will not increase blood pressure, even though it does increase the heart rate. Since vasopressin and angiotensin II appear to be involved in spontaneous recovery under normal circumstances, they would be likely as candidates to improve the effectiveness of CPR. Seki *et al.*[97] have shown that low dose hypertonic saline causes sympathetic activation. Two studies evaluated[98,99] vasopressin in model

of uncontrolled hemorrhage in pigs. The trigger for vaso-pressin infusion was a fall in heart rate that occurred surprisingly late at 30 minutes after onset of hemorrhage. Vasopressin increased heart rate and blood pressure without causing further bleeding, and resulted in improved survival. Nevertheless, it is not completely clear if the mechanism of cardiovascular collapse in these studies was HISI or vasodilatory shock. Exciting recent work by Osei-Owusu and Scrogin[100] has shown that Buspirone raises blood pressure after HISI through sympathetic activation and direct activation of α1-adrenergic receptors.

The increased production of nitric oxide as the blood pressure falls in HISI may be more amenable to intervention. Transient non-selective inhibition of nitric oxide synthase (NOS) effectively delays vascular collapse, but this approach to urgent reversal of HISI may be confounded by the finding that there is a significant non-NOS source of nitric oxide during cardiac arrest.[101] Therefore, mechanisms that absorb NO or increase its metabolism may be more effective. Hyperoxia decreases the vasodilatory effect of nitric oxide in two ways, by shortening its half-life (measured in seconds) and by blocking the release of S-nitrosothiols from the red blood cells.[102] Because of increased nitric oxide production and increased formation of S-nitrosothiols,[51] the vasoconstrictor effect of hyperoxia is greatly enhanced early after hemorrhage. Breathing 100% oxygen early after hemorrhage causes a large increase in total peripheral resistance in rats that is associated with an increase in heart rate, cardiac output, plasma norepinephrine, and myocardial contractility(Atkins, unpublished). The sum of these effects results in an increase in mean arterial blood pressure of 60 mmHg, which occurs within 30 seconds of changing the inspired gas to 100% oxygen.[103] PaO_2 averages around 400 mmHg on 100% oxygen, and most of the blood pressure change is seen with inspired oxygen at 60%. The increase in heart rate is prevented by the serotonin blocker ketanserin, but the increase in blood pressure is not prevented by ketanserin, allopurinol, or indomethacin, indicating that this may be a direct effect of decreasing nitric oxide-induced vasodilation. Hyperoxia in early hemorrhage results in a favorable redistribution of cardiac output, causing vasoconstriction in the skeletal muscle[104] and an increase in carotid blood flow.[103] This action may account for the improved survival seen with oxygen inhalation in controlled hemorrhagic shock;[105,106] however, this benefit is not universally seen in uncontrolled hemorrhage,[107,108] presumably because of the increased bleeding caused by the rise in blood pressure. In summary, the results suggest that breathing 100% oxygen may help in reversing HISI.

The desired benefit depends on decreasing levels of nitric oxide rather than meeting tissue oxygen requirements. Nevertheless, high concentrations would be required, and effective delivery during TCPR may be limited by restraints on the use of positive pressure ventilation discussed above. The use of perflurocarbons[109–111] and artificial hemoglobins[112] would also be expected to increase the metabolism of nitric oxide without the same constraints.

The systemic vasodilation resulting from opening of the K-ATP channels in vascular smooth muscle can be reversed by infusion of K-ATP channel blockers glibenclimide and glibizide.[76–79] Vasopressin infusion can also increase blood pressure and prolong survival in very late stage of hemorrhage-induced vasodilatory shock in animals.[113–115,98,116] Evidence suggests that low dose vasopressin may be the most appropriate.[117] On the basis of these promising results in studies of near cardiac arrest it seems reasonable that these same therapies could be useful adjuncts in TCPR, and indeed initial clinical case reports support this conclusion.[118]

Successful TCPR in patients with very rapid hemorrhage and HISI will also certainly require some means to stop the bleeding in the field since effective TCPR with return of spontaneous circulation would likely result in the reinstitution of massive bleeding. Although the relatively selective vasoconstriction of vasopressin may be effective in abdominal bleeding,[114] it is easier to envision success in patients with bleeding in an extremity, in whom the application of a tourniquet before TCPR may prevent a life-threatening rebleed.[119] The population that would likely benefit from glibenclimide or vasopressin are patients with delayed transport to a trauma center.

In summary, recent results make it more likely than ever that the results of TCPR can be dramatically improved in the future by combined strategies of selective vasoconstriction and improved ventilatory techniques. More directed research is needed in this unique cause of cardiac arrest.

Moreover, there may be even more potential to save lives if cardiac arrest can be prevented. In the next sections below, we will discuss therapies and recent advances that may help to prevent cardiac arrest after trauma.

Therapeutic interventions for HS (avenues for the advancement of trauma care)

Clearly, the most effective way of reducing morbidity and mortality related to traumatic arrest is to improve the initial management for the victim of traumatic shock and impending arrest. The approach to resuscitation of the

trauma patient follows a very logical and time-honored sequence designed to address life-threatening conditions in a hierarchical and systematic manner: that is to say, the ABC's of trauma treatment. This general approach has provided remarkable improvement and standardization in the prehospital treatment of multiple trauma victims over the last several decades. With this framework of Airway-Breathing-Circulation in mind, we can now consider advanced therapeutic interventions for use during the initial resuscitation that may delay or eliminate the onset of traumatic arrest.

Airway

Airway control remains the first and foremost concern in trauma care. Without adequate airway control all other interventions are destined to fail. Clearly, the importance of simple airway control can not be overstated. Nevertheless, airway manipulation in trauma patients is not without its drawbacks. Positive pressure ventilation results in increased intrathoracic pressure and a concomitant decrease in venous return and diminished cardiac output. This is particularly important in conditions related to volume depletion, such as hemorrhagic shock.[120] Indeed, the application of endotracheal intubation and positive pressure ventilation may exacerbate the already tenuous hemodynamic state and convert impending arrest to full arrest.[121]

Some investigators have begun to explore the reverse effect of this phenomenon as a mode of intervention. That is, to create a relatively negative intrathoracic pressure by way of airway impedance. The result of this maneuver is to create an intrathoracic vacuum effect, thereby improving venous return and cardiac output. Thus, Lurie and coworkers have developed a inspiratory impedance threshold valve for use during active compression–decompression (ACD) cardiopulmonary resuscitation.[122] The device has been shown to improve perfusion of vital organs during resuscitation and has proven to be effective when used during ACD–CPR.[123,124] Investigators have recently demonstrated that such a device may also be effective in preventing circulatory collapse-associated hemorrhagic shock before full arrest in both animal models,[125,126] and in human studies.[127] Use of an impedance device may be a very simple and reliable method for the field stabilization of the trauma victim.

Breathing

Hemorrhagic shock, a low-flow state created by depletion of blood volume, leads to decreased cardiac output,

reduced hemoglobin concentration, and alterations in microcirculatory blood flow directly resulting in impaired tissue oxygenation, and thus the accumulation of a cellular oxygen debt.[128] This fundamental precept has led to the nearly universal use of supplemental oxygen in the treatment of traumatic hemorrhage. Although, aside from the very basic goal of improving tissue oxygenation by increasing the available partial pressure of inspired oxygen, supplemental oxygen therapy may have a more subtle benefit for the trauma patient. Sukhotnik and coworkers have demonstrated in several models of hemorrhagic shock that oxygen therapy exerts an independent salutary effect on blood pressure, resulting in redistribution of blood flow from skeletal muscle to the splanchnic and renal vascular beds, which they believe to be a critical component of the beneficial effects of hyperoxia following hemorrhage.[107] Nevertheless, this therapy may increase the risk of bleeding in uncontrolled hemorrhage.[107,108]

As noted above, positive pressure ventilation can have negative hemodynamic effects for the volume-depleted patient. Recently, Pepe and coworkers have proposed an alternative strategy of reduced ventilatory rates aimed at limiting this detrimental effect. Experimental evidence from a swine model of hemorrhagic shock suggests that ventilatory rates as low as 6 breaths per minute can reduce the undesirable intrathoracic pressure changes associated with PPV without adversely affecting oxygenation or acid-base status.[121,129]

Oxygenation is a critical consideration for the patient with traumatic shock. The use of supplemental oxygen may need more careful evaluation because of the potential to increase bleeding. This is a recurrent theme in which inappropriate use of therapeutics that increase blood pressure may result in increased bleeding and prove to be counterproductive. Providing appropriate guidelines for such interventions may prove to be a substantive challenge.

Circulation

Hemorrhage control

The first rule in stabilizing the victim of hemorrhage is to prevent further blood loss. This emphasis has changed very little over time. Whereas, the application of pressure dressings or tourniquets to a wounded extremity remains the mainstay of hemorrhage control in the field, bleeding from non-compressible sites, such as organ injury or proximal vascular injury, continues to represent a significant cause of hemorrhage-related mortality. Approximately 30% of trauma-related deaths result from blood loss alone.[130] To address this problem, considerable

attention has been given to the use of both topical and systemic application of procoagulants to stem the tide of blood loss.

Multiple forms of hemostatic wound dressings impregnated with procoagulant compounds have been developed and tested.[131] Active procoagulant compounds used in such hemostatic bandages have included: chitosan, oxidized cellulose, thrombin, fibrinogen, microfibrillar collagen, propyl gallate, aluminum sulfate, and acetylated poly-*N*-acetylglucosamine. A recent direct comparison of several available preparations was conducted in a swine liver injury model. This study demonstrated that a dressing that utilized human fibrinogen, purified human thrombin, factor XIII, and $CaCl_2/cm^2$ freeze dried onto an absorbable polygalactin mesh was most effective,[132] whereas other investigators have shown a chitosan dressing consistently failed within 2 hours after application.[133] In any event, there are sure to be rapid advances in the science of external, emergency hemorrhage control in the near term.

The systemic administration of procoagulants may provide an important advantage to victims of trauma.[134] A retrospective review of in-hospital patients found that 8% of post-traumatic deaths occurred in the operating room. Of these patients, 82% died of uncontrolled hemorrhage and one-quarter of these deaths were attributable to coagulopathy.[135] There are no comparable data on how often coagulopathy contributes to prehospital deaths, but recent data by Brohi *et al*.[136] indicates that a significant number of trauma victims present to the trauma center with a coagulopathy that is not related to the amount of fluid administered, but correlates with the injury severity score. Patients who present with the "fatal triad of death:" acidosis, coagulopathy, and hypothermia, have several independent markers predicting bad outcome.

Although there can be numerous causes of coagulopathy in trauma victims, pharmaceutically enhanced hemostasis has two potential beneficial effects. First, and obviously, it may decrease the amount of initial blood loss, thereby reducing the traumatic insult. Secondly, it may help prevent the hypothermia, acidosis, and dilutional coagulopathy associated with massive transfusions.[137] Interruption of the fatal cycle of worsening hypothermia, coagulopathy, and acidosis may offer a necessary boost needed by these patients. The procoagulant drug that currently appears to be most promising is recombinant factor VIIa (rfVIIa).[138] Boffard and co-workers recently conducted a drug company-sponsored randomized trial of rfVIIa for hemorrhage from both blunt and penetrating trauma.[139] The study demonstrated convincingly that this drug can reduce the overall massive transfusion requirements after blunt trauma, with a similar trend seen in patients with penetrating trauma. While the differences in mortality and reduction in critical complications were less convincing, the drug was shown to be safe in this critically injured population. This may not be a giant leap forward for reduction in trauma mortality, but it is an encouraging advance for the concept of pharmaceutically enhanced hemostasis. A recent review by Ho *et al*.[140] has proposed that the reversal of coagulopathy may be improved with better guidelines for replacement of blood products.

Fluid resuscitation and hemodynamic stabilization

Following adequate airway control, breathing, and the control of hemorrhage, the next step in the standard resuscitation algorithm is to provide fluid resuscitation as needed for hemodynamic stability. The age-old argument of whether to use a crystalloid or colloid fluid for this has evolved into a much more complex and nuanced discussion concerning multiple variables, including volume of resuscitation, blood pressure limits, and an assortment of new fluid choices and additives designed to modulate vascular tone and immune responses. The ideal resuscitative fluid would simulate all of the positive properties of whole blood, be universally acceptable, inhibit further blood loss, abrogate the negative inflammatory consequences of traumatic hemorrhagic shock and subsequent intervention, and provide for hemodynamic stability at low infusion volumes.[141] Consequently, considerable research has been conducted to assess these individual components of resuscitation with the eventual hope of bringing them all together in a simple, easy to use package.

Aggressive fluid resuscitation to normal or even near normal blood pressures has been challenged as a dangerous maneuver likely to lead to exacerbation of blood loss, particularly in patients with non-compressible or uncontrolled hemorrhage.[142,143] This has led to the acceptance of hypotensive resuscitation as a standard of care in some trauma communities.[144,145] The benefit of hypotensive resuscitation for reducing hemorrhage in patients without adequate bleed control is clearly intuitive and has become generally accepted. This approach may also be beneficial in victims with profound blood loss even with adequate hemorrhage control, particularly when there is a delay to definitive care.[66] Currently, hypotensive resuscitation is a concept that is rapidly gaining acceptance in the medical community, but as yet, it is far from a standardized approach ready for insertion into the ACLS guideline. Nonetheless, the benefits of hypotensive resuscitation and the disadvantages of aggressive fluid resuscitation deserve careful consideration. One particular cause of concern is the possibility that hypotensive resuscitation

may result in increased incidence of coagulopathy or multiorgan failure.

Late deaths due to multiple organ failure

Multiple organ failure (MOF), or multiple organ dysfunction syndrome (MODS), was previously considered to be the leading cause of death after severe trauma.[146] This became particularly apparent as trauma care improved between the 1970s and 1980s, resulting in more patients surviving their initial injury to develop MOF.[147] Over the last decade, as trauma care has continued to improve, this trend has been reversed, leading to an overall reduction in the mortality risk associated with MOF after traumatic hemorrhage.[148,149] But, despite this encouraging progress, MOF remains an important cause of morbidity after trauma resuscitation and thus continues to be a therapeutic problem for ICU patients.[150]

This may be particularly true for patients surviving an initial arrest and in patients suffering from profound hypovolemic shock. Recent progress concerning the etiology and progression of MOF may offer important insights into possible early therapeutic interventions. The two-hit model proposed by Moore *et al.*[151] continues to play a central role in our understanding of the progress of MOF. Recent work has shown that the development of MOF is likely to be a complex and multifactorial process, with multiple immunologic and molecular events promoting its onset and influencing its severity. MOF is essentially the result of an overexuberant humeral and cellular inflammatory response leading to the expression and release of numerous mediators, such as toxic oxygen species, proteolytic enzymes, adherence molecules, and cytokines.[152]

The initiating events in MOF after shock may occur very early in the course of hemorrhage and mitigation of these events during the initial resuscitation effort may significantly reduce the likelihood of developing MOF following resuscitation. Some of the more important second hit events that may promote the onset of MOF appear to be related to abdominal compartment syndrome,[153] immune activation by postshock mesenteric lymph,[154] red blood cell transfusion,[155] and intravenous fluid infusion itself.[156–159] An early resuscitation strategy designed to mitigate these inflammatory consequences while providing life-saving hemodynamic support may help to decrease further both trauma-related MOF mortality and morbidity. A detailed discussion of the biology of MOF is beyond the scope of this chapter. We will, however, address some of the recent findings concerning the initiation of MOF and possible strategies of early manipulation below.

Immune modulation

Primary immune stimulation in response to trauma, in addition to secondary stimulation due to a subsequent insult such as surgical intervention, infection, and resuscitative interventions, plays an important role in the natural course of trauma. As noted above, the molecular events responsible for the systemic response to traumatic insult may occur very early in the course of injury and treatment. As such, manipulation or modulation of these events during initial resuscitation may offer an effective means of mitigating an exuberant and disruptive inflammatory response. A detailed description of all of the inflammatory consequences of traumatic hemorrhage is beyond the scope of this chapter. Here we will highlight some of the significant contributors to the inflammatory response along with their potential interventions.

The systemic response to traumatic hemorrhage begins with immediate changes in intravascular volume and autonomic discharge intended to redistribute blood flow to critical vascular beds. While these natural responses are intended to prevent irreversible damage to critical organs, the overall cardiovascular effect of significant hemorrhage results in decreased oxygen delivery, decreased tissue perfusion, cellular hypoxia, and organ damage.[160] The resulting stress on vascular endothelium leads to increased platelet aggregation and neutrophil infiltration mediated in part by the release of platelet activating factor (PAF).[161] This microvascular injury is responsible for changes in endothelial integrity that provide a nidus for the inflammatory cascade, which ultimately results in the generalized release of proinflammatory cytokines such as TNF-, IL-1, and IL-6.[162,163] TNF has recently been shown to play a critical upstream role in left ventricular dysfunction after hemorrhage resuscitation.[164] IL-6 is a very consistent marker of injury after hemorrhage resuscitation, so it very surprising that early infusion of IL-6 blunts production of proinflammatory cytokines.[165] The results suggests that IL-6 may be a basic compensatory response to injury rather than a proinflammatory mediator. Recent studies by Tracey and colleagues have identified a pro-inflammatory cytokine that is released late after injury, HMGBI.[166] This may provide a therapeutic target suitable for late interventions.

The early hemodynamic and inflammatory response to hemorrhage also involves the stimulation of nitric oxide (NO) production via constitutively expressed and inducible NO synthases. NO has been shown to exert both local and systemic effects. The immediate local consequence of

increased NO concentration is vasodilation, and this along with increased production of carbon monoxide[167] serves to preserve tissue perfusion in the face of the release of potent vasoconstrictors. The appearance of inducible NOS is a relatively late event after hemorrhage,[168] but it has been associated with increased liver,[169,170] gut[171] and lung injury,[172] and the induction of pro-inflammatory cytokines.[173] The interactions of induced heat shock protein, heme oxidase, and inducible NOS, however, are complex and the overall effect on tissue injury or protection is not determined by the expression of a single mediator.[174,175] During resuscitation, increased oxygen tension in the tissues and the production of oxygen radicals can react with nitric oxide from any source and with the nitric oxide adducts accumulated during the period of hypotension to produce reactive nitrogen species, such as NO_3^- and peroxynitrite.[176] Recent work has been designed to interrupt the NO-dependent consequences of these reactive oxygen species. McDonald and coworkers have shown that highly selective inhibitors of iNOS activity may effectively attenuate renal dysfunction as well as liver and pancreatic injury caused by hemorrhage and resuscitation .[177] A membrane-permeable radical scavenger (tempol) has been shown to delay circulatory failure as well as multiple organ injury and dysfunction associated with hemorrhagic shock.[178] Thus a strategy designed to prevent the formation of reactive nitrogen species may represent a novel early therapeutic intervention for hemorrhagic shock.

The gastrointestinal tract may be a particularly important source of posthemorrhage cytokines,[179] and injury to the gut is thought to play a pivotal role in the pathogenesis of MOF after hemorrhage resuscitation.[180] Intestinal injury is seen after resuscitation from hemorrhage and is associated with increased intestinal permeability to hydrophobic solutes,[181,182] appearance of translocated bacteria in mesenteric lymph nodes (of rats),[179,181–183] and the appearance of undefined pro-inflammatory mediators in mesenteric lymph.[184–186] Posthemorrhagic shock mesenteric lymph has been shown to prime neutrophils and cause lung injury.[154] Furthermore, lymphatic diversion can eliminate this injury.[154,187]

Oxidative stress and the formation of peroxynitrite[176] are involved in the intestinal damage and this is apparently exacerbated by a progressive vasoconstriction that begins at the time of resuscitation.[188] Therapeutic interventions have been aimed at minimizing the oxidative injury, reducing the formation of pro-inflammatory mediators, and reversal of the persistent vasoconstriction. Xanthine oxidase is abundant in the intestine and this appears to be a major source of the oxidant injury. Xanthine oxidase inhibitors are protective,[189,189] as are pentoxifyllin and the related compound lisofyllin, both of which may exert their

protection by preventing oxidant injury, although other mechanisms have also been proposed.[190,191] The source of pro-inflammatory mediators in mesenteric lymph is not fully resolved but Schmid-Schonbein and Hugli[186] have proposed a novel theory that postulates that pancreatic enzymes gain access to the intestinal cells after ischemic injury and produce multiple digestion products that are pro-inflammatory. The role of pancreatic enzymes in this process is substantiated by the studies of Cohen *et al.* showing that ligation of the pancreatic duct prevents distant organ injury after resuscitation from hemorrhage, even though it does not prevent gut injury.[192] Also studies by Doucet *et al.*[193] have shown that enteral application of pancreatic enzyme inhibitors is also protective. The results clearly indicate that pancreatic enzymes are involved in the formation of pro-inflammatory mediators and potentially provide a real therapeutic option for the prevention of MOF after severe hemorrhagic shock. Therapies that reverse mesenteric vasoconstriction also provide improved survival and are associated with less intestinal pathology. One intriguing approach is that of direct intraperitoneal resuscitation (DPR) proposed by Zakaria *et al.*[188] The local improvement of blood flow caused by DPR has been attributed to the vasodilatory nature of the dialysis solution. The reason for an increase in lung and muscle blood flow after DPR is less intuitive and remains to be explained. The authors postulate that improved cardiac work, removal of inflammatory mediators from the peritoneal cavity, and reduced leukocyte activation are all likely mediators of this beneficial effect.

In addition to the acute phase inflammatory reaction, profound hemorrhage initiates a molecular response that leads to the promotion and upregulation of genes responsible for heat shock proteins (HSP) and apoptosis. HSP are a family of gene products that likely represent a protective mechanism designed to check possible detrimental effects of physiologic stress. Kiang and coworkers have recently demonstrated specific HSP binding to iNOS and its transcription factor KLF6 after hemorrhage.[175] The result of this binding may lead to inactivation of iNOS and thus to a decrease in NO-related cellular injury. As a result of these findings, it has been postulated that the exogenous stimulation of HSP may be helpful during initial resuscitative efforts.

The stress response to injury concurrently initiates a process of apoptosis, or programmed cell death, designed to limit the extent of inflammation, to clear non-viable cells, and to maintain overall integrity of the organism. As the severity of hemorrhagic shock-related stress increases, the magnitude and extent of apoptosis increases. An exaggerated apoptotic response leads to cell death in multiple

cell types and tissues. The subsequent release of inflammatory intracellular components and debris may lead to further local tissue damage as well as detrimental effects at distant organ sites. For example, gastrointestinal apoptosis can result in breakdown in the gut barrier, leading to release of inflammatory intermediates into mesenteric lymph that exacerbate pulmonary apoptosis and the subsequent development of MOF.[194,195]

It has been suggested that regulation of the complex cascade of apoptosis may provide an opportunity for early intervention in the development of organ injury and failure.[196] Therefore, investigators have examined resuscitative strategies designed to limit the negative effects of apoptosis. It has been demonstrated that hemorrhage and resuscitation produce immediate apoptosis and that the magnitude of apoptosis depends, to some extent, on the choice of resuscitative fluid.[197,198] Ongoing work has identified several candidate resuscitative fluids, such as pyruvate Ringer's solution and hypertonic saline, which may help specifically to diminish the magnitude of apoptosis during resuscitation. Additionally, work with pharmacologic adjuncts such as crocetin and glutamine have been shown significantly to improve restoration of cellular energy stores, reduce apoptotic cell death, and improve overall survival.[199]

Cell-mediated immune responses after trauma-hemorrhage are gender-related. Male and female sex steroids produce differing immunomodulatory effects.[200] Proestrus females have been shown to demonstrate beneficial responses following trauma and hemorrhage with respect to splenocyte proliferation, IL-2, IL-3, IFN-gamma release, splenic macrophage IL-6 release, and TNF-alpha.[201] It is likely that this gender-dependent advantage is mediated in part via upregulation of HO-1 expression and activity.[202] These findings support the contention by some authors that the administration of agents such as flutamide, designed to antagonize androgen-receptors and simultaneously upregulate estrogen receptors, may play an important role in improving outcome from shock.

Complement activation has long been recognized to contribute to the inflammatory cascade leading to MODS following hemorrhagic shock.[203] Indeed, inhibition of complement activation before resuscitation has been suggested as a useful adjunct in patients experiencing major hemorrhage for the prevention of the sequelae of gut ischemia.[204] A single bolus treatment of Cl-esterase-inhibitor was shown to abrogate leukocyte adhesion and rolling in the mesenteric microcirculation after hemorrhagic shock.[205]

Recent studies have emphasized the interaction of the neuroendocrine response to hemorrhage and the immune response.[57] Tracey has shown that vagal stimulation blunts the immune response[206] and Guarini *et al.*[207] have shown that vagal stimulation blunts NF-κB activation after hemorrhage and improves short term survival. Moreover, this pathway mediates the protective effect of adrenocorticotropin.[208]

Endothelial dysfunction

A very recent preliminary publication by Mathru and Lang[209] has demonstrated that trauma patients have significant endothelial dysfunction despite adequate resuscitation. Although the authors did not speculate on the presence of nitric oxide inhibitors as a potential cause of this effect, Cooke[210] has postulated that asymmetric dimethyl arginine (ADMA), a naturally occurring inhibitor of nitric oxide synthase, may be an important cause of endothelial dysfunction. This hypothesis is particularly appealing because of the finding by Nijveldt *et al.* that the plasma level of ADMA is an independent risk factor for ICU mortality[211] and a potential cause of multiorgan failure.[212] The link between this and other factors involved in multiorgan failure is yet to be resolved.

New treatment modalities in shock

Hemoglobin-based oxygen carriers (HBOCs)

The hemoglobin-based oxygen carriers, polymerized hemoglobin solutions, represent a potentially significant advance in the treatment of hemorrhagic hypovolemia. The use of HBOCs may meet multiple critical needs of the trauma patient, including volume replacement, oxygen-carrying capacity, and immune modulation. Historically, the treatment of hemorrhagic shock has relied mainly on crystalloid infusion for the immediate stabilization of hemodynamics, followed by surgical intervention and transfusion of stored red blood cells (RBCs). Whereas transfusion with allogenic RBCs remains the gold standard treatment for acute traumatic anemia, human RBC transfusion is not risk-free. Aside from issues of compatibility, disease transmission, and supply limitations, the number of infused RBC units and the age of those units are directly proportional to the risk of subsequent MOF. Resuscitation with an HBOC may offer a means of mitigating these risks. Even though early clinical evaluation of HBOC resuscitation was plagued by increased mortality,[213] current work with newer formulations appears to be quite encouraging.[141,214]

Hemoglobin avidly binds nitric oxide and therefore all the first-generation HBOCs are all vasoconstrictors, as is the hemoglobin within the RBCs. Thus, the question

normally posed is whether HBOC absorbs significantly more nitric oxide than the RBCs already present within the circulation. One possible mechanism for an increased vasoconstriction with HBOC is related to the ability of HBOC to extravasate from the vascular compartment and thereby gain access to nitric oxide normally "out of reach" of the RBCs. This is more likely to occur in fenestrated vessels.[112] Persistent hypotension seen with some models of low volume resuscitation may make even a small effect evident.[66] Purification of the HBOC to remove small complexes would tend to minimize this effect.

Recent findings provide another possible explanation for the relative vasoconstrictor effect of HBOCs. Atkins *et al.*[51] have recently shown in rats that RBCs have an increased content of *S*-nitrosothiols after hemorrhage. Stamler and colleagues[215,216] have proposed that *S*-nitrosothiols may be released from RBCs in vascular beds with low oxygen tension as a result of the conformational change in hemoglobin. The released *S*-nitrosothiols would tend to vasodilate the tissue. Although there is no direct evidence that this "targeted release" occurs in hemorrhage, this "safety valve" mechanism could be functionally important, even if the amount of nitric oxide delivered is small compared to the overall rate of nitric oxide production. If the mechanism is operative in hypoxic vascular beds during hemorrhage, then the endogenous circulating RBCs would tend to vasodilate these beds while transfused RBCs and HBOCs would tend to vasoconstrict them. It remains a very difficult problem to demonstrate this effect *in vivo*, but resolving these questions may help to define the best strategies for the use of HBOCs.

Vasopressin

Return of spontaneous circulation following cardiac arrest due to hemorrhage has historically been considered extremely unlikely. So much so, that interventions, such as CPR and or ED thoracotomy, are discouraged except for the minority of cases involving penetrating torso injury in the patient who has loss of vital signs very close to or in the trauma room. Recently, investigators have begun to explore the use of vasopressin as an adjunct in hemorrhagic shock and cardiac arrest.[217] Administration of vasopressin has been successful in at least one case, albeit temporary, in the treatment of traumatic arrest.[218] The value of this drug may actually be for the hemorrhage victim before frank arrest in helping to stabilize a tenuous hemodynamic state and allowing time for further treatment.[219] Some have argued that in situations of uncontrolled hemorrhage, vasopressin administration along limited fluid infusion may be preferable to standard fluid resuscitation algorithms.[220]

Controlled modest hypothermia

Animal studies have shown a protective effect of modest hypothermia (28°C to 32°C) in head trauma and cardiac arrest. Likewise, numerous animal studies have also shown a beneficial effect of modest hypothermia in hemorrhagic shock. Nevertheless, substantial controversy remains about the use of mild (36°C to 32°C) or modest hypothermia in trauma, because hypothermia is associated with cardiac arrhythmias, coagulopathies, and increased incidence of infections. Moreover, as previously mentioned, patients who present to the trauma center with hypothermia have a worse outcome. Numerous animal studies have shown that mild or modest hypothermia, however, can improve survival and decrease late organ injury in hemorrhage resuscitation.[94,108,221–225] The controversy may never be resolved, and recently Wu *et al.*[224,225] have begun a search for the mechanisms that provide the survival benefit from mild hypothermia. Although a daunting task, this may prove to be the most acceptable way to provide this protection to trauma patients.

Conclusions

In developed countries, trauma systems with rapid transport to the hospital continue to make significant improvements in survival and outcome after injury. These advances have been largely based on improved roads and expanded and standardized trauma care systems. Unfortunately, it is unlikely that underdeveloped countries will be able to apply such resource-intensive responses to prevent the predicted increase in deaths from traffic accidents. In this context, improvements in the initial care of trauma patients at the scene could have a very significant impact. Even with the excellent road system and advanced transport systems in the USA, there is still the potential to save many lives through improvements in early care.

Introduction

The pathophysiological changes associated with hypothermia make cardiopulmonary resuscitation a unique challenge in patients with severe accidental hypothermia.[1–5] Hypothermia offers protection from ischemic tissue injury. Therefore, hypothermic patients have survived prolonged periods of untreated cardiac arrest and resuscitation efforts lasting for hours.[2,6,7] The arrested hypothermic heart often does not respond to electrical or pharmacological therapy unless rewarmed.[3,8,9] Therefore, diagnosis of irreversible cardiorespiratory arrest is difficult during hypothermia and is often defined as "the failure to revive with rewarming".[3] It is widely accepted that "nobody is dead unless warm and dead."[1] In addition to basic and advanced cardiac life support adopted to the particular needs of hypothermia, rapid core rewarming is an essential cornerstone of any resuscitation effort. Extracorporeal circulation is considered the method of choice to accomplish core rewarming in arrested hypothermic patients while offering optimal circulatory support.[10,11]

Pathophysiology of hypothermic cardiac arrest

Hypothermic cardiac arrest may occur in clinically distinct groups of patients. Cardiac arrest may affect otherwise healthy individuals trapped in cold environments, with cardiac arrest being the sole consequence of the deleterious effects of hypothermia on the cardiovascular system.[12,13] Cardiac arrest may occur in individuals submerged in ice water or snow, who suffer from asphyxia while rapidly cooling.[14,15] In these patients cardiorespiratory arrest is, at least partly, a consequence of asphyxia, and hypothermia may offer protection from irreversible ischemic injury when substantial hypothermia has developed before cardiac arrest. The healthy human body responds to cold stress in a rather uniform way, resulting in a predictable pattern of clinical symptoms and organ dysfunctions depending on the degree of hypothermia (Table 57.1). The two single most important responses to cold stress are an increase in endogenous heat production (e.g., shivering) and an intense sympathetic stimulation.[4,9,16] This results in a central pooling of blood, a marked temperature gradient between the core and the shell of the body of up to 20 °C, cold diuresis, an increase in hematocrit, volume depletion, and depletion of glucose stores.[4,9,17] The response to cold depends on the rate of cooling.[9] The overwhelming cold stress during submersion in ice water will result in a different cardiovascular and metabolic response compared to the prolonged cooling process in an exhausted mountaineer. Sometimes accidental hypothermia affects patients suffering from co-morbidities that alter thermoregulation per se and thus the response to cold stress. Extremes of age, traumatic shock, cerebrovascular accidents, spinal cord injuries, and endocrine disorders (myxedema, hypoglycemia) are the most important among these conditions.[4,9] Mortality of hypothermic patients with disorders of their thermoregulatory system is often determined by their underlying disease rather than by hypothermia.[9,18] Alcohol and drugs like sedatives and opiates also significantly alter the physiological response to cold stress.[19,20] It is important to consider the individual pre-arrest pathophysiology in a hypothermic patient and to adopt treatment protocols to the specific needs of the individual patient.

Table 57.1. Symptoms of accidental hypothermia

	Mild hypothermia 35°C–32°C	Moderate hypothermia 32°C–28°C	Severe hypothermia < 28°C
Motor function	Involuntary shivering	Shivering gradually disappears	Muscles and joints rigid
Cerebral function	Intellectual impairment Agitated, feels intensely cold	Consciousness increasingly depressed	Deep coma[a] Pupils may be fixed, dilated
Respiratory function	Hyperventilation	Increasing respiratory depression	Hypoventilation[b] Increased bronchial secretion
Cardiocirculatory function	Hypertension, tachycardia Strong central pulses	Supraventricular tachyarrhythmias Only central pulses palpable	Bradycardia[b] Danger of ventricular fibrillation Pulses may be undetectable

[a] Electroencephalogram becomes isoelectric at a core temperature of 20°C; [b] asystole and respiratory arrest occur at a core temperature around 23°C.

Metabolism, oxygen demand, and protection from ischemic tissue injury

The capacity of hypothermia to protect tissue from ischemic injury has been well known for decades and is routinely used in cardiac surgery. After controlled induction of hypothermia (core temperature below 20°C), circulatory arrest is tolerated without obvious neurological injury for periods of up to 45 minutes in adults and up to 60 minutes in infants.[21] In short-term profound hypothermia, the reduction in metabolic rate is the principal component responsible for maintaining tissue viability in cases of ischemic injury. Basically, a reduction in oxygen demand of 5 to 9% of baseline value can be expected with each degree of reduction in body core temperature.[17,22,23] Nonetheless, the impact of hypothermia on metabolism varies significantly among different organs, different cells in a particular organ, and even for different enzymatic reactions within an individual cell.[24] It has been stated repeatedly that during spontaneous circulation the hypothermic myocardium is more susceptible to ischemic injury than is the brain.[25,26] Experimental data suggest that the effect of hypothermia is not linear for various degrees of hypothermia. The temperature coefficient for myocardial protection, which describes the relation between temperature and myocardial preservation for every 10°C change in temperature, is 2.2 for a change from 35°C to 25°C, but 1.6 for a change from 15°C to 5°C.[27] Experimental and human clinical experience suggests that decreasing core temperature below 15°C to 10°C results in a decline in resuscitability rather than further enhanced protection from ischemic injury.[28,29] It is widely accepted that myocardial preservation is optimal during cardioplegic cardiac

arrest in open heart surgery within the temperature range between 10 and 20°C.[24,28] With a core temperature around 10°C, local organ cooling (e.g., brain) is better tolerated than total body hypothermia.[30] Obviously, with such low core temperatures total body hypothermia itself becomes deleterious. One possible explanation for these deleterious effects is the marked difference in the temperature dependence of biological processes. The phenomenon of tissue swelling in response to profound hypothermia, for example, has been attributed to the more pronounced inhibition of the active ion pumps in comparison to passive diffusion among electrochemical gradients.[24] Although extreme hypothermia per se is detrimental, it is not possible to define a borderline temperature below which hypothermia-induced tissue injury is irreversible. Most likely this borderline is different for various organs and depends on the type of cooling (e.g., rapid, controlled cooling with extracorporeal circulation versus slow, uncontrolled cooling during accidental hypothermia). Most of our knowledge about the protective as well as detrimental effects of hypothermia is derived from experimental and clinical data during controlled cooling with use of extracorporeal circulation. It is unclear whether and how these data can be extrapolated to patients with severe accidental hypothermia.

Effects of hypothermia on the myocardium

Hypothermia alters myocardial conduction and results in ECG abnormalities like progressive bradycardia, Q–T prolongation, QRS prolongation, and the "J" wave.[31] Cooling of the heart increases the risk for arrhythmias. Atrial fibrillation is common early during cooling;[16,17] when body core

temperature falls below 30 °C, the likelihood for ventricular arrhythmias and ventricular fibrillation is also markedly increased.[2,3,16,17] Possible explanations for the increased irritability of the myocardium during hypothermia are the alterations in the membrane potential secondary to defects of membrane ion channels.[32,33] Consequently, in experimental studies antiarrhythmic drugs like bretylium increase the threshold for ventricular fibrillation in the hypothermic heart.[34–36] Hypoxia, acid–base disturbances, high levels of endogenous catecholamine, myocardial temperature gradients, and rapid endocardial cooling caused by a sudden return of cold blood from the shell of the body (afterdrop) may be additional mechanisms contributing to myocardial irritability during clinical hypothermia.[2,4,9]

Acid–base balance during hypothermia

A unique problem in patients with severe accidental hypothermia is the management of their acid–base balance.[37] Electromechanical neutrality is temperature-dependent and to maintain electromechanical neutrality, pH must increase when temperature decreases. In an electromechanically neutral cell, pH will be 7.40 at 37 °C, but 7.80 at 20 °C. When temperature decreases, the solubility of gases in blood will increase. Consequently, when keeping total CO_2 content in blood constant, the increased solubility will result in a reduction in PCO_2. For example, a given blood CO_2 content corresponds to a PCO_2 of 40 mmHg measured at 37 °C, but only to a PCO_2 of 16 mmHg when measured at a blood temperature of 20 °C. Taken together, this causes a situation where electromechanical neutrality is maintained with temperature changes. Electromechanical neutrality is thought to be essential for the preservation of many cellular processes, e.g., the optimal function of the imidazole buffering system.[21,37]

In clinical practice, blood samples are heated to 37 °C before measuring the acid–base status (temperature uncorrected values). With use of the software of the blood gas analyzer, the values for a given blood temperature can be calculated with the help of nomograms (temperature corrected values). For patient management either corrected or uncorrected PCO_2 values can be taken. Choosing uncorrected values will keep the CO_2 content constant and maintain electromechanical neutrality (alpha-stat acid–base management), whereas choosing the temperature-corrected values will increase total CO_2 content and keep pH constant (pH-stat acid–base management).[21,37] Whether an alpha- or pH-stat regimen should be used during severe hypothermia is a matter of debate. Some experimental animal and clinical data from pediatric cardiac surgical patients indicate that using a pH-stat

regimen may improve neurological outcome after cardiocirculatory arrest, reduce myocardial irritability, and increase tissue oxygen delivery.[21] Results are inconsistent, however, and are limited to short-term controlled hypothermia. Therefore, most clinicians use an alpha-stat approach, not only because the preponderance of evidence supports the use of uncorrected blood gas values at least in adult patients,[16] but also because CO_2 to be added to the inspired gas is rarely available in emergency departments or intensive care units. To reach a sufficient CO_2 accumulation for pH-stat management solely by hypoventilation necessitates a degree of hypoventilation that will result in alveolar collapse and hypoxia.[16,38]

Experimental models of hypothermic cardiac arrest

Several experimental studies in animal models of hypothermic cardiopulmonary resuscitation have been published during the last few years. These studies have improved our knowledge and understanding of therapeutic interventions for hypothermic cardiac arrest. Experimental animal data may be of particular interest for evidence-based decision-making, as so far no prospective clinical studies of hypothermic CPR have been published.

External chest compression

Little was known about the efficacy of external chest compression during hypothermia before Maningas studied organ blood flow produced by conventional closed-chest CPR in a swine model in 1986.[39] Maningas demonstrated that, when compared to normothermia, blood flow during hypothermic CPR was lower when comparable forces of chest compression were used, but that it did not decrease over time. The reduced organ blood flow with standard compression forces may be caused by changes in the viscoelastic properties of the thorax during hypothermia. That blood flow is maintained during prolonged external chest compression can be explained by the profound vasoconstriction potency of deep hypothermia. These experimental data suggest that increasing the force of chest compression may improve blood flow, although it is not known whether this increases the risk for CPR-associated injuries.

Drug administration and defibrillation

Several recent experimental studies have focused on the effects of drug administration on coronary perfusion

pressure and success of defibrillation. Drug administration is controversial when the core temperature is below 30 °C.[40,41] Vasopressor drugs may not be necessary because of the vasoconstrictor potency of severe hypothermia. Furthermore, antiarrhythmic drugs may not be effective during hypothermia and any drug administered repeatedly may accumulate to toxic levels owing to decreased metabolism.[5]

Experimental studies demonstrated that coronary perfusion pressure during hypothermic CPR increases to a level necessary for restoration of spontaneous circulation only after administration of epinephrine or vasopressin, clearly questioning the assumption that vasopressor drug administration is neither necessary nor effective during hypothermic CPR.[40,41] In accordance with these experimental data, restoration of spontaneous circulation after vasopressor drug administration has been described in case reports of hypothermic clinical CPR.[42–45] Vasopressor drugs, however, may be necessary only after prolonged periods of cardiac arrest. After a short 4-minute period of hypothermic cardiac arrest, coronary perfusion pressure has also been maintained around the threshold associated with restoration of spontaneous circulation without drug administration.[46] The increase in coronary perfusion pressure associated with administration of vasopressor drugs facilitates transient restoration of spontaneous circulation.[40] Without concomitant rewarming efforts, however, no positive effects on long-term survival rates were observed. By contrast, when combined with warm fluid thoracic lavage at 40 °C, 0.4 U/kg of vasopressin significantly improved 1-hour survival rate.[41] Kornberger *et al.* demonstrated a significantly enhanced mixed venous hypercarbic acidosis and a deteriorated CPR outcome after treatment with epinephrine.[46] This is most likely due to the beta-mimetic side effects of epinephrine and, at least in this pig model of hypothermic CPR, vasopressin may be the vasopressor drug of choice. Two further animal studies demonstrated no positive effects of the antiarrhythmic drug amiodarone alone or in combination with vasopressin on success of defibrillation during hypothermic CPR.[47,48]

A recent experimental animal study evaluated the energy requirements for defibrillation during normothermia and hypothermia.[49] Interestingly, severe hypothermia (30 °C) decreased energy requirements for defibrillation after ventricular fibrillation of short duration. At energies of 20 Joule (J), 30 J, and 50 J the percent success of defibrillation was higher in severe hypothermic conditions. Moderate hypothermia (33 °C) did not affect energy requirements. These findings cannot be explained by a change in transthoracic impedance and transthoracic

current, because transthoracic impedance rose and transthoracic current fell. The mechanism for the reduced energy requirements during hypothermia is unknown, but it may be due to altered electrophysiologic or mechanical properties of the hypothermic myocardium.

Clinical management of the hypothermic patient with cardiac arrest

Hypothermic cardiac arrest in the prehospital setting

Because accidental hypothermia may be associated with a multitude of clinical conditions, there is a real risk of overlooking it.[50] Recognition in the prehospital environment is nevertheless important, because of the increased risk for lethal arrhythmias and the good prognosis even during prolonged cardiopulmonary arrest.[2,51] Basically, the possibility of accidental hypothermia should be kept in mind in any patient with a decreased level of consciousness. Depending on the degree of hypothermia, the clinical condition may vary from obtundation to deep coma.[9,16] Sometimes external causes for hypothermia may be obvious, e.g., immersion of the victim in cold water. The potential for significant hypothermia is often less evident, e.g., indoors if subjects are immobile, there is insufficient heating, and drug or alcohol intoxication ("urban hypothermia"). In particular, elderly people seem to be at a increased risk.[9] Profoundly hypothermic patients found outdoors may be considered dead by inexperienced care providers despite a perfusing rhythm, because of the absence of a palpable pulse, shallow and slow breathing, the paleness of the skin, and the stiffness of the limbs.[4,5] In the prehospital setting, resuscitation should be withheld only if the patient has obvious lethal injuries, hypothermia clearly followed normothermic cardiac arrest, or the body is completely frozen, making CPR impossible.[5]

Temperature monitoring

Reliable diagnosis of accidental hypothermia necessitates prehospital determination of body core temperature. Although various sites and different methods to determine body core temperature in the prehospital environment have been described.[2,51,52] The optimal method is controversial. Theoretically, without the possibility of measuring body temperature, a rough estimate can be obtained by feeling the warmth of a central part of the body that has not been in direct contact with the cold environment (e.g., abdomen in a person lying on the back). According to clinical experience, if the skin feels cold to the examiner's hand, hypothermia should be suspected.

Measurements of tympanic membrane temperature are widely used in European emergency medical systems. These measurements are simple and fast to obtain, but may be inaccurate if the victim has been submerged and the ears are wet or full of snow.[51,52] Prehospital measurements are best done with an electrical thermistor probe, as the reliability of infrared emission thermometers in the prehospital environment has been questioned.[53] Other sites accessible for prehospital measurements are the nasopharynx, the esophagus, and the rectum, but appropriate probes and monitors are rarely available in the prehospital environment. Conventional thermometers generally lack a scale that displays temperatures below 32–33 °C. Rectal temperature measurements require undressing of the patient and the thermometer must be inserted deep enough to give accurate readings. Insertion of an esophageal temperature probe may induce arrhythmias.[2,8] Nasopharyngeal temperature measurements often do not give a reasonable estimate of core temperature in the prehospital environment.

General assessment

The most feared complication in the prehospital management of patients with severe accidental hypothermia is a sudden cardiocirculatory collapse during rescue or evacuation ("hypothermic sudden cardiac death," "circum-rescue collapse," "sheltering death").[2–4,51] "Circum-rescue collapse" occurs almost exclusively at a core temperature below 30 °C, and cardiac arrest is usually due to ventricular fibrillation.[3,8] Although there is no solid scientific evidence that ventricular fibrillation is provoked by patient movements, clinical experience suggests that a perfusing rhythm often turns into ventricular fibrillation during rescue or initial patient assessment.[4,16,51] Therefore, if hypothermia is suspected, the operator should avoid any brisk maneuver and unnecessary movements and evacuate and assess the patient as smoothly as possible. It has been argued that movements of the patient mobilize and transfer cold blood from the shell to the center of the body, causing a sudden further decrease in core temperature of 1 °C–2 °C ("afterdrop").[8,9] This may induce ventricular fibrillation, but solid scientific evidence is missing. After prolonged cold water immersion a different explanation for sudden unexpected cardiocirculatory collapse ("post-immersion collapse") has been suggested.[54,55] Rescue from water is associated with a sudden loss of the hydrostatic pressure acting on the human body during submersion, which may cause a marked decrease in myocardial preload and arterial pressure. The phenomenon is further enhanced by evacuating immersed victims vertically.[55] Consequently, evacuating immersed hypothermic

subjects horizontally is a recommended standard procedure for most sea rescue crews.[55]

Diagnosis of cardiopulmonary arrest in the prehospital setting

Signs of life are often hard to detect in patients with severe hypothermia as there is a marked reduction in heart rate, respiratory rate, and cardiac output. Diagnosis of hypothermic cardiopulmonary arrest is therefore often difficult for the lay rescuer or emergency medical personnel not equipped with an ECG.[5] Consequently, the determination of the patient's cardiac rhythm with the help of an ECG in the prehospital environment has a high priority in a suspected cardiac arrest situation. In an obviously lifeless person, besides VF or asystole, an organized bradycardic rhythm without a detectable pulse may be found. In the case of severe hypothermia, slow, weak myocardial contractions may generate a cardiac output sufficient temporarily to meet the reduced demands of the hypothermic brain. Starting external chest compression will often convert this organized rhythm into ventricular fibrillation.[2,4] In extreme bradycardia, it is difficult to decide whether external chest compression should be started or the patient should be transported to hospital without CPR. Although controversial, it may be reasonable to start external chest compression as long as CPR can be maintained without any major interruptions until hospital admission.

Basic and advanced cardiac life support in the prehospital setting

Alterations in the technique of basic life support have been suggested for patients with severe hypothermia.[4,8] Nevertheless, standard ventilation and external chest compression are performed by most clinicians. There is little scientific evidence supporting suggestions to increase the force of chest compression or to reduce the rate to half of normal. The hearts of hypothermic patients undergoing internal cardiac massage were described as "frozen stiff" and "hard as stone".[12] Therefore, the efficiency of external chest compression has been questioned as the myocardium is obviously not compressible.[12] Considering the large number of hypothermic patients successfully resuscitated after prolonged periods of external chest compression, however, conventional external chest compression obviously provides sufficient blood flow to sustain life. The efficiency of external chest compression is best explained by blood flow generated by a general increase in intrathoracic pressure (thoracic pump mechanism) rather than by direct compression of the heart.[56] This is supported by findings from an echocardiographic study that showed blood flow generated by the

thoracic pump mechanism in hypothermic patients with a non-compressible myocardium.[57]

In the hypothermic patient, ventricular fibrillation often persists despite defibrillation or recurs immediately after defibrillation.[2,3] Nevertheless, up to three attempts at defibrillation to terminate ventricular fibrillation are generally recommended.[5] If VF continues or recurs, immediate transfer to an appropriate hospital during ongoing CPR is recommended. Because there is no evidence that prehospital drug administration will increase the success of further attempts at defibrillation,[40,48] transfer to hospital should not be delayed by any time-consuming attempts to obtain intravenous access for drug administration. Asystole often indicates prolonged arrest times, concomitant asphyxia, or hypothermia developing after normothermic cardiorespiratory arrest. If standard CPR efforts fail, the prognosis of each patient has to be assessed individually on the basis of history and clinical presentation. If the patient is considered to be potentially salvageable, immediate transfer to an appropriate hospital for rewarming should occur without further delay. There seems to be no reliable correlation between initial cardiac rhythm and outcome as long as cardiac arrest is primarily due to hypothermia.[58]

Whenever possible, an arrested hypothermic patient should be transferred to a hospital with cardiopulmonary bypass capability.[59] Patients tolerate much longer periods of conventional CPR during hypothermia.[6,7] Therefore, the closest hospital is not necessarily the best choice if a center with cardiopulmonary bypass is within reasonable range. Excellent outcome has been reported even after hours of external chest compression before institution of cardiopulmonary bypass.[10,11] Advance notification of the incoming patient is essential to cut treatment delays, and where possible CPR should be continued without major interruptions during patient transfer. Prevention of further heat loss in hypothermic patients in cardiac arrest is recommended,[5] but efforts to rewarm these patients should be withheld until hospital admission.[59]

In-hospital treatment of patients with hypothermic cardiac arrest

Decision to rewarm and resuscitate

The first decision to be made is whether prolonged resuscitation and rewarming efforts should be started in a patient admitted with hypothermic cardiopulmonary arrest. Considering the protective effects of hypothermia, basically the term "nobody is dead unless warm and dead" should be applied. Lifesaving procedures should never be withheld on the basis of clinical presentation alone.[1,5] On the other hand, mortality of hypothermic cardiac arrest is

high in many case series despite aggressive resuscitation efforts.[13,60,61,62] Risk factors associated with poor outcome have been identified and may help to determine when to stop resuscitation (Fig. 57.1). Asystole often indicates concomitant asphyxia or hypothermia following normothermic cardiac arrest. In a hypothermic patient, asystole occurs at a core temperature below 23 °C.[4,16,17] Asystole with a higher core temperature typically indicates that factors apart from hypothermia have contributed to cardiopulmonary arrest. Ventricular fibrillation occurs in patients suffering from hypothermic sudden cardiac death and prolonged resuscitation is normally justified as it is in all patients with witnessed cardiocirculatory collapse.[2,3,10] Patients with a history of exposure to cold have a markedly better prognosis when compared to victims with a history of near drowning or snow burial after avalanche accidents.[10,13,58,62] Hypothermia after near drowning normally indicates prolonged submersion, significant tissue hypoxia, and an extremely poor prognosis.[63,64] Only in case of documented very rapid cooling in ice water protection from ischemic injury can be expected. Survivors of ice water-drowning normally have submersion times of less than 40 minutes with a documented maximal submersion time of 66 minutes.[4,14] Most avalanche victims die from asphyxia and only become hypothermic thereafter. Hypothermia should be considered as underlying reason for cardiac arrest in those few avalanche victims with a history of prolonged snow burial and a documented air pocket at extrication.[65] Body core temperature per se does not seem to determine outcome, except that a significant protective effect should be expected only in patients with a core temperature below 30 °C. The lowest body core temperature documented for a survivor of accidental hypothermia is 13.7 °C, and for a survivor of intentional hypothermia the temperature is 9 °C.[66,67] A plasma potassium level exceeding 10 mmol/l may be used to support the diagnosis of irreversible cardiopulmonary arrest.[13,61,62] Survival may be possible despite extraordinarily high plasma potassium concentrations in patients with extensive local freezing injuries.[68,69] On the other hand, plasma potassium levels exceeding 10 mmol/l are a recommended, clinically useful triage criterion in avalanche victims.[65] Taken together, there is no single factor that reliably predicts irreversible cardiopulmonary arrest in the individual hypothermic patient. Common sense and good clinical judgement often allow identification of those hypothermic arrest victims without a reasonable hope of survival. Determining the prognosis of an individual patient is particularly important when several hypothermic arrest victims are admitted simultaneously in avalanche or climbing accidents.

yes →

Do not terminate CPR based on

plasma potassium determinations

↓ no

– found outside without signs of life

– cooling after normothermic arrest possible

yes →

Consider terminating CPR if:

plasma potassium > 10 mmol/l in adults

plasma potassium > 12 mmmol/l in children

Fig. 57.1. Severe accidental hypothermia with cardiac arrest: in-hospital decision-making and management.

Prevention of cardiocirculatory collapse during in-hospital treatment

Sudden unexpected ventricular fibrillation (hypothermic sudden cardiac death) is not unusual during in-hospital treatment of patients with a core temperature below 28 °C.[2,3,10] Precautions to avoid sudden cardiac death are therefore important in the treatment of severe accidental hypothermia. Although there are no formal studies, it is widely recommended that any direct irritation of the heart (Swan-Ganz catheter, invasive pacing) be avoided and to reduce active and passive movements to a minimum.[2,3,9,16] Insertion of an esophageal temperature probe or of a gastric tube, bladder catheterization, and placement of a thoracostomy tube[2,4,44,70,71] have all been proposed as triggers inducing ventricular fibrillation. The clinician may be well advised to reduce stressful or painful interventions to a minimum. Endotracheal intubation can provoke ventricular fibrillation in profoundly hypothermic patients,[72,73] although this is a very rare event, and it is widely accepted that the advantages of a secure airway and adequate oxygenation outweigh the potential risk of provoking life-threatening arrhythmias.[2,5,16] Rapidly rewarming patients with a core temperature below 28 °C by using an invasive method of active internal rewarming should keep the risk

interval for ventricular fibrillation short.[5,16] The efficiency of invasive active internal rewarming techniques such as hemodialysis or body cavity lavage is variable, however, and often there is a significant discrepancy between experimental and clinical efficiency.[16,74–77] Studies demonstrated that forced air rewarming may be a non-invasive, effective and safe alternative for treatment in smaller hospitals.[78–80] Bretylium increases the threshold for ventricular fibrillation during hypothermia and chemical defibrillation after bretylium administration has been reported in a hypothermic patient.[35,81] Amiodarone has no documented antiarrhythmic effects during hypothermia.[47,48] Prophylactic administration of antiarrhythmic drugs to avoid hypothermic sudden cardiac death is neither recommended nor widely used.[5]

Assessment of vital organ perfusion during profound hypothermia

Diagnosis of cardiocirculatory arrest is straightforward in hypothermic patients with asystole or ventricular fibrillation. Diagnosis of inadequate vital organ perfusion, however, may be a problem in patients presenting with extreme bradycardia or unrecordable blood pressure. Extreme bradycardia and weak myocardial contractions

may generate a blood flow adequate for the reduced demands during profound hypothermia.[5] The use of Doppler ultrasound probes to detect minimal cardiac output and peripheral blood flow has been suggested.[5] The lowest level of blood pressure that can be tolerated, together with a certain degree of hypothermia, is unknown. Experimental animal data suggest that blood pressure is physiologically reduced to about 50% of baseline at a core temperature of 25 °C.[82] Autoregulation of cerebral blood flow is maintained to a mean arterial pressure as low as 30 mmHg in previously healthy individuals.[83,84] On the other hand, clinical experience demonstrates that many hypothermic patients present with normal arterial pressure despite severe hypothermia, and in some clinical studies low systolic blood pressure was a marker of poor prognosis.[4,85] Interpretation of hemodynamic findings is further obscured by pre-existing cardiovascular diseases, concomitant trauma, or hypovolemia. Sometimes, an obvious discrepancy between the degree of hypothermia and the severity of the hemodynamic compromise may raise doubts that hypotension is solely associated with hypothermia. Furthermore, the therapeutic options to correct bradycardia or hypotension are limited and often controversial. Whether catecholamines, volume load, or vasopressor drugs increase cardiac output and blood pressure or if they can be used safely during hypothermia is controversial and not well studied.[85–88] The efficiency of beta-adrenergic drugs like isoprotenerol in increasing heart rate during hypothermia is controversial.[86,87] Pacing may improve hemodynamics during hypothermia,[89] but invasive transvenous pacing is normally not used as it may induce ventricular fibrillation. The safety and efficiency of transcutaneous pacing has been documented only in a single animal study.[89] Most clinicians would agree to start external chest compression in the in-hospital environment in all hypothermic patients without palpable central pulses or with unrecordable blood pressure, despite the presence of an organized activity in the ECG.

Advanced cardiac life support after hospital admission

Conventional approaches to CPR are often not effective in hypothermic patients with a core temperature below 28 °C.[3,5,9] Repeated administration of epinephrine often proves futile and may damage the heart and result in drug accumulation and delayed toxicity.[5] More than three attempts at defibrillation are considered to be a waste of time without previous rewarming of the myocardium.[5] On the other hand, restoration of spontaneous circulation has been reported in hypothermic patients with a core temperature below 28 °C.[80,90] Electromechanical cardiac activity can be reestablished in patients with a rectal tem-

perature below 20 °C.[80,91] In several case reports, restoration of spontaneous circulation has been reported in close timely association of administration with epinephrine or vasopressin.[8,42,80] In addition, experimental animal data demonstrate that vasopressor drugs increase coronary perfusion pressure during hypothermic CPR (experimental models of hypothermic cardiac arrest). The increase in coronary perfusion pressure may result in an improved CPR outcome when combined with rewarming or after prolonged cardiopulmonary arrest.[41,42] Thus, a pragmatic approach may be to administer at least a single dose of epinephrine or vasopressin. Experimental data available do not support the use of antiarrhythmic drugs during hypothermic CPR.[47,48] It is difficult to perform good quality manual CPR for prolonged periods, because chest compression causes operator fatigue after a few minutes. Use of portable mechanical chest compression devices may achieve an improved and more consistent blood flow.[92] Open chest CPR is an option during prolonged in-hospital resuscitation. Based on his experience in 11 hypothermic patients, Brunette suggested that early emergency room thoracotomy and internal cardiac massage may improve outcome.[71] Nevertheless, in most institutions external chest compression is the preferred method during prolonged CPR efforts. It is perhaps of minor importance how advanced cardiac life support is performed in a hypothermic patient as long as measures do not delay rapid core rewarming in patients without immediate restoration of spontaneous circulation (Table 57.2).

Rewarming options

For hypothermic patients with prolonged cardiac arrest the most important cornerstone of in-hospital resuscitation is initiation of rapid core rewarming.[5] Despite the lack of prospective randomized studies, it is widely accepted that extracorporeal circulation is the method of choice to rewarm arrested hypothermic patients.[3,5,10] When extracorporeal circulation is not available within a reasonable time, successful resuscitation is possible by use of alternative methods of core rewarming during ongoing CPR.[5,71,77,80] Successful resuscitation has been described using non-invasive methods of active rewarming;[80,93,94] nevertheless, invasive methods of active internal rewarming are the recommended therapeutic approach.[5] Experience with peritoneal dialysis, hemodialysis, or warmed fluid thoracic lavage has been reported.[5,74,75,77] The combination of closed chest thoracic lavage with external chest compression seems to be a reasonable, minimal invasive choice suitable for most hospitals (Table 57.3).[77,95–97] Spontaneous circulation was restored in the majority of patients within 2 hours in a

Table 57.2. Key points for the in-hospital treatment of hypothermic cardiac arrest

- Defibrillate three times in case of ventricular fibrillation
  - Consider further attempts after a single dose of epinephrine or vasopressin
- Consider epinephrine or vasopressin in case of asystole
- Check whether blood flow is sufficient to sustain life despite extreme bradycardia
  - Thoroughly check for weak central pulses
  - Consider use of a Doppler ultrasound probe to detect cardiac output
- Decide whether prolonged resuscitation and rewarming is justified
- Check for availability of cardiopulmonary bypass rewarming
  - Advance notification will cut treatment delays
  - Consider an alternative rewarming technique when transfer time to cardiopulmonary bypass exceeds 3 hours
- If prolonged periods of external chest compression are anticipated
  - Check for the availability of a mechanical chest compression device
  - Change resuscitator to avoid poor CPR performance due to fatigue
- Check for alternative rewarming strategies if cardiopulmonary bypass is not an option
  - Closed chest thoracic lavage is a minimal invasive, widely available option

Table 57.3. Suggestion for a minimal invasive treatment protocol for hypothermic cardiac arrest using closed chest thoracic lavage

- Continue external chest compression and consider use of a mechanical compression device
- In case of previous thoracic surgery or thoracic trauma, consider an alternative approach
  - Surface for heat exchange may be limited due to pleural adhesions
- Insert two large bore chest tubes into the left hemithorax
  - One in the mid clavicular line into the second to fourth intercostal space
  - One in the mid axillary line into the fifth to sixth intercostal space
- Infuse 40 °C warmed fluid into the mid clavicular chest tube
  - Actively inject with commercially available pressure-driven fluid warmers
  - Infusion by gravity may be sufficient
  - Use sterile saline if available (use of tap water has been reported)
- Connect standard thoracostomy drainage container to mid axillary chest tube
  - Monitor effluent output to avoid intrathoracic hypertension
- Defibrillate every 15 to 20 minutes of rewarming at least three times
  - Consider application of vasopressin or epinephrine before defibrillation
  - Preferential rewarming of the heart enables defibrillation at low core temperature
- Consider two additional chest tubes in the right hemithorax in case of slow rewarming
  - Rewarming rates of 3 °C to 4 °C/hour should be achieved
- Rewarm to a core temperature > 32 °C before terminating CPR efforts
- Consider use of prophylactic antibiotics after restoration of spontaneous circulation

recently published review on the use of thoracic lavage in arrested hypothermic patients.[77] It is possible that preferential rewarming of the heart during thoracic lavage re-establishes electromechanical activity of the heart more rapidly.[77,95] Experimental animal data suggest that supporting coronary perfusion pressure with vasopressin during rewarming may enhance restoration of spontaneous circulation.[41]

Cardiopulmonary bypass rewarming for hypothermic cardiac arrest

Historical notes

Cardiopulmonary bypass was introduced by Gibbons more than 50 years ago.[98] This technique enables perfusion of the body with oxygenated blood while the heart is arrested. Barratt-Boyes and Kirklin introduced hypothermic circulatory arrest for correction of complex congenital defects and operations involving the aortic arch.[98,99] On the basis of these two techniques, Althaus *et al.* successfully applied cardiopulmonary bypass rewarming to patients with accidental hypothermia and cardiac arrest.[12] Cardiopulmonary bypass rewarming spread rapidly and

has been used worldwide, with mixed results. Reasons for poor outcome are mainly related to indications involving asphyxiated or multitraumatized patients who are either brain-dead due to anoxia, or who develop severe cerebral hemorrhage due to heparinization.[10,100,101]

Indications for cardiopulmonary bypass rewarming

Patients in hypothermic cardiac arrest, without signs of asphyxia or severe brain trauma, are optimal candidates for cardiopulmonary bypass rewarming. Severe hypothermia with impaired cardiorespiratory function can also indicate the need for cardiopulmonary bypass rewarming if the patient is admitted to a hospital with a cardiac surgery

unit.[62,102,103] Hypothermic patients without cardio-respiratory arrest can be rewarmed with less invasive or non-invasive methods, such as forced air warming.[5,43,78,79] The latter method is increasingly used in even severely hypothermic patients with good results and is applicable also in small hospitals and for multitraumatized patients.[43,78,79] Possible contraindications to cardiopulmonary bypass rewarming are multisystem-trauma, especially with brain injury since normally a certain level of heparinization is required during cardiopulmonary bypass rewarming.[104] Anticoagulation is necessary even though most hypothermic patients suffer from a severe coagulation disorder. This coagulation disorder may correct itself partly during rewarming, leading to thrombus formation in the cardiopulmonary bypass circuit. Recently, fully heparin-coated cardiopulmonary bypass circuits have permitted the use of lower doses of heparin and, in one published case, the avoidance of any heparinization during cardiopulmonary bypass rewarming.[69]

Advantages and limitations of cardiopulmonary bypass rewarming

The advantages of cardiopulmonary bypass rewarming certainly outweigh the limitations: rapid preferential core rewarming, immediate adequate perfusion and oxygenation of vital organs such as the brain, improved blood rheology, and rapid correction of homeostasis (e.g., acid–base balance). Insertion of a hemofilter into the bypass system allows elimination of noxious substances in cases of intoxication.[10] Nonetheless, some limitations of cardiopulmonary bypass rewarming should be considered. The rate of rewarming with cardiopulmonary bypass is around 8°C per hour.[10,11] It is not clear whether such rapid rewarming is necessary or could even prove harmful.[105,106] During cardiac surgery fast cooling and rewarming rates are used routinely, but patients with induced hypothermia cannot be compared to patients with accidental, uncontrolled hypothermia. Furthermore, cardiac surgeons try to keep the cardiopulmonary bypass time as short as possible to prevent complications related to the time on an artificial circuit.[107,108] Considering reports of the efficiency of mild hypothermia in preventing brain injury, it may be beneficial to stop rewarming at a core temperature of 33–34°C and keep the patient mildly hypothermic for 12 to 24 hours.[109] Edema formation is another common problem observed after cardiopulmonary bypass rewarming. Most patients in the study by Walpoth *et al.* developed pulmonary edema already during rewarming,[10] which probably represents a reperfusion injury and there is no reason why a similar phenomenon does not exist in other organs, such as the brain.

Technical aspects of cardiopulmonary bypass rewarming

Technically, cardiopulmonary bypass rewarming is a minor intervention for experienced centers. In the adult patient, peripheral femoral cannulation is preferred and a standard cardiopulmonary bypass circuit or an extracorporeal membrane oxygenation system may be used.[110,111] Extracorporeal membrane oxygenation systems allow cardiopulmonary bypass rewarming outside the operating theatre, e.g., in the emergency department or in an outside hospital.[111–113] Cannulation may be performed percutaneously, allowing rapid cannulation during ongoing CPR.[110,111] In children and infants sternotomy and central cannulation is preferred. In some centers initially low flow perfusion is used,[10] for a few minutes, after which flow rates and temperature are increased step-wise, keeping in mind never to exceed a temperature gradient of 10°C between the perfusate and the patient's core temperature. With rising temperature, the flow will be increased to calculated full flow values.[10] Defibrillation will occur spontaneously in about 50% of the cases when the temperature rises above 30°C; defibrillation attempts below 27°C are rarely successful.[5,10] After weaning from cardiopulmonary bypass care should be taken rigorously to correct the bleeding disorder since there is a synergy of heparin and hypothermia-induced coagulopathy.

Outcome of cardiopulmonary bypass rewarming

The outcome of patients with hypothermic cardiac arrest without asphyxia or brain trauma was excellent in a long-term follow-up study after cardiopulmonary bypass rewarming.[10] Nearly all patients had severe transient pulmonary, brain, or kidney dysfunction immediately after rewarming. Interestingly, cardiovascular complications were rare, probably because of the longer ischemic tolerance of the heart compared to other organs.[10] Outcome after cardiopulmonary bypass rewarming has been described predominantly in case reports or small case series. As most patients not successfully resuscitated will not be reported, it is difficult to determine the exact morbidity and mortality of cardiopulmonary bypass rewarming as long as no international registries that include failed patients have been formed.

Summary

Hypothermic patients have survived prolonged periods of untreated cardiac arrest and resuscitation efforts lasting for hours owing to the protective effects of low body core temperature. Standard protocols for advanced cardiac life

support often prove futile in profoundly hypothermic patients and aggressive core rewarming is therefore a cornerstone of any resuscitation effort. Cardiopulmonary bypass rewarming is state-of-the-art for hypothermic patients with cardiac arrest, providing that the technology is available on an immediate basis.

Cardiac arrest due to poisoning

Kenneth Heard and Norman A. Paradis

University of Colorado Health Sciences Center, CO, USA

Introduction

Cardiac arrest from poisoning results from direct effects on the cardiovascular or the central nervous system (CNS). Cardiac effects may be caused by perturbation of the autonomic system, antagonism of ion channels, or interference with myocardial metabolism. CNS active poisons cause cardiac arrest through either respiratory suppression (leading to asphyxial arrest) or CNS stimulation with seizures or severe agitation (and the resultant metabolic abnormalities). Restoration of hemodynamics often requires addressing the effects of the poisoning in addition to standard treatment of cardiac arrest.

There are very few studies of specific treatment for cardiac arrest from poisoning. The utility of some interventions, such as ensuring ventilation and oxygenation for patients with cardiac arrest due to CNS depressants, is self-evident. The last two ACLS updates include a section on the treatment of cardiac arrest from poisoning.[1,2] This section was a major advance in that it recognized that cardiac arrest from poisoning is a unique situation, but it also highlighted the lack of quality data in this area. If studies of naloxone are excluded, the recommendations are based on fewer than 500 patients, and most of these data are anecdotal.[3] A few interventions have been studied systematically in animal models of severe poisoning, but there are no systematic animal studies of therapy for cardiac arrest. Given the lack of systematic data, the treatment of cardiac arrest remains more art than science, and the standard of care is poorly defined except for initial supportive care. The recommendations in this chapter are a guide to clinicians, but they should not be considered as standard of care.

Special considerations in the management of cardiac arrest from poisoning

Although many different poisons cause cardiac arrest, the initial treatment must start with standard life-support measures. There are only a handful of specific antidotes that require special consideration during cardiac arrest. Table 58.1 includes the clinical manifestations and treatment of several poisonings that commonly cause cardiac arrest. Although these antidotes may reverse the cardiotoxic effects, they are unlikely to restore perfusion, and must be considered as adjuncts to standard cardiopulmonary resuscitation. Antidotal therapies may help reverse the cardiotoxic effects once perfusion has been restored.

Cardiac arrest from poisoning often occurs in otherwise healthy patients. If the patient's hemodynamics can be supported, there is a potential for recovery. When medications fail, extracorporeal support should be considered.[4–14] For example, one animal study suggested that cardiopulmonary bypass was superior to medical treatment for amitriptyline poisoning.[15] There is also a potential for neuroprotection if the patient is poisoned with barbiturates or calcium channel blockers.[16]

Another consideration is that the optimal doses of commonly used vasoactive medications have not been determined for poisoned patients. In many common overdoses, there is competitive or non-competitive antagonism of the adrenergic receptors. Thus, for example, it is reasonable to exceed the commonly recommended dose range for adrenergic vasopressors.[1,17] Details of treatment for specific poisons are considered below.

Table 58.1. Presenting symptoms of poisons that commonly cause cardiac arrest and require specific antidotal therapy. These treatments should be used as an adjunct to standard resuscitation measures

Presentation/symptoms	Possible poisoning	Treatment
Bradycardia, heartblock, ventricular or atrial ectopy, hyperkalemia	Acute cardioactive steroid	Digoxin Fab, magnesium, lidocaine, ventricular pacing, amiodarone
Bradycardia, refractory hypotension	Calcium channel antagonists, beta-blocker	Calcium, high dose adrenergic agonists, glucagon
Bradycardia, vasodilatory shock, coma, profound acidosis	Cyanide	Cyanide antidote kit, hydroxocobalamine
Wide complex dysrhythmia, coma, seizures	Tricyclic antidepressants, chloroquine, cocaine	Hypertonic sodium bicarbonate, high dose adrenergic agonists, high dose benzodiazepines
Ventricular fibrillation, shock, profound hypocalcemia	Hydrofluoric acid	High dose calcium chloride
Seizures, pulmonary edema, vomiting/diarrhea, small pupils	Acetylcholinesterase inhibitor (insecticide or chemical weapon)	High dose atropine, high dose benzodiazepines
Marked tachycardia, seizures, vomiting, hypokalemia	Theophylline	Vasopressin, alpha-adrenergic agonists, high dose benzodiazepines
Wide complex dysrhythmias, hypotension	Sodium channel blocking drugs[a]	Hypertonic sodium bicarbonate, adrenergic agonists

[a] See thext for list of drugs reported to block sodium channels.

Calcium channel blockers and beta-adrenergic blockers

Although calcium channel blockers (CCB) and beta-adrenergic blockers have very different mechanisms of action, they produce very similar clinical manifestations when taken in overdose. These medications account for more poisoning deaths than any other cardiovascular drugs and are the second and third most common causes of death from non-narcotic prescription drug poisons.[18]

Pathophysiology

Calcium channel blockers, also known as calcium channel antagonists, bind to and decrease the opening of L-type cardiac and vascular calcium channels. At high doses, these drugs may occupy the channel and completely block entry of calcium, thus preventing the influx of calcium into the cell that is required to activate contraction (or conduction) in these organs. Patients will develop hypotension due to a combination of vasodilatation, bradycardia, and decreased myocardial contraction. Other effects include blocking insulin release, with resultant hyperglycemia and ketosis.[19]

Beta-adrenergic receptor blockers, more commonly known as beta-blockers, are competitive antagonists.

Bradycardia and hypotension are the major manifestations of toxicity from these drugs, which are categorized by their selectivity for beta-1 or beta-2 receptor subtypes. Propranolol also blocks cardiac sodium channels and may produce toxicity similar to quinidine. A few beta-blockers, such as pindolol, have partial beta-adrenergic agonist activity,[19] but it is not clear how these effects alter toxicity following overdose.

Presentation and diagnosis

Calcium channel blocker or beta-blocker poisoning should be suspected when a patient has hypotension, heartblock, and profound bradycardia. Although the hypotension is well tolerated initially, patients often deteriorate rapidly.

Treatment

There are several case reports of successful resuscitation of patients in cardiac arrest after overdose from both CCB and beta-blockers. These reports suggest that multiple therapies, including high-dose calcium, adrenergic agents, and glucagon are often required (see below). Extracorporeal support, including cardiopulmonary

bypass and intra-aortic balloon pump, has also been used to treat hemodynamically unstable patients.

Calcium, which has a rapid onset of effect, has been used as first line treatment of hypotension and cardiac arrest from CCB and beta-blocker overdose.[20–24] There are also reported failures of calcium therapy, however, possibly because of inadequate dosing.[25,26] One to 3 grams of calcium chloride may be given as repeated boluses; indeed, one patient required more than 30 g over 12 hours.[27,28]

Adrenergic vasopressors are of rapid onset, and should be considered first line therapies for patients with hemodynamic instability or cardiac arrest. Epinephrine is most commonly used for treatment of cardiac arrest, but norepinephrine and isoproterenol have been used successfully to treat hypotension from CCB poisoning. Phenylephrine is less effective than other vasopressors in animal models.[29,30] Very high doses of vasopressors may be effective when standard doses are inadequate.

Glucagon is considered the "antidote" for both beta-blocker and CCB toxicity. Several animal studies suggest that glucagon may reverse hypotension from these agents, but human case reports are mixed.[31–34] In animals and humans the effects may not be noted for 15–30 minutes after administration,[30] suggesting that glucagon is at best an adjunct to more rapidly acting drugs for patients in cardiac arrest. The normal dose is 5–15 mg as a bolus, followed by an infusion of 1–10 mg/hr.[19]

The most recent advance in the treatment of CCB toxicity is utilization of high-dose insulin therapy. Several well designed animal trials have shown improved survival and metabolic indices compared to standard therapies.[36–40] and this therapy has also been used in several human cases. The effects of insulin are not immediate, and patients may not improve for 30 minutes or more.[41] Therefore, insulin should be considered as a post-resuscitation supportive treatment. The usual dose is 1 unit/kg as a bolus followed by a 1 unit/kg/hour infusion. A glucose infusion is also started to maintain euglycemia.

Non-adrenergic vasopressors are of uncertain efficacy. Vasopressin increased mortality in an animal study of verapamil poisoning.[42] There are no compelling human reports suggesting that vasopressin is effective for hypotension or cardiac arrest in the setting of verapamil poisoning. Animal studies of phosphodiesterase inhibitors gave mixed results.[43,44] In several case reports amrinone was used as an adjunct to other vasopressors, and phosphodiesterase inhibitors are a reasonable adjunctive therapy for patients with refractory hypotension.[34,45,46]

Stimulants

Cocaine and amphetamine derivatives are the most commonly encountered CNS stimulants. As most patients are not taking these drugs with self-harm intent, cardiac arrest is a rare complication of their use. Nevertheless, stimulants still account for several thousand deaths each year. Most intensivists and emergency physicians will have to care for critically ill patients intoxicated with these drugs.

Pathophysiology

Stimulants act directly on the brain to cause agitation and seizures.[47] Activation of the sympathetic nervous system can also cause vasospasm. In addition, cocaine blocks cardiac sodium channels, and patients may require specific treatment to reverse sodium channel antagonism (see sodium channel blocking drugs below).[47]

Presentation and diagnosis

Most patients with stimulant intoxication present with restlessness, anxiety, hypertension, tachycardia, and other signs of sympathetic nervous system activation. Ventricular tachycardia may be due to ischemia from increased oxygen demand or vasospasm. Cocaine may produce a wide complex tachycardia from direct antagonism of sodium channels; these channels are pH-dependent, so that the binding wide tachycardia most commonly occurs after a seizure.[48] Cocaine use can also cause subarachnoid hemorrhage, which may present as cardiac arrest.[49]

Treatment

There are several reports of successful treatment of cardiac arrest from cocaine toxicity.[48] These patients had severe agitation and seizures followed by hemodynamic collapse. Patients should be treated with benzodiazepines (diazepam 5–20 mg i.v.) to control the seizures, sodium bicarbonate (1–2 meq/kg i.v.) to reverse the myocardial sodium channel antagonism, and epinephrine (1 mg i.v.) to restore perfusion.[48]

Cocaine use is also associated with accelerated atherosclerosis, vasospasm, and is prothrombotic.[50–52] Thus, patients may present with sudden cardiac death from an acute coronary occlusion precipitated by cocaine use.[53] In general, management of these patients is similar to the management of other myocardial infarction patients. Once perfusion has been restored, patients with appropriate electrocardiographic criteria should be

considered for early revascularization. Patients with CNS symptoms of sympathomimetic intoxication should be sedated with benzodiazepines as described above?[54,55] Beta-blockers are contraindicated in the setting of acute cocaine poisoning.[1]

Asphyxiants/CNS depressants

These two types of poisons are considered together because they both kill patients by producing systemic hypoxia. Asphyxiants are gases that displace oxygen in the atmosphere, producing a hypoxic environment. Common asphyxiant gases include methane, propane, carbon dioxide, and nitrogen, but any gas can become an asphyxiant at high concentrations. Common CNS depressants include ethanol, benzodiazepines, opioids, barbiturates, and many other therapeutic and abused drugs. Although some of these drugs may have effects beyond CNS depression (e.g., cardiodepression from high doses of barbiturates, sodium channel antagonism from norpropoxyphene, or cardiac sensitization from chloral hydrate), most cases of cardiac arrest are due to respiratory depression and hypoxia.

Pathophysiology

The importance of oxygen for cellular function has been described in detail in several previous chapters. As described above, simple asphyxiants cause hypoxemia by decreasing the concentration of oxygen in the environment. This hypoxemia produces an initial increase in respiratory drive, and ventilation will increase until the respiratory centers become depressed from hypoxia. CNS depressant drugs inhibit respiratory centers and cause hypoxia through hypoventilation.

Presentation and diagnosis

Patients exposed to asphyxiants usually develop signs of hypoxia before losing consciousness. Upon removal from the hypoxic environment, they often improve dramatically. Persistent symptoms suggest that there is hypoxic brain injury. Patients with a brief period of asphyxia may respond rapidly to resuscitation once the heart is oxygenated. Patients who suffer cardiac arrest due to hypoxia and hypoventilation from CNS depressant toxicity may also have a rapid return of circulation once myocardial oxygen delivery is restored. Nevertheless, they do not usually have a rapid return of consciousness, as the effects of the CNS depressant remain.

Treatment

The key to treatment for cardiac arrest from exposure to either asphyxiants or CNS depressants is to provide adequate oxygenation as soon as possible. One study of prehospital cardiac arrest from these poisons found that many patients recovered pulses with CPR alone.[56] There are no specific animal studies of cardiac arrest due to poisoning by CNS depressants, but high dose epinephrine or vasopressin plus epinephrine is more effective at restoring circulation than vasopressin, and improves survival in an animal models of asphyxiated cardiac arrest.[57] Whereas there is no evidence that prolonged resuscitative attempts are warranted, many of the CNS depressant medications have been shown to have neuroprotective effects in animal models of cardiac arrest and this clinical scenario is similar to the pretreatment design of animal studies.[16] This has led to the recommendation that prolonged resuscitative attempts may be warranted in these patients. There are no controlled data, however, and this author was unable to find any quality case reports to support this assertion.

Theophylline

Theophylline use has decreased dramatically over the past 10 years, with only 10 theophylline poisoning deaths reported to US poison centers in 2003.[18] Theophylline and caffeine are both methylxanthines that occur naturally in coffee and tea; more concentrated sources include energy supplements and diet pills. Caffeine toxicity rarely results in cardiovascular or neurologic effects, but when serious toxicity occurs, the effects and management are similar to those of theophylline.

Pathophysiology

Theophylline is an indirect activator of the adrenergic system and this increases plasma catecholamines and causes increased sympathetic activity.[58] The methylxanthines do not cause severe peripheral vasoconstriction and therefore patients are not usually hypertensive. Theophylline is also a potent adenosine receptor antagonist, and this effect may be the primary mechanism of therapeutic action. Adenosine antagonism is responsible for the seizures that are the hallmark of severe theophylline intoxication.[59]

Presentation and diagnosis

The diagnosis of theophylline toxicity should be considered when patients present with marked tachycardia,

vomiting, and seizures.[60] Most patients have a history of pulmonary disease. Laboratory findings that suggest theophylline poisoning include hypokalemia, metabolic acidosis, and hyperglycemia.[58]

Treatment

The most common cause of cardiac arrest following theophylline poisoning is ventricular dysrhythmias.[60] A patient with recurrent episodes of ventricular fibrillation and prolonged hypotension survived with repeated defibrillation, lidocaine (a total of 240 mg/h), metoprolol (10 mg), benzodiazepines (20 mg diazepam followed by a midazolam infusion of 5 mg/hour), electrolyte replacement, and hemoperfusion once hemodynamics were restored.[61] Another report of a patient with chronic theophylline intoxication who developed cardiac arrest also was readily defibrillated.[62] In a series of 38 theophylline overdoses, there were three cases of ventricular fibrillation and two responded "promptly" to defibrillation.[63] Finally, there is one well documented case of a patient who developed hypotension refractory to 160 mcg/min of epinephrine and 250 mcg/min of phenylephrine. This patient survived for 48 hours but was treated with several different combinations of vasopressors (including norepinephrine), and ultimately developed ventricular dysrhythmias and hypotension that were refractory to treatment.[64]

On the basis of these case reports, patients with ventricular fibrillation in the setting of theophylline poisoning should be treated with prompt defibrillation and lidocaine. There are no reports of the use of amiodarone, but it is a rational choice. Patients may require high doses of adrenergic agents to maintain adequate blood flow. There are no data on the use of vasopressin as a vasopressor for theophylline overdose, but, given the role of endogenous catecholamines in the adverse cardiovascular effects of theophylline poisoning, it is a reasonable choice. Vasopressin has been used to treat refractory hypotension from caffeine poisoning.[65] Beta-blockers have been used successfully to treat the cardiovascular effects of theophylline,[66,67] and they should be considered for patients who recover hemodynamics after cardiac arrest. Esmolol should be administered to patients with persistent ectopy or dysrhythmias and an adequate mean arterial pressure. Low doses should be administered initially, after which the dose should be titrated to control ventricular rate and prevent ectopy.

Adenosine is an intriguing potential antidote for theophylline poisoning. A 1-mg bolus of adenosine reversed the hemodynamic effects of 50 mg/kg of theophylline in a rat model;[68] this would translate into very high doses

(approximately 200–400 mg) for a human. One theoretical treatment that might be reasonable in severe cases is administration of dipyramidole, which is an adenosine uptake inhibitor, and may therefore prolong the activity of adenosine. The dose used in cardiac stress testing is 0.56 mg/kg i.v. over 4 minutes.[69]

Hydrocarbon inhalation

Deliberate inhalation of hydrocarbon products ("huffing", "glue," or "paint sniffing") is a growing problem among US adolescents.[70] Death from hydrocarbon abuse may be from dysrhythmias ("sudden sniffing death") or from asphyxia.

Inhalation of hydrocarbons must be differentiated from aspiration of hydrocarbons. Inhalation does not cause acute pulmonary symptoms. The hydrocarbon is volatilized, allowing the gaseous form to pass through the alveoli and into the blood. Aspiration occurs when the liquid hydrocarbon enters the lung, usually when the product is swallowed or vomited. In liquid form, the hydrocarbon can interact with lung structure causing atelectasis and non-cardiogenic pulmonary edema.

Pathophysiology

Butane and toluene are commonly found in abused products in the USA and benzene is used in many industrial types of glue; it is frequently abused in other countries. These drugs are abused for their effects on the CNS. They have general anesthetic properties, and inhalation is associated with euphoria, followed by CNS depression. There are several techniques for inhaling these products: the most common is to pour the substance on a cloth and then inhale the vapors from the rag. Over time, the patient develops tolerance, and requires higher doses of the vapor to achieve the desired effect. Tolerant subjects may increase their dose by inhaling the vapors in a bag rather than on a cloth. Sometimes subjects will place a bag over their head or use other elaborate delivery systems to increase the concentration of the hydrocarbon. These techniques not only increase the concentration of hydrocarbon in the inhaled vapor, but also decrease the amount of oxygen that is inhaled. The combination of hypoventilation and hypoxic environment leads to asphyxial cardiac arrest.

In addition to asphyxia, inhaled hydrocarbons also may precipitate cardiac dysrhythmias.[71] Acute exposure to hydrocarbons sensitizes the myocardium to epinephrine.[72–74] This is the proposed mechanism of "sudden sniffing death"; a hydrocarbon abuser is startled and has an

acute release of adrenaline, which precipitates ventricular dysrhythmias.

Presentation and diagnosis

Symptoms of hydrocarbon intoxication include slurred speech, ataxia, confusion, and somnolence; chronic use leads to tremor and encephalopathy. The diagnosis can often be confirmed by the presence of paint on the patient's face or hands and a strong odor of hydrocarbons. Patients who present with these symptoms are unlikely to develop complications. Hydrocarbon abusers may also present with ventricular dysrhythmias. Premature ventricular contractions and non-sustained ventricular tachycardia suggest myocardial sensitization. Patients may also present in cardiac arrest from ventricular fibrillation. Finally, toluene may cause a renal tubular acidosis and profound hypokalemia that may lead to paralysis and respiratory arrest.

Treatment

Patients who present with only CNS symptoms can be observed and discharged when their mental status has returned to baseline. Patients who present with ventricular ectopy or dysrhythmias may benefit from beta-blockade (metoprolol 5 mg i.v.); however, most cases will resolve without therapy. It is reasonable to check electrolytes, including magnesium, in patients with ventricular ectopy. Two patients with ventricular fibrillation following butane abuse were successfully resuscitated with amiodarone.[75,76] Other cases have also responded to standard ACLS treatments.[77,78]

Some authors have advocated avoiding adrenergic vasopressors (i.e., epinephrine) when treating cardiac arrest in the setting of hydrocarbon intoxication,[76] arguing that the dysrhythmia is precipitated by myocardial sensitization to epinephrine, and that additional epinephrine should be avoided. Vasopressin offers a reasonable alternative with no beta-adrenergic effects, but there are no experimental data to support this position. Patients who have hemodynamically significant cardiac ectopy after return of a perfusing rhythm should be treated with beta-blockade.[76]

As toluene abuse causes renal wasting of cations, toluene abusers who develop polymorphic ventricular tachycardia should be treated with magnesium (2 g i.v.). Overdrive pacing is a reasonable therapy, but medical treatments to increase heart rate (e.g., isoproterenol) should be avoided as they may worsen myocardial irritability. As hydrocarbons appear to have a mechanism of action similar to the inhaled anesthetics, it is possible that

they will provide some neuroprotection during cardiac arrest. Therefore it is reasonable to prolong resuscitative therapy.

Tricyclic antidepressants, chloroquine, and other sodium channel blocking agents

Deaths from tricyclic antidepressant (TCA) poisoning have decreased over the past decade, yet these drugs remain an important cause of mortality from poisoning. Most emergency physicians and intensivists will have to care for a critically ill TCA-poisoned patient during their careers. Other poisons share some of the toxic properties of TCAs (sodium channel blockade), but not all of these poisons produce the seizures and cardiovascular collapse that are the hallmark of TCA poisoning.

Pathophysiology

Sodium channel blockade is responsible for the major cardiac effects of TCA toxicity and for the dysrhythmias observed in many other poisonings. By decreasing inward sodium currents, intracardiac conduction of electrical impulses is slowed. These effects are first detected on the ECG as prolongation of the terminal depolarization of the heart, which can then progress to prolongation of the QRS, and eventually the patient develops a wide complex rhythm.[79] The effect of these drugs on the cardiac conduction system is pH-dependent,[80] and systemic acidosis increases the chance of dysrhythmias.[48]

Although large overdoses of many medications can produce cardiac dysrhythmias, TCA and chloroquine-poisoned patients appear to be more likely to result in cardiovascular collapse and death than patients poisoned with other medications that cause sodium channel blockade. TCAs are potent alpha-adrenergic antagonists and cause vasodilatation;[81] they also directly impair myocardial contractility.[82] Furthermore, TCAs frequently cause seizures, and the resultant lactic acidosis increases sodium channel antagonism. TCA-mediated altered mental status and seizures have been attributed to antagonism of muscarinic cholinergic, histamine, and GABA receptors.[83,84]

Presentation and diagnosis

TCA intoxication should be suspected in any patient who develops seizures and cardiac dysrhythmias after self-poisoning.[85] Patients who present with a complaint of TCA ingestion require intensive monitoring as abrupt deterioration is common. The electrocardiogram is the diagnostic

test of choice; the risk of dysrhythmias is correlated with the duration of the QRS interval. One prospective study suggests that a QRS duration of more than 160 ms indicates that the patient is at risk for cardiac dysrhythmia,[86] but others have disputed this cutoff.[87]

Overdoses of chloroquine, quinine, hydroxychloroquine, flecanide, and propafenone cause severe cardiovascular effects from sodium channel blockade. Many other drugs cause QRS widening due to sodium channel antagonists, but do not cause cardiovascular collapse. The treating physician should not expect that these cases will develop cardiovascular effects, but he should be prepared to treat them if they do occur.

Treatment

There are multiple reports of survival following cardiac arrest from TCA poisoning,[88–90] but patients presenting with acute severe TCA poisoning require several simultaneous interventions. Airway management allows hyperventilation (to help raise serum pH) and ensures adequate oxygenation.[91,92] Seizures, which often precede cardiovascular collapse,[93] should be treated with high-dose benzodiazepines (lorezepam 4–6 mg repeated as needed). Paralysis will stop the neuromuscular activity associated with the seizures that produces the metabolic acidosis. Dysrhythmias should be treated with sodium bicarbonate boluses.[94,95] An initial dose of 2 meq/kg should be administered, and this dose should be repeated at least every 5 minutes or until a perfusing rhythm has been restored. Magnesium has been used in animal models and a single case report, but human experience is insufficient to recommend its routine use.[95,96] High-dose vasopressors may be required. Animal data suggest that epinephrine is more effective than norepinephrine.[97] A reasonable initial dose is 1 mcg/kg per minute as an infusion, but the dose should be rapidly increased if perfusion is not improved. The only available human data suggest that norepinephrine is more effective than dopamine; however, this study was uncontrolled and the dosing was at the discretion of the treating physician.[98] Glucagon has also been used as a vasopressor for patients with refractory shock, but there are no controlled data.[99,100] Phenytoin and beta-blockers are not recommended for treatment of TCA overdose.

There are also several reports of survival following cardiac arrest from chloroquine poisoning.[87,101–104] These patients are treated with an epinephrine infusion, high-dose benzodiazepines (diazepam 1–2 mg/kg), and early intubation. Animal data suggest that sodium bicarbonate may also be useful.[105]

Fluoride and hydrofluoric acid

Fluoride and hydrofluoric acid account for several deaths each year in the USA.[18] Exposure to fluoride-containing dental products rarely produces serious symptoms,[106] and most cases are due to exposure to hydrofluoric acid or other industrial fluoride products (ammonium fluoride). Indeed, severe fluoride toxicity may occur after exposure to as little as an ounce of a household rust remover.[107]

Pathophysiology

Fluoride is the most electronegative element and therefore it binds avidly to divalent cations, producing profound hypocalcemia and hypomagnesemia. These abnormalities are thought to cause the cardiac effects observed in fluoride-poisoned patients. Fluoride also interferes with the function of several enzyme pathways, however, including the Krebs cycle.[108] In animal models, cardiac arrest is temporally associated with a profound hyperkalemia, which is thought to be due to release of intracellular potassium from erythrocytes.[109] Nonetheless, hyperkalemic animals did not respond to standard treatment, suggesting that hyperkalemia is not the only cause of arrest.[110] Ultimately, fluoride-poisoned patients develop cardiovascular collapse from dysrhythmias, vasodilatation, and myocardial dysfunction.

Presentation and diagnosis

Severe fluoride toxicity may occur after ingestion of products, after dermal exposures, or after inhalation of fluoride-containing vapors. Patients with ingestion of HF products may develop life-threatening effects without significant gastrointestinal complaints. Dermal exposures to low concentration products (<10%) are unlikely to produce toxicity unless they are extensive. Nevertheless, severe toxicity may occur with only a 1% BSA exposure to a 50% HF preparation.[111,112] Patients who develop fluoride toxicity after inhalational exposure present with severe respiratory complaints and acute lung injury before developing effects from the fluoride exposure.[113]

Diagnosis of fluoride poisoning is based on history of exposure, clinical presentation, and laboratory findings. Severe effects should be anticipated for patients who present after deliberate oral exposures. Clinical effects may be minimal initially, and the patient may progress to cardiovascular collapse without other significant symptoms.[107] Serum fluoride levels are not routinely available and are not considered useful in the acute management

of patients. Serum calcium levels are markedly low in patients who develop serious fluoride toxicity.

Management

No systematic human studies have evaluated treatment of cardiac arrest due to fluoride poisoning, but several reported cases of cardiac arrest have responded to large doses of calcium (5–10 g of calcium chloride).[114–117] Animal studies suggest that early administration of calcium salts may attenuate fluoride toxicity and increase the dose of fluoride required to produce cardiac arrest.[118,119] Systemic alkalosis has also been reported to prolong survival in animal models.[120]

As there are very few adverse effects from acute hypercalcemia, patients who have deliberately ingested HF products should receive empiric treatment with calcium salts (1–3 g i.v. over 30 minutes) while awaiting results.[108] The goal of calcium therapy is to maintain serum levels in the high–normal range. Low serum calcium levels are an ominous sign and these patients should receive 1–3 g of calcium chloride iv bolus. Patients who have dysrhythmias or hypotension should receive a minimum of 3 g of calcium as an iv bolus and be treated with systemic alkalinization to a serum pH of 7.5. Patients with cardiac arrest in the setting of fluoride poisoning should be treated with 3–5 g of calcium chloride and sodium bicarbonate (1–2 meq/kg) in addition to vasopressors and defibrillation. Resuscitation after prolonged cardiac arrest has been reported.[114–117]

Cardioactive steroids

The most commonly encountered cardioactive steroids are the medications digitalis and digitoxin. Plant sources of cardioactive steroids include foxglove (the source of digitalis), oleander, and red squill. Animal sources of cardioactive steroids include bufotoxin, which is produced by the boreal toad. There have been several cases of severe toxicity and even deaths reported following ingestion of aphrodisiacs made from bufo toad skin.[121] These toads also produce a hallucinogenic toxin, so there have been reports of mild intoxication following "toad licking."

Pathophysiology

Cardiac glycosides have two main effects on the cardiovascular system. They have potent negative chronotrophic effects, partially mediated through the vagal system, slowing the rate of sinus node firing and slowing conduction through the AV node. Cardioactive steroids also alter transcellular ion

gradients, causing atrial and ventricular ectopy. The overall effect is the classic finding of digoxin toxicity: increased ectopy (atrial or ventricular) with heartblock.[122]

Presentation and diagnosis

The presentation of cardiac arrest may differ in acute and chronic cardioactive steroid poisoning. Acute poisoning frequently causes refractory heartblock and bradycardia, leading to bradyasystolic arrest. Patients with chronic cardioactive steroid poisoning usually have bradycardia, and many also have intracardiac conduction abnormalities. These patients usually die from refractory ventricular dysrhythmias. Non-cardiac symptoms include vomiting, confusion, and changes in vision. After acute ingestion of any cardioactive steroid, the serum potassium is the most important marker of toxicity. In a large series of poisoned patients (before the development of digoxin Fab), the mortality for patients with a serum potassium level above 5.5 meq/ml was 100%, whereas no patients with a serum potassium level below 5.0 meq/ml died.[123] Interestingly, low serum potassium exacerbates dysrhythmias observed in the setting of chronic digoxin toxicity.[124,125] Serum digoxin levels do not accurately discriminate toxic from non-toxic patients.[125,126]

Treatment

The treatment of cardiac glycoside poisoning was revolutionized by antidigoxin antibody fragments (Fab). Before Fab was available, the mortality of cardiac arrest from acute digoxin poisoning approached 100%. In the initial trial of Fab, almost half of cardiac arrest patients treated with digoxin Fab survived.[127] The recommended dose for cardiac arrest is 20 vials as an intravenous bolus.[127] If possible, higher doses are recommended for non-digoxin cardioactive steroids.

The treatment of cardioactive steroid poisoning when digoxin Fab is not available is obviously more complicated. Most hospitals do not stock sufficient Fab to treat critically poisoned patients.[128] The treatment of cardiac arrest depends on the manifestation: thus, bradydysrhythmias may respond to atropine,[129–131] but pacing is considered the treatment of choice.[132] Ideally, the pacer should be placed before severe dysrhythmias develop. The rate should be increased until the ventricular ectopy is suppressed. Ventricular dysrhythmias have been treated with phenytoin, magnesium, and lidocaine. Phenytoin is administered as an i.v. bolus in doses of 100–350 mg.[123,133] Magnesium has also been used to treat ventricular ectopy[134–137] and, in one case report, intracardiac magnesium administration was

associated with restoration of circulation.[138] Lidocaine was used frequently to treat ventricular dysrhythmias from digoxin, but there is very little published experience, and at least one death was temporally associated with lidocaine administration.[139,140] There are two case reports of successful use of amiodarone to treat patients in cardiac arrest, although in one case digoxin Fab was also administered.[125,141–143] Finally, there is a report of successful use of extracorporeal support to treat a severely poisoned child.[9]

Acetylcholinesterase inhibitors (insecticides and nerve agents)

The organophosphate insecticides are an uncommon cause of poisoning death. The nerve agent chemical weapons are also organophosphates, however, so there is a potential that a mass exposure could result in multiple casualties.

Pathophysiology

Organophosphates act by inhibiting acetylcholinesterase in plasma and in synapses. This results in an excess of cholinergic stimulation and produces the classic DUMBELS (Defecation, Urination, Miosis, Bradycardia+ Bronchorrhea, Emesis, Lacrimation, Seizures) presentation. These effects are primarily due to excess stimulation of muscarinic cholinergic receptors. Acetylcholine excess at the neuromuscular junction causes fasciculations and weakness that may progress to respiratory paralysis. Although deaths can occur from the combination of weakness and pulmonary secretions, animal studies suggest that early deaths are due to the effects of excess acetylcholine in the CNS.[144]

Presentation and diagnosis

The effects of organophosphate poisoning range from non-specific malaise and gastrointestinal effects to seizures, coma, and cardiovascular collapse. The diagnosis will usually be made clinically, on the basis of the presentation of a patient with profound vomiting and diarrhea, seizures, muscle fasciculations, and small pupils. In the event of a chemical attack, multiple patients may present with similar symptoms. Exposure to an organophosphate can be confirmed by measurement of cholinesterase levels, serum and red blood cells, but this test is not available rapidly. Clinicians should also realize that government identification of a chemical agent during an attack may be misleading. For example, the poison in the sarin attacks on the Tokyo subway was initially identified as cyanide.

Treatment

Patients must be decontaminated before treatment. Many victims in the Tokyo subway attack were healthcare workers exposed while treating patients who had sarin vapors trapped in their clothing.[145] After decontamination, patients should have ventilation established, ACLS implemented, and treatment with atropine and benzodiazepines initiated. As noted above, CNS effects play a significant role in severely poisoned patients. Therefore, critically ill patients should be treated with very high doses of benzodiazepines (20 mg of diazepam or the equivalent; this should be repeated rapidly if seizures do not cease). Atropine should be administered in 1-mg boluses and titrated until it results in drying of pulmonary secretions. If patients do not respond rapidly, the bolus dose should be doubled. In a series of patients reported after the Tokyo attack, four patients were successfully resuscitated by using these therapies.[146]

Cyanide

Cyanide and hydrogen sulfide are both mitochondrial poisons that can produce rapid onset of coma and cardiovascular collapse. Cyanide is commonly used in industry and hydrogen cyanide could be used as a chemical weapon. The most common forms are salts such as sodium or potassium cyanide and these may cause toxicity following ingestion. When these salts are exposed to an acid, hydrogen cyanide gas is released. Hydrogen sulfide is a strong smelling gas often released with methane. Occupational exposures may occur when workers enter an enclosed space such as a storage tank or sewer. Unfortunately, the characteristic smell disappears at high levels.

Pathophysiology

Cyanide and hydrogen sulfide bind to cytochrome proteins in the electron transport chain and prevent ATP formation. This results in rapid loss of function in organs with a high metabolic rate (such as the brain and heart). As aerobic metabolism is not possible, all ATP production will occur through anaerobic metabolism.

Presentation and diagnosis

The main CNS effects include headache and nausea at low levels, but loss of consciousness and seizures occur very rapidly with high level exposures. The initial cardiovascular effects are tachycardia and hypertension, followed by a

vasodilatation hypotension,[147] myocardial suppression, and cardiovascular collapse.[148] Wide complex bradydysrhythmias are a pre-terminal rhythm. Common metabolic abnormalities include lactic acidosis and hyperkalemia. Patients who survive may have permanent injury to the basal ganglia.[149,150] Whereas most cases of cardiac arrest from cyanide occur soon after exposure, acetonitrile (found in some artificial fingernail products) is metabolized to cyanide and there is a report of cardiac arrest 24 hours after exposure.[151] Hydrogen sulfide causes a rapid onset of coma, but cardiovascular effects are less common. The effects generally resolve quickly if the patient is removed from the exposure.

Acute cyanide poisoning is primarily a clinical diagnosis. It should be considered in patients with a history of poisoning, altered mental status, and cardiovascular collapse. Laboratory studies such as hyperkalemia, profound metabolic acidosis, and high serum lactate are supporting data, but treatment should not be delayed while waiting for results. A whole blood cyanide level will confirm the exposure, but this test is not available on an emergent basis.

Treatment

Secondary exposure of healthcare workers while treating a cyanide-poisoned patient is unlikely, although it is possible that the vomitus of a patient who ingests cyanide salts could release cyanide gas. Therefore, workers should protect themselves from exposure to vomitus, and the patient should be treated in a well ventilated area. Several cases of cardiovascular collapse and recovery after cyanide poisoning have been reported, as have cases of resuscitation from cardiac arrest.[133,148,152,153] Standard ACLS should be initiated. Patients may have an initial response to vasopressor therapy, but this response may be short-lived if antidotal treatment is not administered. Several antidotes are available for treatment of cyanide poisoning; all work by binding the cyanide. In the United States, a three-part kit is used. Amyl and sodium nitrite are administered to induce formation of methemoglobin, which can bind cyanide. Amyl nitrite is provided as a ampule that can be broken allowing the vapors to be inhaled. Once intravenous access is established, sodium nitrite can be administered. The third component of the kit is sodium thiosulfate, which provides substrate to allow the formation of thiocyanate in the liver; the thiocyanate is then excreted in the urine. The usual dose of sodium nitrite is 300 mg and the dose of sodium thiosulfate is 12.5 g. Hydroxocobalamin is another antidote that is used commonly in Europe; it binds cyanide to form

cyanocobalamin (vitamin B_{12}). This drug has an excellent safety profile and is used routinely in France to treat smoke inhalation victims with suspected cyanide poisoning. It causes peripheral vasoconstriction in animal models of cyanide poisoning,[154,155] and this may improve coronary perfusion during cardiac arrest . The usual dose of hydroxocobalamin is 5 g, which should effectively neutralize a serum level of 40 mcg/ml in an adult.[156]

Introduction

Without the inherent risk of cardiac arrest (CA), anesthesia might not have developed as an acknowledged medical specialty in its own right. Only a year after painless surgery was made possible in 1846 by W.T.G. Morton's use of ether as an anesthetic, cases of death under inhalation anesthesia occurred in England. In 1848, Hannah Green, a young healthy patient undergoing a trivial procedure for removal of an infected toenail, became the first reported fatality from chloroform anesthesia and, even today, her name stands for every anesthesiologist's nightmare.[1]

John Snow, whose work on resuscitation is less well known than his contributions to the scientific foundations of anesthesia for infants,[2] had by 1841 accumulated considerable expertise in the field of resuscitating asphyxiated stillborns.[3] With his monograph *On Chloroform and Other Anaesthetics* published in 1858, John Snow became the world's first scientific anesthesiologist, and with his review of 50 cases of fatal chloroform administration he also became the first researcher on the mechanism of critical incidents and the first promoter of modern resuscitation medicine. Some of his recommended techniques of resuscitation included use of the "tracheal tube," administration of oxygen, mouth-to-mouth or mouth-to-nostril ventilation, compression of the ribs and abdomen, and introduction of galvanic current.[4] Thus, CA strongly influenced the professionalization of anesthetic practice, while at the same time anesthesia offered the hitherto unknown opportunity for investigating and treating a multitude of expected, observed, and, later on, monitored and instrumented

cases of CA that have facilitated the successes in modern resuscitation medicine during the last 150 years.

Initially, CA seemed only to be related to the use of general anesthesia (GA), but with the increased use of regional anesthesia (RA) during the first half of the twentieth century, fatal outcome of painless surgery was shown not to be restricted to GA. Neuraxial anesthesia, intravenous RA (Bier-Block), peripheral RA, and local anesthesia were associated with risks specific for CA because of the loss of sympathetic reflexes, drug toxicity, convulsions, and early or delayed hypoxia.

For many years, efforts to decrease fatal adverse events concentrated on the technical, pharmacological, equipment, and monitoring aspects of anesthetic care; more recently human factors involved in anesthesia management (presence, experience, and carefulness of personnel providing care) have been shown to significantly influence severe morbidity and mortality of patients exposed to anesthesia.[5] Mishaps and human failure to recognize and handle fatal adverse events are among the most frequent bases for all closed-claims' investigations. Litigation rarely considers that personal failings usually reflect organizational or working place deficiencies.

Anesthesiologists tend to feel that proficiency in cardiopulmonary resuscitation is part of their natural area of expertise. Nevertheless, the poor quality of resuscitation skills among medical staff is well documented[6–10] and this, unfortunately, includes anesthesiologists.[11] Educational programs must consider these realities.

This chapter focuses on creating care and vigilance in the multicausal etiology of fatal outcome in perioperative states and contributing to preventive measures for major adverse events.

Epidemiology

Incidence, definitions

CA in association with anesthesia is rare and, in contrast to the out-of-hospital area, is associated with an excellent outcome with good recovery in over 80% of cases. Several recent studies report similar rates between 0.5 and 1 case per 10 000 anesthetics for adults[12–15] and up to 1.4 cases per 10 000 anesthetics for children.[16] There are major problems in comparing reports in the literature, however, because of lack of uniformly accepted definitions and reporting methods. These include:

(a) Considerable variation in keywords used as trial inclusion criteria: pulselessness, circulatory collapse, CA requiring external chest compression, indication for electric defibrillation, asystole, ventricular fibrillation, electromechanical dissociation, death in association with anesthesia.

(b) Different time-periods studied: preoperative (from drug intake for premedication) to the induction of anesthesia, during stay in the operating room (OR) emergence from anesthesia, postoperative transport, recovery room, intensive care unit (ICU), ward (up to 6 hours after anesthesia, up to 24 hours after anesthesia with a maximal postoperative time of up to 30 days).

(c) Use of different reporting systems: most information is based on case series, closed-claim analysis, computer record systems, and voluntary critical incident and national anesthetic record systems. CAs managed without postoperative consequences were probably not uniformly recorded and therefore underestimated. The quality of data depends on the accuracy and honesty of those reporting them, so that use of defined terms by all participants would aid obtaining uniform results.

(d) Assessment of the heterogeneity of the investigated patients: no uniformly used grading system is available to quantify age-mix, comorbidities, and complexity of surgery performed.

(e) Use of retrospective data records, which cannot provide first-hand information about the case.

Beecher and Todd in 1954 reported on the first prospective cohort study on mortality and morbidity of anesthesia and identified 384 deaths out of 599 548 anesthetics administered between 1948 and 1952 in ten large American teaching hospitals as being attributable to anesthesia alone or anesthesia as a major contributing factor. They calculated an incidence of 6.4 deaths per 10 000 anesthetics and concluded that "deaths from anesthesia are certainly a matter for public health concerns."[17]

Six major cohort studies were published between 1980 and 1990 with more than one million anesthetics administered (Table 59.1). Incidence of CA was between 1.3 and 6 per 10 000 anesthetics with a mortality rate between 0.3 and 3 per 10 000 anesthetics. These six studies are not comparable, as they report on different observation time periods, that is: 1 year;[18] 17 years;[19] time periods from 1967 to 1987, age-mixed cohorts[20] or just children and infants,[21] nationwide cohort studies[20] or individual hospital surveys.[22,23] Nevertheless, these reports do offer rough figures for incidences of that time period and investigated patient populations.

The 10 years between 1995 and 2005 included nine large investigations from the United States,[14,16] Australia, New Zealand,[24,25] Japan,[13,26] and Europe,[12] reflecting more than 4.5 million anesthetics and over 5200 reported claims. Incidence of CA in the perioperative period varied between 0.15 and 1.1 per 10 000 anesthetics in adults and up to 1.4 per 10 000 in children, with a mortality rate between 0.1 and 0.9 per 10 000 for adults and 0.4 for children.

The incidence of anesthesia-related CA is believed to have decreased over the last decades (Fig. 59.1). Comparing the periods from 1980 to 90 and 1995 to 2005 and that the published studies were not performed in a similar manner, the reported incidence declines from a range of 1.3 to 6 per 10 000 anesthetics (1989–90) to a range of 0.5 to 2.8 per 10 000 (1995–2005). There is no clear trend with regard to anesthetic-related deaths resulting from CA with a rather stable incidence between 0.1 and 0.9 per 10 000. Nevertheless, after an extensive literature search, Lagasse *et al.*[27] argue that the anesthetic-related mortality rate has been stable over time since 1992 and that, because of lack of a worldwide standardization in definitions and methodology, no scientific evidence demonstrates an increased safety in anesthesia in the last decade.

In contrast, a dramatic change in the characteristics of the surgical population over the last 20 years is well documented. Today, patients are older and sicker, and more complex surgical procedures are being performed. A large French survey of over 7 937 000 anesthetic procedures in 1996 compared these data with data from 1980 and concluded that the number of anesthetic procedures increased by 120% over the 16 years, which corresponds to an increase in the population-corrected rate from 6.6 to 13.5 per 100 population. Elderly patients and those with high American Society of Anesthesiologists (ASA) physical status classifications (Table 59.2) had the greatest increase: ASA class 1: + 30%, ASA class 3: + 268%.[28]

Several studies comparing early with more recent observation periods provide insight into the development of CA

over time with less methodological bias. A computer-based anesthetic record system at Karolinska Hospital, Stockholm, Sweden was used to analyze 170 CAs out of 250 543 anesthetic record files between 1967 and 1984. There was a nearly 10-fold decrease in incidence of CA during anesthesia between 1967 and 1984, most prominent between 1967 and 1974.[19] In the non-cardiac surgical patient collective study at the Mayo Clinic, Rochester, MN between the years 1990 and 2000, of 518 294 patients, 223 experienced CA between the start of anesthesia and discharge from the recovery room.[15] Incidence for patients receiving GA decreased over the 11 years from a rate of 7.8 per 10 000 anesthetics (1990–92) to 3.2 per 10 000 (1998–2000). But only 24 of these 223 CAs were attributed to anesthesia. Analysis of the Finnish Mortality Associated with Anesthesia and Surgery Survey 1986 (325 585 procedures)[29] compared these results with a similar study of the Finnish collective in 1975 (338 934 procedures).[18] Tikkanen

et al. identified 5 cases in the 1986 survey compared with 67 cases in the 1975 survey and calculated a more than 10-fold reduction in the incidence of death related to anesthesia (from 1.9 to 0.15 per 10 000 anesthetics) over this 20-year period.[29]

The debate continues as to whether the safety of anesthesia has improved over time. The reported rates of anesthesia-related mortality vary widely among published studies. No uniform methods, definitions, observation periods, and/or markers are used for normalizing patient age-mix, comorbidities, and complexity of surgical procedures, thus making comparisons of published data extremely difficult. Nevertheless, as highlighted by Cooper and Gaba,[30] the truth will end up somewhere between major progress as declared by the Committee on Quality of Health Care in America in 1999[31] and no progress in the improvement of safety in anesthesia over the last 25 years, as concluded in the literature review published by Lagasse *et al.* in 2002.[32]

Risk factors

CA during anesthesia is predominantly multifactorial in origin: poor preoperative patient conditions associated with inadequate preoperative risk estimation, inappropriate or delayed anesthesia management, and human error or misjudgement.[12,15] The incidence of anesthetic-related CA or death is so low that no statistical single variables are identifiable as being independent and solely responsible risk factors leading to CA and consequent mortality. Moreover, without uniform definitions, CA in acute coronary syndrome or severe kidney failure would not be attributed by most authors as anesthetic-related, but rather as an underlying patient disease. Thus, we have only discussed studies where the categories of risk factors were identified by univariate or multivariate analysis.

Infants and children

Compared with adults, the incidence for perioperative CAs in infants and children is increased. In 1985, Keenan and Boyan reported a threefold increased risk for the pediatric group.[23] A French survey of over 40 240 anesthetics in patients younger than 15 years reported an incidence of CA in infants of 19 per 10 000 and in children of 2.1 per 10 000.[21] Respiratory failure was predominant in infants, whereas respiratory and circulatory events were equally distributed in children. The most comprehensive survey on the pediatric patient collective reported 289 cases

recorded in the Pediatric Perioperative CA (POCA) Registry:[16] 150 cases (52%) were related to anesthesia: 83 of these (55%) occurred in infants (less than 12 months), and 47 (31%) in children aged 12 months to 5 years; the remaining 20 cases were in older children. Distribution for ASA classifications were 33% in ASA physical status classes 1 and 2, and 67% in ASA classes 3 to 5. Causes were categorized as 37% medication-related, 32% cardiovascular, and 20% respiratory events. The medication-related cause significantly predominated in ASA classes 1 and 2 patient groups, and cardiovascular causes in the ASA classes 3 and 4 patient groups. In 68% of all reported cases, the patients recovered without long-term injury. Higher ASA classifications and emergency procedures were most often associated with poor outcome.

Compared to the Pediatric Closed Malpractice Study[33] in 1993, where respiratory events (43%) were the most common, the distribution of causes in the POCA registry represents a major change in reported causes. Nonetheless, that study could be biased, because chest compression was mandatory as an inclusion criterion for the POCA registry. Mason emphasizes that use of pulse oximetry and capnography in the POCA registry was 98% and 86%, respectively, compared with only 7% for pulse oximetry in 1993, and she concluded that increased use of these monitoring devices was probably effective in preventing adverse respiratory events.[34] Newland et al. reported 22 CAs out of 16,051 cases in patients younger than 20 years with an incidence of 13.7 per 10000 anesthetics.[14] Eighteen of these patients were preoperatively classified as very ill (ASA class 4 or 5), and therefore do not represent the typical pediatric patient population.

Age

In 2001, a consecutive cohort analysis of over 101 769 anesthetics identified 24 CAs including 13 not related to anesthesia.[12] Age above 80 years was identified in a univariate analysis as a risk factor. This corresponds with the results of Olsson and Hallen that indicated[19] a four times higher risk for patients aged over 80 years compared with patients aged 30–39 years, but age was not an independent risk factor in the recent survey of Sprung et al.[15]

ASA physical status classification

The ASA physical status classification was introduced as a marker for estimated perioperative risk. It assigns the preoperatively assessed comorbidities of a patient to a score between 1 and 5. ASA class 1 indicates a "healthy patient" without increased anesthetic risk and ASA class 5 indicates a "moribund patient not expected to survive 24 hours with or without surgery." Coexisting diseases such as acute or chronic coronary syndrome, acute renal failure or diabetes, and patient factors such as morbid obesity that increased risk were summarized and normalized by the ASA physical status classification.

It is not surprising that a higher ASA physical status classification is associated with an elevated risk of CA and death (Table 59.3). The risk of perioperative CA for patients with an ASA class 5 is 300 times that of class 1 or 2, and patients with class 3 have a higher risk than ASA class 1 or 2.[14] Similar distributions of ASA classifications were found by Biboulet et al.[12] (8 of 11 anesthetic-related CAs

and 5 of 6 mortalities, ASA physical status class over 2), and by Sprung *et al.*[15] (44% of all CAs, ASA class of 4 or 5, and 18 of 24 of the anesthetic-related CAs (75%) occurred in patients with an ASA class of 3 or 4).

Obstetric anesthesia

Anesthesia for cesarean section and other emergency peripartum procedures has been associated with a relatively high risk of death among otherwise young and healthy women. Failed airway management due to the anatomical changes during pregnancy, increased risk of gastric acid aspiration during airway management, and acute respiratory distress syndrome have been identified as major risk factors for perioperative death. The 2005 published report on 50 years of the "Confidential Enquiries into Maternal Death" in Great Britain concludes that anesthesia for cesarean section is now 30 times safer than it was 50 years ago,[35] with a major contributing factor being the change in anesthetic technique (avoidance of GA whenever possible and use of neuraxial anesthesia). Rates of direct death attributable to anesthesia were 36 per 10 000 cesarean sections in 1964–66 and 1 per 10 000 in 2000–02.[36] Pregnancy is apparently not associated with an increased risk of fatal outcome from neuraxial anesthesia. There were no deaths directly attributed to RA in the 2000–02 report and only one case in the 1997–1999 report.[36,37]

Regional anesthesia

Although CA might actually be less likely to occur under RA compared with GA, our review of the literature over the last 20 years shows an incidence between 0.04 and 1.8 per 10 000 major regional blocks[12,38–40] which is the same order of magnitude reported for GA, but it appears to have declined over the last 20 years. Neuraxial anesthesia techniques are associated with a higher risk of CA compared with peripheral plexus or nerve blocks, and the highest risk is associated with spinal anesthesia.[38,39,41] This result has to be interpreted with caution, however, as there is no correction for the large increase in spinal anesthesia compared with epidural anesthesia over the last years.[28] Furthermore, the analyses of Critical Incidence Reporting Systems may represent only the worst outcome associated with a particular technique, rather than all results from a broad population. Also, patients receiving GA and those receiving RA were not similar with regard to ASA physical status classifications, comorbidities, types of surgery, and ratios of elective to emergency surgery.

A comprehensive report representing 20 years of RA at the Mayo Clinic, Rochester, MN analyzed over 70 000 neuraxial anesthesias.[39] CA was defined as hemodynamic instability (severe hypotension and/or bradycardia) that resulted in loss of consciousness requiring defibrillation, chest compression, and/or vasopressors. They included only the period after initiation of regional anesthesia and before discharge to the recovery room or ICU. Twenty-six patients in the last 15 years who had a CA were described in detail. The overall incidence of CA was 1.8 per 10 000 neuraxial procedures with a predominance for spinal compared with epidural anesthesia (2.9 vs. 0.9 per 10 000). The ratio of patients who survived CA to discharge did not differ between spinal and epidural anesthesia (14 of 20 vs. 3 of 6, p = 0.29). The incidence declined between the first 5 years (1988–92) from 3.3 to 1.0 per 10 000 in the last 5 years (1998–2002). In particular, in the spinal anesthesia group, incidence declined from 5.6 per 10 000 in the first 5 years of the study to 1.4 per 10 000 in the last 5 years (1998–2002). Table 1 from Kopp *et al.* shows 40 CAs, 28 of them in the period after 1988 where the number of anesthetics was known and the corresponding incidence was calculated. Two patients from the original 28 were apparently lost and were not included in his results.

Auroy *et al.* performed two large French surveys on complications of RA.[38,41] In the 2002 report, 487 anesthesiologists voluntarily reported 56 serious complications related to RA (overall, 150 083 regional blocks were performed in adults (74%), children (3%), or for obstetric purposes (23%)). CA occurred in 10 patients during spinal anesthesia and in 1 patient during a posterior lumbar plexus block, with an incidence of 0.83 vs. 0.08 per 10 000. In a 1997 French report of 103 730 regional blocks there were 89 serious complications related to anesthesia: CA in 32 cases (spinal: 26, epidural: 3, peripheral nerve block: 3), and fatal outcome in 7 cases (spinal: 6 of 26, epidural: 0, peripheral nerve block: 1 of 3). Bradycardia was the main precursor in all CAs during spinal anesthesia, and more elderly than younger patients were involved.

Liu and McDonald emphasize that risk factors for bradycardia are baseline heart rate lower than 60 beats/ min, ASA physical status class 1, use of β-blockers, prolonged PR interval on the electrocardiogram, and spinal block higher than T5.[40] The closed-claim analysis identified administration of sedation and lack of early treatment with epinephrine as typical patterns of management in cases of CA.[42] Pollard argues that the evidence for a respiratory etiology for CA during neuraxial anesthesia is sparse and that CAs occur with oxygen saturation readings of 95%–100%.[43] Bradyarrhythmia is commonly found before CA and could be related to blockade of sympathetic activity and/or

cardiovascular reflexes[44] related to a relative hypovolemia induced by vasodilatation. Unfortunately, some CAs that occurred during spinal anesthesia have fatal outcomes even in young and otherwise healthy patients.[43,45]

Causes of cardiac arrest

The vast majority of CAs are ascribed to concomitant disease or surgical factors. Fatal outcome associated with anesthetic and surgical procedures in Finland was about the same in 1986 as in 1975. But the role of surgery had decreased to about one-third and of anesthesia to less than one-tenth as the main contributing cause of the death;[29] similar progress in anesthetic safety has been reported for the same time period.[46,47] A large Japanese survey divided etiologies of fatal accidents into four categories, those resulting from: preoperative complications (65%); surgical procedures (24%); intraoperative pathological events (9%); and those attributable to anesthetic management (2%).[26] The major cause of preoperative complication-related deaths was pre-existing hemorrhagic shock, followed by cardiovascular diseases, such as myocardial ischemia and congestive heart failure. Excessive surgical bleeding comprised 70% of surgical procedure-related deaths. The major causes of intraoperative pathological events were myocardial ischemia, pulmonary embolism, and severe arrhythmias. Half the anesthetic management-related deaths were caused by airway or ventilatory problems, followed by medication accidents, and infusion/transfusion mishaps.

Principal causes of CA and other critical incidents due to etiologies during anesthesia and surgery are listed in Table 59.4.

Several epidemiological studies have analyzed the possible causes for intraoperative CA.[12–15,19,21,23,25,29,48,49] Identifying the causes of CA that are primarily attributable to anesthetic management would allow for institution of preventive measures. From the very beginning, as has been shown for incidences, the classification of deaths and causes of CA during surgery and anesthesia has varied considerably.[50–54] In addition, it is often impossible to retrieve sufficient information retrospectively in order to reliably identify the causative factors. Moreover, adverse events are generally multifactorial in origin, and CA in particular is often the culmination of different reasons,[14,27,30] one of which might well include anesthetic interventions or, rather, the lack thereof.[15]

Thus, in an Australian study, 129 cases of CA were grouped into five categories reflecting monofactorial and multifactorial origins: (a) anesthetic technique (11 cases with this category alone; 32 with this and one or more of the other categories, representing 25% of all 129 CA); (b) drug-related (16; 32, 25%); (c) associated with surgical procedure (9; 29, 22%); (d) associated with pre-existing medical or surgical disease (30; 82, 64%); (e) unknown (8; 14, 11%).[24]

Patients

Hypoxemia

For all anesthesiologists, hypoxia as a main cause of CA is always worrisome, especially in a "cannot intubate – cannot ventilate" scenario. Hypoxia during anesthesia occurs in failure of airway management; misplacement of the endotracheal tube (esophageal or endobronchial; accidental tracheal extubation in the prone position);[14,15,19] aspiration of gastric contents;[14] laryngospasm mainly due to mechanical irritation during inadequate depth of anesthesia;[19] severe bronchospasm because of anaphylactic or intrinsic reactions; and/or errors in oxygen supply.

During the first 100 years of anesthesia, hypoventilation in spontaneously breathing patients resulting from deep inhalation anesthesia and accompanying cardiovascular compromise was a major source of fatal outcome. In their 1985 study of incidence and causes of CA due to anesthesia, Keenan and Boyan found failure of adequate ventilation in 50% and overdose inhalation in 33% of the cases.[23] In a contemporary Scandinavian survey, ventilatory problems were the most frequent causative factors of "anesthetic CA."[19] More recently, Irita et al. similarly attributed half of anesthesia-related deaths to airway and ventilatory management.[26] Sprung et al. classify 46% of CA that are attributable to anesthesia as associated with airway/ventilation problems:[15] CA due to a loss of airway patency had a poor outcome. Of note, none of the patients who experienced CA from anesthesia and had resuscitation for longer than 20 minutes survived; all of these patients had lost airway patency.

With the introduction of endotracheal intubation and controlled mechanical ventilation, the inability to establish a secure protected airway became more common. In a survey of patients whose lungs could not be ventilated and whose tracheas could not be intubated, Nagaro et al. identified 26 out of 151 300 cases of GA in university hospitals in Japan.[55] Newland et al. attributed only 20% of CA to problems of airway management.[14] Respiratory depression due to narcotics or benzodiazopines and inadequate reversal of muscle relaxation contribute to hypoventilation during the emergence from anesthesia.[19] Monitoring the intensity of muscle relaxation at the end of surgery and introduction of

Table 59.4. Causes of cardiac arrest

I   *Respiratory events*
  A.   Failure to ventilate
   • Airway management failure: cannot intubate – cannot ventilate; misplacement of the endotracheal tube; aspiration of gastric contents; laryngospasm
   • Inability to ventilate despite secure airway: bronchospasm; tension pneumothorax; tracheal disruption; tube dysfunction / occlusion; mediastinal collapse (mediastinal mass)
  B.   Apnea/Hypoventilation
   • Respiratory depression in spontaneously breathing patients
   • Failure in ventilator setting
   • Loss of gas supply; breathing circuit disconnection
   • Apnea in neuraxial blockade
   • Pneumoperitoneum
  C.   Lack of oxygen carrier
   • Severe anemia
   • Carboxyhemoglobinemia; Methemoglobinemia (Prilocaine)
  D.   Ventilation/Perfusion-Mismatch
   • Pulmonary embolism
   • Pulmonary hypertension / vasoconstriction
II.   *Circulatory events*
  A.   Vascular failure
   • Hypovolemia: hypovolemic shock; surgical bleeding
   • Failure in systemic resistance: anaphylaxis; sepsis; neurogenic shock; neuraxial sympathetic block; pheochromocytoma; monoamino oxidase inhibitors; eclampsia; thyroid storm; Addison crisis
   • Tension pneumothorax
   • Mediastinal collapse (mediastinal mass)
   • Embolism: thrombus (surgical sources: hip replacement); air (sitting position and neurosurgery); amniotic fluid
  B.   Pump failure
   • Arrhythmia: coronary artery disease; conduction abnormalities (Wolff–Parkinson–White syndrome; high-degree conduction block; sick sinus syndrome); mechanical stimulation (inadequate depth of anesthesia and sympathetic stimulation; central venous or pulmonary artery catheterization); vagal reflexes; local anesthetics; hypokalemia; hyperkalemia (succinylcholine); hypocalcemia; hypomagnesemia; interference of pacemakers/AIDs; hypothermia
   • Ischemia: hypoxia; anemia; increased oxygen demand (tachycardia); thrombus (myocardial infarction); end-stage congestive heart failure
   • Myocardial depressant factors: volatile anesthetics; induction agents; endotoxins
   • Valvular/congenital heart disease: neuraxial anesthesia and aortic stenosis
III.   *Environmental causes*
  A.   Equipment failure
   • Loss of gas supply
   • Tube disconnection
   • Failure of anesthetic machine; breathing circuit; laryngoscope; airway device
   • Laser/electrocautery mishaps (airway fire)
   • Monitor malfunction
  B.   Human factors
   • Inadequate vigilance
   • Monitoring negligence
   • Drug overdose (induction agents, inhalational anesthetics, muscle relaxants)
   • Drug selection error
   • Blood transfusion error
   • Line misconnection (venous – arterial – epidural)
   • Gas flow/ventilator setting error
   • Gas misconnection (N_2O instead of O_2)
   • Inappropriate airway management
   • Inadequate fluid management (hypovolemia; fluid overload)
   • Organizational deficiencies: lack of educated and trained personnel; lack of support; workload; fatigue; communication problems; lack of checklists; missing standard operating procedures

---

short-acting muscle-relaxing drugs probably reduced complications during recovery. In addition, the availability of postanesthesia care units was a great advantage in preventing perioperative ventilatory disasters. More recently, use of monitored anesthesia care as the technique of choice for a variety of invasive or non-invasive procedures is increasing.[56] In a closed-claims analysis, severity of monitored anesthesia care claims was comparable to GA claims, with 41% of the claims being for death or permanent brain damage. Respiratory depression as a result of oversedation was the most common mechanism of injury.[57]

During neuraxial anesthesia, cardiovascular collapse can develop secondarily after the unrecognized development of apnea. A spinal anesthetic followed by excessive patient movement or coughing might promote arrival of the local anesthetic (LA) at cervical levels that are high enough to produce blockade of motor fibers to both the diaphragm and inspiratory muscles of the chest and neck (e.g., C3). In contrast with spinal anesthesia, epidural anesthesia usually does not compromise ventilation, unless the injection is performed cervically. Nonetheless, accidental subarachnoid injection of an anesthetic intended for the epidural space could produce apnea because the dose is 6- to 8-fold higher than that intended for subarachnoid injection, resulting in a high level of blockade and compromise of ventilatory muscles. Apnea might similarly result from an unintended subarachnoid injection of LA during retro-orbital, interscalene, or greater occipital nerve blocks.

Tension pneumothorax

During controlled mechanical ventilation, tension pneumothorax is a potentially fatal problem.[13] Awareness of its possibility, especially following central venous catheterization, and the decreasing use of nitrous oxide have reduced incidence of this complication.

Anemia

There are few data regarding CA secondary to normovolemic anemia. Anesthesiologists currently tolerate lower levels of hemoglobin than formerly, but in patients with pre-existing coronary artery disease, myocardial ischemia can occur. If hemoglobin levels in healthy patients are allowed to fall below 8 g/dl, intensified monitoring such as mixed venous saturation and/or control of serum lactate is required to prevent inadequate oxygen delivery and acidosis.[1]

Pulmonary embolism

A sudden decrease in oxygen saturation along with an additional decrease in end-tidal CO_2 measurement are strong indicators for pulmonary embolism. After a brief evaluation of ventilator settings and ruling out mechanical obstruction of tubing and other ventilation-perfusion mismatches, immediate diagnosis, as for example, with transesophageal echocardiography, is mandatory.

Allergic reactions

Allergic reactions are relatively common during anesthesia (frequencies range from 2.2 per 10 000 to 22.4 per 10 000), but only 3–4% of them are lethal or otherwise serious.[29,58] Anaphylaxis can occur as a result of drug administration (e.g., antibiotics, thiopental, muscle relaxants) or repeated exposure to latex. Intravenous administration of drug boluses in short sequences is characteristic of GA. It has been suggested that many unexplained deaths during GA can be retrospectively attributed to anaphylactic reactions.[59] In a Scandinavian study, 5 CAs that occurred during 200 543 anesthetic procedures were related to anaphylaxis;[19] and in a Japanese survey, 4 CAs occurred out of a total of 2.3 million.[13] With dextran as a prophylaxis against thrombosis, anaphylactic CA occurred more often,[19,29] and a case report described a fatal intraoperative event related to aprotinin after local application of fibrin glue.[60] Severe anaphylactic shock due to antibiotic wound cleaning occurred after tourniquet release at the end of minor orthopedic surgery of the limbs under RA.[61] Muscle relaxant allergies have accounted for 60 to 80% of the cases of anaphylactic shock during anesthesia.[62] Unfortunately, during GA, signs and symptoms of allergic reactions are often hidden, and hypotension, tachycardia, and bronchospasm are misinterpreted as, for example, inadequate depth of anesthesia or ventilator problems.

Allergy to LA drugs

Allergy to LA drugs is a rare cause of hypotension and circulatory arrest, particularly for amide anesthetics, but this may occur with amino-ester drugs because of their metabolites related to p-aminobenzoate. Skin testing is of uncertain utility. Allergies can also exist for methylparaben and metabisulfite used as preservatives. Many events attributed to allergy can also be the result of absorption of the coinjected epinephrine.

Cardiovascular events

Serious arrhythmias, myocardial infarction, ischemia, coronary spasm as well as pulmonary embolism account for the third to fifth ranked principal causes of total CA during surgery in Japan.[13] CA patients who had coronary ischemia preoperatively had the worst prognosis: 47% of these patients died.[63]

Neuraxial block and aortic stenosis

Hypotension from extensive neuraxial block can be especially problematic in the presence of aortic stenosis.

Although coronary perfusion pressure falls with development of systemic sympathetic block, left ventricular systolic pressures may remain high because of the stenotic valve, resulting in high oxygen demand. Development of myocardial ischemia and contractile dysfunction further compromises coronary perfusion pressure, and a vicious cycle is initiated that could result in CA.

Vagal reflexes

Vagal reflexes due to mechanical stimulation of parasympathetic nerves are associated with CA.[14] Olsson and Hallen found that succinylcholine administration resulted in 23 cases of CA;[19] notably, only 3 cases were elicited by the first administration of the drug; additional doses were given up to seven times! The authors note that succinylcholine-induced CA became rare after routine use of a small dose of non-depolarizing muscle relaxant before administration of succinylcholine although it still occurred. Sprung *et al.* describe many asystolic CAs after application of neuromuscular reversal agents.[15] In all of these cases, prognosis for successful resuscitation was very good.[15,19]

Postinduction hypotension

Hypotension is a common precursor of anesthesia-related CA.[12,14,15,19] In one of these studies, 50% of CA patients had received more than 5 mg/kg of thiopental.[19] Data from all studies suggest that CA after postinduction hypotension can be regarded as a relative overdose of narcotic and/or hypnotic induction dose (see below).

Hypovolemia

Hypovolemia and/or impaired venous return is another important cause of intraoperative CA.[12,14,19] This group includes misguided fluid replacement of expected or hidden hemorrhage, as well as other fluid losses, such as sudden evacuation of ascites. Mediastinal compression by tumor or lymphatic masses is dangerous, reducing venous return especially if combined with positive pressure ventilation.[19,64–68] Intraoperative mobilization of a hypovolemic patient can also trigger CA.[12] Prone position reinforces relative hypovolemia resulting from impaired venous return and can induce circulatory collapse together with a reduced compensatory ability.[19]

Acid–base and electrolyte imbalances

Acid–base and electrolyte imbalance are other major sources of CA.[13,19,69] Dehydration and hypokalemia are possible contributors, but the effect of hypokalemia has been studied only in small randomized trials.[70] Nevertheless, hypokalemia might contribute to a worse outcome in patients with myocardial infarction.[71,72] Most commonly,

hyperkalemia triggers CA. Inadvertent administration of potassium and calcium can affect myocardial activity and could result in cardiovascular standstill during diastole or systole. The ratio of potassium-to-calcium in blood is important; hyperkalemia is more dangerous in the presence of less ionized calcium. Evaluation of serum potassium must consider effects of changes in serum pH. When serum pH decreases, serum potassium increases because potassium shifts from the cellular to the vascular space. Likewise, when serum pH increases, serum potassium shifts intracellularly. Elevated levels of serum potassium should be anticipated before use of succinylcholine in abnormal muscle states like paraplegia or tetraplegia, inactiveness, tissue breakdown (ischemia of bowels or limbs, rhabdomyolysis, tumor lysis, hemolysis, and burn injuries), specific drugs (angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, potassium-sparing diuretics, non-steroidal anti-inflammatory drugs, β-blockers, and trimethoprim), metabolic acidosis, and endocrine disorders (Addison's disease, or hyperkalemic periodic paralysis).[73] Hyperkalemia causing anesthesia-related CA in pediatric patients has been observed after massive transfusion, reperfusion following liver transplantation, and in renal insufficiency.[16] Renal failure is the most common reason for increasing of total body potassium. Acute exacerbation of hyperkalemia occurs if acidemia develops secondary to hypoventilation or hypoperfusion. Typically, during emergence from GA, patients with acute or chronic renal failure become acidotic because of hypoventilation, and are at risk of an additional and potentially fatal shift of intracellular potassium into the intravascular compartment.[74] For treatment of hyperkalemic CA, aggressive reduction of extracellular potassium is mandatory. Hyperventilation, calcium chloride, sodium bicarbonate, and glucose plus insulin drive potassium back into the intracellular compartment and support return of the cellular membrane potential towards normal.

Environment

Anesthesia is an area in which environmental effects influence the margin of patient safety. Lagasse defined and distinguished different types of error.[27] Table 59.5 summarizes categories for system error and human error, with common examples of each.[32,75]

CA during anesthesia is not always regarded as caused by error. But if the definition of error is "an act that through ignorance, deficiency, or accident departs from or fails to achieve a desired outcome," all adverse outcomes, especially ultimately serious ones like CA, are errors.[27] Lagasse's

Table 59.5. Types of error

	Error	Example
System error	Technical accident	Postdural puncture headache follows a properly performed spinal anesthetic
	Equipment failure	Equipment malfunction results in death despite proper maintenance and checks
	Communication error	Medical consultant's report is delayed when following the usual channels of communication
	Limitation of therapeutic standards	Appropriate resuscitative efforts result in death of a multiple trauma victim
	Limitation of diagnostic standards	Preoperative assessment fails to predict difficult airway management
	Limitation of available resources	Lack of available blood products results in death due to massive bleeding
	Limitation of supervision	Attending anesthesiologist is unable to prevent a resident anesthesiologist from committing a human error because of multiple supervisory responsibilities
Human error	Improper technique	A short catheter placed in an internal jugular vein dislodges and results in hematoma formation
	Misuse of equipment	Neglecting to perform the prescribed equipment check results in equipment failure that contributes to patient death
	Disregard of available data	Failure to avoid known drug allergen results in unplanned hospital admission
	Failure to seek appropriate data	Failure to check appropriate extubation criteria results in premature extubation, subsequent respiratory failure and need for reintubation
	Inadequate knowledge	Incorrect interpretation of hemodynamic variables results in pulmonary edema

(From Ref. 27, reproduced with permission.)

definition is consistent with the definition from the Committee on Quality of Health Care in America: "Failure of a planned action to be completed as intended" or "use of a wrong plan to achieve an aim"; the accumulation of errors results in accidents.[31]

Kawashima *et al.* identified detailed causes of CA due to equipment failure including gas supplies or sources, anesthetic machine, breathing circuit, airway device, laser machine, and other sources.[13] Disconnection or misconnection of breathing circuit, arterial/venous lines and loss of gas (oxygen) supplies have been described.[19] Equipment complications following central venous or pulmonary artery catheterization such as arrhythmia that progresses to ventricular fibrillation, tamponade, hemothorax, or pneumothorax are well known. Complications associated with central venous access caused 20% of CAs in one study;[14] in pediatric anesthesia-related CA, complications of anesthesiologist-placed central lines are the most common equipment-related problems.[16] CA from pulmonary outflow-tract obstruction due to a double-lumen tube has been described.[76]

CA during anesthesia is traditionally considered to occur generally in the OR. In the Australian Incident Monitoring Study, 129 reported CA occurred in the OR (70%), recovery room (11%), introduction room (7%), ICU (5%), general ward (4%), imaging room (1.5%), and in transit (1.5%).[24] In contrast, induction room CA is considerably higher, and CA during the course of anesthesia is significantly lower (20%) in two American surveys (Fig. 59.2).[14,15] For neuraxial anesthesia, the CA occurred at: time of block placement (4%), between block placement and surgical incision (19%), during the surgical procedure (62%), and after surgical closure (15%).[39] Proper recovery room care is very important in reducing anesthetic complications,[58] because as many as 60% of patients need special attention in the postanesthesia care unit.[77] The limiting factor to appropriate postoperative care seemed to be lack of personnel.[29]

Monitoring negligence, malfunction, or available but not used monitors relate to human error (Table 59.5): inadequate vigilance, overdose of drug or inhaled agent, selection error, and inappropriate airway management are among the most frequent causes of so called "human factors."[13] Selection error refers to mistaking one drug for another,[78] as well as to application mishaps, such as CA resulting from an inadvertent overdose of lidocaine through an arterial pressure line.[79] Errors in drug administration occur during anesthesia; "syringe swap" (selection of the wrong syringe and the erroneous administration of its contents) is the most frequent error,[80,81] occurring in 0.11%–0.75% of cases.[82,83]
Fig. 59.2. Locations and phases of anesthesia-related cardiac arrest in three studies.

The impact of emergency procedures compared with elective anesthesia remains controversial. Earlier studies found higher overall mortality during emergency operations,[20,84–86] which was also observed in a study of intraoperative CA in the tropics: 75% of CA occurred during emergency procedures as opposed to 25% for elective cases.[87] Keenan and Boyan found a 6-fold higher incidence of CA in emergency cases, but, surprisingly, only a very small difference in incidence between ordinary hospital working hours and other times of the day.[23] Similarly, newer studies do not suggest a higher incidence of CA during non-regular hospital working hours.[14,15,39] Newland *et al.* showed that although 60% of CAs were emergencies, none of the CA cases attributable to anesthesia were emergencies.[14] In the survey by Sprung *et al.*, 168 (75%) CAs occurred during standard working hours and only 53 (25%) occurred during the night or on weekends.[15] Notably, if not the incidence of CA, then at least the likelihood of survival was better for patients who had CA during standard versus non-standard working hours.[15]

This finding might be partly explained by poorer performance induced by fatigue. For example, sleep loss and circadian disruption result in reduced attention vigilance, impaired memory and decision-making, prolonged reaction time, and disrupted communications. These create a situation where there is increased risk of the occurrence of errors, critical incidents, and accidents.[88] On the other hand, worse outcome for CA during non-regular working hours might also be explained by delayed access to surgical resources and fewer available personnel; Sprung *et al.* calculated the overall CA outcome and not that related to the anesthesia.[15]

Arbous *et al.* performed a seminal case-control study on the importance of the "human environment" for anesthesia patient safety.[5] Simple anesthetic management principles appear to have a major effect on perioperative mortality: direct availability of an additional anesthesiologist to help or troubleshoot when needed, the use of full-time compared with part-time anesthetic team members, and the presence of two persons from the anesthetic team

during emergence from anesthesia had dramatically positive effects that were associated with reduced perioperative mortality within 48 hours after surgery and anesthesia.

General anesthesia

As discussed above, CA during anesthesia occurs under GA, RA, or monitored anesthesia care. The higher incidence observed during GA reflects the higher percentage of more complex interventions in more complex surroundings for sicker patients rather than the technique itself. Nevertheless, there are inherent risks during GA related to drugs and techniques.

Inhalation anesthetics

The type of anesthesia affects hemodynamic variables before and during the onset of CA. In animals the effect of induced CA differs widely based on the anesthetic protocol adopted before CA, a variable that is unfortunately not always controlled.[89] In general, anesthetic drugs can significantly affect the cardiovascular system in various ways: direct myocardial depression, parasympathetic stimulation, sympathetic stimulation, increased excitability of ventricular muscle, hypotension (especially in patients who are unable to increase cardiac output by increasing heart rate, such as those with severe valvular stenosis), heart block, constrictive pericarditis, or anaphylactic reaction.[90] Inhalation anesthetics can exacerbate and slow atrioventricular conduction and also have an added negative inotropic effect. GA can also sensitize the myocardium to the antiarrhythmic effect of catecholamines.[91] In animal models, where a critical constriction has been created, of inhalation agents reduces coronary flow autoregulation and transient episodes of sympathetic overactivity can be associated with myocardial ischemia. The presence of coronary artery disease is often found postmortem in patients who die from CA during anesthesia and whose resuscitation was ineffective.[92] Although the ischemia resolves at the end of the anesthetic, mild reductions in the ejection fraction might persist and contribute to postoperative cardiovascular complications that can be exacerbated by the use of large doses of α-blockers and β-blockers.[93]

Muscle relaxants

CA related to loss of airway has an extremely poor outcome; essentially no patients survive without neurological deficits after resuscitation requiring more than a few minutes after the loss of airway. The use of neuromuscular blocking agents accounts for the largest category of hypoxic CA[14,19,23,94]. In general, the adverse effects of non-depolarizing muscle relaxants are related to the inability to ventilate or intubate a patient who does not have spontaneous ventilation after induction or after extubation. Irreversible hypoxic brain damage is the most apparent consequence of this type of CA during GA, while hypoxic brain damage can also be an unexpected finding following dysrhythmic CA.[95]

Succinylcholine continues to be the drug of choice for urgent tracheal intubation in the perioperative period, in the emergency room, in the ICU, and even outside the hospital during emergency transportation of patients.[96–98] Because succinylcholine has a rapid onset of effect even when administered intramuscularly, it is also used to treat laryngospasm, especially when there is associated desaturation with no intravenous access. In some instances, however, adverse hemodynamic consequences, including death may occur. One of the most deleterious side effects is the acute onset of hyperkalemia and cardiovascular instability associated with its administration in susceptible patients.[99] In particular, depolarizing muscle relaxants are associated with bradycardia and asystole, especially in children[100] and in adults after repeated doses.[19,101] Bradycardia and asystole probably arise from direct stimulation of the carotid baroreceptors producing reflex bradycardia and accumulation of acetylcholine, because of competition for available cholinesterase by the paralytic agent.[101] Patients with congenital muscular dystrophies are susceptible to hyperkalemia and rhabdomyolysis following administration of succinylcholine.[102] This also occurs with acquired pathological states such as upper or lower motor denervation, immobilization, infection, direct muscle trauma, muscle tumor or inflammation, and burn injury.[99]

The electrophysiological effects of CA during hypoxemia elicited by misuse of muscle relaxants are dramatic and unique.[103] An initial sympathetic stimulation is followed by severe bradycardia and asystole. Increased serum potassium and acute metabolic and respiratory acidosis potentiate the cardiovascular depressant effect of the anesthetic. Hypercapnia from hypoventilation results in increased circulating catecholamines, but increased serum potassium levels will eventually enhance the asystole induced by vagal stimulations.

Intravenous anesthetics and sedatives

Several intravenous anesthetic agents can contribute to the onset of asystole, including etomidate, with or without depolarizing relaxants,[104,105] and propofol, the putative mechanism being increased vagal activity.[106–108] Several

surgical stimuli can enhance or initiate the dysrhythmia through a vagal reflex mechanism that can lead to bradycardia or asystole. These surgical areas include: rectum, uterus and cervix, larynx, bronchial tree, bladder and urethra, mesentery, carotid sinus, heart, biliary tract, extraocular muscles, and testicles. In addition, long-term propofol infusion has been shown to be associated with metabolic acidosis, rhabdomyolysis, and cardiac failure in adults,[109,110] as well as in children.[111]

Dexmedetomidine, a recently introduced α_2-adrenergic receptor agonist with sedative, analgesic, and anxiolytic properties has been associated with CA.[112] This agent, a full agonist of the α_2-adrenergic receptor that decreases the requirement of GA with relevant respiratory depression, is associated with severe bradycardia and hemodynamic instability. The effects of dexmedetomidine can be increased by an epidural block, and dexmedetomidine itself can potentiate other negative chronotropic drugs such as digoxin and pyridostigmine. The asystole is usually brief and responds to parasympatholytic agents. In patients undergoing GA with dexmedetomidine, the potential for asystolic CA should be kept in mind.

Medication associated with prolonged Q–T interval

Sudden episodes of unexplained CA during surgery have been attributed to Q–T prolongation. In general, CA is unexpected in this patient population and very difficult to reverse.[113] High adrenergic state, intrinsic myocardial disease, electrolyte abnormalities such as hypokalemia, hypocalcemia, and anti-arrhythmic agents like quinidine, procainamide, imipramine, amiodarone, and phenothiazines can all promote acquired Q–T prolongation. This latter group of patients often has a normal preoperative baseline electrocardiogram. If the diagnosis is suspected or confirmed, preoperative aggressive electrolyte correction of calcium, potassium, and magnesium as well as mild β-blockade and perioperative cardiac pacing should be considered.

Malignant hyperthermia (MH)

Malignant hyperthermia (MH) is a rare but well-described cause of CA during GA.[114] Although there are no stereotypically clinical features of MH, conditions such as masseter spasm by exaggerated response to succinylcholine could indicate the syndrome. Hypermetabolic state follows with increased lactate levels, body temperature, and CO_2 production; muscle rigidity with evidence of massive rhabdomyolysis is seen in both urine and serum. The ultimate cause of death is usually asystole

from hyperkalemia secondary to massive rhabdomyolysis and extrusion of potassium from damaged cells that is exacerbated by sympathetic stimulation and severe metabolic acidosis. The pathophysiological trigger of this disease is an increased sensitivity to halogenated anesthetic drugs such as halothane, isoflurane, sevoflurane, and desflurane, or depolarizing neuromuscular blocking agents, e.g., succinylcholine. The triggering agent causes an imbalance of ionized calcium homeostasis within skeletal muscle cells. Increased intracellular calcium increases glycolysis demand for ATP and metabolism. The massive activity of ATPase becomes important in lack of myofilament relaxation and calcium sequestration of the sarcoplasmic reticulum and sarcolemma. Increased body temperature and CO_2 production (end-tidal CO_2) are usually indicators that the hypermetabolic response has already started. More than 50% of MH families have mutations in the ryanodine receptor, the calcium channel of the sarcoplasmic reticulum.[114] This pharmacogenetic disease is inherited as an autosomal dominant trait, and penetrance is variable. In MH families with known MH causative mutations, molecular genetic diagnosis of MH susceptibility is an established procedure.[115,116] Because of the heterogeneity of the MH trait, an MH-negative diagnosis must not be concluded without the halothane and caffeine *in vitro* muscle contraction test. Clinical findings that raise suspicion of MH are: family history, masseter rigidity, respiratory acidosis, hypoxemia, rhabdomyolysis with increased creatine kinase and myoglobin urea, increasing temperature (usually a late sign), and cardiac dysrhythmias.

Awareness of the problem and introduction of sodium dantrolene have decreased the mortality of MH during GA from 80% in the 1960s to less than 10% today.[117] If MH is thought to be the cause of CA in the OR, the triggering agent must be immediately discontinued and the patient should be ventilated with 100% oxygen at high flow. Use of calcium as an add-on to the resuscitation protocol should be an immediate consideration; a solution of dextrose 50% in water and IV insulin 1 unit for each 10 g of glucose should also be given. Early administration of bicarbonate and hyperventilation might be necessary to decrease extravasation of potassium. The patient should also be cooled as soon as feasible. The main therapy is immediate administration of sodium dantrolene. Ideally, the therapy is started with a dantrolene bolus of 2.5 mg/kg and repeated every 5 minutes to a total dose of 10 mg/kg. A proven MH should trigger rapid and comprehensive communication with the patient and the family to take appropriate steps to protect themselves from an MH crisis if they undergo GA.[118]

Regional anesthesia

Introduction

RA is often chosen over GA because of the belief that disastrous complications will be less likely. Although this is certainly true for peripheral nerve blocks with a small volume of LA, such as a digital block, evidence indicating a lower CA rate for RA is weak. In part, this is due to the overall low rates of catastrophic circulatory complications during both RA and GA. There are, however, factors unique to RA that are inherently risky. Sudden loss of sympathetic activity in an extensive portion of the body is unique to neuraxial (spinal and epidural) anesthesia. Also, RA is the only routine medical treatment in which the intended target for injection might be only a few millimeters from a locale that would result in a massive toxic response, such as intravascular injection of LA solution during brachial plexus blockade, or intrathecal injection during epidural blockade.

Systemic LA toxicity

The desired effect of LAs when used for RA is temporary interruption of axonal conduction in peripheral nerves, thereby suspending sensation and motor activity of the distal body part. LA toxicity/neurotoxicity at the injection site is a rare clinical problem that could produce cauda equina syndrome after lidocaine spinal anesthesia or delayed recovery of function after peripheral nerve blockade. Much more serious systemic consequences may follow unintended intravascular injection of large doses of LA solution intended for nerve plexus blockade or epidural blockade.

Presentation

The earliest signs of systemic LA toxicity are due to subtle cerebral dysfunction, including tinnitus, odd metallic taste, or confusion and dysphasia, which may be followed by generalized seizure activity. Higher serum levels may be tolerated if levels rise slowly, whereas abrupt increases in circulating levels, such as from unintended intravascular delivery of a large LA bolus, are more likely to cause complications. The predominant circulatory manifestations in the deeply sedated patient or in one in whom RA is combined with concurrent GA are low cardiac output and blood pressure. Alternatively, dysrhythmias are often the initial circulatory manifestation in awake patients. A less common mechanism for systemic LA toxicity is rapid uptake from the injection site in the absence of direct injection into a vessel, such as when a large volume of agent is administered throughout a large area of tissue so that a large surface is involved in uptake. This occurs with multiple intercostal blocks or extensive subcutaneous infiltration for liposuction.

Etiology

Peripheral circulatory effects of LAs
Studies of direct effects of LAs on vessels show highly variable responses, from constriction to dilatation, depending on dose.[119,120] Toxic levels of bupivacaine in intact animals raise systemic vascular resistance, and when systemic toxicity leads to seizures, increased sympathetic tone causes vasoconstriction. Thus, the principal mechanism by which LAs depress the circulation is through actions on the heart.

Depression of myocardial contractility
LAs produce a dose-dependent decrease in myocardial contractile force. Whereas the clinical efficacy of LAs is through blockade of neuronal voltage-gated Na^+ channels, myocardial depression probably results from other mechanisms.[121] LAs, especially bupivacaine, block cardiac Ca^{2+} channels,[122] which in turn, reduces the Ca^{2+} available for triggering its release from intracellular Ca^{2+} stores. Release from this sarcoplasmic Ca^{2+} pool is also inhibited by the action of LAs on the Ca^{2+} release channel of the sarcoplasmic reticulum.[123,124] The final result is a lower level of cytoplasmic Ca^{2+} and therefore weakened contraction.

Additional evidence points to disruption of cellular energy metabolism by LAs at various sites in the production and use of ATP.[125,126] Two processes have been identified as targets for inhibition by LA. In isolated mitochondria, LAs uncouple mitochondrial oxidative phosphorylation and increase metabolic rate. Additionally, inhibition of complex I of the respiratory chain reduces energy production.[127] The relative contribution of lowered intracellular Ca^{2+} and inhibition of energy metabolism to myocardial depression is not clear, but the high LA concentrations necessary to inhibit Ca^{2+} entry indicate that altered energy metabolism might predominate at usual concentrations. LA inhibition of cyclic AMP production (particularly by bupivacaine) might also contribute to myocardial depression and interfere with the therapeutic effects of epinephrine,[128] probably by inhibiting binding of β-adrenergic receptor agonists.[129] At equipotent doses, bupivacaine depresses contractility somewhat more strongly than lidocaine, as demonstrated by injections into the coronary arteries, which avoids other systemic effects.

Altered cardiac electrophysiology

The pattern of dysrhythmia caused by toxic doses of long acting agents such as bupivacaine and etidocaine differ from that of other LAs. Whereas lidocaine in progressive doses eventually leads to circulatory failure and hypotension with only sinus bradycardia or atrioventricular block, the typical pattern with bupivacaine is widening of the QRS complex, malignant ventricular dysrhythmias, electromechanical dissociation, and refractory asystole. Cardiovascular collapse occurs at doses only 3.7 times the dose that causes seizures. This "safety ratio" for lidocaine is 7.1 and etidocaine is intermediate at 4.4. In many clinical and laboratory reports, resuscitation is especially difficult with bupivacaine.

These unique features of bupivacaine are due to the kinetics of its binding to cardiac Na^+ channels. LAs bind channels during their open configuration. Bupivacaine dissociates from the inactivated channel with a time constant of 1.5 seconds, unlike the 0.15 second for lidocaine. Even with normal heart rates, bupivacaine does not completely leave the channel during diastole, so that the next depolarization and channel opening binds more bupivacaine, producing an accumulation in the heart.[130] Lidocaine has time to leave the inactivated channels during diastole, so accumulation and intensification of blockade do not occur. At death, the heart:blood concentration ratio for bupivacaine is 3.5 compared with 2.0 for lidocaine.

Automaticity is somewhat depressed by LAs in most studies. Phase 4 depolarization of pacemaker cells during diastole is slowed, due to Ca^{2+} channel blockade. In isolated hearts, pacemaker rates are slowed more by bupivacaine than by lidocaine and the effect is amplified by hypoxia and acidosis. Both effects are greater in neonatal hearts.[131] Conduction alterations occur at concentrations of LA lower than are necessary for changes in automaticity, and are responsible for the most troublesome electrophysiological complications, namely ventricular tachydysrhythmias for the long-acting amides and heart block for the other agents. Cardiac impulse conduction is slowed by LAs,[132–134] because diminished inward Na^+ current depolarizes adjacent membrane more slowly, which produces a prolonged PR interval, a widened QRS complex, and atrioventricular block. Slowed conduction also leads to unidirectional block and reentry, which in turn can produce ventricular tachycardia and fibrillation. Intracoronary doses necessary to produce these dysrhythmic arrests are 16 times greater for lidocaine than for bupivacaine.[135] A central nervous mechanism might contribute to bupivacaine cardiotoxicity. Direct intracranial bupivacaine administration is followed by ventricular dysrhythmias,[136] probably via activation of the sympathetic nervous system,[137] but this has been disputed.[138]

Contributory factors

Hypoxia and acidosis have consistently been observed to increase the cardiac toxicity of LAs, especially bupivacaine. Hyperkalemia decreases the dose of lidocaine and, especially, bupivacaine necessary for cardiovascular collapse in ventilated dogs, whereas it has no effect on seizure threshold.[139] Pregnancy probably does not increase bupivacaine cardiotoxicity.[140]

New LA drugs

Levobupivacaine, the S(-) enantiomer (one of a pair of mirror image isomers) of bupivacaine, has been known for some time to be less toxic than the R(+) enantiomer or the racemic mixture.[141] Ropivacaine is similar in structure to bupivacaine and mepivacaine, but is prepared as a pure S(-) enantiomer. Ropivacaine exits the Na^+ channel more rapidly than bupivacaine does, but still much more slowly than lidocaine.[142] Myocardial depression produced by circulating ropivacaine, bupivacaine, and lidocaine is proportional to their nerve-blocking potency.[143] With the more serious complication of conduction disturbance, in vitro studies show ropivacaine and levobupivacaine are much less potent than bupivacaine in depressing cardiac excitation and conduction.[144–146] The diminished dysrhythmogenesis from levobupivacaine is supported by studies with intact animals,[147–149] whereas results for ropivacaine are less clear.[140,150] Like bupivacaine, demise from ropivacaine is most often accompanied by ventricular dysrhythmias.[150] Higher circulating levels of ropivacaine after equal doses compromise its increased cardiac safety. Comparisons of ropivacaine and levobupivacaine toxicity in vivo have not demonstrated a difference in dysrhythmogenesis.[151,152]

Sympathetic block-related bradycardic arrest

Presentation

Bradycardia or nausea may be the first indications of circulatory compromise from extensive blockade.[153] Factors that increase the risk of hypotension after spinal anesthesia include age (greater in adults than in children and in adults over 40 years of age), extensive block, low initial blood pressure (systolic less than 120 mm Hg), in combination with GA, higher puncture site for injection, and inclusion of phenylephrine in the anesthetic solution.[154–156] Additional factors may include female

gender, cementing a prosthesis, and deflation of a leg tourniquet.[157,158]

Whereas hypotension during neuraxial anesthesia is common and easily treated, a combination of profound bradycardia, asystole, and circulatory collapse can occasionally develop without any obvious precipitating cause during spinal or epidural anesthesia, often with poor outcome.[42,159] The patient may be conscious and talking right up to the moment of arrest. The typical bradycardic event occurs well after injection of the anesthetic and is not clearly related to unintended levels of blockade,[45] unlike the incidence of hypotensive events.[160] The timing of the onset is a mystery, but it may be due to a situation of diminished stimulation of the patient. The initial presentation might be apnea or bradycardia. Prodromal slowing of the heart rate is not a uniform feature, nor is hypoxia or excessive sedation,[42,43,161] although these can contribute. In one study, however, use of sedation decreased the incidence of hemodynamic side effects of spinal anesthesia,[160] conceivably due to avoidance of emotional stress that may also trigger severe bradycardia during sympathetic blockade.[162] Epinephrine infusion is not preventive.[42] It appears that bradycardic CA during neuraxial anesthesia is increasing.[163]

Factors predisposing to the common form of bradycardia without arrest are more easily determined than are those leading to reflex bradycardic arrest, which is rare. These risk factors include low baseline heart rate, use of β-adrenergic blockers, prolonged PR interval, extensive anesthetic block, young age, and low ASA status (i.e., healthy subjects).[154,158,164] It is not certain that these factors also put a patient at risk for full arrest, but they require extra attention. It is possible that obesity and the prone position are also risk factors.

Etiology

Neuraxial anesthesia substantially limits sympathetic activity to the areas of the body affected by sensory blockade. Whereas a block limited to the lower extremities rarely produces serious hemodynamic problems, more extensive blockade can produce hypotension and diminished cardiac output. Blockage of sympathetic innervation to the heart (T1–T5) minimally affects myocardial contractility, and chronotropic responses to isolated cardiac denervation are mild. Unlike narrow segmental block, however, extensive spinal or epidural block with significant vasodilatation typically produces bradycardia and a depressed baroreceptor response, so that low systemic blood pressure fails to induce accelerated heart rates. This change in baroreceptor performance does not require blocking of T1–T5, indicating that the heart rate response to neuraxial anesthesia is not due to blockade of cardiac accelerator fibers. Indeed, heart rate changes and increased baroreceptor reflex sensitivity due to blockage of T7 and below can be reversed by compression of the legs and abdomen by inflation of MAST trousers.[165] The reflex changes following neuraxial block are probably due to unloading of low-pressure receptors in the heart and great veins. Endogenous opiate mechanisms in the central nervous system contribute to abrupt vasodilatation that accompanies substantial hypovolemia, so naloxone therapy could be considered.[166]

The mechanism behind these phenomena originates with sensory events in the heart.[167–169] Inhibitory depressor reflexes can be initiated by vigorous contraction around an almost empty ventricular chamber, which produces wall deformation.[170] The combination of an increased inotropic state of the heart and decreased left ventricular volume is the most potent stimulus for this response.[171] The Bezold–Jarisch reflex is a similar depressor phenomenon originating in the heart in response to chemical stimuli.[44]

As noted above, the sympathectomy state is unique with regard to regulation of heart rate. Low systemic blood pressures are not accompanied by high heart rates. This creates an unstable system with positive feedback: venodilation, especially of the splanchnic circulation,[172,173] decreases cardiac filling and leads to further sympathetic withdrawal and vagal hyperactivity. Increased cardiac contractility from elevated sympathetic activity in unblocked segments may amplify the cardiac wall deformation that stimulates the depressor reflex. There is evidence that neuraxial anesthesia may trigger such a reflex sequence.[174] Overall, these events resemble typical fainting from other causes in upright subjects. Like fainting, this hemodynamic sequence is not found in patients receiving sedation or GA. Patients who develop hypotension and bradycardia display a sudden increase in the baroreceptor sensitivity and frequency domain, which is evidence of elevated sympathetic activity.[175] Sympathetic block prevents an effective baroreceptor-driven compensation. A downward spiral is further encouraged by cerebral hypoperfusion and an obtunded response to hypoxia from epidural block.[176]

Prevention

Although there are no data to guide strategies to avoid sudden bradycardic arrest during neuraxial anesthesia, development of substantial hypovolemia should be avoided in patients with extensive neuraxial blocks, especially if they are young and fit, and hypovolemia should be corrected before initiating neuraxial anesthesia. Treatment of heart rates lower than 50 beats/minute should be considered, in

order to anticipate and prevent the potential development of more severe bradycardia and arrest.[43,177]

Anesthesia outside the operating room (non-OR anesthesia)

Overview

Anesthesia outside the operating room (non-OR) has the same inherent risk factors and causes of CA as described above, but with certain specific problems. Most are linked to anesthetic drugs, techniques, and equipment being used in unfamiliar and less controlled surroundings, often by less trained personnel. Consequently, risks of CA as a fatal complication to anesthetic practice may be higher than in the more controlled OR environment.[178]

GA is frequently used for emergency airway management. Anesthetic drugs are used for procedural sedation in the emergency department with the inherent risk of complications such as CA, especially in children.[179]

Office-based anesthesia and anesthesia in remote areas

Office-based anesthesia has become increasingly popular. It can be viewed as an extension of ambulatory (day case) anesthesia taking place in free standing (solo) physicians' and dentists' offices.[180] Most procedures involve a combination of LA and sedation or GA with drugs like propofol and sevoflurane.

In the day-surgery clinics, in both private and academic practices, overdosages of either inhalation or intravenous anesthetics have been described as associated with CA,[181,182] in particular in dental practices. Indeed, in a disproportionate number of patients CA occurs in oral/dental maxillofacial office practices, which suggests that the anesthetic risk might be significantly increased in this patient population even though the event is still relatively rare.[183] In the early 1990s, a questionnaire was sent to all dentists practicing in the United States and follow-up letters describing 43 cases of CA were reported with a total mortality of 81.4% of the cases.[184] Remarkably, pre-existing diseases were not statistically associated with mortality, but multiple pharmacological agents and limited monitoring and resuscitative efforts were statistically associated with mortality. Basic and advanced cardiac life support was used in fewer than 50% of the cases.

Both GA and monitored anesthesia care were responsible for CA although the data were limited. The greater the number of pharmacological sedative agents used, the higher the risk of CA, indicating the need for a more wide-spread knowledge of anesthetic agents and their adverse effects, and of resuscitation skills for health professionals involved in dental practices.[185,186] The danger of CA with office-based anesthesia was brought to public attention when a review in the United Kingdom showed several cases of anesthetic deaths in dental offices.[187] This resulted in specific recommendations on who should provide anesthesia and what resuscitation equipment and emergency drugs should be available. With an ever increasing demand for anesthesia in this context, there are obvious medico-legal aspects as to who provides the anesthetic service.[188]

There are scant data on the epidemiology of CA during office-based anesthesia. The overall mortality and risk of severe morbidity appears to be very low,[180] particularly when solo practitioners report their own data,[189,190] whereas state or national audits report less favorable safety records.[187,191]

Office-based anesthesia aims to reduce overhead costs of ambulatory surgery. This can conflict with the obvious need to provide national practice guidelines for anesthetic personnel, anesthetic equipment, monitoring, recovery areas, availability of emergency equipment, and resuscitation drugs. Patients should demand the same standards of care for both solo ambulatory surgical and diagnostic units.[180]

Other non-OR anesthetic locations are classified as "remote areas":[178,180] psychiatric hospitals for electroconvulsive therapy, gastroenterology laboratories for endoscopy, the radiology department for diagnostic procedures such as computed tomography and magnetic resonance imaging or interventional neuroradiology, and, increasingly, the cardiology laboratory for acute percutaneous coronary angiography and/or percutaneous coronary intervention. Sprung *et al.* studied the outcome of CA in patients undergoing invasive cardiology procedures over an 11-year period (1990–2000).[192] The overall incidence of CA was 21.9 per 10 000 procedures; this rate decreased from 33.9 per 10 000 before 1995 to 13.1 per 10 000 after 1995. Overall survival to hospital discharge after CA was 56.1%.

In all "remote" locations anesthesia providers may not be accustomed to the special machines and monitors, and have limited access to both the patient and an experienced assistant. Although the risk of anesthesia complications resulting from technical and human failures in remote areas might be expected to be higher than in a hospital setting, this has not been frequently studied[178] and problems tend to be illustrated by case reports.[193]

Anesthesia and sedation in the ICU and emergency department

In the ICU and emergency department (ED) anesthesia is mainly used to facilitate emergency airway management

in critically ill and injured patients. Rapid sequence endotracheal intubation in these patients carries the risk of CA linked to patient factors, to the use of cardiodepressive drugs in patients with circulatory failure with different etiologies, and to hypoxia and bradycardia following difficult or failed intubation. Assistance during the procedure and back-up help from more experienced personnel might not be available to the same extent and adequate monitoring and alternative airway devices might also not be present. Hence, the use of anesthesia in these circumstances carries a higher risk of complications than in the more controlled environment of the OR.

Anesthetic drugs like propofol, etomidate, ketamine, or fentanyl are generally used alone to provide procedural sedation and analgesia, but they can also be used in combination, and although descriptions like "sedo-analgesia," "controlled sedation," and "awake sedation" are used, this practice carries the same risks (overdosing patients, losing control of the airways, and other side-effects) for CA as with giving "full anesthesia".[179,194,195] In most hospitals, doctors (anesthesiologists, intensivists, emergency physicians) provide this care, although elsewhere, it may be provided by nurse anesthetists. Independent of care provider training, both quality and safety aspects of airway management must be considered in deciding who should provide anesthetic and sedative service in the ICU and emergency department, and how such service is provided.

Prehospital anesthesia and analgesia

The same concerns also apply to prehospital anesthesia and analgesia. Again, anesthetic drugs are mainly used to facilitate endotracheal intubation.[196] One difference compared with hospital care is that in many emergency medical service systems non-physicians (paramedics, flight nurses) are allowed to use rapid sequence endotracheal intubation.[197] Further, the prehospital working environment is variable, not secure, and uncontrolled. Hence, the legal, quality, and safety aspects of prehospital anesthesia are of major concern. Although in many studies, self-reporting of data has concluded that the prehospital use of anesthetic drugs and techniques by non-anesthesiologists is both safe and improves outcome, recent studies[198,199] and editorials[197] have cast doubt on the benefits and safety of this practice. Importantly, even in prehospital EMS staffed with anesthesiologists, the incidence of critical incidents with the potential for CA is reported to be almost 10%.[196] Hence, both training and experience of personnel, adequate monitoring and equipment, as well as documentation are

important to ensure high quality prehospital anesthesia and analgesia. Patient safety is the key word. The potential benefits of inducing anesthesia must always be weighed against its risks, whether the goal is to ensure ETI in critically ill patients or to provide adequate pain relief in trauma patients.

Prevention

Perioperative CA is rare and has a better outcome than either in-hospital or out-of-hospital CA.[94,200] A substantial percentage of anesthetic-related CAs are caused by human error (inadequate vigilance, inappropriate airway management, drug overdose) and are considered to have been preventable (53% Kawashima *et al.*;[13] 91% Biboulet *et al.*[12]). We describe below some key elements that can contribute to effective crisis management.

Monitoring requirements

Large closed-claim analyses have identified associations and causes leading to CA.[13,15,42,201,202] Adequate monitoring is mandatory for real-time assessment of a patient's condition, especially as adverse outcomes occur as a result of unexpected reactions. Thus, monitoring devices that provide sufficient real-time information to manage unexpected adverse events should be available whenever patients are exposed to increased risk due to iatrogenic intervention. The minimal recommended monitoring consists of: a two-lead electrocardiogram monitor, non-invasive blood measuring device, and pulse oximetry. Capnography is mandatory whenever endotracheal intubation is performed. Nasal side stream capnography is more sensitive than pulse oximetry in detecting hypoventilation during conscious sedation. Whenever artificial ventilation is used, oximetry of the inspired gas and a disconnecting alarm system should be available. Invasive arterial blood pressure monitoring is very helpful in patients with a higher risk for cardiovascular collapse during induction or maintenance of anesthesia. Bispectral index monitoring is a new device used as a marker for the patient's hypnotic state. Several case reports indicate a potential benefit for its use during resuscitation in the perioperative setting.[203–206] There should be continuous monitoring from the start of anesthesia until the patient is in the recovery room or intensive care unit, including the transfer between the different suites.

While monitoring requirements have been defined for areas where anesthesia is normally administered, remote areas such as obstetric wards have less equipment. Notably,

in an RA closed-claims analysis, most of the CA cases that were not monitored occurred outside the OR.[163] Discordance between different monitoring devices or between clinical signs and the results from monitoring equipment must be carefully checked and reassessed,[207] to avoid likely medical errors.

Minimal safety standards

Because these are only a few major causes for the majority of all adverse events, and most of these adverse events are considered to be preventable and are associated more often with human error than with technical or equipment failure, practice standards (rules or requirements representing generally accepted principles of sound patient management) and guidelines (systematically developed recommendations that have a higher degree of adherence) have been developed.[201,202,208] They describe a range of broadly accepted basic management strategies judged to be feasible by experts and based on the best available evidence from the literature;[209,210] nevertheless, they can be modified depending on circumstances. Many national societies of anesthesiologists have promulgated collections of practice standards, recommendations, and/or guidelines that contain minimal safety standards.[211]

Minimal safety standards for anesthesia require the following:

- A sedated or anesthetized patient is never without surveillance by an anesthesiologist or a nurse anesthetist.
- During induction and emergence, the person in charge of the anesthesia has to be supported by another qualified person trained to assist with anesthesia.
- A staff anesthesiologist has to be immediately available.
- The minimal equipment (including prepared drugs for management of potential side effects) and monitoring devices must be available and checked for function before the anesthesia is started.
- Each patient has an intravenous line inserted as soon as possible and checked for correct infusion.
- Emergency materials such as defibrillator, difficult airway management tools, and ventilation bag with transportable oxygen are easily available.
- Standard operation protocols for RA and GA techniques including rapid sequence induction have to be defined and implemented.

Checklists for control of equipment and material before the start of a procedure as well as for defined emergencies (i.e., CA, toxicity of LA or MH) offer clear-cut guidance during complex and stressful crisis management. In contrast to the aviation industry, acceptance and daily use of checklists are still not yet established in medicine.

Treatment principles

If minimal safety standards[211] are followed, CA during anesthesia will always be witnessed and immediately diagnosed. Indeed, CA during anesthesia has clear advantages compared with other in-hospital or out-of-hospital locations: pre-established intravenous access, emergency drugs, oxygen, airway management devices, monitoring equipment, and a defibrillator are immediately available. Furthermore, anesthesiologists and nurse anesthetists should be familiar with resuscitation guidelines and should also be regularly retrained. Additional personnel should be close by or at least on call and quickly available. These advantages may explain the far better outcome of patients who have CA during anesthesia compared with CA in other situations. Guidelines and all the specific technical and pharmacological aspects of resuscitation are discussed in detail in Chapters 25–42.

Some features of CA specific to perioperative conditions are addressed briefly: the major cardiac rhythm at the onset of CA from anesthesia is bradycardia or asystole (45%); other pathological cardiac rhythms are tachycardia, ventricular tachycardia, or ventricular fibrillation (14%), pulseless electrical activity (7%), and not assessed rhythms (33%) (Table 59.6).[24] Treating CA during anesthesia must take these different circumstances into account and the published CPR guidelines, which were developed for the non-anesthesia-related CA patient population, must be adapted to the situation.

The basic goal is to restore cardiac pump function without hypoxic side effects to the brain and heart. Today, the use of pulse oximetry and capnography is mandatory and CA as the first sign of hypoxemia should be the exception. Nevertheless, inadequate alveolar oxygen supply must be ruled out: 100% oxygen should be administered in all cases of CA. If supplemental oxygen administration is a standard operating procedure (SOP) for all patients experiencing GA or neuraxial RA, a supranormal alveolar oxygen tension at the beginning of CA can be expected.

Maintenance of perfusion pressure and blood flow in coronary arteries and cerebral circulation is the other most important goal to ensure oxygenation and drug transport to the target organs and improve the chances for successful restoration of cardiac pump function. In witnessed CA with tachydysrhythmia, immediate defibrillation is the therapy of choice.[212] If a defibrillator is not instantly available or if the cardiac rhythm at the time of arrest is not shockable, chest compression must be started immediately and rigorously,[213,214] despite the risks of compromised asepsis and/or mechanical tissue damage at the surgical field as well as at the cardiopulmonary site. Epinephrine

Table 59.6. ECG rhythm at time of cardiac arrest (%)

	Runciman[24]	Spring[15]
Asystole/Bradycardia	46	83
Tachycardia/VF/VF	14	13
Normal	7	4
Not Indicated	33	

and atropine, if indicated, should be administered aggressively. The side effects of the recommended dosages have to be balanced against the potentially harmful blood pressure elevations during ongoing surgery. There is evidence that management of CA in association with anesthesia tends to be less aggressive than recommended,[24,163] but the impact of these defensive reactions on outcome is unknown.

Identifiable causes of CA during anesthesia have to be treated aggressively during ongoing CPR. Hypovolemia must be prevented and, if present, aggressively corrected. Tension pneumothorax must always be kept in mind during mechanical ventilation. Opioids, muscle relaxant drugs, and sedative or anesthetic drugs influence physiological respiratory regulation. Hypoventilation during mechanical and spontaneous ventilation leads to acute respiratory acidosis and could cause harmful electrolyte disorders with the risk of CA, especially in susceptible patients. Thus, during emergence from anesthesia and immediately thereafter (transfer to and early recovery room period) patients must be carefully checked.

CA and RA

Effective management of CA during RA must be aware of the toxicity of LAs, relative or absolute hypovolemia, and/or imbalanced vegetative nervous system reactions caused by neuraxial RA.

Toxicity from LAs: Early and aggressive treatment of seizures and cardiovascular collapse, including repeated large doses of epinephrine, might reduce mortality from massive intravenous doses of bupivacaine.[215] Although both epinephrine and bupivacaine are dysrhythmogenic drugs, epinephrine is less likely to cause dysrhythmia after bupivacaine than without.[216] Amiodarone can prevent cardiovascular collapse.[217] Magnesium sulfate suppresses bupivacaine-induced dysrhythmias.[218] Unfortunately, there is no magic cure for CA that results from LA toxicity. Aggressive standard resuscitation techniques should be sustained for a prolonged period and electrolyte as well as acid–base imbalances should be normalized.

CA during neuraxial anesthesia: CA is typically associated with extensive blocks reaching to sensory levels

T4–T5. With a sensory block of T4, the cardiac accelerator fibers originating from T1–T4 may be completely blocked. Effects of direct blockade of cardiac sympathetic outflow and indirect mechanisms via cardiac reflexes cause severe bradycardia.[44,219] The relative hypovolemia induced by vasodilatation also results in reduced venous return. Basic treatment must increase cardiac frequency (β-mimetic effect of epinephrine and atropine blocking the increased vagal tone) and restore the intravasal volume (fluid resuscitation, supported by vasoconstricting agents). Successful resuscitation aims for efficient coronary perfusion pressure. Epinephrine is recommended at doses of 0.01 to 0.1 mg/kg for profound bradycardia, whereas 1 mg of epinephrine is recommended for CA.[42,43,220,221] Vasopressin might be advantageous for CA during RA compared with epinephrine.[222]

Instant call for help, communication, organization, and delegation of tasks are crucial for managing CA successfully. Resuscitation requires a team leader who coordinates and gives clear directions. CA is always stressful for the team involved. Checklists should help participating personnel to proceed in a well organized fashion and without missing key points even when managing CA caused by rare events. Debriefing should be part of the procedure, irrespective of the outcome.

Educational aspects

"To Err is Human: Building a Safer Health System" was published in 1999 by the Institute of Medicine.[31] This report stated that as many as 98 000 people die annually as the result of medical errors, which initiated a worldwide expression of concern about patient safety. Although progress since then has been slow, the Institute of Medicine report truly "changed the conversation" to a focus on changing systems, stimulated a broad array of stakeholders to engage in patient safety, and motivated hospitals to adopt new safety practices (Table 59.7). The pace of change is likely to accelerate, particularly in the implementation of electronic health records, diffusion of safe practices, team training, and full disclosure to patients following injury.[223] The concept that bad systems, not bad people, lead to the majority of errors and injuries, will become one of the mainstays in healthcare education.

Impact of human factors

Most of the anesthesia-related CAs are considered to be preventable and to have involved human error or

Table 59.7. Clinical effectiveness of safe practices

Intervention	Results
Perioperative antibiotic protocol	Surgical site infections decreased by 93%[a]
Physician computer order entry	81% Reduction of medication errors
Pharmacist rounding with team	66% Reduction of preventable adverse drug events 78% Reduction of preventable adverse drug events
Protocol enforcement	95% Reduction in central venous line infections[b] 92% Reduction in central venous line infections[c]
Rapid response teams	Cardiac arrests decreased by 15%
Reconciling medication practices	90% Reduction in medication errors
Reconciling and standardizing medication practices	60% Reduction in adverse drug events over 12 mo (from 7.6 per 1000 doses to 3.1 per 1000 doses) 64% Reduction in adverse drug events in 20 mo (from 3.8 per 1000 doses to 1.39 per 1000 doses)
Standardized insulin dosing	Hypoglycemic episodes decreased 63% (from 2.95% of patients to 1.1%) 90% Reduction in cardiac surgical wound infections (from 3.9% of patients to 0.4%)[d]
Standardized warfarin dosing	Out-of-range international normalized ratio decreased by 60% (from 25% of tests to 10%)
Team training in labor and delivery	50% Reduction in adverse outcomes in preterm delivery[e]
Trigger tool and automation	Adverse drug events reduced 75% between 2001 and 2003
Ventilator bundle protocol	Ventilator-associated pneumonias decreased by 62%[a]

inadequate human resources.[13,24] The incidence of CA coincides with the number of qualified anesthesiologists in a department (Fig. 59.3),[19] and organizational factors such as intraoperative presence of trained anesthetic personnel are associated with decreased mortality after surgery.[5] The mortality rate and failure to rescue from CA were lower when anesthesiologists directed anesthetic care and when a board-certified anesthesiologist was in charge.[224,225] A higher nurse-to-patient ratio and higher level of education of the nurses decreases postoperative mortality and failure to rescue.[226,227] It is suggested that the best outcomes take place when anesthesia is provided by a professional care team.[228,229] Such care teams cannot rely merely on new scientific developments or technology, but they must also incorporate non-technical information. This has recently been introduced,[230] because a profound deficit of core skills still remains, such as: team performance, behavior, learning from and with others, and increasing sensitivity to the pitfalls and human factors influencing interactive and interdisciplinary procedures. In a recent editorial, Gaba addresses the important question, "What makes a "good" anesthesiologist?".[231] Although good clinical care in anesthesia has many components, the ability to diagnose and treat acute, life-threatening perioperative abnormalities is near the top of most anesthesiologists' lists.[232]

Individual behavior and team

Medical education must include information that considers "human factors." Disciplines and companies traditionally involved in risk management procedures originally focused on improving safety and usability at the interface between humans and machines through improved design. The term "human factors" relates to a much broader interdisciplinary study of the working environment. Human factors draw on the fields of sociology and psychology (emphasizing cognitive, industrial,
Fig. 59.3. Incidence of anesthesia-related cardiac arrest and numbers of departmental specialists. (From Ref. 19, reproduced with permission.)

organizational, personality, and social psychology) as well as engineering. Research in human factors includes the discovery and application of knowledge about individual and team interactions with technology. An important aspect is the use of a system perspective that considers both the influence of individual as well as group characteristics and the contribution of organizational and national cultures.[233] With regard to "error culture," the aviation industry's experience has shown that the majority of accidents in technical professions are caused by human error and this is undoubtedly true for anesthesia-related fatal accidents in the OR.[30,208] These errors tend to involve interpersonal issues: communication, conflicts, leadership, and/or flawed decision-making. The aviation community responded by initiating formal instruction in the interpersonal aspects of human factors through programs that are known as "Crew Resource Management."[234] Interestingly, hazardous industries such as aviation have succeeded in becoming relatively safe. Unfortunately, modern health-care technology is certainly more complex than that of most other industries, and a busy OR is a perfect model of complexity. Different types of medical specialties and subspecialties interact with each other and with an equally large array of

allied health professions with different hierarchies such as nursing staff and technicians. Separate procedures during anesthesia on different patients occur simultaneously; for instance, induction of anesthesia is done in one area, while emergence from anesthesia is cared for in another, with the same personnel involved and responsible for both. Sadly, the more complex a system, the more possibilities it has to fail. There is considerable evidence that team communication and information-sharing is one of the most important team behaviors for developing common situation assessment, overcoming "groupthink," stimulating creative problem-solving, learning from experiential feedback, encouraging full participation, and achieving enhanced performance.[235–237]

Another challenge is medicine's tenacious commitment to individual professional autonomy. Creating cultures of safety requires major changes in behavior that professionals easily perceive as threats to their personal authority.[238] Comprehensive anesthesia simulation is considered to be a useful tool in studying the "chain of accident evolution".[210,239] Simulation studies involving residents, faculty, and community anesthesiologists challenged the ubiquitous perception that "experience" itself is a guarantee of success in all tasks:[240–242] some

highly experienced personnel failed catastrophically in managing certain acute events, whereas some juniors performed exceptionally well.[241] Acute care skills simulation can be used to study complex task-solving capabilities in near-fatal anesthetic complications.[243]

With surgical factors responsible for sizeable numbers of intraoperative CAs, changes in the climate of surgical education have been considered.[244] Whereas formerly the OR was regarded as the best classroom for surgical education, this point of view has recently been challenged. In the OR, a teaching session cannot be well designed or predicted; steps cannot be repeated, and the patient cannot be reassembled to start over if failure occurs. Furthermore, the greatest learning and performance potential occurs in an environment of moderate stress.[244] High-end simulation is an ideal tool to create such an environment. Strategic management simulations accurately assess the performance of surgical residents,[245] and team factors that determine resuscitation success have been identified.[246] For the specific circumstances of perioperative CA, suitable case scenarios should be included within simulation-based education that reflects the different features caused by GA or RA.

Algorithms

As mentioned above, autonomy in the medical profession is a very strong attitude favoring working procedures that depend on personal experiences, circumstances, temporary mood, or time of the day. What might be a reasonable approach under controlled conditions, however, may become hazardous in the face of potentially escalating complications. This is why SOP have been defined for management of critical incidents in risk-prone enterprises. These SOPs should be clear to every team member especially for team organization, course of action, priorities, aims of intervention, task distribution, and rescue strategies, so that the group functions along a well-structured and predictable pathway. Algorithms have been established to deliver evidence-based standards of care for management of otherwise fatal or near-fatal complications. For SOP to work within stress-burdened and uncontrolled escalating emergencies, they have to be integrated far ahead of the emergency and become part of our professional armamentarium. SOPs should be integrated into formal medical education, and medical staff should be trained and periodically retrained in SOPs to guarantee that SOPs become instinctive when needed. Algorithms for the immediate management of life-threatening conditions have become a cornerstone in the treatment of serious complications and the knowledge and

skills required are, therefore, a mandatory prerequisite for competent professional performance.

For anesthesiologists, management of difficult airways is a core competence that is best accomplished by relying on algorithm-based sequence of action. Benumof described the advantage of a well-structured approach in expected or unforeseen difficult circumstances in which the patient's lungs could not be ventilated or the trachea could not be intubated.[247] Several recommendations[248–250] have established practice guidelines for management of the difficult airway, which is of an overwhelming importance for all anesthetic care providers. Circumstances in which the lungs cannot be ventilated and the trachea cannot be intubated continue to occur after the induction of anesthesia with any induction method, after repeated attempts at tracheal intubation with any intubation method, and after malplacement of a tracheal tube in patients with anatomical abnormalities of the face and/or neck.[55]

Algorithms can also be helpful to indicate potentially dangerous circumstances during the different phases of anesthesia. Post-induction hypotension triggers substantial episodes of CA. SOP should therefore include close monitoring of hemodynamic stability following induction of GA and neuraxial anesthesia, and the decreased blood-pressure measurement interval during this critical period will enable an immediate response should hemodynamic compromise occur.

Unfortunately, established management-guidelines and algorithms[212] do not reflect the peculiar features of intraoperative CA. The pattern of etiological factors is different, as are the prevailing cardiac rhythms, with bradycardia and asystole predominating. Thus, the statement in the American Heart Association's guidelines, "although the algorithms provide a good cookbook, the patient always requires a thinking cook",[251] accurately describes the peculiar circumstances of perioperative CA. Two factors significantly influence diagnosis and treatment of anesthesia-related CA: first, there is a continuous reduction of cardiac output that makes it difficult to determine at which point it becomes significant; second, an arbitrary decision has to be made about what constitutes a serious duration of arrest. For example, should a vaso-vagal arrest of 30 seconds with prompt recovery be counted? When to react and by which degree of invasiveness? Consequently, management of CA related to anesthesia tends to be less aggressive than is recommended in the respective guidelines. In their Australian study, Runciman *et al.* suggest that chest compression was not performed in 28% of CA patients.[24] On the other hand, the efficacy of early and aggressive intervention for anesthesia-related CA has been confirmed clinically and in animal models.[39,252]

Checklists

Formal education should also include and support use of checklists to control material, equipment, ventilator and monitor settings, identification of drugs, patient identification, intended procedures, available preoperative information, and patient's consent. Most anesthesiologists theoretically support the importance of checking anesthetic equipment before use, but do not follow the guidelines because they perceive checklists as too time-consuming.[253,254] A further disadvantage of routine checking might be that routine measures have an inherent risk of reducing awareness. Nevertheless, machine checks detected significant percentages of defaults, of which 11% to 18% were deemed serious.[255,256] Investigators of critical incidents identified failure to perform an equipment check as a frequent risk factor.[22,208,257–261] Equipment checks, performed with a checklist and protocol, are associated with a decreased risk of perioperative morbidity and mortality, as well as documentation of the check.[5] Using an airline pilot's checklist to investigate errors and omissions in anesthesia, a simulation study by Hart and Owen found that important checks were often forgotten when memory alone was relied upon and that the use of a checklist improved performance.[262]

Critical incidents reporting systems

A critical incident is a human error or equipment failure that could have led (if not discovered or corrected in time) or did lead to an undesirable outcome, ranging from increased length of hospital stay to death.[208] The theory of organizational safety stresses that "safety" is a never-ending process whose success cannot be measured strictly by epidemiological methods.[263] The willingness and readiness to communicate critical incidents can be another method to improve safety. Equipment failure is often reported because it shifts responsibility from the person to the technical or manufacturer's side. As the development of more and more sophisticated electronics in anesthetic machines and monitoring devices continues to create an increasingly complex environment, reporting technical failures becomes even more important. Prompt reporting of critical incidents of technical failure allows rapid investigation and implementation of design improvements to this equipment.[264]

Physicians and nurses have considerable difficulty in dealing with human error when it occurs. The culture of medical practice continues to involve its members in striving for error-free practice.[238] Therefore, medical schools and clinical institutions have to fight to change attitudes.

Introduction of reporting systems should be accompanied with serious efforts to maintain anonymity, confidentiality, and privacy of the participating individuals. Nevertheless, adverse events have to be collated, analyzed, and regularly discussed among those responsible for the department or unit; gradually, consistent reporting activities should result in improved safety behavior. Without a strong commitment to such tasks from unit or departmental leaders, most systems will fail.[265]

Reporting systems can successfully identify specific features of CA in association with anesthesia,[24] as the diagnosis is made earlier and with greater precision compared with resuscitation situations encountered elsewhere. But, at the same time, SOPs are used less frequently and to a lesser degree. If CA is encountered and treatment is initiated, alleviation of specific anesthetic or surgical causes is often possible and the outcome is generally good, with the majority of patients leaving the hospital alive and apparently well.

Conclusions

Undergoing anesthesia is intrinsically hazardous for the patient. Anesthesiologists have struggled for years to determine the incidence of catastrophic adverse outcomes.[30] Anesthetic risk has continued to be the subject of numerous investigations, editorials, and journal correspondence since the first anesthetic death was reported in 1848.[266] Undoubtedly, anesthesia for healthy patients is now much safer than it once was. But even though patients are increasingly older and enter the OR with serious pre-existing diseases, the perioperative rate of mortality for surgical patients is still too high. Ascribing CA to preoperative conditions may transfer responsibility from the individual who provides the anesthesia and shift it towards patient's factors, but, whatever the cause, CA and/or death following surgery remains devastating. CA during anesthesia has some unique features that are beyond the scope of current guidelines, and anesthesiologists have to develop and maintain awareness and competence to handle the situation. Without constant effort to improve, anesthesiologists will lose their leadership role in addressing organizational safety culture in all of health care.[30] Nearly 60 years ago, Macintosh stated that no patient should be harmed *by* anesthesia.[267] Today, we, as anesthesiologists, should go beyond this statement and increase our responsibilities beyond the causative aspects and consider pre-existing disease, preoperative conditions, and surgical factors. For the future, our aim should be that fewer and fewer patients are harmed during or following anesthesia.

Resuscitation of the pregnant patient suffering sudden cardiac death

Mark Stacey and Stephen Morris

Anaesthetic Department, Llandough Hospital, Cardiff, UK

Clinical scenario: A 20-year-old pregnant woman is admitted to the emergency room having had a cardiac arrest at home. Cardiac massage and intubation had been performed at home with the patient in the left lateral position. An emergency Cesarean section takes place on the emergency room trolley in "not particularly aseptic conditions", and a live infant is born. The mother's cardiovascular system now responds to resuscitative measures. Three weeks later, after a stormy period in the intensive care unit, she is discharged to the ward with a left hemiparesis. Eighteen years later she sees her son get a place at university.

Introduction

Pregnancy places considerable stress on the cardiorespiratory system. Despite this, cardiac arrest is uncommon – Willis and Rees estimated it to occur once in approximately 30 000 late deliveries,[1] but survival from such an event is exceptional. The United Kingdom's Confidential Enquiry into Maternal and Child Health (CEMACH), formerly known as the Confidential Enquiry into Maternal Deaths, reports that most maternal deaths are from acute causes, with many mothers receiving some form of resuscitation. Nevertheless, the number of indirect deaths (deaths from medical conditions exacerbated by pregnancy) is greater than that of deaths from conditions that arise from pregnancy itself. These indirect deaths seem to be increasing as a result of both social trends and medical progress. The advance of surgical procedures and medical treatments has meant that women who previously would not have survived to adulthood may now reach pregnancy. Those who

have had corrective surgery for congenital cardiac lesions provide a good example. Causes of cardiac arrest during pregnancy include those found in the normal population (arrhythmias, congenital and acquired heart disease, pulmonary emboli, trauma) and those specific to pregnancy (amniotic fluid embolism, hemorrhage, and iatrogenic causes such as magnesium overdose, intravenous bupivacaine, syntocinon-induced pulmonary edema) (See Table 60.1). The dramatic cardiovascular and respiratory changes that occur in pregnancy mandate that several aspects of resuscitation have to be modified if they are to have any prospect of success in a very different clinical situation.

The following recommendations are based on summaries of relevant case reports and knowledge of maternal physiology. In terms of the strength of evidence, because of the obvious difficulties in carrying out research into maternal cardiac arrest, they are at best the opinions of respected authorities, based on clinical evidence, descriptive studies, or reports of expert committees.

Physiological changes in pregnancy

Cardiovascular system

In normal parturients, plasma volume increases throughout pregnancy to approximately 150% of prepregnancy values at 32 weeks' gestation. About half the increase occurs by 10 weeks' gestation and 80% at 20 weeks. Increased erythropoiesis causes an increase in the red cell mass in a more linear fashion by about 25%. The discrepancy between these changes in plasma volume and red

Table 60.1. Examples of pathology that has caused cardiac arrest in pregnancy

Causes	Ref
Pregnancy-related	
Peripartum cardiomyopathy	58, 59
Amniotic fluid embolus	60, 61

Adenocarcinoma	75

cell mass account for the fall in hemoglobin throughout pregnancy.[1-3]

Pulse rate also rises throughout pregnancy, ultimately reaching 10 to 20 beats per minute higher at term, with most changes occurring by 8 weeks' gestation. Stroke volume has been shown either to increase or decrease, but usually shows little change.[4] The increased oxygen consumption in pregnancy causes cardiac output to increase throughout pregnancy, reaching a peak at 32 weeks. It remains at this level only to increase further during labor.

It was previously believed that cardiac output decreases in the latter stages of pregnancy. This decrease in cardiac output, however, is due to aortocaval compression. In ten maternal volunteers, who had pulmonary artery flow catheters inserted to measure cardiac output, it was found that there was a decrease in cardiac output in the supine position. This fall could be reversed by using the left or right lateral positions.[5] This study showed no difference between the two positions, but the left tilt is used preferentially, as the inferior vena cava lies on the right side of the vertebral column. Significant rises in systemic and pulmonary vascular resistance occurred to maintain arterial pressure when cardiac output fell with the subject in the supine position.

The gravid uterus, by virtue of its weight and size, compresses not only the inferior vena cava but also the aorta. This compression is responsible for an additional fall in cardiac output of 10%–25% when the mother is supine, and exacerbates the reduction in venous return that already exists during cardiopulmonary resuscitation. Uteroplacental blood flow is also further compromised by compression of the abdominal aorta by the uterus. Placing the mother in the left lateral position or displacing the uterus to the left is essential to minimize aortocaval compression.

Systemic vascular resistance in pregnancy is usually low, thereby minimizing the rise in blood pressure associated with the increase in circulating volume. The central venous and pulmonary capillary wedge pressures seem to remain at prepregnancy values.

During labor there are further dramatic changes in cardiac output. Basal cardiac output increases by 13% in the first stage of labor between contractions and by 34% during contractions. Each contraction displaces a further 300 ml of blood back into the central circulation.[6] Within 24 hours of delivery, all hemodynamic values return to normal.[7]

Respiratory system

Appreciable changes in the respiratory system also occur during pregnancy. Unfortunately, they make the mother less able to tolerate a cardiac arrest. Pregnant women hyperventilate to excrete the excess waste products produced by the feto-placental unit. This hyperventilation leads to a respiratory alkalosis, which is partly compensated for by a decrease in serum HCO_3^- levels that reduces the mother's buffering capacity during circulatory hypoperfusion or cardiac arrest.

Functional residual capacity decreases by as much as 25%, because of upward displacement of the diaphragm.[8] This is further decreased with the patient in the supine position and the dependent airway may close during tidal breathing.[9] Normal oxygen consumption in non-pregnant women is about 3 ml kg^{-1}min^{-1}, but in pregnancy it increases by up to 16% due to the metabolic demands of the feto-placental unit and the enlarging uterus. Both these factors markedly reduce the tolerance of gravid women to apnea: they rapidly become hypoxemic.

Generalized vasodilatation occurs in the skin and mucous membranes during pregnancy.[9a] Progesterone-induced engorgement of the mucosal membranes can lead to nasal stuffiness and epistaxis.[10] Pregnancy-induced hypertension or upper respiratory tract infection may lead to further edema, exacerbating upper airway problems that add to the difficulty of securing the airway.

Gastrointestinal tract

Progesterone also causes decreased motility of the gastrointestinal tract. Moreover, the position of the stomach is altered by the enlarging uterus, which pushes its long axis – which is usually parallel to the spine – into a more horizontal position.[11] This may hinder gastric emptying and increase the risk of aspiration. The concern over aspiration adds to the importance of securing the airway rapidly during cardiac arrest.

Fetal physiology and outcome

The outcome of resuscitation of the mother determines fetal outcome. The more rapidly the mother is resuscitated (which may include immediate delivery), the more likely the fetus will recover with intact neurological and cardiovascular function. Primate research and human case reports show successful fetal resuscitation if delivery occurs between 5 and 20 minutes after arrest.[12,13]

The fetus has several physiological responses to hypoxia. Shunting and other compensatory mechanisms are known to occur, which may help the infant tolerate hypoxia for slightly longer than adults. Peeters *et al.* showed in sheep that as PO_2 drops, blood is shunted to the heart, brain, and adrenals.[14] Windle found that in rhesus monkeys brain damage occurred after as little as 6 minutes of asphyxia.[15] Clinically there is likely to be additional time taken to deliver and reoxygenate the neonate. Despite these tight timetables, there have been at least two successful resuscitations of a baby after 45 minutes of unsuccessful resuscitation, both in previously healthy mothers who suffered traumatic death.[16,17] It is possible that maternal cardiac arrest may occur after a period of impaired placental perfusion such that fetal adaptive mechanisms may already have been exhausted. For this reason, results from animal models of acute cardiac arrest may not be directly applicable to humans. It is therefore in the interests of both mother and fetus for delivery to occur in as short a time as possible, preferably within 5 minutes of arrest.

Cardiopulmonary resuscitation in pregnancy

Although there is very little research on cardiac arrest in pregnancy, it is generally accepted that conventional protocols recommended by the Resuscitation Councils should be followed, with the modifications listed below. The most recent guidelines can be found on www.resus.org.uk and www.americanheart.org.

Basic life support

Airway

A clear airway must be rapidly established with a head tilt-jaw thrust or head tilt-chin lift maneuvre which must be maintained. Suction should be used to aspirate vomit. Badly fitting dentures and other foreign bodies should be removed and an oral airway inserted. When inserting the airway it is important to place fingers behind the posterior ramus of the mandible in order for the airway to sit behind the tongue. Four-hand ventilation involves using two hands to provide the jaw thrust and another two hands to provide the bag squeezing.[18] These procedures should be performed with the patient inclined laterally or supine with the uterus displaced laterally (see lateral displacement of uterus below).

Breathing

In the presence of apnea, positive pressure ventilation should be started once the airway is cleared; mouth to mouth, mouth to nose, or mouth to airway ventilation should be carried out until a self-inflating bag and mask are available. Ventilation should then be continued with 100% oxygen and reservoir bag. Because of the increased risk of pulmonary aspiration of gastric contents in late pregnancy, cricoid pressure may protect the airway until it is secured by a cuffed tracheal tube. In practice, cricoid pressure may be difficult to apply during the course of resuscitation, particularly in a patient in the lateral position. In addition, when applied by personnel not trained in its regular use, cricoid pressure may cause or worsen airway obstruction and make tracheal intubation more difficult.

Ventilation of the lungs is made more difficult by reduced chest compliance caused by rib flaring and splinting of the diaphragm by the abdominal contents. Because of the increased oxygen requirements of pregnancy, effective pulmonary ventilation is especially important. Observing the rise and fall of the chest in pregnant patients is also more difficult.

Circulation

Circulatory arrest is diagnosed by the absence of a palpable pulse in a large artery (carotid or femoral). Chest compressions are performed at a rate of 100 per minute in a ratio of 15 compressions to 2 breaths. Chest compression is made more difficult by large breasts, obesity, flared ribs, raised diaphragm, and reduced chest compliance. Although no current guidelines exist, it is possible that the hand position for cardiac massage should be moved up the

sternum as the diaphragm, and hence the heart, are pushed upwards by the abdominal contents.

The complicating factor of aortocaval compression by the gravid uterus has already been mentioned. Some authorities believe that all attempts at resuscitation will be futile unless the compression is relieved by either placing the patient in an inclined lateral position, using a wedge, or by displacing the uterus manually. Raising the patient's legs will also improve the venous return. Nevertheless, even optimal chest compression with adrenaline in the supine non-pregnant victim produces at best 30% of normal cardiac output, 30%–50% of cerebral blood flow, and only 5%–20% of coronary blood flow.[19] It is not known whether the output from chest compressions with the pregnant patient in the lateral position is adequate for maternal or utero-placental circulation.[20] As early Cesarean section is recommended in such resuscitation situations, open cardiac compression has been advocated because the simple equipment required is already at hand.

In cases of pre-eclampsia or acute fatty liver of pregnancy, the enlarged liver may be more prone to damage during chest compression. If the cause of arrest is thought to be pulmonary embolus, the use of thrombolysis or surgical embolectomy may be life-saving.

According to the 2002 CEMACH report, 34% of mothers were classified as overweight and 23% as obese, an increase from 16% in 1993. Obesity is known to increase the risk of almost every complication of pregnancy and delivery, and the exaggeration of all the physiological difficulties described will make resuscitation more difficult.

Lateral displacement of the uterus

Effective forces for chest compression can be generated with patients inclined at angles of up to 30 degrees, but pregnant women tend to roll into a full lateral position at angles greater than this, making chest compression difficult. Different methods of tilting the mother for cardiac massage include the Cardiff resuscitation wedge[1], the human wedge, or the upturned chair (see Figs. 60.1–60.3). These offer a firm base for chest compressions, at an angle sufficient to displace the uterus. In the human wedge technique, the patient is tilted on to a rescuer's knees to provide a stable position for basic life support, although with an obese parturient this may be uncomfortable for the rescuer. Alternatively, a pillow or foam wedge may be used[21] to wedge the patient into the left inclined position. An assistant should move the uterus further off the inferior vena cava by lifting it with two hands to the left and towards the patient's head. The important principle is to relieve aortocaval compression while allowing adequate chest compression to be performed.
Fig. 60.1. The Cardiff wedge consists of a board with a 30 degree tilt allowing cardiac massage to be performed with the uterus displaced to prevent aorto-caval compression.

Fig. 60.2. The human wedge: the rescuer uses their knees in order to tilt the patient.

Fig. 60.3. An upturned chair or pillow can also be used to tilt the patient.

Advanced life support

Intubation

Three deaths cited in the anesthetic section of the most recent CEMACH report[22] were directly associated with the failure of airway skills – highlighting the importance of the technique and training of basic airway skills, the use of four-hand ventilation, the right molar approach (see below), and ensuring the correct position of the endotracheal tube after intubation.

Tracheal intubation should be carried out as soon as facilities and skill are available. Difficulty in tracheal intubation is encountered up to 10 times more frequently in

women who are pregnant compared with those who are not.[23] Specialized equipment for advanced airway management may be required. A short obese neck and full breasts due to pregnancy may make it difficult to insert the laryngoscope into the mouth. The use of a short-handled laryngoscope or one with its blade mounted at more than 90 degrees (polio/adjustable blade) or demounting the blade from the handle during insertion into the mouth may help. Use of the right molar approach may improve the laryngeal view and increase the likelihood of successful intubation – the laryngoscope is passed down the right molar teeth to access the epiglottis.[24] Furthermore, it is useful to have a gum elastic bougie at hand to aid intubation.

Mouth-to-mouth or bag and mask ventilation is best done without pillows under the head so that the head and neck are fully extended. The position for intubation, however, requires at least one pillow to flex the neck and extend the head. Any pillow removed at initial ventilation must therefore be kept at hand for intubation.

In the event of failure to intubate the trachea or ventilate the patient's lungs with a bag and mask, insertion of a laryngeal mask airway (LMA) should be attempted. Cricoid pressure must be removed temporarily in order to place the LMA successfully.[25] Once the LMA is in place, cricoid pressure should be reapplied. In the non-pregnant population, ventilation through the laryngeal mask is associated with a lower incidence of regurgitation than bag and mask ventilation, suggesting it might have a role as a first-line airway device[26] If the patient has pre-eclampsia, a smaller cuffed endotracheal tube (6.0 mm) should be used for intubation, as there is the potential for laryngeal edema.

Confirmation of correct tube positioning in the trachea ideally would include using capnography to measure end-tidal carbon dioxide levels, but reliance on clinical methods – seeing the endotracheal tube pass through the cords – or use of an esophageal detector[27] may be necessary, depending on the location of the arrest and available equipment.

Defibrillation and drugs

Defibrillation and drug administration should follow advanced life support recommendations. It is difficult to apply an apical defibrillator paddle with the patient inclined laterally, and great care must be taken to ensure the dependent breast does not come into contact with the hand holding the paddle. It is easiest to avoid this problem if adhesive electrodes are used, although defibrillation in an anteroposterior direction is an option. Case reports indicate that shocks of up to 300J have not led to adverse effects in the fetus.[28] Furthermore, elective cardioversion

suggests that the fetal heart is not compromised by the external shock applied to the mother's chest.[29]

Drug delivery

Ideally, all drugs should be injected *via* the intravenous route, preferably by using a central vein. The action of drugs given into the femoral or saphenous veins may be delayed in the presence of aortocaval compression. The administration of drugs by the transtracheal route is probably ineffective[30] because of erratic absorption and unpredictable pharmacokinetics. It is limited to drugs such as adrenaline (epinephrine), atropine, and lidocaine and probably requires doses at least 2–3 times more than the intravenous dose. In the absence of venous access, the intraosseous route is probably a more reliable method of injecting drugs, but its use has not been reported in the resuscitation of pregnant patients.

Intravenous fluids

If the arrest is due to hypovolemia it is appropriate to transfuse intravenous fluids: crystalloid, colloid, or blood may be given. It is always advisable to give resuscitation drugs into a fast running intravenous infusion. If a coagulopathy develops, for example following amniotic fluid embolus, appropriate blood products should be used (fresh frozen plasma, platelets, cryoprecipitate) in consultation with a hematologist. In a resuscitation involving massive blood loss, all fluids should be given via a rapid infusor capable of reliably warming fluids at high flow rates. Such devices should be available in every labor ward and emergency department.

Drug therapy

Standard drug therapy should be used without modification in pregnancy as the primary goal is resuscitation of the mother.[31] Adrenaline should be used, even though vasopressors induce uteroplacental vasoconstriction. Neither calcium nor bicarbonate is recommended in the current resuscitation algorithms. Magnesium, recommended for the treatment of eclampsia, is also often used in the management of pre-eclampsia, and in overdose can cause cardiorespiratory arrest. It is therefore important that volumetric infusion pumps be used, with careful monitoring of plasma concentrations to prevent any inadvertent overdose. If cardiopulmonary arrest is thought to be due to a magnesium overdose, the infusion must be stopped at once, calcium chloride or gluconate should be administered, and immediate delivery should be considered.

The use of sodium bicarbonate to treat maternal acidosis is contentious, as its use will lead to fetal hypercarbia

and acidosis.[20] Nonetheless, maternal metabolic acidosis increases the reactivity of the uteroplacental vasculature to alpha-adrenergic agents so that it may be useful to administer bicarbonate post-arrest to correct acidosis if maternal PO_2 and PCO_2 are normal.

Local anesthetic toxicity

Bupivacaine is the commonest long-acting local anesthetic used in obstetric practice, but can produce profound cardiovascular depression after intravenous injection. Bupivacaine rapidly blocks sodium channels by entering intracellular spaces during systole, but its dissociation from sodium channels during diastole is slow, leading to an increase in sodium channel blockade and reduction in traffic through the conducting system.[32] It has been recognized for many years that resuscitation from overdose may be difficult,[33] and this has spurred much animal research into the most effective method of resuscitation. Amrinone,[34–36] vasopressin,[37] insulin and glucose,[38] noradrenaline, isoprenaline, dopamine,[39] magnesium,[40] and lipid emulsion[41] have all been tried with varying degrees of success. Appreciable species differences have been reported in experimental animals.[34,36,42] For this reason and because of the various study methodologies, extrapolation of results to humans requires caution. Some reports do, however, deserve consideration. Adrenaline may worsen ventricular arrhythmias associated with bupivacaine toxicity,[36,39,43] whereas amiodarone may have a role as a relatively safe antiarrhythmic[44] after the discontinuation of bretylium, which was considered the drug of choice for treatment of ventricular arrhythmias.[45–47] Lidocaine should not be used because it lowers the threshold to ventricular tachycardia.[45,48] Weinberg and colleagues[41] found that after a 10 ml/kg bolus of 10% lipid emulsion, normal rhythm was established within 5 minutes, with no electrical countershock, in all of nine experimental dogs even when the administration of the lipid was delayed for 10 minutes to simulate a more realistic arrest scenario. The potential human applications of these findings have been discussed in an editorial (Picard & Meek, 2006). Either the lipid provides a fat-rich compartment into which the local anesthetic becomes partitioned, or the inhibition of carnitine acylcarnitine translocase by the local anaesthetic is overwhelmed. An example of Weinberg's dose regimen for humans is described. (See below). The use of propofol as a source of lipid is not recommended, however. Magnesium is now the treatment of choice for torsades de pointes[49] and should be considered in cases of refractory VF, particularly as patients in late pregnancy may have hypomagnesemia. Its usefulness in cardiac arrest may be limited in that the 2 g

loading dose has to be given over 15 minutes. It is contraindicated if women have received magnesium for the treatment of pre-eclampsia or eclampsia.

Despite these concerns over the toxicity of bupivacaine, it does have a very good safety record in obstetric practice, with **no** reports of maternal death in CEMACH. Furthermore, with the advent of the newer, less toxic, amide local anesthetics ropivacaine and levobupivacaine, the risk of cardiac arrest should be reduced even further.

Weinberg's dose regimen for use in humans (Weinberg, 2004). In cardiac arrest secondary to local anaesthetic toxicity which is unresponsive to standard therapy, intravenous administration of a lipid such as Intralipid® 20% is recommended in the following regimen:

1. give 1 ml kg.$^{-1}$ over 1 min;
2. repeat twice more at 3–5 min intervals;
3. then (or sooner if stability restored), convert to an infusion at a rate of 0.25 ml kg^{-1} per min, continuing until haemodynamic stability is restored;
4. increasing dose beyond 8 ml kg^{-1} is unlikely to be useful;
5. in practice, in resuscitating an adult weighing 70 kg:
   - take a 500 ml bag of Intralipid® 20% and a 50 ml syringe;
   - draw up 50 ml and give it *stat* intravenously, then draw up and give another 20 ml;
   - do exactly the same thing up to twice more as you give epinephrine – if necessary or appropriate;
   - then attach the Intralipid® bag to a giving set and run it intravenously over the next 15 min.

Cesarean section

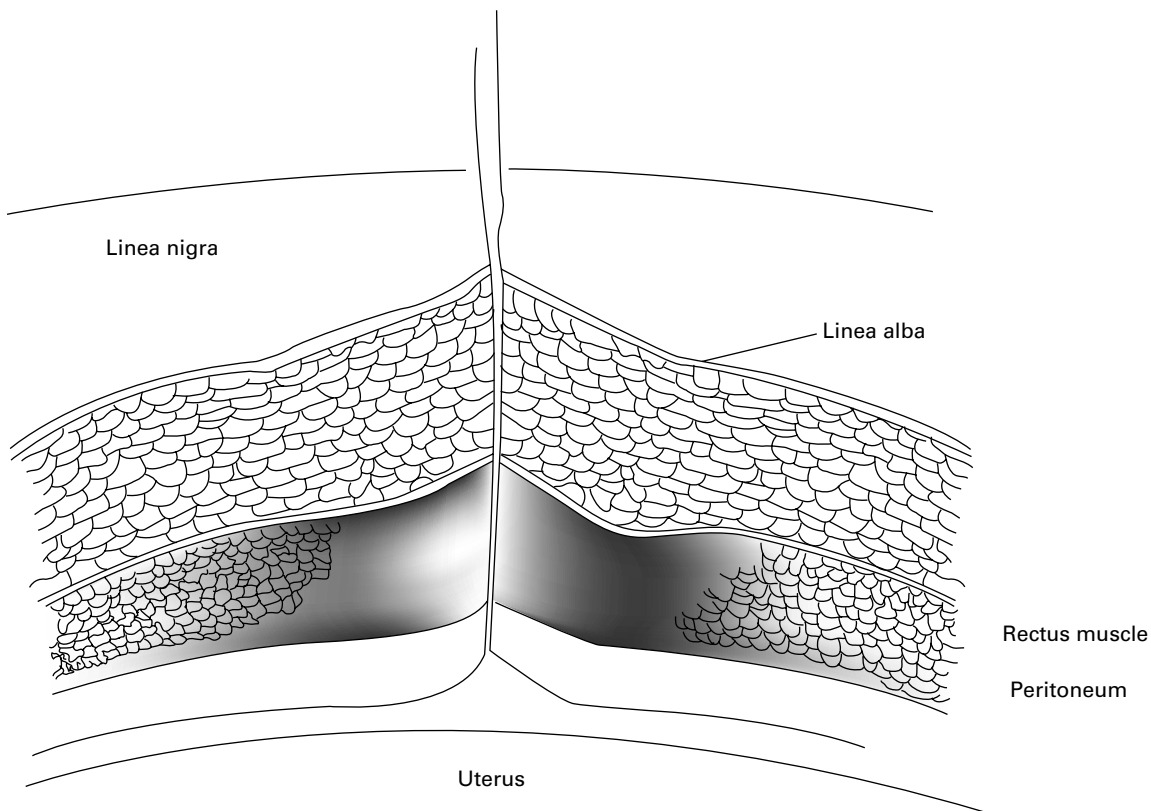
In 715 BC, the Roman senate decreed that no woman in advanced pregnancy should be placed in the sepulchre until the child was removed from the parent body.[50] Cesarean section was practiced in Egyptian, Persian, Hindu, Finnish, and North American Indian culture.[13,51] Even Shakespeare refers to the practice in "the Scottish play."[52] Because delivery of the fetus is essential to improve maternal and fetal survival, it is advisable to have a simple Cesarean section pack on the maternity unit cardiac arrest cart. Maternal and fetal outcome is determined by a number of factors including: gestational age of fetus, time from maternal arrest to delivery, cause of the arrest, and previous maternal health. Prognosis after cardiac arrest in pregnancy is improved if Cesarean section can be performed within 5 minutes of maternal arrest; after 20 minutes the prognosis is poor.[13,16,53] Once a decision has been made to perform a perimortem Cesarean section, cardiopulmonary resuscitation must be continued throughout and after delivery.


Fig. 60.4. A cross-section of the abdominal layers demonstrating the relatively avascular layer in the midline.

Performing the perimortem Cesarean section

As discussed above, a perimortem Cesarean section is indicated on a pregnant patient in cardiac arrest who has failed to respond to initial resuscitation attempts. The procedure should begin as soon as it is accepted that the mother has little chance of recovery. Resuscitative measures are continued during the surgical procedure in order to maximize uteroplacental perfusion. A few moments are allowed for sterile abdominal preparation, while the bladder is catheterized to decompress it.

A surgeon who is an experienced obstetrician may wish to use a conventional Pfannenstiel incision, but a vertical incision using a scalpel offers the most rapid access into the peritoneal cavity and is probably through one of the more anatomically uncomplicated areas of the abdomen.[54,55] The incision should run from pubis to umbilicus along the linea nigra, between the usually divaricated recti. Ideally the incision should be through the fascial and peritoneal layers, avoiding bowel, bladder, or uterine vessel injury (Fig. 60.4).

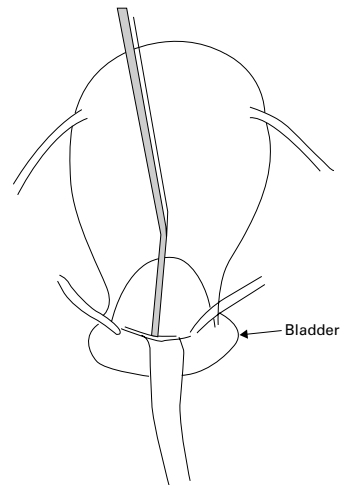
Once the peritoneal cavity is entered, the bladder is retracted caudally, away from the uterus. The uterus is entered in the lower segment, just above the bladder, and


Fig. 60.5. Initial incision into the uterine segment avoiding the bladder.

the vertical incision is extended cranially using scissors. The other hand is placed inside the uterus to protect the fetus from the scissors as the incision continues towards the fundus of the uterus (Figs 60.5 and 60.6). A sufficiently long incision is the key to a rapid delivery.

Fig. 60.6. Extension of the uterine incision using the fingers to protect the fetus.

If the placenta lies anteriorly, it must be incised rapidly to deliver the baby.

After completing the uterine incision, all retractors are removed in order to avoid injury to the fetus on delivery. If the fetus is in a vertex position, a hand is inserted between the fetal head and the pubic symphysis; the head is then lifted gently out of the incision. Delivery of the head and shoulders is followed by spontaneous delivery of the body. If the fetus is in breech or transverse position, a feet-first delivery is easiest. Traction to the feet is applied in a gentle progressive manner. In order to minimise damage to the fetus, pressure on the abdomen or lower back should be avoided, with the fetal neck kept in flexion to avoid injury to the cervical spine. Upon delivery of the infant, gentle suction should be applied to nose and pharynx, and clamps applied to the umbilical cord and the placenta.

The child should then be resuscitated as necessary. The open abdomen permits the use of internal cardiac massage. The inside of the uterus must be palpated to exclude the possibility of twins and remove the placenta. After successful delivery, both mother and infant should be transferred to their appropriate intensive care units as soon as clinical conditions permit.

Medicolegal considerations

A perimortem lower segment Caesarean section has the potential for major ethical and consent issues. Operating without consent may be considered as assault on the woman. The doctrine of an "emergency exception" to consent would be applied in most countries, however, allowing for legally acceptable implied consent when a

delay in treatment may cause harm or injury.[13] In an emergency situation, where consent cannot be obtained, then doctors may under common law (in some countries), provide treatment to anyone who needs it, provided the treatment is limited to what is immediately necessary to save life or prevent significant deterioration (unless they are aware of a valid advance refusal).

In reality, in view of the 5-minutes time frame, the responsible physician will have to act rapidly and decisively to maximize the chance of a successful resuscitation.

Training

Because cardiac arrest in pregnancy is so rare, it is difficult for groups such as obstetricians and midwives to maintain their skills. There are a number of resuscitation courses available. Some, such as MOET used in the UK,[56] are specifically designed for staff working on delivery suites. Nevertheless, regular update sessions and "fire drills" are essential for the teams to practice their response to life-threatening emergencies.

Ideally, members of the public and healthcare professionals in the emergency service should be aware of the additional problems associated with resuscitation in late pregnancy, because they may have to act as the first responders in the crucial first few minutes after collapse.

Summary

Cardiac arrest in pregnancy is rare, but, if it occurs, requires decisive and rapid treatment. Modification to normal CPR protocols include left tilt, early intubation, and early delivery of the fetus. The key factors for successful resuscitation are that all midwifery, nursery, and medical staff concerned with obstetrics should be trained in cardiopulmonary resuscitation.[57]

Drowning refers to submersion and immersion. This chapter focuses on submersion and reviews the epidemiology, pathophysiology, and treatment of this mainly respiratory problem. Hypothermia-related immersion issues are described in Chapter 49.[1]

Epidemiology

Circumstances of drowning vary around the world; from healthy toddlers to desperate boat refugees, and from beach to bathtub. According to the WHO report, each year between 350 000 and 450 000 persons die from drowning. In addition, in some years, over 500 000 persons have drowned in floods and tsunamis. Most drowned victims are children, and the potential years of life lost are immense. Within this global perspective, 97% of all drowning occurs in South East Asia, the Pacific, and Africa. In some areas, the drowning rate is as high as 400 persons per 100 000 inhabitants. The leading cause of drowning in these areas is multifactorial. Leisure, work, transport, and collecting water for household purposes occur in the surroundings of water. Swimming skills are lacking, as is the knowledge on how to perform rescue, first aid, or basic life support (BLS). Also, prevention efforts, rescue resources, or communication equipment are poor.[2–4]

In the Western world, a combination of socioeconomic factors, legislation, multifaceted prevention programs, improved rescue techniques, and up-to-date medical systems have resulted in a 10- to 20-fold decrease in drowning rates during the last 50 years. The death rate is between 0.1 and 2.5 per 100 000 inhabitants. High risk groups are children (because of their exploratory behavior), ethnic minorities (because they have poorer swimming skills and are unfamiliar with water hazards), car occupants (because of blocked escape routes from cars with maximum active safety protection), and water recreationers (because of inadequate preparation and alcohol use). Certain countries or areas have specific, and sometimes unique, risk groups: Alaska and Iceland (commercial fisherman),[5,6] Japan (hot tub drowning),[7] and Australia and the southern areas of the USA (private swimming pool drowning).[8,9] Recent data from the Netherlands suggest another new trend: scoot-mobiles and walker-related drowning in the elder generation.[10] An important cause of drowning in the Western world is suicide, and in some countries the incidence of suicidal drowning is three times larger than that of accidental drowning.[11] Homicide has been suggested to be underreported in pediatric bathtub drowning.[12] For most types of drowning, males have an approximately 4-fold greater incidence of drowning than do females, except for suicide.[12,13]

Prevention remains the most powerful therapeutic intervention and can be effective in more than 85% of drownings. Many predisposing and etiological factors have been identified that can be influenced by improved understanding and training on prevention.[14]

Definition of drowning and data collection

During the 2002 World Congress on Drowning, a consensus was reached on a new definition of drowning: Drowning is the process of experiencing respiratory impairment from submersion or immersion in liquid. This definition is

accepted by the World Health Organization but needs further classification of causes, morbidity, and mortality.[15,16] Also during this congress, a standard nomenclature on drowning incidents and a standardized reporting mechanism for these data were proposed.[17]

In the definition, two different drowning mechanisms are included. During submersion the head of the victim remains under water and the primary problems are related to hypoxic injuries. During immersion, the head of the victim initially remains above water and the life-threatening dangers are related to the immediate or late consequences of hypothermia. During immersion, splashes of water in the face can result in aspiration, hyponia and unconsciousness with submersion as a result. So both mechanisms can occur simultaneously.

Recognition of a drowned person

A drowning victim usually does not wave or call for help, but remains with the mouth just above the water level and with the arms extended laterally, slapping the water. The victim may submerge and surface several times during 10 to 60 seconds before final submersion occurs. Because all efforts are desperately needed to inhale air, the victim is usually unable to cry out for help.[18] Individuals close by may therefore not recognize that a person is drowning. Children and toddlers typically disappear instantaneously under water without any sign or call of distress.

Pathophysiology of drowning

In spite of the wide variety of drowning circumstances, the pathophysiology of drowning has common characteristics. Some characteristics are distinct from cardiac arrest (for example, gradual onset of circulatory arrest in drowning vs. immediate onset in cardiac arrest) or from trauma (for example: no energy impact in drowning vs. massive energy impact in trauma). Cardiac arrest due to drowning occurs as a result of prolonged anoxia, in a time frame between a few minutes and an hour, or as a result of cold-induced cardiac arrest in a time frame of hours or even days, and is the result of the mechanical impairment of the hypothermic heart and conduction disorders, typically ventricular fibrillation. The most important pathophysiological mechanisms, hypoxia and hypothermia, may be complicated by other factors, such as the diving reflex, aspiration, and trauma.

Submersion

Hypoxia and the circulatory consequences of submersion

When a victim submerges (disappears under water) the most likely immediate response to hypoxia is a short period of tachycardia. As the vagal response of the diving reflex blunts the tachycardia, the victim becomes progressively bradycardic, which is sometimes associated with ventricular ectopy.[19–21] Hypoxia will lead to hypotension and a narrow pulse. This may progress to profound cardiac dysfunction and then cardiac arrest with pulseless electric activity (PEA) or non-perfusing ventricular fibrillation (VF) or ventricular tachycardia (VT). The extreme hypoxic–ischemic insult will ultimately result in asystole.

The circulatory consequences of submersion are in contrast to an arrhythmogenic VF cardiac arrest, where the cardiopulmonary system initially has abundant oxygen. In a submersion cardiac arrest the cardiopulmonary system has profound depletion of oxygen which is clinically obvious by a profound metabolic and respiratory acidosis.[22,23]

Hypoxia and the neurological consequences of submersion

The brain is exquisitely sensitive to interrupted delivery of oxygen and glucose, even if for only a few minutes. Energy failure causes unregulated neurotransmitter release and failure of neurotransmitter reuptake. This leads to excitotoxic stimulation of postsynaptic neurons and breakdown of transmembrane ionic gradients critical for neuronal function. Abrupt cessation of energy supply also causes global shutdown of protein synthesis and failure of proteins to be folded into functional tertiary structures. This creates a toxic state in the endoplasmic reticulum that must be reversed before protein synthesis can recover. In selectively vulnerable structures, this latter process may not be reversible.[24,25]

At the same time, hypoxia impairs mitochondrial function and leads to formation of reactive oxygen and nitrogen species (ROS-RNS) during the early phase of recirculation. Oxidative stress stimulates cellular mechanisms designed to eliminate injured cells by apoptosis and also upregulation of inflammatory mediators. The reaction of ROS-RNS with cell membranes, DNA, and proteins disrupts functions and stimulates futile efforts to repair molecular damage, but at the same time consumes large quantities of energy, thus contributing to further hypoxic damage. The inflammatory responses activate microglia and recruit

neutrophils, which in turn further promote oxidative stress. Selective neurological vulnerability is demonstrated in survivors of cardiac arrest. Hippocampal damage may be prominent, while other parts of the brain are unaffected. As a result, survivors who recover consciousness still may have sustained permanent impairment of new memory formation.[26] More severe anoxic insults cause tissue damage in the basal ganglia, cortex, and cerebellum, resulting in motor deficits or permanent impairment of consciousness and cognition. Virtually no study of cerebral pathology has been performed in drowning models. Hence, our understanding of brain damage resulting from drowning is extrapolated from the knowledge of other brain injuries.[27]

Hypoxia and the double role of hypothermia in submersion

Water has a heat conductance capacity that is 25 times greater than air and the body temperature of a person in water drops five times faster than it does in air. As a result, depending on water temperature, body temperature can drop to a lethal level within minutes to hours. This is attributable to hypothermia-induced cardiac arrest. In some drowning cases, however, hypothermia can provide a protective mechanism that allows victims to survive prolonged submersion episodes, in exceptional cases longer than 60 minutes.[28] An important underlying mechanism is reduction of energy consumption by the brain. Reduced oxygen consumption prolongs the interval until cellular anoxia and ATP depletion occur. Hypothermia also stabilizes cellular integrity and slows pathologic processes. Through these mechanisms, hypothermic cells can retain viability until circulation is restored. There is less acidosis and neurotransmitter release, mitochondrial functions are less impaired, and there are fewer signs of oxidative stress and disrupted protein synthesis. These factors are in contrast to non-hypothermic cardiac arrest where deranged brain metabolism has its onset within seconds of interrupted circulation. Hypothermia reduces the electrical and metabolic activity of the brain in a temperature-dependent fashion. The rate of cerebral oxygen consumption is reduced by approximately 5% per °C reduction in temperature within the range of 37–20 °C.[29–33] Thus, reduction of brain temperature by 10 °C reduces the rate of ATP consumption by approximately 50%, doubling the duration of time the brain can survive absence of blood flow. Colder temperatures provide even more profound preservation of energy stores, such that reduction of temperature to 16–18 °C can allow intervals of no-flow of more than 60 minutes in humans.[22]

Table 61.1. Circumstances that facilitate hypothermia and allow the protective effects of low body temperature to become effective

Water colder than 5 °C
Young age
No insulating clothing or body fat
Aspiration of large quantities of water
No survival struggle
Immersion followed by submersion

The conditions that permit miraculous outcomes with cerebral preservation are summarized in Table 61.1. Hypothermia, if present, may prolong the window of opportunity for successful resuscitation, allowing victims of a cardiac arrest secondary to submersion in cold water potentially to have a much better outcome than would otherwise be expected.[34]

The diving reflex and submersion

Some experts on drowning speculate that the diving reflex provides a protective mechanism against drowning pathophysiology. The diving reflex is a well-known reflex in aquatic mammals, such as whales and dolphins, and occurs when the animal submerges under water.[19,21] The diving reflex has also been studied in humans during diving into very deep water,[20] in studies on the diabetes-related autonomic dysfunction of the sympathetic and parasympathetic nervous systems, and in other diseases.[35,36]

Selective vasoconstriction is the mechanism of protection in the diving reflex. When the head, and specifically the sensory distribution of the trigeminal nerve, is in sudden contact with water, blood flow is preferentially directed to the heart and brain, the organs most vulnerable to hypoxia. Cold water enhances the occurrence of the reflex. Because oxygen consumption in these two organs is less than total body oxygen consumption, oxygenation of the brain and heart is better sustained. The reduced total body oxygen consumption delays the time interval until a hypoxia-induced cardiac arrest occurs. It is hypothesized that the diving reflex buys time until the organ-protective effects of hypothermia come into action. Bradycardia is the clinically observed consequence of the diving reflex, with a heart rate often below 40 beats per minute.[20,21]

Aspiration and submersion

A still less understood pathophysiological factor in submersion is aspiration. Although drowning victims, by

definition, have signs of respiratory impairment, not all drowning victims have signs of aspiration, and respiratory impairments often resolve spontaneously. Signs of aspiration are found in 80–90% of the autopsies of fatal submersion incidents.[37] The percentage of patients who are admitted with signs of aspiration varies among countries and health systems. Clinical signs of aspiration occur only in 10%–20% of submerged victims admitted to hospitals in The Netherlands,[38,39] while this is almost 100% in hospitals in Brazil.[40]

In many drowning victims, laryngospasm occurs instantaneously when inhaled water contacts the vocal cords and this laryngospasm will temporarily prevent aspiration. Many victims will be saved before laryngospasm has ceased. In other victims the dying process will have advanced to a stage where efforts to breathe occur after laryngospasm has ceased. For this reason, but possibly also due to other yet unknown factors, massive aspiration is seldom present and most drowned victims will have aspirated limited amounts of water.

Small amounts of aspirated water may have serious clinical consequences. Water in the alveoli causes wash-out of surfactant (mostly in fresh water) or destruction of surfactant (mostly in salt water), or both. Differences in osmotic gradients can pull water from the lungs to the circulation with fresh-water drowning. In contrast, more water can be drawn into the lungs from the circulation with salt-water drowning. In either situation, the effect of the osmotic gradient on the very delicate alveolar-capillary membrane can disrupt the integrity of the membrane, increase its permeability and exacerbate fluid, plasma, and electrolyte shifts.[41,47]

The clinical picture of the damage caused to the alveolar–capillary membrane is a massive, often red stained, pulmonary edema. The combined effects of fluids in the lungs, loss of surfactant, and increased capillary–alveolar permeability can result in decreased lung compliance, increased right-to-left shunting in the lungs (up to 80%), atelectasis, and bronchospasm. Although the clinical picture resembles the classical adult respiratory distress syndrome (ARDS), the underlying mechanism in drowning is due to local damage rather than systemic inflammatory reactions. This is probably the main reason why ARDS after drowning resolves within 48 hours, unless an underlying pulmonary infection, chemically induced pneumonia, or massive aspiration of gastric contents is present.[38]

Electrolyte disorders during submersion

In the 1970s, electrolyte disorders were considered to be the most relevant pathophysiological threat in drowning.[42–44]

It has now been confirmed that electrolyte disorders play a minor role in the initial cardiovascular events after submersion. These disorders, if they occur at all, can be corrected by common regulatory mechanisms when the victim reaches a hospital. The salinity of the water in which the victim has been submerged generally has limited impact on the pathophysiology and outcome, except in extreme conditions such as drowning in the Dead Sea or drowning in unusual industrial environments.[45–47] No evidence exists for any therapeutic benefit of administration of hypertonic solutions after fresh water submersion or hypotonic solutions after salt-water submersion.[48]

Treatment

Very few emergency medical system (EMS) personnel and clinicians have had sufficient clinical experience with the treatment of drowned victims. Those who have this experience often have a specific geographically determined focus on the treatment of these victims, such as drowning on the beaches of Rio de Janeiro (most of which are in warm water) or drowning in the cold North Sea (most of which are in cold water). Since the body's response to drowning is related to the environment in which drowning occurs, local circumstances should be taken into consideration in deciding treatment strategies and protocols.[49]

Rescue and in-water basic life support

Rescue and in-water BLS is a typical link in the management of drowning victims (Fig. 61.1). All persons who attempt a rescue from the water should be aware of the risks of the sometimes hostile environment.[50]

Rescuers should avoid becoming second victims by advising the victim on how to get out of the dangerous situation, by reassuring that assistance is coming, or by using a "throw or reach rescue technique." When entering water is unavoidable, this should be done cautiously. The victim should be transported to shore immediately without further treatment, and removed from the water, when possible with the head above body level to avoid vomiting and aspiration. The victim should then be placed parallel to the waterline, and, when the accident occurs on a seashore, far enough from incoming waves.

Trained rescuers have learned how to avoid unnecessary risks, to calm the victim, to reach out in a safe way, and to bring the victim to land.[50,51] In some countries rescuers have learned in-water ventilation (Perkins, 2005). Although this may seem futile, in-water ventilation applied by two or three professional lifesavers in Rio de Janeiro
Fig. 61.1. Basic life support (BLS) is a typical link in the management of drowning victims.

(Brazil) can increase survival sevenfold.[52] In most other situations, ventilation is initiated after the victim is removed from the water, when the physical support of ground, boat, or surfboard is available. Even for trained rescuers a pulse check in water is unreliable and thoracic compressions in water are impossible.[50]

There has been some concern about cervical spine injuries, especially from high energy impact, such as occurs with kite-surfers, water skiers, and occupants of motorized water craft.[54,55] Yet in several large studies of water-related episodes, the incidence of cervical spine injuries among submersion victims is less than 0.5%.[11,51] The possibility of a spinal injury causes conflicting priorities with respect to whether resuscitation or spinal stabilization should take precedence. If there are no signs of cervical spinal injury (history of trauma or a bruised forehead), no time should be spent to immobilize the cervical spine. BLS measures always have priority above spine stabilization. Indeed, if the victim is not breathing spontaneously, resuscitation should start without any special attention to the cervical spine. When spinal cord injury is suspected, however, rescuers should float the victim horizontally supine with an open airway well out of the water. If there is spontaneous breathing, the hands of the rescuers can stabilize the neck in a neutral position. If immediately available, a floating back support device can be used to facilitate alignment of the victim's head, neck, chest, and body before moving the victim.[53]

Basic life support (BLS) on land

Cardiopulmonary or respiratory arrest occurs only in 0.5% of all rescued victims, but most drowning victims have some level, albeit temporary, of respiratory, circulatory, or neurological impairment (Szpilman 1997). Immediate bystander BLS on land is crucial in all these situations, but is most important in victims of cardiac arrest. Chance of

survival dramatically decreases if BLS is delayed.[56] For this reason, policemen, firefighters, and EMS personnel should know how to perform a water rescue, and those who work or live close to water should know how to perform BLS on a drowning victim.[57]

The first BLS action for an unconscious drowning victim on land is to open the obstructed airway and to place the victim in a recovery position. When the victim is not breathing, mouth-to-mouth ventilation should be started. This can be strenuous because of increased airway resistance, loss of surfactant, and hypothermia-induced tissue rigidity.

After 2 minutes of mouth-to-mouth ventilation, the presence of circulation should be assessed to determine if thoracic compressions should be performed. A pulse check in drowning victims is likely to be unreliable. Vasoconstriction and bradycardia are often present, caused by hypoxia, hypothermia, and the diving reflex, but if there are no signs of circulation, thoracic compressions should be started.

Ventricular fibrillation is rare in drowning patients. The automated external defibrillator (AED) therefore has a limited role in BLS after drowning[58] (www.ilsf.org: position statement). Limiting BLS to thoracic compressions only, as recommended as a good alternative in primarily cardiac arrest, is counterproductive in drowning because the lethal component is hypoxia. Thus, ventilation of the lungs must be restored first.

Prevention of aspiration of vomitus is important. Vomiting occurs in 50% of initially symptom-free victims, in more than 65% of victims who need ventilation, and 85% of victims who need BLS.[8,51] Vomitus in the mouth must be removed. A check for seaweed, sand, or mud in the airway is only performed in rare situations, when effective ventilation cannot be achieved.

Active drainage of the lungs by placing the victim head down, by firmly compressing the thorax, or by abdominal thrust is not recommended, because this increases the risk

of vomiting more than fivefold and leads to 19% increase in mortality (www.ilsf.org: position statement).

Advanced Life Support (ALS) on land

The skills and qualifications to provide ALS by EMS providers differ among countries and even within counties.[1,56] The preferred situation is that all ALS measures be provided by the EMS system, but if the EMS is unable to do so, BLS should be continued while the victim is transported as soon as possible to a hospital. When on shore, both the victim and the rescuer should always receive medical attention from the EMS team.

The immediate treatment of the respiratory consequences is essential. Also, when circulation is intact, oxygen is the first-line therapy. Initially, oxygen can be administered by a non-rebreathing mask at 15 liters per minute. Minor cases may require only a nasal cannula with 5 liters of oxygen per minute. With respiratory arrest, artificial bag-mask ventilation is initially performed with 15 liters of oxygen and an estimated tidal volume of 5–8 ml per kg of body weight. If the respiratory situation does not improve, an endotracheal tube should be inserted immediately. Suctioning through the endotracheal tube to enable visualization of the vocal cords when intubating may be necessary when copious pulmonary edema foam drains from the trachea. Once the victim is intubated, oxygenation and ventilation with positive end expiratory pressure (PEEP) can be started. The initial PEEP-level at 5 cm H_2O is increased when hemoglobin oxygen saturation, as measured by pulse oximetry, is below 92%. The initial oxygen inspiration fraction (F_iO_2) is 1 but can be reduced to 0.45 or less when hemoglobin oxygen saturation is above 92%. The quality of the signal of the pulse oximeter in the cold, and thus vasoconstricted, patient should always receive extra attention when interpreting the results, as in this situation readings may be inaccurate.[59,60]

In many life-threatening postrescue situations, the initial rhythm is an extreme bradycardia or PEA. If improvement of oxygenation has not resulted in improved circulation, cardiotonic drugs are started. Because of the cold-induced vasoconstriction and the non-cardiogenic pulmonary edema fluid in the airways, both the peripheral and endotracheal administration of drugs are unreliable. A central venous approach via the external or internal jugular vein is the preferred route.[18]

In a cardiorespiratory arrest situation, cardiac compression should be started as soon as oxygenation and ventilation are secured. High-dose epinephrine can be considered in drowning if 1-mg doses fail, because the pathophysiological mechanisms are different, the cardiac arrest is secondary to hypoxia, the pharmocodynamic effects of hypothermia require a higher initial dose to be effective, and the time elapsed to cardiac arrest can be very long. Many victims have initially marginal cardiac function. If circulation and a regular cardiac rhythm with a mean arterial pressure (MAP) below 90 mmHg is present after rescue, and circulation measures do not improve with oxygenation and lifting of the legs, rapid crystalloid infusion is indicated.[18,61]

Drowning severity and treatment decision scheme

One of the most difficult medical decisions for those who provide BLS or ALS at the rescue site is how to treat victims with less life-threatening conditions appropriately. In these situations, a treatment decision scheme can be used (Table 61.2). The scheme is validated for 41 279 rescues, including 1831 drownings.[40]

Treatment in the emergency department

In situations where the EMS system has established all ALS measures, treatment in the emergency department (ED) focuses on:

– acquisition of information
  ● circumstances of the drowning incident
  ● previous illnesses of the victim
  ● quality of rescue, BLS and ALS
– further optimization of ALS measures and diagnosis
– decision-making
  ● continue or stop resuscitation efforts
  ● admit to an ICU
  ● observation in the ED
  ● discharge

When the EMS system is not able to provide some, or all, ALS measures in the prehospital situation, all remaining ALS measures must be established first.

Additional ALS measures may also be needed in the ED, for example when the clinical condition of the patient worsens after an initially mild clinical course. Notably, in these patients a very aggressive therapeutic approach is needed in order to stay ahead of a rapidly evolving life-threatening complication.

Acquisition of information in the ED

Relevant information includes details on the location, cause, and circumstances of the accident, water and air temperature, water salinity and contamination (bacteria,

Table 61.2. Drowning treatment decision scheme at the rescue site

Grade	Signs and symptoms	Treatment on land (basic and advanced life support)	Mortality on site (%)	Mortality in hospital (%)
Rescue	Conscious, normal auscultation, no coughing, foam or difficulty in breathing	Evaluation and release from the accident site without further medical care	0	0
1	Normal pulmonary auscultation, coughing, no foam in mouth or nose	Rest, warm and calm the victim. No further medical care	0	0
2	Rales in some pulmonary fields, small amount of foam in mouth or nose	5 liters oxygen per minute by nasal cannula; warm and calm the victim; recovery position, hospitalization	0.6	4.0
3	Large amount of foam in mouth or nose, normotension, palpable radial pulse	15 liters oxygen per minute by non-rebreathing mask, intubation when possible; recovery position if unconscious; hospitalization.	5.2	11.5
4	Large amount of foam in mouth or nose, hypotension, no radial pulse but palpable carotid pulse	Grade 3 treatment extended by crystalloid infusion via peripheral vein until restoration of systolic arterial pressure > 90 mmHg; hospitalization	19.4	19.4
5	Isolated respiratory arrest	Mouth-to-mouth (when possible with 15 liters of oxygen) until restoration of normal breathing, then treat as grade 4.	44.0	33.3
6	No cardiac activity on ECG, cardiopulmonary arrest	Start CPR; insert tracheal tube, obtain venous access, give epinephrine; defibrillate if necessary. After succesful CPR: follow grade 4.	93.0	43.5
Dead body	Submersion time over 1 hour and no cardiac activity on ECG monitoring; or obvious rigor mortis, putrefaction or dependent lividity	Do not start BLS or ALS; arrange morgue.	100	100

Adapted from ref. 40.

chemical), wave conditions, submersion time, timing and quality of rescue, BLS and ALS.

Causes of the submersion incident should be sought and may include accidents,[54] epilepsy,[62] acute myocardial infarction, stroke, alcohol use, drug use, and psychiatric conditions.[39] History of the victim, but also of family members, may reveal the possibilty of a prolonged QT syndrome.[63–65] Focal neurological signs suggest stroke or trauma. A significant number of submersion victims are foreign to the area and language difficulties may cause problems in acquiring this information.[66]

Further optimizing ALS measures and diagnosis in the ED

The position of an endotracheal tube inserted out-of-hospital should always be checked immediately on admission to the ED, because the wet surface of the skin, transport on rough ground, and high inflation pressures increase the risk of tube dislocation. Airway obstruction due to foreign bodies is rare, but fiberoptic bronchoscopy should always be considered. Bronchoscopy allows therapeutic clearing of sand, gravel, and other solids, which can lead to atelectasis of large lung areas. The extent of airway injury can be

determined and cultures obtained to define bacterial infection.

Each drowned patient needs a thorough respiratory check-up. Inspiratory crackles indicate the presence of ARDS or atelectasis as a result of aspiration.[67] Arterial blood gas analysis, with and without oxygen, and a chest radiograph will further confirm the presence of pulmonary problems and provide baseline information. When an endotracheal tube is in place, a nasogastric tube should also be placed. The reduction of gastric distention, resulting from insufflation during BLS, facilitates ventilation and prevents further aspiration.

The respiratory condition of a submersion victim often improves during the first 6 hours. In some patients, however, the condition can seriously deteriorate and continous pulse oximetry as well as regular arterial blood gas analysis and monitoring of respiratory rate and respiratory efforts are needed to identify this category. An altered chest radiograph on admission should not be interpreted as pneumonia, as this is usually the result of pulmonary edema and aspirated water in the alveoli and bronchi. Young victims are often able to compensate for respiratory insufficiency with extra respiratory effort during prolonged periods. These patients are likely to seriously decompensate and it is advised not to wait until the moment of exhaustion to perform endotracheal intubation. In some patients, continuous positive airway pressure (CPAP) or other non-invasive respiratory therapies may be beneficial, provided that this is not contraindicated for the patient and this technique does not cause panic or gastric distension.[68–70]

Ventilation in drowning patients with ARDS can be extremely difficult because of massive pulmonary edema, decreased pulmonary compliance, and bronchospasm. High levels of PEEP improve oxygenation after drowning, but may impair hemodynamics. PEEP may be increased by 2 to 3 cm H_2O increments until arterial blood gases show an intrapulmonary shunt (QS:QT) of 20% or less, or until a PaO_2:FiO_2 ratio of 250 or more is achieved. Optimal PEEP can also be titrated by determining the lower inflection point of the compliance curve of the respiratory system, or by PEEP trials between 5 and 15 cm H_2O PEEP.[71–73] Once the desired oxygenation is achieved, that given level of PEEP should ideally be maintained unchanged for 48 hours before attempting to decrease the PEEP level. This period is needed for adequate surfactant regeneration. Unlike ARDS of a systemic cause, arterial oxygenation often improves dramatically when local lung damage has recovered and PEEP can be progressively decreased. Once weaning from the ventilator commences, it is almost always successful within 48–72 hours

and some 75% of the patients with ARDS after drowning survive.[38]

The Brain Resuscitation Task Force at the World Congress on Drowning 2002 concluded that maintenance of normocapnia is recommended during the ICU period for the best chance of neurological recovery.[27] Because both hypocapnia and permissive hypercapnia have unwanted circulatory and neurological effects,[74] the usual strategy for lung protection by permitting hypercapnia should be avoided.[75]

Low cardiac output is common after severe drowning and is the result of the hypoxic insult, arrhythmias, relative or absolute hypovolemia, and hypothermia.[48] Often, the circulation state improves with better oxygenation, 2–3 liters of crystalloid fluid, and rewarming. Monitoring of urine output and clinical assessment of the peripheral circulation in the extremities provides relevant information on the quality of circulation. Poor response to the therapy requires additional information (e.g., by central venous pressure measurements, echocardiography, or transesophageal echocardiography) for further assessment of cardiac function. Depending on this information, further volume loading with colloids, inotropic support, or use of vasopressors may be indicated. Titration of adrenaline or dobutamine administered through a central venous catheter to a MAP of 90–100 mmHg is reasonable. The sometimes paradoxical hemodynamic effects of these drugs in a hypothermic patient should always be taken into consideration.[76–78] Traumatic blood loss should always be excluded in hemodynamically unstable patients.[79] The pulmonary edema seen in drowning patients is most likely of non-cardiogenic origin and thus furosemide is rarely indicated. The use of prophylactic antiarrhythmics, even after ventricular fibrillation, is controversial. Treatment of arrhythmias that have negative effects on circulation is appropriate. Before starting with antiarrhythmic drugs, oxygenation, circulation, sedation, and pain treatment should be adequate and electrolyte abnormalities (especially K^+ and Mg^{2+}) should be corrected.

The majority of the submerged victims in the ED have a metabolic and respiratory acidosis.[18,22,80–82] This should be corrected with adequate ventilation and circulation. The use of bicarbonate is only indicated when the pH remains below 7.1, or the bicarbonate level remains below 12 mEq/l, despite improved circulation and ventilation.

Extremes of temperature may occur. Hypothermia is often present and can contribute to a reversible loss of consciousness. Hypothermia may have some potential benefit for organ preservation. Attempts at rewarming should be tempered by the potential neurological benefits associated

with induced hypothermia after cardiac arrest.[27,83,84] Hypothermia also adds complex management issues with regard to the appropriate timing, speed, and techniques for rewarming. In the case of a hypothermic cardiac arrest, resuscitation should be continued until the temperature reaches 33 °C, because below this temperature many drugs, as well as defibrillation, are less effective. Above 33 °C the cardiac physiology returns to normal.

The several methods of rewarming are included in Chapter 49.

On the other hand, hyperthermia may also occur as an overshooting reaction on rewarming or as a systemic response to pulmonary or systemic damage. Hyperthermia should be prevented or aggressively treated as the increased temperature severely enhances neurological damage.[27]

Important other investigations in the ED include measurement of electrolytes, blood urea nitrogen, creatinine, and hemoglobin. Free hemoglobin measures hint at aspiration of fresh water.[85] Additional investigations should be guided by the presentation and likelihood of abnormalities.

If cervical spine injuries are suspected, appropriate radiological procedures should be undertaken to guide further management.[86] High-speed impact injuries should be treated as if caused by trauma and films of cervical spine and pelvis are needed. Focal neurological signs suggest a need for a head computerized tomogram (CT).

Decision where to go after the ED

Hospitalization can be avoided in drowning victims who have a normal pulmonary examination, a normal chest radiograph, normal room air oxygen saturation after 6–8 hours of observation, and who have no significant comorbid disease.[38,40,87] Prediction of the likelihood of successful resuscitation is very difficult and survivors have been reported after particularly severe physiological conditions. In hypothermic pediatric patients, prognosis is even more difficult.[1,22,23,82,88,8,9] In general, a submersion period of 10 minutes is associated with good survival when rescue, BLS, and ALS are performed adequately and no other factors interfere (such as previous illnesses or trauma). Often the submersion duration is unknown. Most normothermic adult and pediatric patients are neurologically intact if restoration of spontaneous circulation occurs within 25 minutes of the initiation of ALS techniques or within 1 hour of the initiating submersion event.[39,90,91]

Given reports of asystolic drowning victims who were eventually resuscitated after several hours of ALS, it is appropriate to continue cardiopulmonary resuscitation efforts until adequate rewarming has occurred. The decision to proceed with time, material, and manpower measures that are so time-consuming must be based on clinical experience, availability of resources, and the patient's premorbid state. Information on a slow speed and low quality of rescue, the delayed start of bystander resuscitation, injuries, co-morbidities, and complications is relevant to the decision to discontinue resuscitation. In deep hypothermic cardiac arrest, cardiopulmonary bypass (CPB) is the most effective therapy to improve circulatory, ventilatory, and biochemical indices.[92] The transfer of a hypothermic cardiac arrest child to a center with CPB facilities has been life-saving on several occasions.

Complications in the ICU

In the Intensive Care Unit (ICU), the treatment that started in the prehospital setting and ED must be continued. Most complications that occur in the ICU are common for intensive care patients, but some additional considerations are needed.

Respiratory complications at the ICU

Usually, the water from pools and beaches have too few bacterial colonies to result in pneumonia just after the incident. If the victim needs mechanical respiratory assistance, the incidence of secondary pneumonia increases to 52% on the third or fourth day of hospitalization, a time when pulmonary edema caused by drowning has usually resolved.[38] As a general rule, prophylactic antibiotics should be avoided in the ICU as they tend to select out resistant organisms. This should be limited to scenarios where obviously contaminated water has been involved. The choice of antibiotic agents is complex, but beta-lactam agents (e.g., penicillins or cephalosporins) are reasonable first-line agents for prophylaxis.

In all cases, daily monitoring of tracheal aspirates with Gram stain, culture, and sensitivity is recommended. A large variety of common and uncommon endogenous and exogenous micro-organisms can be detected. The first signs of pulmonary infection usually occur after the first 48 to 72 hours: prolonged fever, sustained leukocytosis, persistent or new pulmonary infiltrates, and presence of leukocytes in the tracheal aspirate. Antibiotic therapy is selected on the basis of the predominant organism in cultures in the ICU and their sensitivities. Some pulmonary infections are very severe. Irreversible multiple organ failure and other septic complications have been reported in the first 24 hours after successful resuscitation.

Artificial exogenous or endogenous surfactant has been used successfully in these very serious ARDS cases as rescue treatment, although insufficient data exist about the appropriate delivery techniques, quantities, and timing of administration.[93,94] Also extracorporeal membrane oxygenation[95,96] and the use of the prone position have been reported to be successful.[97] Treatment of pulmonary edema with corticosteroids has no benefit,[98] although corticosteroids may be useful together with bronchodilators to treat bronchospasm.

Apart from ventilation-related infections, the intensivist must be constantly vigilant for volutrauma and barotrauma. Spontaneous pneumothoraces, secondary to positive pressure ventilation, and local areas of hyperinflation occur in some 10% of ventilated drowning patients admitted to the ICU. Sudden hemodynamic instability during the first hour of mechanical ventilation should be considered to be due to volume depletion, after which a tension pneumothorax (or other barotrauma) should be excluded as a cause.

Circulatory complications

Hypotension may initially be attributed to a period of severe hypoxia, hypovolemia, or hypothermia. When hypotension persists after adequate treatment, pre-drowning myocardial disease, hypoxic myocardial dysfunction, or a profound inflammatory response (that develops over the subsequent hours) should be considered. Information from echocardiography and a pulmonary artery catheter about preload and contractility may be required to facilitate diagnosis and optimal management. A protocol with routine use of central venous catheter and SVO_2 in the early resuscitative phase of patients with sepsis appeared to improve outcome,[99] but the use of invasive monitoring (including a pulmonary artery catheter) still remains controversial.[100,101] The role of these or newer methods of monitoring the circulation, such as PICCCO® , has yet to be studied in drowning.

Neurological complications

Among survivors of a drowning accident, success will be measured in terms of the quality of neurologic recovery.[102] Despite this, there is little information derived from either patients or from animal models that specifically addresses appropriate cerebral resuscitation. This is most likely attributable to the sporadic presentation of drowning victims to any one center and the considerable variability of severity of insult with respect to duration of circulatory arrest, body temperature, and efforts by first responders to provide BLS. Thus, current practice to treat neurological complications is largely extrapolated from the study of anoxic encephalopathy, traumatic brain injury, and stroke.

Restoration of oxygenated blood flow to the brain is the highest priority in drowning victims to restore lack of oxygen, the principal cause of cellular demise in the brain. Immediate cardiopulmonary resuscitation remains the most effective response to drowning.

When circulation and ventilation are established, additional therapies are of limited benefit. Tissue plasminogen activator (t-PA) has been effective for treating some forms of ischemic brain injury. t-PA serves to lyse clots in stroke victims however, and thus has little or no role in drowning patients. Although the anachronistic practice of treating brain injury patients with steroids persists in some environments, both experimental and human evidence indicates that steroids are most likely to increase mortality and worsen neurological outcome, either by promoting hyperglycemia or increasing the frequency of systemic complications.[103] Thus, pharmacological therapy for drowning victims is currently limited to management of seizures, which, at least in cardiac arrest are a common complication of anoxic encephalopathy.

Physiologic factors can play a major role in achieving an optimal neurological outcome from acute brain injury. Although none of these factors has been studied specifically in human or experimental drowning scenarios, sufficient evidence is available from study of other forms of acute brain injury to suggest recommendations for the management of temperature, blood glucose concentration, and blood gas characteristics.

Of these, temperature management seems most promising. In most animal models, brain temperature causes profound effects on the extent of ischemic brain injury. Mild hypothermia (32–34 ℃) is highly protective, even if started after circulation has been restored, but postresuscitation-induced hypothermia must be sustained for intervals of 12–24 hours to provide persistent benefit. With use of this strategy, benefit from induced mild hypothermia in comatose survivors of out-of-hospital ventricular fibrillation cardiac arrest has been demonstrated.[78,104,105]

In many drowning victims, resuscitation is started in a mild or severe hypothermic patient. Therefore, the Brain Resuscitation Task Force assembled at the World Congress of Drowning 2002 recommended that hypothermic drowning victims who remain comatose after restoration of spontaneous circulation be maintained at 32 ℃ –34 ℃ or be treated with deliberate mild hypothermia initiated as soon as possible,[27] and sustained for 12–24 hours. Patients treated with mild hypothermia should be endotracheally

intubated, mechanically ventilated, with shivering prevented. Hypnotics, analgesics, and neuromuscular blockade may be used as required to maintain hypothermia. Electroencephalographic monitoring should be considered to detect seizures. At completion of induced hypothermia, passive rewarming is recommended at a rate no greater than 0.5–1.0 °C per hour.

Hyperthermia is a common sequel to acute brain injury in humans, with the incidence in cardiac arrest survivors approaching 70%[106] is also common in drowning victims in the ICU. Hyperthermia has been shown repeatedly profoundly to exacerbate brain injury in experimental animals, even when onset of hyperthermia occurs many hours after the primary insult.[107] It is therefore recommended that hyperthermia in drowning survivors be treated aggressively.

Hyperglycemia exacerbates most forms of experimental brain injury. This has been attributed to enhanced anaerobic glycolysis resulting in intracellular acidosis and increased corticosterone concentration.[105,108] Although hyperglycemia is most damaging when present during the insult, there is accumulating evidence that ongoing strict regulation of blood glucose reduces mortality and complications.[109–111] Based on this evidence, blood glucose concentration in the drowning patient with a neurologic deficit should be monitored frequently and it appears reasonable to aim for normoglycemic values (80–110 mg/dl; 4.4–6.1 mM).

There is an increasing capability to monitor both the physiology and neurophysiology of brain-injured humans. Although monitoring of evoked potentials, intracerebral microdialysates (neurotransmitters and lactate concentrations), jugular venous oxygen saturation, and intracranial pressure (ICP) have been utilized in traumatic brain injury, there is little evidence that use of these monitors alters outcome from anoxic encephalopathy (but see ref.112). ICP monitoring may be considered, however, if permissive hypercapnia is required for oxygenation in drowning victims with ARDS.

In cardiac arrest studies, repeated assessment of S-100B and neuron specific enolase has been shown to have value in predicting neurologic outcome,[113,114] but although promising, there is insufficient evidence at this time to recommend routine use of these neurochemical markers in guiding management of drowning encephalopathy.

Other complications

Hypoxia and hypothermia result in pathophysiological injuries at a celluluar level in all organs. The brain and the heart are the most vulnerable, but all other organs can also be affected. Many drowning victims suffer from a wide range of complications that can extensively prolong the ICU stay, ranging from the induction of otherwise asymptomatic conditions (Yoshinaga *et al.* 1999), to various acute stresses on the respiratory and cardiovascular systems, including myocardial infarction, stroke, renal failure, and rhabdomyolysis.

Specific pediatric aspects

Drowning is a leading cause of morbidity and mortality in the pediatric population of most countries.[2–4] There is less information concerning morbidity, but it is estimated that, for each drowning death, there are 1 to 4 non-fatal submersions requiring hospitalization. Such submersion injuries are often severe, requiring prolonged care and considerable monetary and emotional costs.[3,11,90,91] Childhood drowning generally occurs in two groups: toddlers and adolescents. Toddlers often enter water unintentionally and during brief lapses in supervision. Once immersed in even small amounts of water, toddlers are unable to rescue themselves because of their cognitive and physical immaturity. Both males and females have a peak in drowning rates during toddler years.

The pathophysiology of childhood drowning is similar to that for adults except that children have a relatively larger ratio of surface area to body mass. Therefore, children can become hypothermic during icy water drownings much more readily than adults, perhaps resulting in better protection of the brain and heart. Also the diving reflex is more likely to occur in children. At the same time, toddlers rarely show panic when drowning, but remain calm while under water. Both aspects keep the oxygen consumption low. This may explain the great preponderance of children in reports of impressively good saves, notably from prolonged icy water drownings.

Most will agree that childhood deaths have a greater impact on society than do adult deaths. For each child drowning death, more years of productive life are lost compared with an adult drowning death. Furthermore, there is a devastating impact on multiple persons associated with the victim. Childhood death from drowning leads to far-reaching impacts on public health[3,91,115]

Coping with a sudden unexpected death is always difficult. When the victim is a child, the loss is generally even more devastating. In modern developed countries, childhood death is unusual and many people have a strong belief that children are not supposed to die. Consequently, the death of a child is often difficult to accept. Children are an integral part of a family unit and their death has a deep and lasting impact for those close to them. The death of

their child is frequently inconceivable to parents. In addition to immediate family, the profound and long-lasting impact often affects large numbers of people who have relationships with the child and family.

Childhood death is also stressful for health care providers. They may feel an additional burden in caring for the family as well as for the victim, while concurrently attempting to deal with their own emotions regarding childhood death. Many prehospital and emergency personnel are inexperienced in caring for children and feelings of inadequacy may provoke additional stress after an unsuccessful pediatric resuscitation. Decision-making is different when the victim is a child and some health care providers are uncomfortable with a process that involves an extended family unit. Others may appreciate the support system that families typically provide for their children.

Support for families of childhood drowning victims and for healthcare providers involved in the unsuccessful resuscitation deserves great emphasis.

Summary

In low and middle income countries, drowning is an important but neglected issue. In high income countries the incidence of drowning is low and attracts limited clinical and research attention. It is important to realize that drowning is primarily a process of acute respiratory impairment. The drowning patient is most of all a challenge for those involved in preventive medicine, rescue, BLS, and ALS. Diagnostic flaws and therapeutic obstacles have to be dealt with in the prehospital situation. In the hospital, rapidly presenting ARDS, optimal usage of hypothermic protection, providing cardiovascular stability, and optimal neurological outcome are therapeutic challenges.

Anaphylactic shock

Richard Pumphrey

Department of Immunology, Manchester Royal Infirmary, Manchester M13 9WL, UK

The discovery of anaphylaxis

In 1902, Richet and Portier were attempting to immunize dogs with venom extracted from sea anemones (Actinia). To their surprise, instead of being protected, some dogs had apparently become more sensitive to the effect of the venom: they became acutely ill and died within minutes of the second injection. They had expected protection (prophylaxis) but had, they thought, achieved the opposite, which they termed anaphylaxis.[1] It soon became clear that this was not enhanced toxicity of the venom, but rather a dangerously severe acute allergic reaction that could equally be triggered by non-toxic proteins. Prausnitz demonstrated in 1921[2] that this hypersensitivity could be transferred by a heat-labile component of the serum, but it was not until 1966 that the Ishizakas identified this component as immunoglobulin E (IgE).[3]

Hypersensitivity reactions take many forms and these were classified in 1968 by Gell and Coombes;[4] IgE-mediated hypersensitivity was labelled type I. More recently, the nomenclature committee of the European Academy of Allergy and Clinical Immunology (EAACI) has recommended it should simply be called "IgE-mediated hypersensitivity."[5]

Definitions of anaphylaxis

The term "anaphylaxis" has been used for all types of acute life-threatening illness triggered by abnormal sensitivity to a trigger agent, and for apparently spontaneous attacks with similar features (idiopathic anaphylaxis). This has made it difficult to define. The EAACI Nomenclature Committee proposed the following broad definition:[5]

> Anaphylaxis is a severe, life-threatening, generalized or systemic hypersensitivity reaction.

The term allergic anaphylaxis should be used when the reaction is mediated by an immunological mechanism such as IgE, IgG, or complement activation by immune complexes. An anaphylactic reaction mediated by IgE antibodies, such as peanut-induced food anaphylaxis, may be referred to as IgE-mediated allergic anaphylaxis. The term "anaphylactoid" reaction had been introduced for anaphylactic reactions not mediated by IgE,[6] but the EAACI committee has recommended that this term should no longer be used. These proposals were updated in 2003.[7]

This proposal has not been universally accepted. An authoritative recent American practice parameter[8] states: "Anaphylaxis is defined . . . as a condition caused by an IgE-mediated reaction. Anaphylactoid reactions are defined as those reactions that produce the same clinical picture as anaphylaxis but are not IgE mediated."

Diagnosis

In practical terms, **anaphylaxis is a variable acute illness, characteristically evolving over minutes. It may cause fatal shock or asphyxia, but otherwise resolves spontaneously within hours** (Table 62.1)**.**

Although anaphylaxis commonly involves respiratory, cutaneous, and circulatory changes, variations such as shock with gastrointestinal disturbance or shock alone are possible. Alternatively, reactions may be fatal without

Table 62.1. Mode of death in 188 cases of fatal anaphylaxis recorded in the UK fatal anaphylaxis register

	Age (years)	0–9	10–19	20–29	30–39	40–49	50–59	60–69	70–79	≥ 80
Foods	shock		1	2	2					
	larynx			5	1	4		1		1
	d.i.b		3	10	4		1			
	asthma	4	18	6	4	2	1	1		
	inhaled vomit		2			1				
Stings	shock			1	3	7	3	4	3	2
	larynx					2	3	1	3	1
	d.i.b					1	1	2		
	asthma			1			1		1	
Drugs	shock	2	1	3	5	5	9	14	13	3
	larynx			1	1	1	3		2	
	d.i.b			1		1		2		1
	asthma		1		3		1	3	2	1

"d.i.b" signifies difficulty breathing due to a combination of upper and lower airways obstruction or cases where the location of the obstruction was uncertain; "larynx" includes laryngeal and other upper airway angioedema.

significant shock except as the terminal event following respiratory arrest.[9] Because of its variability, certain other conditions have commonly proved difficult to distinguish from anaphylaxis.

1. There is a continuous spectrum between anaphylaxis, from anaphylaxis with predominantly asthmatic features, to a pure acute asthma attack with no other features of anaphylaxis. Even life-threatening asthma with no features of anaphylaxis may be triggered by food allergy,[10] in which case it should be classified as an acute severe generalized or systemic hypersensitivity reaction – in other words, anaphylaxis.

2. Similarly, there is a continuous spectrum between angioedema and anaphylaxis, and between various forms of urticaria and anaphylaxis, with shock and/or difficulty breathing in the most severe reactions. Particular care must be taken to recognize cases where asphyxia due to upper airway angioedema has been caused by ACE inhibitors or C1 esterase inhibitor deficiency, as this often does not respond to adrenaline, may need tracheostomy, and may respond to infusion of normal fresh frozen plasma[11] or C1 esterase concentrate.

3. Panic is usual in anaphylaxis, which is often accompanied by a characteristic sense of impending doom. Panic without anaphylaxis may cause a sensation of difficulty swallowing, of difficulty breathing leading to hyperventilation, or may cause uncontrollable coughing and difficulty with inspiration. Patients presenting with these features may be anywhere along the spectrum between panic and anaphylaxis.

4. Vasovagal attacks are commoner than anaphylaxis after injections for immunization and also may occur after stings, particularly around the mouth. This has led to confusion with anaphylaxis.

5. Anaphylactic shock may occur without other visible features of anaphylaxis and will cause myocardial ischemia:[12] it may therefore be difficult to distinguish from myocardial infarction due to coronary artery disease.

In distinction to the endless variability of features caused by anaphylaxis, the time course is characteristic and reactions evolving over a longer time period or resolving too quickly are more likely to have a different diagnosis. The time course may be more rapid (as short as a minute to cardiorespiratory arrest after intravenous injection) or slower (but rarely more than 6 hours to reach a peak) depending on the cause(s), severity, general health and make-up of the patient, and any medication taken daily by the patient or given to treat the reaction. In most cases when the onset of severe symptoms was as slow as 5–6 hours, antihistamines or adrenaline taken for early symptoms may have delayed the reaction.

Anaphylactic shock may be cardiogenic (typically older patients in hospital with pre-existing cardiac pathology) or due to volume redistribution (typically younger patients, slower reactions, outside hospital). Myocardial ischemia with ECG changes is expected within minutes of anaphylactic shock becoming severe (Fig. 62.1).

Asphyxia may be due to upper airway occlusion caused by angioedema, or bronchospasm with mucus plugging of

the lower airways; the latter most commonly occurs in patients taking daily treatment for asthma. Both these processes may occur simultaneously in patients reacting to foods, latex, beta-lactam antibiotics, or aspirin.

Anaphylaxis usually resolves in 2–8 hours but secondary pathology arising from the reaction or its treatment may prolong the condition. In a few cases of food anaphylaxis, the reaction itself may be prolonged, possibly because the causative agent is still being absorbed from the gut. Resolution is complete except when cerebral anoxia at the peak of the reaction has caused significant brain damage, or when disordered clotting leads to bleeding, or when panic during the reaction leads to a lasting phobia of the cause. A third of fatal cases are resuscitated after the reaction, but die from complications a variable time later (median 60 hours) without regaining consciousness.

Causes and epidemiology of anaphylaxis

Foods

Acute allergic reactions have been triggered by almost every food, but some cause reactions more commonly than others.[13] Eight food groups have been singled out as high risk in the USA:[14] cereals containing gluten, crustaceans, eggs, fish, peanuts & soybeans, tree nuts, milk (lactose included), and sulphite in concentrations of 10 mg/kg or more. Three additional foods are regarded as high risk in Europe (celery, mustard, sesame);[15] these potently allergenic foods and all their products are subject to additional regulatory control during manufacture of packaged foods and must be identified in ingredient lists to help those with food allergy to avoid reactions. Which foods are most allergenic depends on geographic and ethnic factors: for example, celery (or more precisely, celeriac) allergy predominantly affects German Switzerland;[16] in Japan the list of potently allergenic foods includes buckwheat (*Fagopyrum esculentum*).[17] Allergy to cow's milk most commonly affects infants, and resolves within 1–3 years except in a small proportion.[18] In the UK deaths from milk anaphylaxis have mostly occurred in patients aged from 5 months to 16 years, reaching a peak around age 8 years;[19] all these were predominantly asthmatic reactions. Although allergy to hen's eggs is also commonest in infancy, the only recent UK death from egg allergy was in a 43-year-old. The prevalence of peanut and tree nut allergy is increasing and currently affects around 1% of UK[20] and US[21] children, with lower prevalence in most other countries; deaths from this cause occur predominantly in teenagers and young adults.[22]
Fig. 62.1. Time from allergen exposure to first arrest. Median times were 5 minutes for injected drugs, 15 minutes for stings, 25 minutes for oral drugs and 30 minutes for food.

Animal dander and secretions

Allergy to domestic animals is common. The dominant allergen in cats is a protein present in the sebum and saliva,[23] whereas for horses the dominant allergen is in the dander,[24] and in rats, the urine.[25] The allergy most commonly manifests as rhinitis, asthma, or contact urticaria but anaphylaxis may occur, for example, following bites from rats in laboratory workers or domestic animals such as horses[26] or hamsters.[27]

Pollens, spores and dust

Microscopic airborne particles contain a wide variety of bacterial, fungal, plant, and animal allergens that cause reactions on mucosal surfaces. Occasionally reactions may become systemic, particularly if there is contact with a larger amount of allergen; for example, pollen accumulated on the surface of late snow and inoculated into the skin by grazing contact during winter sports caused anaphylaxis.[28] Allergen-specific immunotherapy (repeated injection of increasing quantities of allergen in the hope of

inducing tolerance) has repeatedly led to anaphylaxis when an inappropriately large dose has been given.[29] The digestive proteins of a variety of common mites (including *Dermatophagoides pteronyssinus*) are particularly potent allergens, affecting 15–20% of population in temperate climates where these mites abound.[30] Although respiratory and conjunctival symptoms are very common, anaphylaxis is rare and there has only been one report of a fatal reaction to natural exposure.[31]

Latex

Natural rubber latex is the sap of the rubber tree *Hevea braziliensis*. More than a dozen allergenic proteins have been identified in the sap and on rubber goods made from latex.[32] Some of these proteins cross-react with proteins found in pollens, fruit, and other plant products: thus around half of those allergic to latex will also react to one or more of banana, avocado, sweet chestnut, kiwi fruit, and, less commonly, a range of other foods. There is genetic[33] and geographical variation in the foods most commonly cross-reactive with latex. IgE-mediated reactions to latex are mostly limited to contact urticaria or asthma from inhaling latex protein-impregnated starch particles from powdered gloves. A small fraction of those with latex allergy suffer severe generalized reactions and latex anaphylaxis has occasionally been fatal.[34,35] The National Patient Safety Agency recently issued an alert which requires NHS Trusts to have policies and procedures in place to reduce the risk to patients who have allergies associated with latex. As well as surgical gloves and catheters, latex is widely used for manufacture of bathing caps, condoms, hot water bottles, and adhesives; one fatal anaphylactic reaction followed the use of a latex-based adhesive designed to attach hair pieces during coiffure.[36]

Stings

Venom in the stings of bees, wasps, and related insects such as fire ants contains highly allergenic proteins and peptides.[37] IgE antibodies are commonly formed following stings, reaching a peak 3–8 weeks after a sting and sometimes persisting for many years;[38] a second sting from the same or cross-reactive venom will then cause an allergic reaction. Sting allergy may be specific for a particular family or genus; less commonly it is broadly cross-reactive, so that some people will react to stings from both bees and wasps.[39,40] Severe reactions to stings cause shock or upper airway blockage;[41] asthmatic reactions are uncommon and largely restricted to those taking daily treatment for asthma.[19] Anaphylaxis is not the

only cause of death from stings: some were caused by local angioedema around the upper airway due to the direct toxic effect of the sting,[41] and high numbers of stings when a large nest had been disturbed have caused death through the systemic toxic effects of the venom.[42] There may be other manifestations of acute illness following stings: serum sickness-like illness[43] or other unusual symptoms may occur.[44] The geographical distribution of sting anaphylaxis is obviously dependent on the habitats of the stinging insects: these have already changed due to global warming and further changes are to be expected.

The venom in scorpion stings triggers maximal release of endogenous adrenaline:[45] it is therefore interesting that whereas other stings commonly cause anaphylaxis, there are no reports of anaphylaxis to scorpion stings.

Other plant, animal, or human products

Rare cases of anaphylaxis have been caused by coelenterate (jellyfish) stings,[46] bites by hemiptera (bugs),[47] diptera (flies)[48] and other insects, animal[49] and human seminal fluid,[50] extracts of plants and animals used as food coloring such as annatto,[51] cochineal[52] and so on. No clear pattern has yet emerged that reliably predicts which proteins will be allergenic and which will not.

Parasites including hydatid disease

IgE antibodies are thought to have evolved principally to protect against infestation by parasites[53] and many helminthic parasites are very effective at inducing this class of antibodies. Sudden exposure to antigens from these parasites can trigger anaphylaxis: this has been most commonly observed when an echinococcal cyst has been ruptured during surgery,[54] but there are cases of anaphylaxis following spontaneous rupture of hydatid cysts; some have been fatal.[9] Anaphylaxis has also been triggered by fish nematodes (*Anisakis*) when these have been accidentally eaten in a fish meal.[55]

Drugs

During the early years of its use, penicillin became famous as a potent cause of anaphylaxis.[56] Reactions to penicillin V or G are now rare, but aminopenicillins such as ampicillin and amoxicillin, and similar cephalosporins such as cefaclor are now the commonest causes of fatal antibiotic anaphylaxis.[57] Interpretation of the literature on cross-reactivity between penicillins and cephalosporins is complicated by the variety of mechanisms for these adverse reactions and the low frequency of reactions on challenge

among those claiming "penicillin allergy:" nevertheless, significant cross-reactivity between aminopenicillins and aminocephalosporins is common for IgE-mediated anaphylaxis.[58,59]

By far the commonest situation for iatrogenic anaphylaxis is at induction of anesthesia, when an opioid, an intravenous anesthetic, and a muscle relaxant are injected within seconds of each other. There is compelling evidence that these reactions are IgE-mediated and that there may be cross-reactivity between opiates and relaxants,[60] giving scope for synergism between these drugs when they are injected together. Recent observations by a Norwegian group suggest a curious possibility for how patients become sensitized to relaxants. The first observation was that anaphylaxis to relaxants such as rocuronium was far more common in Norway than in Sweden. Because previous theories for sensitization to relaxants focused on environmental quaternary ammonium compounds such as those found in cosmetics and detergents, Florvaag *et al.* investigated the differences in exposure and found that pholcodine cough syrup was a likely candidate:[61] this medicine is widely used in Norway but is not available in Sweden. A dramatic rise in IgE reactive with pholcodine, morphine, and relaxants followed exposure of individuals sensitized to pholcodine.[62]

Aspirin and other non-selective cyclooxygenase (COX) inhibitors will trigger attacks of asthma or urticaria/angioedema in susceptible individuals.[63] The mechanism is widely thought to be due to diversion of the arachidonic acid pathway away from prostaglandin towards leukotriene production,[64] combined with susceptibility to the effects of the leukotrienes. High levels of mast cell tryptase found in some of these reactions, however,[65] suggest the possibility of more complex interactions including mast cell activation. This is non-IgE-mediated, at least in the majority of cases.

Epoxylated castor oil (cremophore) is used as a solvent for several water-insoluble drugs such as althesin, vitamin K, and taxol. After repeated use, it may cause non-IgE-mediated anaphylaxis. Complement activation occurs, but the mechanism for this is not known.[66] Excipients such as Povidone (polyvinyl pyrrholidone) can cause IgE-mediated anaphylaxis. As they are used in many different medicines, the pattern of reactions to the solvents may be confusing and the cause difficult to establish if this possibility is not considered.[67]

Immunization

Passive immunization with antisera or antitoxins raised in horses carries a high risk of anaphylaxis. In those who have previously received horse antiserum, this is likely to be due to high levels of IgG anti-horse antibodies, leading to immune complex formation and rapid complement activation. Patients with pre-existing IgE-mediated allergy arising from contact with horses may suffer IgE-mediated anaphylaxis on their first injection of horse serum.[68]

Active immunization carries a much lower risk of anaphylaxis and fatalities are exceptionally rare. In addition to the antigen for immunization, the allergenic agent may be contaminant proteins or antibiotics left over from production, such as avian egg or chick proteins,[69] an excipient such as gelatine,[70,71] a preservative such as a mercury-containing compound,[72] or an adjuvant such as alum. Acute adverse events following immunization, however, are more commonly due to vasovagal attacks or panic; these have resulted in medical emergencies when inappropriate treatment was given, such as intravenous adrenaline or even intramuscular adrenaline during a panic attack when the endogenous adrenaline is already high.

Infusions and transfusions

Of all the types of transfusion reaction, anaphylaxis must be among the rarest; a variety of allergens have been described and both non-IgE-[73] and IgE-dependent mechanisms have been postulated.[74]

Contrast media

Large volume bolus injections have obvious potential for triggering adverse effects, so it is perhaps surprising that more reactions to contrast media do not occur. The mechanism of most non-IgE-mediated reactions is still unclear[75] but they are more common when ionic media of high osmotic strength are used.[76] Fatal reactions have usually been associated with grossly raised mast cell tryptase, occur mainly in males[9,77] (whereas non-fatal reactions have a strong female predominance),[78] and may be associated with IgE antibodies. Occasionally individuals are identified with positive skin prick tests (SPT) to contrast media,[79] although this may not necessarily indicate IgE-mediated allergy to the contrast medium.[80]

Disinfectants, sterilizing agents, and fixatives

Chlorhexidine is widely used as a disinfectant and has emerged recently as a cause of anaphylaxis both in the operating theatre and at home.[81]

Orthophthaldehyde is used to sterilize instruments and endoscopes; these may then cause anaphylaxis

in susceptible individuals. These reactions may take an hour or more to become severe and thus often occur after the patient has left the operating theater.[82] Formaldehyde can also cause anaphylaxis: this has been reported in a variety of circumstances, including, for example, root canal treatment in dentistry.[83] Positive skin prick tests have been reported following reactions to chlorhexidine, orthophthalaldehyde and formaldehyde and standard commercial tests are available to detect IgE antibodies to formaldehyde.

Physical causes

Urticaria may be triggered in many ways, including heat and cold. In some cases it is possible to block heat-induced urticaria by anticholinergic drugs[84] – its original classification as "cholinergic" followed speculation that acetylcholine caused release of histamine:[85] some of these patients have positive SPT to their own sweat,[86] providing an explanation of how anticholinergic drugs might block the reaction. Occasionally cholinergic urticaria is severe enough to be classified as anaphylaxis. Other mechanisms must exist whereby exercise can lead to anaphylaxis – some are dependent on food allergy, some on aspirin, and some when both are present.[87]

It seems likely a variety of processes can lead to cold-induced urticaria, but the precise explanation remains obscure.[88] Cold-induced urticaria may lead to anaphylaxis – for example, after immersion in cold water.[89]

Amniotic fluid embolus

This has been termed the anaphylactoid syndrome of pregnancy and has many features of anaphylaxis, including the time course and mast cell degranulation[90] with raised tryptase levels;[91] it is fatal in 30%–86% of cases.[92] Estimates of incidence range from 1:8000 to 1:120000 pregnancies, attacks typically occurring during vigorous labor but also following termination or blunt injury during pregnancy. The mechanism leading to mast cell activation is not known but speculation includes IgE antibodies reactive with amniotic fluid,[96] non-IgE-mediated allergy and non-immune anaphylaxis.

Rare causes

Occasionally unusual causes are identified for anaphylaxis that do not fall into any of the categories already described. For example, although reactions to hair dye (reaction products of hydrogen peroxide with *p*-phenylenediamine or *p*-toluidinediamine)[94] usually result from contact sensitization, rarely reactions are IgE-mediated and lead to anaphylaxis; this has been fatal.[19,95]

Idiopathic

If no external cause of anaphylaxis can be identified, the reaction may be labelled as idiopathic. This is not simply a failure to identify the cause; these reactions commonly have characteristics that set them apart from the reactions described above. In one subgroup, the reaction typically starts with itching of the palms and/or soles (not common in allergen-mediated anaphylaxis), followed by abdominal cramps with diarrhea, and then severe tremor affecting all muscle groups. There may be loss of consciousness due to hypotension during the later phases of this acute illness. Mast cell tryptase is grossly raised in some cases, but not in others.

Another type of idiopathic anaphylaxis is at the severe end of idiopathic urticaria/angioedema; in these reactions there may be difficulty in breathing due to bronchospasm. The difference between these attacks and reactions to recognizable allergens lies in the timing of the reaction; they often have a more insidious onset and frequently recur several times over the course of a few days. Reports of "biphasic reactions" may arise from failure to identify these attacks as idiopathic anaphylaxis.[92] There may be a single attack, or there may be recurrences at intervals varying from a few days up to months or even years; generally the first or second attack is the worst, and subsequent attacks decrease in severity. Various epidemiological studies report the fraction of anaphylaxis that is idiopathic as 5–37%.[96–107]

Conditioned anaphylaxis

Neurological processes may possibly trigger repeat reactions in the absence of the original cause.[108,109]

Pathophysiology of anaphylaxis and factors increasing the probability of cardiorespiratory arrest

Because anaphylaxis in its broad sense comprises a heterogeneous collection of acute severe transitory illnesses, it has proved difficult to study in humans, and experimental animal models may not accurately portray the human conditions. Mouse models suggest that mast cell activation is only one of the pathways – macrophage triggering by IgG antibodies leads to a platelet activating factor-dependent,

histamine-independent pathway.[110] They also suggest that cytokines such as IL-4 and IL-13 can alter the sensitivity of mice, increasing the tendency for anaphylaxis. There is no doubt that human susceptibility for severe reactions varies from time to time as a result of infection or stress, consistent with the idea that we too may respond to cytokines in this way.

In human anaphylaxis, IgE-mediated reactions are generally regarded as the most typical, such as might be triggered by a sting, peanuts, or amoxicillin. At some time prior to the reaction the subject must have become sensitized, leading to the production of antibodies of the IgE class.[111] After their synthesis and release by plasma cells, these bind to the high affinity IgE receptor ($Fc_{\varepsilon}RI$) on cytoplasmic membranes of mast cells and basophils. Triggering of these cells requires that the mobility of at least two receptor molecular complexes is limited by bridging between them – usually when the IgE antibodies bind to allergen;[112] large rafts of cross-linked receptors

lead to more rapid triggering, causing a sequence of changes within the mast cell or basophil.[113] Redistribution of calcium within the cell then leads to release of granules containing histamine and a variety of proteins including mast cell tryptase, chymase, and carboxypeptidase, and proteoglycans including heparin and chondroitin sulphate.[114] Other synthetic pathways are initiated, leading to release of arachidonic acid from phospholipids in the nuclear membrane and its conversion to prostaglandins such as PGD2 and leukotrienes such as LTC4; platelet activating factor (PAF) is also formed (Fig. 62.2).

PAF may be the key to the difference between mild allergic reactions and anaphylaxis: it comprises a variety of related phospholipid derivatives with an ether linkage at the sn-1 position of the glycerol backbone, a short acyl chain, usually an acetyl residue, at the sn-2 position, and the polar head group of choline or ethanolamine at the sn-3 position. The length of the alkyl chain at the sn-1 position and the number of double bonds also affect its
Fig. 62.2. Outline scheme for generation of the principal mediators of anaphylaxis. Preformed mediators including histamine are released from mast cell granules. PAF, leukotrienes and prostaglandins are synthesized from membrane lipids. Kinins are split from kininogens, possibly by proteases released from mast cell granules. There is evidence from mouse models that some types of anaphylaxis are caused by PAF release from macrophages: similar processes may play a part in human reactions.

biological activity. PAF has potent effects on the heart, blood vessels, and the airways, all of which cause changes typical of severe anaphylaxis.[115] PAF acetyl hydrolase comprises a family of enzymes that inactivate PAF; genetic variants with reduced or absent activity have been associated with increased severity of asthma and anaphylaxis.[116]

The kinin system is also activated in anaphylaxis.[117] Mast cell peptidases detach bradykinin from its precursor, the high molecular weight kininogen,[118] and kallidin from the low molecular weight kininogen. There may be other routes of activation such as the more usual activation of factors XII and XI of the blood clotting cascade and of kallikrein.[119] These kinins have potent effects on blood vessels, similar in many ways to those of histamine but with a slower time course.[120] Because angiotensin converting enzyme (ACE) is one of the main brakes on the kinin system (it acts as a carboxypeptidase, inactivating the kinins), ACE inhibitors potentiate anaphylaxis, increasing the tendency to both shock[121] and swelling, both because they increase the bradykinin activity and because they lower angiotensin activity; angiotensin is a natural antagonist of anaphylaxis.[122] Genetic deficiency of aminopeptidase P (another enzyme like ACE that inactivates bradykinin) is another cause of angioedema when ACE inhibitors are administered.[123]

Anaphylatoxin (split products of complement activation) was one of the earliest recognized mediators of anaphylaxis.[124] It is produced in vitro during complement activation and if injected, leads to anaphylaxis. Plasma carboxypeptidases quickly inactivate anaphylatoxin,[125] however, and it is less certain what effect this has in vivo. Complement activation occurs in dextran reactions,[126] where IgG antibodies form immune complexes with the dextran. The resulting anaphylaxis may well be due to anaphylatoxin but multiple other pathological changes occur.[127] Dextran anaphylaxis may be fatal.[128]

As might be expected with so many potent mediators, there are rapid effects on many tissues and organs. Arterioles relax and dilate, increasing the pressure in capillaries and venules. The postcapillary venular endothelium leaks fluid into the tissue resulting in angioedema and augmenting the decrease in vascular return caused by the increase in intravascular volume. In other cases, direct action of mediators on the myocardium[115,129] may reduce cardiac output by decreasing contractility or causing arrhythmia of any kind; when this happens there may be insufficient pressure to cause urticaria or angioedema, resulting in anaphylactic shock with no other manifestation of an allergic reaction.

Shock is affected by posture and there is a remarkable association between upright posture and irreversible cardiac arrest from anaphylaxis, to the extent that in all fatalities from anaphylaxis outside hospital where the postural history was known, there had either been a change to a more upright posture or an upright posture had been maintained after loss of consciousness.[12] A possible mechanism for this is that although the blood pressure is low, there is some venous return while the posture is horizontal, but on assuming a more upright posture insufficient blood returns to the vena cava and it rapidly empties. Within a few beats, the heart becomes empty and as there is no cardiac output, the vena cava remains empty and resuscitation by external cardiac massage is impossible. As with all severe shock, the decreased cardiac output leads to myocardial ischemia with typical ECG changes. When there are no other manifestations of anaphylaxis, this has been mistaken for primary myocardial infarction.

Simultaneously, mediators may lead to respiratory difficulty, either through angioedema in the pharynx, larynx, or trachea, or through bronchospasm. In asthmatics with remodelling of the airways this will be more severe and is accompanied by secretion of viscid mucus which contributes to the airways occlusion. Asthma, particularly when it is not optimally treated, is a risk factor for fatal anaphylaxis, particularly to foods and NSAIDs.[9,22]

There may also be rhinitis with sneezing, irritation of airways with coughing, and panic because of a feeling of loss of control over what is happening in the body. A sense of impending doom is characteristic of panic and is frequently reported by those with anaphylaxis.[130] Nevertheless, panic with hyperventilation (which may lead to wheezing, particularly if the subject has exercise-induced asthma), coughing with panic and paradoxical vocal chord movement or laryngospasm with stridor, have all been mistaken for anaphylaxis and vice versa. Both the increased sympathetic tone and the rise in circulating adrenaline that occur in panic protect against progression to anaphylaxis; this may explain why exhaustion may promote severe reactions, because of depletion of sympathetic reserves.

The formation of PAF during anaphylaxis in mice[110] causes disordered clotting with intravascular coagulation.[131] Clotting is also disturbed in human anaphylaxis and the ensuing bleeding may be difficult to manage, particularly when there are other sequelae such as cerebral ischemia or adult respiratory distress syndrome.

Biphasic reactions have been reported to occur commonly by some authors.[132,136] and to be unusual by others.[9] Possible explanations include undertreatment leading to recurrence of symptoms (particularly omission of steroids from the initial treatment, predisposing to late-phase asthmatic symptoms), or inclusion in the series of idiopathic

anaphylaxis, where there may be one or more cycles of partial resolution and recrudescence over days or even weeks. Mouse models suggest the late phase may be related to PAF activation.[133]

Management of anaphylaxis

There is more to the management of anaphylaxis than simply giving the correct treatment to anyone who has a reaction. The first problem is recognizing that the acute illness (or if the patient is already ill, the acute deterioration) is due to anaphylaxis.

Strategies for optimal management of anaphylaxis depend on the likely mode of death, and this in turn depends on the cause of the attack. Once the patient has been rescued from this danger, the cause for the reaction must be found and the patient advised about how to prevent a recurrence, both by preventing reexposure and by minimizing the severity of a reaction if accidental re-exposure occurs.

Diagnosis

Anaphylaxis is surprisingly difficult to diagnose. It is usually unexpected; and even in situations when it might be expected, experience shows that the correct diagnosis is frequently not achieved in time to give treatment that will stop progression to anaphylaxis. The main confusions have been listed above.

Treatment of the acute reaction

Even patients with severe untreated reactions recover with much the same time course as those of similar severity who are treated. The primary objective of treatment is to prevent the incipient illness turning into anaphylaxis; once cardiac arrest is established it should be treated according to standard protocols.

Recommendations for management of anaphylaxis vary according to the situation. What is appropriate for a paramedic is not what will be needed by an anesthetist. Separate UK guidelines have been published for first responders,[134] paramedics, anesthetists, and radiologists; the guidance for immunization reactions has now been brought in line with that for first responders. Other countries have published consensus guidance (e.g., USA).[8] In every situation, however, the first drug to be given is adrenaline. Although there has never been a randomized controlled trial, there are good theoretical grounds to suppose this is a logical treatment[135] and there is sufficient anecdotal evidence supporting its use to ease breathing difficulty and restore adequate cardiac output. Both alpha and beta activity are needed, centrally increasing the force of the myocardial contractions and, paradoxically, slowing the rhythm by increasing peripheral resistance, which in turn helps reduce peripheral leakage from the postcapillary venules by a combination of increased arteriolar tone and reduced venular permeability. In the lungs, the beta-2 activity relaxes the bronchiolar smooth muscle, easing bronchospasm. In some cases, upper airways angioedema may respond dramatically to adrenaline, whereas in others there may be little benefit and tracheostomy may occasionally be needed.

The earlier adrenaline is given, the higher the probability it will prevent anaphylaxis from developing.[136] In addition to the actions listed above, there are beta-2 adrenergic receptors on mast cells[137] that inhibit activation[138] and consequently early adrenaline administration attenuates the severity of IgE-mediated allergic reactions. Because of this, beta-blockers enhance the severity of anaphylaxis.[139]

There has been argument about the optimal route for administration of adrenaline.[140] Absorption of adrenaline from muscle depends on the blood flow. Blood flow through subcutaneous tissues (predominantly alpha-adrenergic receptors) is restricted by even very low concentrations of adrenaline[141] and adrenaline is poorly absorbed from this site, which should not be used when treating anaphylaxis. Beta-adrenergic activity at physiological concentrations causes vasodilatation:[142] absorption therefore depends on the ratio of beta- to alpha-adrenergic receptors. Beta receptors are induced in muscle blood vessels by exercise;[143] possibly because of this, absorption is better from the extensor muscles of the thigh than from the arm.[144] The preferred site for intramuscular injection of adrenaline is therefore the midpoint of the thigh, on the anterolateral aspect. If an autoinjector is used, it is important to ascertain that the needle is long enough to deliver the injection into the muscle [see below].[145]

Once shock is established, however, adrenaline loses its effectiveness[146,147] and repeated bolus injection may have only transient effect on the blood pressure.[148] In this case, infusion has proved more effective in experimental models[149] and anecdotally in humans. In cases where adrenaline fails to restore the blood pressure, selective alpha-agonists may be tried[150] but it may be more logical to use vasopressin.[151] There is some evidence that glucagon may be helpful for those who are unresponsive to adrenaline because they are on beta-blockers.[152] Rapid fluid infusion is essential if the pressure is so low that the central venous return is threatened; in this situation posture can be critical and raising the legs may assist venous return as much as 0.5–1.0 l of fluid.[153]

While 1.0 mg of adrenaline i.v. is recommended in the treatment of cardiac arrest, it is crucial to realize that intravenous adrenaline is dangerous in the conscious patient. Bolus injection of as little as 0.5 mg leads to dangerous elevation of the blood pressure with a range of harmful, sometimes lethal effects. Pulmonary edema is a regular effect (intravenous adrenaline is the basis for experimental models of pulmonary edema):[154] if the resulting difficulty in breathing is mistaken as a worsening of the anaphylaxis and more adrenaline is given, a vicious spiral may result, ending with the death of the patient. Alternatively, the rapid extreme increase in blood pressure may lead to dissection of arterial intima – typically in the vertebral arteries, with subsequent thrombosis which may detach and lodge at the bifurcation of the basilar arteries, causing infarction of the thalamus and optic cortex. In other cases there has been arterial bleeding into the brain. Persistent memory, cognitive, and intellectual impairment has regularly followed intravenous bolus injection of adrenaline. There may also be myocardial ischemia.[155] It is therefore strongly recommended that intravenous adrenaline is only used in monitored patients and the dose titrated against the effect.[134] Even so, vomiting is common following slower i.v. adrenaline use. This is particularly dangerous if the patient's stomach is loaded with allergen: inhalation of vomit has been a regular cause of death in such cases.

Although adrenaline will relieve bronchospasm, it is usual in addition to treat wheezing by nebulized salbutamol. Bronchospasm resistant to both adrenaline and salbutamol may be a result of excessive daily use of salbutamol.[156] In this case a bronchodilator acting through a different mechanism will be needed, such as aminophylline or magnesium sulphate.[157,158]

After adrenaline, an antihistamine should be used such as chlorphenamine 10 mg by intramuscular or slow intravenous injection and steroids are recommended to prevent late phase recrudescence of the reaction: these are commonly given as hydrocortisone 100–400 mg i.v., but this may cause very unpleasant side effects with intense paresthesia and sometimes shock.[159] This has been mistaken as a sudden worsening of the reaction and has led to inappropriate injection of adrenaline.

Various other strategies have been suggested. Military antishock trousers may reverse some of the volume redistribution.[160] Methylene blue antagonizes the effects of NO on the vessels.[161]

Investigation of causes and mechanisms

A recurrence of anaphylaxis is common[162] and has been fatal. It is therefore essential that anyone with anaphylaxis is referred to an appropriate specialist for investigation of the cause and advice about management.

Minimizing chance of reexposure

The cause of the reaction may seem obvious, but mistakes are common. Proper investigation is important because, however careful the avoidance is, it will be ineffective if the patient avoids the wrong thing. Effective allergen avoidance may demand a lifestyle change and is likely to affect the quality of life.[163] The patient needs to know more after penicillin anaphylaxis than simply that they should avoid penicillin, or after reacting to food, that it may have contained nuts and they must avoid nuts in future. Patients are more likely to get good advice from an appropriately trained specialist and should therefore be referred accordingly.

Minimizing danger from effects of reexposure

Allergen avoidance can never guarantee safety from accidental exposure[164] but the effect on the patient of such an accident can be minimized in a variety of ways. Allergen-specific immunotherapy (desensitization) is available for bee and wasp sting anaphylaxis and will greatly reduce the risk of a recurrence. Gradually increasing doses of pure venom are injected, followed by maintenance treatment at 4–6 week intervals for 3–5 years: this leads to long-lasting protection.[165] This therapy has proved too dangerous for routine use with food allergy,[166] but as most food-induced anaphylactic deaths have been dominantly asthmatic reactions in those taking suboptimal daily treatment for their asthma,[9,22] improved daily asthma management will be at least partially protective.

Patients with anaphylaxis to food or stings may be advised to carry self-injectible adrenaline.[167] Devices are available that deliver one or two doses of 0.3 mg or, suitable for those under 30 kg body mass, 0.15 mg of adrenaline. This equipment will only be effective if the patient carries the adrenaline at all times there is a risk of exposure, knows how and when to use the injection, and has an autoinjector that can deliver an intramuscular injection. One or more of these conditions are commonly not met.[145,168] Needle length depends on the make and varies from 9 to 16 mm. It is important to confirm that the skin-to-muscle thickness is less than this in the target area (anterolateral aspect of the mid-section of the thigh).[145] Skin-fold thickness may give an estimate in some patients; others will need an ultrasound or MR scan. Patients with autoinjectors need to have regular reviews to ensure that their device is still appropriate, that they remember how and when to

use it, that it is in date, that they have not been prescribed drugs that have adverse interactions with adrenaline and so on.[169]

High altitude resuscitation

Philip Eisenburger, Benjamin Honigman, Susan Niermeyer, Robert Roach and Wolfgang Voelckel

Universität fur Notfallmedizin, Vienna, Austria

Cardiac arrest in remote areas such as in the wilderness and at high altitude cannot be compared directly with cardiac arrest in the urban setting, and both scenarios merit specific consideration. Given that mountains and, in particular, ski resorts have become increasingly popular with tourists, the occurrence of cardiac arrest in more remote places becomes an epidemiologic problem. Moreover, millions of people worldwide travel by plane, where they are exposed to a high altitude environment that may contribute to cardiocirculatory problems or even cardiac arrest. This chapter focuses on both of these specific settings and their relevant physiologic and epidemiologic characteristics.

Cardiac arrest resulting from high altitude on mountains

Worldwide, it is estimated that approximately 40 million individuals live above 8000 feet, and 25 million live above 10 000 feet.[1] Both travelers who arrive abruptly into an hypoxic environment and residents who live year round at such altitudes have different risks for cardiac arrest. Mountain sports activities and tourism are attracting increasing numbers of participants each year. This, combined with the rapid ascent made possible by air transportation, results in increased members of unacclimatized individuals at risk for high-altitude illness. More than 1 million visitors travel annually to the remote high mountain ranges of Asia, Africa, and South America.[1] Approximately 35 million visitors travel annually to high-altitude recreation areas in the western United States.[1]

The clinical syndrome of high-altitude illness comprises several symptoms that may overlap and share a common pathophysiology. If individuals fail to acclimatize and ignore the clinical signs of the typically benign and usually self-limited acute mountain sickness (AMS), they are at risk of developing high altitude pulmonary (HAPE) or cerebral edema (HACE). Approximately 8% of individuals who develop AMS at 14 000 feet (4000 m) will develop these life-threatening conditions at higher altitudes,[2] and both HAPE and HACE can deteriorate and result in cardiac arrest.

The incidence of AMS varies with altitude and rate of ascent. It increases from 3% at 6000 ft (1829 m) in trekkers in the eastern Alps not staying at this altitude overnight[3] to 9% at 2850 m (9000 ft)[4] to 25% in tourists in the western US at 2400 m (8000 ft),[5] 47% in those who fly into the Khumbu region of Mt Everest at 12 000 ft (3600m)[2] and 67% in hikers on Mount Rainier at 14 000 ft (4000 m).[6] These incidence rates depend on many variables, including the velocity of ascent, highest altitude reached, sleeping altitude, duration of stay at any altitude, and individual susceptibility. Both HAPE and HACE are more common with a longer duration of visit and higher sleeping altitude. Gender does not affect the incidence of AMS; however, women may have less risk of developing HAPE.[2,7]

The number of elderly people visiting mountain resorts is increasing. Six million visitors older than 55 years of age travel annually to the Colorado Rocky Mountains, according to the Colorado Tourism Board. Many of these individuals have underlying health problems, including lung disease (10%), heart disease (25%), and hypertension (30%).[8] Despite these pre-existing risk factors, older adults are less likely to develop AMS when compared with other age groups,[8] yet there are clues that the elderly may not

react well to acute high-altitude exposure. Pulmonary vital capacity decreases almost one-third in elderly individuals who go from sea level to 14 000 feet (4000 m) for 1 week, producing a significant drop in both oxygen saturation and maximal oxygen uptake during exercise. For elderly individuals residing at moderate elevations, oxygen saturation is approximately 92% at rest.[8]

Epidemiology of AMS-induced cardiac arrest

While AMS may contribute to fatalities of other causes such as trauma, and misjudgment of danger in a proportion of deaths, the disease itself is uncommonly lethal. From 1950 to 2003, among approximately 30 000 mountaineers in the Himalayas, 664 died. Of those, 43 (6.5%) died of AMS/HACE/HAPE and 53 (8%) had AMS as a contributing factor to some other form of death[9] (e.g., "Hammann [. . . had] cerebral edema and froze to death;" Report DHAI-951-02 of the Himalayan Database).

Of 23 people who died on expeditions to summits > 7000 meters, 4 died of worsened AMS.[10] In a period of 3 1/2 years, helicopter rescue flights at moderate altitude in the Himalayas responded to 1 HAPE and 2 HACE patients out of 23 dead and to 38 AMS patients out of 111 live trekkers who were evacuated.[11] The response time for the helicopter to arrive was more than 24 hours. There are no data on the actual number of fatalities. It is estimated that there are about 100–200 deaths world-wide secondary to altitude illness and most of these are in soldiers in Pakistan and India, climbers on Kilimanjaro and Aconcagua, and unknown tourists in Asia and South America. In the United States and Europe, deaths are obviously rare, and no reliable data are available (personal communication, Peter Hackett 2005).

Definitions

Moderate altitude is between 8000 and 12 000 feet (2400–3600 m) of elevation. Although most people do not experience significant arterial oxygen desaturation until they reach higher altitudes, high-altitude illness is common with rapid ascents above 2500 m (8200 ft). Individuals with underlying medical problems may be predisposed to developing altitude illness at these lower levels.

High altitude is between 12 000 and 18 000 feet (3600–5500 m). Most serious altitude illness occurs at these levels. The pathophysiologic effects of high altitude begin when the oxygen saturation of the arterial blood begins to fall below the 90% level. The sigmoidal shape of the oxyhemoglobin dissociation curve prevents a significant fall of
Fig. 63.1. SaO_2 dissociation curve changes with increasing altitude = decreasing partial pressure of oxygen

arterial oxygen saturation (SaO_2) in most individuals up to an altitude of approximately 12 000 feet. At this altitude, the steep portion of the curve is encountered, and rapid desaturation begins, with relatively small increases in altitude (Fig. 63.1). Some predisposed individuals may become desaturated to less than 90% at altitudes as low as 8000 feet (2400 m).

Extreme altitude is above 18 000 feet (5500 m). At this height, the human organism is not able to cope with the environmental conditions, and to adjust physiologic function for long-term survival. Accordingly, prolonged visits above this level will inevitably result in progressive deterioration. Moreover, in cases of life-threatening high-altitude illness, air rescue by helicopter – although proven feasible – is unavailable.

Acclimatization

Acclimatization occurs gradually and involves multiple respiratory, cardiovascular, and hematologic adjustments, allowing a greater ability to survive and perform in the high-altitude environment. It begins at the altitude that causes the oxygen saturation of arterial blood to fall below sea-level values. The ability to acclimatize is different among individuals, in part depending on the so-called hypoxic ventilatory response, the hyperventilation triggered by the carotid bodies, and central mechanisms in the medulla.[1,12]

Respiratory adaptation consisting of an increase in minute ventilation is the most important physiologic

change that occurs during acclimatization, causing a decrease in the partial pressure of carbon dioxide in arterial blood ($PaCO_2$). The alveolar gas equation states that, as the alveolar PCO_2 decreases, a corresponding increase in PO_2 occurs, thereby increasing arterial oxygenation. Thus the level of ventilation determines alveolar oxygen for a given inspired oxygen tension.

Pathophysiology

The clinical syndrome of high-altitude illness represents a spectrum of symptoms (Table 63.1) sharing common and interconnected pathophysiologic mechanisms.

For a detailed description of the pathophysiology of altitude illness, the reader is referred to several references.[13–17] Briefly, the initiating factor is believed to be hypobaric hypoxemia which sets into motion a complex pathologic process that involves the circulatory, pulmonary, endocrine, and central nervous systems and leads to the development of the various clinical symptoms.

Hypoxemia alters fluid homeostasis, resulting in a generalized fluid retention, followed by the shift of fluid into the intracellular spaces. This is regulated by an interplay of antidiuretic hormone (ADH), the renin-angiotensin-aldosterone system, and the atrial natriuretic peptide. The inappropriate release of these hormones is thought to be the underlying pathogenic mechanism for the development of high-altitude edema.

Hypoxia is a potent pulmonary vasoconstrictor, and pulmonary vascular resistance is increased. In the lungs, hypoxemia resulting from high-altitude exposure causes pulmonary artery hypertension. Uneven pulmonary vasoconstriction in HAPE-susceptible individuals may result in distention, injury, and increased permeability of the pulmonary vasculature. Pulmonary blood flow is also increased as a result of hypoxia increasing cardiac output. In HAPE victims an uneven distribution of pulmonary vasoconstriction may result in overperfusion, distention, and leakage in the remaining vessels,[18] which may explain the patchy nature of the infiltrate visualized on chest x-ray films of patients with HAPE (Fig. 63.2). Exercise and cold stress on arrival at high altitudes are commonly associated with HAPE, as well as sympathetic nervous system stimulation with catecholamine release.[19]

The manifestations of mild AMS/HACE appear to be the result of central nervous system dysfunction: vasogenic edema resulting from increased permeability of brain capillary endothelial cells may be the primary mechanism.[20] Hypoxemia also produces changes in cerebral blood flow and blood volume, which along with a loss of

Table 63.1. Symptoms of acute altitude-related sickness

- Ataxia
- Oliguria (< 500 ml / day)
- Sleeplessness

autoregulation may also play a part in the pathogenesis of AMS/HACE.

Hypoxemia also results in an increase of cerebral blood flow, but this is mitigated at high altitude by the vasoconstrictive effect of hypocapnia secondary to hyperventilation.[21] Cerebral blood flow is thought to increase, despite the hypocapnia, when PaO_2 is less than 60 mm Hg (altitude greater than 12 500 feet). This net increase of blood flow increases intracranial volume and may contribute to changes in intracranial pressure.

High-altitude pulmonary edema

HAPE is the most common fatal manifestation of severe high-altitude illness. Although HAPE is uncommon below 10 000 feet, it can occur, and even be fatal, at altitudes as low as 8000 feet. Episodes occurring between 8000 and 10 000 feet are usually related to heavy exercise or due to malformation of the cardiovascular/pulmonary system, but at higher altitudes pulmonary edema may also occur at rest or with only light activity.[22] The incidence of HAPE varies from 0.01% to 2% in most studies, but has reached 15.5% among soldiers who were flown directly to 14 500 feet without a chance to acclimatize at a lower altitude.[23,24]

Susceptibility for developing HAPE may exist in some individuals who may experience HAPE with each ascent to altitude. Many patients, however, have a single episode of HAPE and subsequently are able to return to high altitude without a recurrence. Conversely, those with previously uneventful high-altitude exposures may develop HAPE in a future ascent.

Individuals who have been residents at high-altitude locations for extended periods, pulmonary edema may develop on re-ascent from a trip to low altitude. This phenomenon, which occurs primarily in children and adolescents, has been termed reentry HAPE.

Clinical presentation

The initial symptoms of HAPE usually begin insidiously 2 to 4 days after arrival at high altitude. Although most cases occur during the second night, HAPE may develop rapidly, with early symptoms apparent after just a few hours at high altitude. Marked dyspnea on exertion, fatigue with minimal to moderate effort, and dry cough are early manifestations of the disease. The symptoms of AMS usually occur concurrently with the development of HAPE.

Physical examination reveals a few rales in mild HAPE, usually in the region of the right middle lobe, progressing to unilateral or bilateral rales, then diffuse bilateral rales and audible rhonchi and gurgles that can be heard without a stethoscope. Central cyanosis, tachypnea, tachycardia, and slightly elevated temperatures are also common. A respiratory tract infection may occasionally be seen. As the condition intensifies, cerebral edema or simply severe hypoxemia causes central nervous system dysfunction, such as ataxia and altered mentation. Coma may follow and precede death in a few hours if oxygen therapy is not instituted, or immediate descent is not possible.

Ancillary tests

Chest radiographs can help elucidate the nature of the illness. The infiltrates seen in HAPE victims are fluffy (alveolar) and patchy in distribution, with areas of clearing between the patches. Unilateral infiltrates may be seen in mild cases. Bilateral infiltrates indicate a severe form of HAPE, and involvement of the right midlung field is a common sign (Fig. 63.2). Pleural effusion is rare but may be present in severe cases. The extent of the edema present on the chest film roughly parallels the clinical severity.[22] The radiographic findings of cardiomegaly, batwing distribution of infiltrates, and Kerley B lines, which are typical of cardiogenic pulmonary edema, are absent in HAPE.

Radiographic evidence for HAPE clears rapidly after initiation of treatment; some mild cases may clear in 4 to 6 hours and most clear by 24 hours. In some cases of severe HAPE, however, infiltrates may persist for as long as 2 weeks even though the clinical symptoms have resolved.

An electrocardiogram (ECG) prior to arrest will usually reveal tachycardia and evidence of right-heart strain, including right axis deviation, P-wave abnormalities, tall R waves in the precordial leads, and S waves in the lateral leads (Fig. 63.3).[22] Invasive hemodynamic monitoring shows increased pulmonary vascular resistance, elevated
Fig. 63.2. X-ray HAPE (courtesy Dr. Peter Hackett, with permission). Chest X-ray of a patient with high altitude pulmonary edema (HAPE).

pulmonary artery pressures, but normal pulmonary wedge pressures.[25] Likewise, echocardiography studies demonstrate high estimated pulmonary artery pressures, pulmonary vascular resistance, and normal left ventricular function.[26,27]

High-altitude cerebral edema

HACE is the least common yet most severe form of high-altitude illness. The incidence of HACE is lower than that of HAPE, and although it usually occurs together with HAPE, it may be seen as an isolated entity. Death from HACE at as low as 8200 feet has been reported, although most cases occur above 12 000 feet.[28] Mild AMS may progress rapidly to severe HACE with coma within 12 hours.[5] The usual time course is 1 to 3 days for the development of severe symptoms, but in some cases severe symptoms and coma do not develop for 5 to 9 days.[29]
Fig. 63.3. ECG right heart strain. Right heart strain due to hypoxic vasoconstriction in pulmonary arteries in a patient exposed to high altitude

Clinical presentation

HACE is characterized by evidence of global cerebral dysfunction and represents the most severe manifestation of AMS. Symptoms of severe AMS (headache, fatigue, vomiting), as well as those of HAPE (cough and dyspnea), are usually present. HACE-specific signs include ataxia, generalized seizures, slurred speech, rare focal neurologic deficits, and altered mentation. The last mentioned can range from mild emotional lability or confusion to hallucinations, and ultimately decreased levels of consciousness that may proceed to coma and death.[29] MRI scans in patients with HACE reveal white matter changes consistent with vasogenic edema (Fig. 63.4).[30] Ataxia alone is an indication for immediate descent.

Progression to cardiac arrest

Deterioration of AMS, HAPE, and/or HACE will ultimately result in cardiac arrest if adequate therapy is not available in the appropriate time. Once the patient suffers cardiac arrest, successful resuscitation may be considerably less likely than it is in other settings. First, because of the remote location, i.e., wilderness or high altitude, proper performance of CPR will be limited by several factors, such as fatigue of the rescuers, environmental issues, and the availability of advanced life support means. Second, cardiac arrest caused by deteriorated HAPE or HACE is typically the result of prolonged hypoxemia. While central respiratory depression due to cerebral edema can be treated sufficiently by artificial ventilation, it is obvious that the pulmonary pathology of HAPE will not immediately respond to oxygen therapy. In addition, it is well known that asphyxial cardiac arrest is associated with poor outcome. Third, since resuscitation efforts focus on the restoration of cerebral perfusion and re-oxygenation, cerebral edema and elevated intracranial pressures during HACE will further limit the chance for successful CPR.[31]

The key to successful resuscitation is recognizing the patient's deterioration and treating the underlying problems before cardiac arrest develops. In addition, the specific pathophysiology of altitude-related illness deserves a distinct therapeutic approach. Since the cause of a cardiac arrest at high altitude may not necessarily be AMS, but may also include myocardial infarction, stroke, or pulmonary embolism, it is obvious that therapy will be difficult to direct.

Cardiac arrest in children and young adults at high altitude

The etiology of cardiac arrest in infants and children at high altitude is predominantly asphyxial; respiratory failure often precedes cardiac arrest. Especially during infancy, high-altitude hypoxemia may unmask a pre-existing cardiopulmonary condition that may be well compensated at low altitudes. Interruption of the postnatal decline in pulmonary artery pressure. Unusually severe anemia before postnatal erythropoiesis accelerates, and presentation of previously undiagnosed congenital heart malformations are examples of risks unique to altitude exposure in the very young. Coupled with limited ability of the patient to communicate distress clearly, and the non-specific signs of illness in infancy, diagnosis of altitude-related illness may be delayed until a critical point has been reached. Conversely, the vulnerability of young children usually means that parents protect them from exposure to extremes of high altitude. Lack of exposure to the conditions resulting in severe high altitude cerebral edema may account for the absence of reports in the medical literature of fatal cases of HACE in children.[32]

The pathophysiology underlying cardiac arrest may differ substantially between infants and children who stay temporarily at high altitude (sojourners) as compared to those who are long-term residents there.

Sojourners

Children apparently experience an incidence of AMS very similar to that observed in adults.[32] Acute exposure to high altitude can result in an exaggerated hypoxemia that may potentiate other underlying pathophysiologic conditions, such as bronchopulmonary dysplasia following preterm birth and respiratory distress syndrome, congenital heart disease, severe anemia, or pulmonary hypoplasia. High altitude pulmonary edema does occur in children, although the incidence has not been well established.[32] As in adults, risk varies with rapidity of ascent, altitude reached, and previous history of HAPE. In addition, certain risk factors such as antecedent illness,[33] especially viral respiratory tract infections, or as mentioned above, underlying congenital heart disease, and other genetic conditions may uniquely predispose children to HAPE.

A lethal episode of HAPE has been described in an adolescent with unilateral absence of the pulmonary artery.[34] Several case reports of non-lethal occurrences also document such an association.[32]

Children with trisomy 21 (Down syndrome) have multiple medical risk factors that place them at higher risk for HAPE; these factors include chronic pulmonary hypertension,

Fig. 63.4. MRI HACE (courtesy Dr. Peter Hackett, with permission). Cranial MRI of a patient with High Altitude Cerebral Edema (HACE).

pulmonary overperfusion from left-to-right shunts (ventricular septal defect (VSD), patent ductus arteriosus (PDA), atrial septal defect (ASD), and more complex congenital heart malformations), and frequent infections. A retrospective review of 52 patients treated for HAPE at The Children's Hospital in Denver, Colorado identified 6 children with trisomy 21.[35] All but one of these children had either chronic pulmonary hypertension or an active or surgically repaired left-to-right shunt; the remaining child had a history of preceding or concurrent illness, as did 4 other children in the series. The rapid onset of pulmonary edema and the relatively low altitudes (1738 m to 3252 m – 5100–10700 ft) suggest the need for heightened awareness when children with Down syndrome travel above sea level.

Sudden death has been reported in the setting of high altitude and extreme exertion among young adults with sickle cell trait.[36] Four young men (ages 19–21 years) experienced sickling crises and sudden death during moderate-to-severe exercise after recent arrival at relatively high altitude (1240 m – 4060 ft). Vaso-occlusive and splenic crises have been well described among patients with sickle cell anemia, sickle/hemoglobin C disease, and sickle/thalassemia who travel to the mountains above 2000 m (6600 ft).[37,38]

Residents

Among children resident at high altitude, pulmonary hypertension and high-altitude pulmonary edema are pathophysiologic mechanisms of great importance. Hypoxemia at high altitude also potentiates mortality from lower respiratory infections and may increase the incidence of sudden infant death syndrome.[39–42]

Symptomatic high-altitude pulmonary hypertension must be recognized as an important, and potentially lethal altitude-associated illness.[43] Typically, subacute pulmonary hypertension at high altitude develops in young children (generally under 18 months) of low-altitude ancestry who are exposed continuously to altitudes above 3000 m for periods longer than 1 month.[44–46] Oxygen administration and descent are often sufficient to bring improvement after timely diagnosis. Nevertheless, cardiac arrest occurs in cases with advanced right ventricular failure and irreversible pulmonary hypertension.[46,47] A well-documented autopsy series revealed severe right ventricular hypertrophy and vascular changes of pulmonary hypertension, with medial hypertrophy of pulmonary arteries and extensive muscularization of small pulmonary arteries and arterioles as a result of chronic hypoxic pulmonary vasoconstriction.[46]

Children with congenital heart disease may be at higher risk for developing complications of pulmonary hypertension at high altitude. An autopsy series of 280 infants (under 1 year of age) who died of congenital heart disease revealed 6 cases of severe pulmonary hypertensive changes (Heath Edwards grade IV) in the pulmonary vasculature.[48] A variety of cardiac lesions were represented in the series, including transposition of the great vessels, coarctation/interruption of the aorta, atrioventricular canal, and double outlet right ventricle; common to most cases was the presence of a ventricular septal defect and/or patent ductus arteriosus. Although this series from 1959–1978 predates modern echocardiographic diagnosis and early surgical intervention, similar pathophysiology and clinical evolution may occur today in many high-altitude areas of the world where diagnostic and treatment facilities are remote and poorly accessible.

The nature and incidence of HAPE differ among children resident at high altitude as compared to those who reside at low altitude and then travel to high altitude. Among children who reside at high-altitude, HAPE commonly occurs as a re-entry phenomenon, that is, upon reascent to the altitude of residence after travel to low altitude. Children resident at high altitude have an apparently higher incidence of re-entry HAPE than do adults.[32,49,50] Symptoms respond to supportive care with rest and oxygen. A variety of empirical pharmacologic therapies have been reported as well, most commonly diuretics and calcium channel blockers. Children with re-entry HAPE and abnormal cardiac examinations, ECGs, or echocardiograms, however, may have previously unsuspected underlying abnormalities, such as unilateral absence of the pulmonary artery.[51]

Conflicting reports exist regarding the possibility of increased risk of SIDS among children living at high altitude.[39–41] The most rigorous study conducted at moderate high altitude (500–1900 m – 1640–6234 ft) concluded that the risk of SIDS increased gradually with increasing altitude of residence.[41]

Adult cardiac arrest on mountains not related to acute mountain sickness

(for cardiac arrest due to hypothermia see Chapter 57)

Cardiac arrest and sudden non-traumatic death is an epidemiologic problem in areas of alpine mass tourism, such as major ski resorts or high-altitude sightseeing spots. It is not entirely clear whether death in tourists to high elevations occurs because of natural progression of disease, or whether the hypoxic environment triggers sudden cardiac death. The risk of coronary heart disease at high altitude appears to depend mainly on the population and the amount of physical activity undertaken. Populations frequenting ski resorts are different from those trekking in Nepal, with the former more likely to in poorer health, not very physically active, and overweight. Healthy mountaineers´ hearts can tolerate exertion at the utmost hypoxia of extreme altitude (with arterial oxygen saturations below 50% and oxygen extraction rates of over 80%) without any sign of myocardial ischemia by clinical examination, echocardiography, ECG, or Swan-Ganz catheter determinations.[52–54] By contrast, individuals who died suddenly on a mountain in Austria (mostly in areas of mass tourism at altitudes from 1100 to 2100 m), had known coronary heart disease with or without prior myocardial infarction, arterial hypertension, and lack of regular exercise as independent risk factors of sudden death compared to controls.[55] The issue of whether altitude and the hypoxic environment itself (and not physical activity) poses a risk to people with known coronary artery disease has been discussed extensively.[56]

"Going up to the mountains to trek or ski is a safe undertaking for those who believe they are able to do this"[57] and "At high altitude, physical activity is limited by dyspnea and pulmonary gas exchange and not by the circulatory pump or cardiac output. . ." The patient with coronary disease is therefore more likely to die while running at sea level than trekking at high altitude because "trekking does not involve maximal work, but a comfortable pace that can be

continued for many hours."[58] Rennie[57] and Hultgren[58] state that in asymptomatic patients, there is no indication that a stress ECG is of any help and is likely to lead to false positive results.

Downhill skiing receives little appreciation by some as being a true sport "where the work is done by the lift, . . . not an impressive aerobic challenge. . .".[57] Halhuber *et al.* observed 434 patients during a period of rehabilitation after myocardial infarction at altitudes of 1700 – 3200 m over 4 weeks and found only one reinfarction[59] and no deaths in this group. They also found a very low incidence of sudden death in alpine vacationers (6/151 000) at moderate altitudes (2 by myocardial infarction, 2 unclear, 1 mitral stenosis, and 1 myocardial infarction in the valley).[59]

Others argue that skiing is indeed physical work causing coronary stress. Grover *et al.* used telemetric ST-segment analysis during downhill skiing and found ST-depressions in 5 out of 149 volunteers.[60] Morgan *et al.* compared treadmill performance in nine patients with confirmed coronary heart disease at 1600 and at 3100 meters without acclimatization. They found a significantly shorter time of exercise and a lower workload before onset of ischemia (ST depression or angina) at high altitude.[61] Two out of the nine patients were short of breath after arrival at 3100 meters.

Irrespective of whether altitude is raising or lowering the individual risk of coronary insufficiency, sudden cardiac death does occur in resorts with a large tourist population, but is rarely seen at higher elevations where only trained and experienced mountaineers can (or should) go. Malignant primary arrhythmias also do not appear to play a role in sudden death on mountains.[14,59–62]

Peer-reviewed original publications on the incidence of death on mountains are rare.[11,63,64] Data on sudden death on the mountains originate from various epidemiologic settings, and the overall risk of suffering myocardial ischemia on a mountain is hard to determine. Much of the data presented is from research letters[10,55,65–67] and even articles in yearbooks of mountaineering clubs[68–70] and should be regarded with the necessary scientific caution.

In areas with large tourist populations, i.e., mostly skiing resorts, sudden death accounts for about 30% of all deaths; the other 70% are due to trauma.[55,63,65,67] The totality of cases can only be extrapolated from the different sources, as the included causes of death or populations vary. Cases of pulmonary embolism, intracranial hemorrhage, and dissecting aortic aneurysms, if known, were excluded from some analyses[63] or are incorporated into the "deaths by heart failure."[70] Most of the published data comes from Austria. Here, approximately 8.5 million people engaged in mountain hiking, downhill skiing, or both each year before 1993.[55] In contrast, Lienhart *et al.* cite the presence of

1 million skiers in the year 2004 in one single resort in Austria,[64] with a maximum of 20 000 persons at a time. Burtscher gives different numbers of victims over several overlapping time intervals, depending on the combination of skiing (downhill or cross country), hiking, and climbing. He reports 642 arrests in people who were skiing, hiking, and climbing over 9 years;[66] 416 victims while hiking or downhill skiing over 7 years;[55] and 285 deaths during hiking over 7 years.[65] The Austrian mountain rescue association reported 373 deaths of all causes in 2003[70] encompassing any activity on a mountain, of which 112 were due to non-traumatic sudden death (including pulmonary embolism, stroke, myocardial ischemia, and others). The range of victims between 1984 and 2003 was 205–373, mean 304.[70] The activity before the arrest is depicted in Fig. 63.5.

Usually, alpine cardiac arrest victims appear to be included in reports of regional emergency medical service systems,[71] but this has been debated as being inconclusive.[72] Breitfeld and Voelckel reported all air rescue missions in Austria over 3 years performed by the major air rescue provider in Austria.[68] In total, rescue helicopters responded to 98 cardiac arrests, in which 80 (82%) victims received bystander basic life support. Automated external defibrillators for basic life support were not available to non-physicians at that time. Standard advanced cardiac life support was instituted after 25 ± 5 min. Return of spontaneous circulation was achieved in 6 patients, of whom 3 died before transport. The remaining 3 (3%) reached the hospital alive, but none survived to hospital discharge (unpublished details[68]) The majority of all arrests (62%) were observed during winter and mainly in ski resorts (75%). In summer, at least one-third of all cardiac arrest cases occurred close to lodges or alpine resorts. On the basis of these data, the authors initiated a public access defibrillation programme on a glacier ski resort with 1 million visitors per year and a maximum of 20 000 guests per day. As reported by Lienhart *et al.* four automated external defibrillators were placed at appropriate locations within the resort. Within the following 2 years, 3 cardiac arrest victims received bystander CPR and automated external defibrillation. Two patients survived to hospital admission, and one was discharged in good neurological condition.[64]

In a setting completely different from that described above, the Himalayas, Shlim and Houston[19] report helicopter missions over 31/2 years for trekking (not mountaineering) tourists in Nepal. Among 148 000 persons, 23 died and were evacuated by helicopter, and another 111 were rescued alive. Of the dead victims, none was classified to have died from myocardial ischemia (4 causes were unknown), and among the ones rescued alive, cardiac problems were the chief complaint in only 6 cases. The

Epidemiology deaths on mountains, Austria 2003
Fig. 63.5. Activity before death on mountains, Austria. (Adapted from ref. 70.)

study was repeated with a different methodology. Shlim and Gallie[73] found that four patients had died from heart attacks during trekking among a total of 275 950 trekkers over 4 1/2 years (total number of deaths, 40: traumatic cardiac arrest, 12; acute mountain sickness, 10; non-AMS illness, 14, missing, 4).

Trekkers death rates (15/100 000[11]) contrast sharply to deaths in climbers (2900/100 000[74]) in the Himalayas, which are primarily due to trauma, hypothermia, and avalanches. In the Himalayas, among the 165 non-traumatic deaths, cardiac arrest was caused by illness (not acute mountain sickness) in 27 cases[9] (Fig. 63.6), but the total number of autopsies was extremely rare since most victims could not be transported home and were buried on the spot. Therefore, it usually remains unclear why a person suddenly collapses. The large database by Elisabeth Hawley[9] documenting all mountaineering expeditions to Nepalese summits over 40 years relies on interviews with climbers after their return and their description of events. The symptoms of altitude-related illness are well known and are distinguished from those of other illnesses.

Berghold and Schaffert from Austria assume that fulminant pulmonary embolism accounts for most non-traumatic deaths at extreme altitude,[75] although there are no data to support this (personal communication, Franz Berghold, 2004). Their reasoning is that extreme mountaineers have healthy hearts not susceptible to the injury caused by hypoxia.[54] Therefore, a possible explanation for sudden death besides AMS, hypothermia, or trauma may well be pulmonary embolism. It is known that climbers at

extreme altitudes have a high incidence of deep venous thrombosis due to hyperviscosity caused by elevation in hematocrit and dehydration[76,77] and immobility[77–82] when confined in a tent, constrictive clothing, and cold.[14] Hypobaric hypoxia is thought by some[76,83,84] to be an independent risk factor of thrombosis through altered coagulability[76,80–88] while others dispute this claim.[89,90]

Recently, airplane travel thrombosis – where similar pathophysiologic mechanisms apply – has been stated to occur mainly[91] or only[92] in patients with predisposing congenital coagulation abnormalities such as protein-c deficiency.

Irrespective of the mechanism, pulmonary embolism (PE) is found in 0.3%–57% of patients at altitude (table from Dickinson[94])[93–98] supporting Berghold's[75] assumption. The wide range of these data comes from different groups of patients (6 out of 1692 patients seen at hospital after altitude stay[98] and 9 out of 40 patients presenting with HAPE to hospital).[93] In a series of seven altitude-related deaths, pulmonary embolism was at least a contributing factor to death in 4 patients.[94] The signs and symptoms of PE may mimic those of HAPE, but embolic disease tends to have a more rapid onset, and pleuritic chest pain is a more prominent feature (Table 63.2).

Stroke – both ischemic and hemorrhagic – may also be a cause of sudden collapse and death at high and extreme altitude. High altitude death has been found to be associated with intracranial petechiae or hematomas (table from Dickinson[94]). Stroke is a problem at high altitude,[98–102] but as with pulmonary embolism it cannot

clearly be stated whether the incidence is high, relatively low, or can only be put in perspective when considering the selection mechanism of the populations studied where patients with cardiac or pulmonary diseases are excluded a priori.

Cardiac arrest aboard commercial airplanes

In-flight cardiac arrest is uncommon. About 0.31–0.8 death per million passengers are reported[103,104] annually. With passenger numbers increasing exponentially over recent decades,[105] this converts into large variations in

absolute numbers. Incidence data also vary if the denominator is a single airline,[106,107,107b] an airport,[103,108–110] data collected at the Federal Aviation Administration,[105,106] or the International Air Transport Association (IATA).[104] Rodenberg describes 90 deaths over 20 years in one large airline,[106] and Lyznicki *et al.* found over 33 deaths on domestic US flights over 2 years.[105] O'Rourke *et al.* report 27 cardiac arrests on international flights in 55 overseas airplanes for a death rate of 4.7 per million passengers on Quantas Airlines;[107] only 59% were witnessed arrests. Six passengers had ventricular fibrillation, and 2 of these (7.4%) survived to hospital discharge. No patient with a non-shockable rhythm survived. Whether long flight diversions on international flights from or to Australia played a role is unclear. Magalhäes *et al.*[111] report 3 fatal arrests on 34 of Brazil´s 80 VARIG airplanes over 6 months (passenger numbers not provided). Cummins and Schuback report five cardiac arrests out of 14.4 million passengers arriving at Seattle Tacoma International Airport during 1 year. Interestingly, none of them had the arrest during flight.[108] McKim Davis and Schuriet[109] report 11 cardiac arrests among travellers brought to one out of three hospitals from Dallas/Fort Worth Airport within 1 year. Three received basic life support during flight and one survived with neurological deficits. Speizer *et al.*[103] report 6 cardiac arrest (all fatal) out of 8 375 000 passengers during flights inbound to Los Angeles International airport in a 6-month period. In total, 25 patients were hospitalized for various symptoms including cardiac arrest, but none of the patients was diagnosed with pulmonary embolism. The fatal cardiac arrests were assumed to be of myocardial origin. Sarvesvaran[110] describes 104 deaths that were reported to the coroner of Heathrow Airport over 3 years, of whom 61 were in-flight cardiac arrests. Eleven of these were due to pulmonary embolism and 43 were due to cardiac ischemia. Ten out of the 11 pulmonary embolic deaths occurred in flights of more than 12 hours' duration. In the group of 28 "would-be passengers" with an arrest while still on the ground, only one had pulmonary embolism as the cause of arrest. No patient with a cardiac arrest was younger than 40 years, with the exception of five chronically ill patients, whose disease was their reason of final travel. In a 10-year period with many fewer passengers than today (1971–1980), 10-year incidence of medical events on US domestic flights was 7789 and deaths ranged from 21 deaths to 100 per year.[106] Cummins *et al.*[104] depict 577 in-flight deaths reported to the IATA in an 8-year period, with a response rate of approximately 25% of all IATA airlines, which represent approximately 50–60% of all airlines. Extrapolation of these data to worldwide incidences is not appropriate, however,

because of the distribution of long range flights among carriers and the resulting different incidences ranging from zero to 59 arrests in one airline over 8 years.

It is not completely clear to what extent the hypobaric hypoxic environment in an airplane plays a role. Commercial aircraft set their cabin pressure at a level that refers to an altitude of approximately 1900 m (6200 ft), but sometimes pressure values of 2700 m (8915 ft) are reached.[112] This leads to a decrease of the inspired oxygen partial pressure from 159 mmHg at sea level to 113 mmHg at 9000 ft.

Considering the very low relative and absolute death rate aboard airplanes, it appears that flying is a safe mode of travel for the vast majority of the population. Myocardial ischemia, massive pulmonary embolism, and cerebrovascular disasters are causes of death with sudden onset. In contrast, cancer or other chronic diseases may keep people from flying near the end of life, leading to a selection bias in individuals who die suddenly on airplanes.

Interestingly, there are no reports of acute mountain sickness during flights, although this would be expected to happen regularly. The cabin altitude is high enough for this disease.[3] As stated above, acute mountain sickness usually develops within the first 12 hours[5] (or very rarely even sooner[94]), a time range that is often reached on international flights. Whether the lack of physical activity might be a possible explanation for this phenomenon is still to be investigated.

Commercial air travel with infants and children

The possibility of a link between prolonged (intercontinental) flights and subsequent SIDS was raised in a research article published in a major medical journal.[113] Clinically healthy infants were exposed to 15% oxygen to identify the effects on arterial oxygenation and the frequency of apneic pauses. This publication aroused considerable alarm, especially among families with surviving siblings of SIDS victims, but subsequent critique of the study design, methodology and conclusions, resulted in consensus that such an association is unsubstantiated. There are no reports of cardiac arrest in pediatric passengers during flights in commercial airlines. Even with an assumed strong negative publication bias, the problem would not be a large one in absolute numbers.

Air transport of patients

Medical transport of patients may be accomplished by rotor- or fixed-wing aircraft. Although helicopter emergency medical service (HEMS) programs typically focus on

primary rescue missions, daily interhospital transfer flights are routine. For long distance or intercontinental flights, patients may be transported either on board major airlines or dedicated charter flights. Such aircraft generally are pressurized only to an atmospheric pressure that approximates an altitude of 1515 m (5000 ft) and the cabin altitude may be as high as 2440 m (8000 ft) at the highest cruising altitudes.[114,115]

Transport by helicopter is done in unpressurized cabins, so that pressure inside the aircraft corresponds directly to the flight altitude. Even in alpine rescue or transfer flights, however, flight level typically does not exceed 3000 m.

Nevertheless, rapid ambient pressure change is a major concern in aero-medical transport. Enclosed collections of gas within the body can expand rapidly during normal ascent or sudden depressurization of the aircraft. While expansion of air in the middle ear can be acutely painful, expansion of a pneumothorax, pneumopericardium, or cystic adenomatoid malformation in pediatric patients can lead to critical reductions in cardiac output and subsequent cardiac arrest if unrelieved. Moreover, volume expansion of intestinal gas (i.e., in patients with acute bowel obstruction) may cause gut distension and subsequently impair respiratory function. Accordingly, detection and adequate treatment of the aforementioned pathologies (i.e., chest tube placement) prior to air transport is crucial. Once the patient is on board the aircraft, auscultation of breath sounds will be significantly compromised by the ambient noise and vibration during flight. Thus, it is important to utilize comprehensive hemodynamic monitoring and to have a high index of suspicion for air leaks in patients who present with sudden onset of respiratory distress, hypoxemia, bradycardia, and/or hypotension during transport. For transfer flights of intubated and mechanically ventilated patients, a regular check of tube position, bilateral ventilation, tube patency, equipment (oxygen supply pressure), and stomach distension is mandatory. The cuff of the tracheal tube should be evaluated at different altitudes, as the air inside the cuff expands when the aircraft or helicopter gains altitude (2000 feet or more) and inadvertent high cuff pressures may cause mucosal damage in the trachea.[116] If the patient is intubated on the mountain and flown to the valley, the cuff is compressed and needs to be refilled. Alternatively, as in the hyperbaric chamber treatment for diving accidents, the cuff may be inflated with water or saline.

When a patient is treated with a transport ventilator, at high altitude with lower barometric ambient pressure, the ventilator delivers more volume per minute to the patient (approximately 15% more minute volume at 2000 m[117] or 3000 m[118] when compared with volumes at sea level).

Monitoring of the given ventilation volume is therefore warranted during all kinds of patient transport.

Prior to air transport, patients with impaired cardiopulmonary function must be stabilized appropriately, and supplemental oxygen should be administered routinely in order to maintain adequate oxygenation during transport. If patients are at risk for malignant arrhythmias, an option for defibrillation during flight is given. Although transthoracic defibrillation with hand-held paddles is not likely to interfere with the helicopter's flight safety, self-adhesive electrodes are advantageous, and these electrodes should be attached prior to flight.

Austrian air rescue responds to 15 000 rescue missions per year, and about 3% are for cardiac arrest patients. Therefore, air rescue crews must be familiar with current CPR guidelines, and even more important, must be able to perform CPR in remote locations, difficult terrain, and during flight. Even though the quality of chest compressions is limited during transport (ground and air), ongoing cardiac massage during flight is justified under certain circumstances such as severe hypothermia. The cabin space of modern EMS helicopter allows performance of prolonged chest compressions even during flight, but air rescue teams must be familiar with the management of cardiac arrest patients during flight. An adjusted in-cabin advanced life support training should be part of ongoing educational programs for the entire air rescue crew.

Treatment of high altitude cardiac arrest

In those areas and altitudes where emergency medical services are available in acceptable time ranges, especially in resorts with large tourist populations, myocardial ischemia can be assumed to be the leading cause of death, although other causes of sudden death, i.e., pulmonary embolism, CNS events, and other cardiac and respiratory conditions should also be considered. Accordingly, standard advanced cardiac life support should be instituted by rescuers. Programmes for public access defibrillation[64] should be encouraged. Use of thrombolytics for specific etiologies should follow standard recommendations (See Chapter 41).

For individuals with cardiac arrests in remote areas (wilderness, airplanes, and others), use of expensive and possibly dangerous regimens must be counterbalanced and should not put rescue crew members at inappropriate risk. On mountains, response intervals will be far too long to make resuscitation success likely.[11] There are reports of response times for helicopter evacuation of 24 hours. Even when response times are moderate in wilderness locations, outcomes are exceedingly poor.[68] Nonetheless, there

are a few special circumstances (such as severe altitude illness) in both major tourist resort areas and in remote locations that may require adjustments to usual treatment regimens.

Cardiac arrest management in patients with altitude illness

If a patient is known to be affected by acute mountain sickness and develops cardiac arrest (not suddenly but usually after hours to days), treatment may be different from standard ACLS. Because of the pathophysiologic mechanisms described above, the aim of treatment must be to lower the pulmonary vascular resistance for HAPE patients, as oxygen alone may not be sufficient,[119] and to lower intracranial pressure in HACE patients. No prospective studies have been performed on these rare entities (one death per year in the Himalayas[11]), and there are no case reports with precise descriptions of ACLS except in non-medical mountaineering literature (e.g., J. Krakauer – Into Thin Air). Since literature is limited, it is noteworthy that the following treatment proposal is entirely speculative and is not supported by sound scientific data.

Oxygen is a mainstay of treatment for altitude illness. Rescue personnel should air-drop oxygen supplies if immediate evacuation to lower altitudes will be delayed. High-flow rates of oxygen (10–12 l/min) by mask should be delivered initially to victims with severe HAPE until improvement is seen. Lower flow rates may then be used until recovery or descent is completed. This may take days to weeks, as oxygen alone does not completely solve the problem of pulmonary vasoconstriction.[119] Delivering oxygen with a continuous positive airway pressure mask improves oxygenation in HAPE victims compared with normal oxygen delivery.[120]

Patients with severely altered levels of consciousness require intubation for airway management and hyperventilation to control elevated intracranial pressures, although at moderate and extreme altitude, patients are already spontaneously hyperventilating and hypocapneic.

When a patient is ventilated with supplemental oxygen (via bag valve mask or endotracheal tube), the ventilation volume per minute is not a clear target. Some degree of hyperventilation appears to be desirable in a patient with cardiac arrest from HACE and suspected elevated intracranial pressures. In this regard, the rescuers must be aware that spontaneous hyperventilation and subsequently low arterial PCO_2 values are part of the physiologic adaptation to high altitude (PCO_2 values as low as 7.5 mmHg have been observed on the summit of Mount Everest without any cerebral damage[121]). Accordingly, despite improved

oxygenation after initiation of artificial ventilation, reduction of minute ventilation might be harmful.

Anecdotal reports of the successful treatment of HACE in hyperbaric chambers exist. Coma may persist for several days after descent to lower altitudes, so placement of HACE patients in a hyperbaric device may only delay the more comprehensive care available in the hospital setting. If immediate descent is impossible, portable hyperbaric therapy may be life-saving. Early treatment for HACE generally results in good outcomes, but after coma occurs, mortality exceeds 60%.[122]

Death is usually due to cerebral edema and herniation, and sometimes from antemortem cerebral infarcts from the high intracranial pressure and decreased cerebral blood flow. In addition, the clinician should be careful not to make the patient ischemic secondary to overventilation. If the patient appears to be herniating then hyperventilation appears advisable.

If HAPE is recognized early and treated properly, cardiac arrest and death usually can be avoided. Descent to a lower altitude, bed rest, and supplemental oxygen are the most effective methods of therapy;[22] portable hyperbaric chambers[123,124] generating 103 mmHg (2 psi) above the ambient pressure thereby simulating descent are a valuable substitute if oxygen is not available. Because of the nature and construction of these devices, it is not possible to perform CPR while the patient is in the portable chamber.

Supplemental oxygen administration addresses the primary insult of high-altitude exposure and corrects hypoxemia. Delaying descent while HAPE progresses or waiting for rescue personnel to initiate evacuation has proven fatal. Descents of 1500 to 3000 feet should be adequate to begin the recovery phase.

The evaluation of drug therapy in treating HAPE has been limited. There are no reports of modifications of standard ACLS drugs in patients with HAPE who have cardiac arrest. In addition to standard ACLS drugs, agents that lower pulmonary artery pressure, pulmonary blood volume, and pulmonary vascular resistance would intuitively be useful. Furosemide is beneficial in treating HAPE and, when combined with morphine for the initial dose, results in even greater diuresis and clinical improvement. Some authors caution that deleterious dehydration may result from furosemide therapy and that the potential ventilatory depression caused by morphine can further increase the severity of the hypoxemia that underlies AMS.[22] Others argue that, during the state of antidiuresis found with severe AMS, furosemide may be useful and that no documented reports of deleterious effects from this treatment exist. Furosemide may also be useful in settings where both oxygen therapy and descent are not available;

however, caution must be exercised because of limited experience. Its application in altitude-related cardiac arrest is unclear and without scientific evidence of success.

As used in the treatment of AMS before cardiac arrest, dexamethasone (8 mg parenterally, followed by 4 mg every 6 hours) is likely to result in more benefit than harm.

This is less clear with nifedipine: usually, ACLS aims at raising systemic and coronary blood pressure, and treatment with intravenous boluses of nifedipine can be expected to do the opposite. But, because of its action as a pulmonary vasodilator, nifedipine has been used to treat HAPE prior to cardiac arrest with good results.[26,27,125] Nifedipine does not improve pulmonary hemodynamics as effectively as oxygen and does not have an additive effect when administered with oxygen.[26] Therefore, intuitively it does not appear to be beneficial in a patient during ACLS who is intubated and receiving 100% oxygen.

Cardiac arrest from chronic pulmonary artery hypertension (not related to altitude) has been treated with bolus injections of 50 μg of iloprost, a prostacyclin analogue,[126] but this was not a randomized controlled trial. Of 513 patients with cardiac arrest, 8 survived with no neurological deficit; 7 of these patients had correctable causes of cardiopulmonary arrest, such as vasovagal reactions, digitalis toxicity, or pericardial tamponade. In 3 of the 8 survivors, iloprost had been used, but in many of the unsuccessful attempts it was used it was not reported.

Recent studies have shown the effectiveness of the phosphodiesterase type 5 inhibitors on the pulmonary vasoconstriction associated with HAPE in human and animal studies. Sildenafil has been used successfully for lowering pulmonary vascular resistance when given 100 mg orally in healthy volunteers,[127] or 1 mg/kg in children with congenital heart disease (without altitude-related problems).[128] In a small study of 6 patients it has been shown to lower pulmonary arterial pressure if taken orally (40 mg 3 times per day) beginning several hours after arrival at altitude of 4350 m.[129] As both a preventive and non-preventive treatment strategy, sildenafil lowered pulmonary artery pressure in rats at doses of 25 and 75 mg kg^{-1} per d.[130] Because of its potential to cause severe hypotension, however, it should be used with caution in patients in extremis.

Bosentan, an endothelin antagonist, has been discribed in long-term use for treating children with pulmonary hypertension and HAPE due to congenital heart disease,[51] but not for acute treatment of HAPE. Other treatment options used for pulmonary hypertension[131] have not been studied in HAPE.

Beta-2 agonists such as salmeterol have been applied in the prevention of HAPE with a reduction from 74 to 33% in susceptible persons going to 4559 m within 22 hours,[132] but again, this was not a treatment for acutely decompensating, overt HAPE. If available, in-line beta-agonists may be attempted for the ventilated patient during resuscitation.

With respect to treatment of HACE, anecdotal reports support steroid therapy, which resulted in recovery without neurological deficits in some patients. The initial dose of dexamethasone is 8 mg parenterally, followed by 4 mg every 6 hours.

Diuretics (e.g., furosemide) and hypertonic solutions (e.g., mannitol) have been used to decrease intracranial pressure. Many patients with HACE are already volume-depleted from poor fluid intake and loss of fluid through hyperventilation, and care must be taken to ensure adequate intravascular volumes if a diuretic agent is used. Acetazolamide is a carbonic anhydrase inhibitor that induces a renal bicarbonate diuresis causing a metabolic acidosis, thereby increasing ventilation and arterial oxygenation. This drug also lowers CSF volume and pressure, which may play an additional role in its therapeutic and prophylactic use. The use of acetazolamide parenterally in cardiac arrest has never been reported but with other drugs used for lowering intracerebral pressures, an IV bolus of 250–375 mg, may be beneficial.

Between one-half and two-thirds of arrests on mountains are caused by trauma.[9,11,55,70,73] The prognosis of these patients, which is very serious in urban settings, is disastrous in the wilderness. If patients are found by rescuers without a pulse, resuscitation is virtually futile (see chapter 57 for traumatic arrest).[133] Since trauma represents the largest group, the suggested strategy of preventive anticoagulation treatment anticipating salvageable victims of sudden death by myocardial ischemia or pulmonary embolism does not appear to be of value.[134]

In conclusion, the key to success in AMS-related cardiac arrest lies in prevention, early diagnosis, early therapy with descent and oxygen with positive endexpiratory pressure (PEEP), acetazolamide, and dexamethasone. Once asphyxial cardiac arrest has occurred, treatment is unclear and survival is unlikely.

Electrical injuries

Wolfgang Lederer[1], Erga Cerchiari[2] and Norman A. Paradis[3]

[3] University of Colorado Health Sciences Center

Today, human-made and natural sources together kill about 1100 to 1200 people each year in the United States.[1,2] The number of people injured worldwide by electricity, however, remains unclear, because it is generally underreported and it is common for survivors to avoid medical care initially. Although scientific investigations of electrical injuries date back to 1884, with current scientific knowledge and the clinical appearance of electrical injuries, we now know that the outcomes of electrical injuries differ substantially, depending on whether technical electricity with low-volt household current, high-volt current, or lightning is the underlying cause.

Injuries after electrocution are often dramatic and potentially fatal. In the majority of victims injuries are caused by the effects of electrical, thermal, and mechanical energy. Secondary trauma may result from falls, explosions, or violent muscle contractions.[3] Cardiac and respiratory arrest may occur immediately or secondary to direct effects of current.[4] Many victims die before advanced life support can be provided, and survivors may suffer permanent disabilities.[5] What is unique about electrical injuries, however, is the potential for good resuscitation outcome even after long arrest times.[4,6] This may be a result of the electrical shock itself or because these accidents tend to occur in younger persons with few or no underlying pathological conditions.

Considering the magnitude of the voltage and current involved, it is amazing that anyone survives an encounter with a bolt of lightning. Lightning can cause harm by electrical energy (e.g., direct hit, side splash, upward streamer, ground strike, conducted current, step voltage) and can cause trauma (e.g., heat, explosion, fall).[7] Circulatory arrest due to asystole or after prolonged respiratory arrest, hypoxia and acidosis can be expected in about one-third of patients.[4] Lightning-associated injuries such as burns, fractures, mechanical injury to internal organs, or hemorrhage are contributing factors.[8,9] Contrary to general opinion, victims of lightning strike have a good prognosis if appropriate cardiopulmonary resuscitation is instituted without delay.[10]

Epidemiology

Technical electricity

Human-generated technical electricity causes about 5000 non-fatal injuries per year and accounts for about 5% of all admissions to burn centers in the United States. Electric shock is associated with a mortality rate of 0.5 to 2.5 per 100 000 persons/year.[2] Because of a lack of reliable reporting services and data recording, the incidence may be much higher and may vary considerably in different countries. There is thus a need for a comprehensive worldwide epidemiological survey of current-induced casualties. Up to 70% of electrical deaths from high-volt current are related to occupation (Table 64.1).[11–13] Electrocution-related deaths predominate in young males, comprising 7.5% of all lethal occupational accidents in the United States.[12] Approximately three-quarters of deaths occur in electrical and construction workers and result from direct contact with power lines. Most cases of high-voltage injury occur in linemen and construction workers, but they also occur in adventurous persons, usually juvenile males, who climb trees or poles near electricity lines.[14] Late mortality in those who survive initial injuries is mostly due to septicemia, pneumonia,

Table 64.1. Epidemiology of low volt and high volt technical electricity and lightning associated injuries

| Characteristic | Technical electricity | | Lightning |
	Low volt	High volt	
Incidence (/100 000/yr)	Approx. 70		Approx. 0.09–0.12
Fatality rate	Approx 3%	Up to 30%	10% to 30%
Sex preponderance	Male	Male (> 85%)	Male (> 85%)
Age of greatest risk	Children	20 to 29 yr	20–29 yr
Time of day	Daytime	Working hours	4 to 6 PM
Season	Any	Summer	Summer
At occupation		up to 70%	up to 33%
Activity	Playing, household	Linepersons, electricians	Farmers, golfers

and renal failure.[15,16] Electrocution has been reported as a method of suicide and is still practiced as a means of torture and capital punishment in some countries.[17–19]

About 60% to 70% of electrical injuries are due to low-voltage current, which accounts for one-half of deaths from electricity and up to 1% of accidental household deaths.[16] More than 20% of all electrical injuries occur in children.[20] Household low-voltage electrical injuries are more frequently observed in pre-school children and toddlers,[15,21,22] while high-voltage exposures are more common in those over 12 years old.[23]

Electrocution during pregnancy entails high risks for fetal health because the fetus is exquisitely sensitive to electrical shock.[24] Spontaneous abortions after electrical injury and injury from electric-shock weapons have been reported.[25,26] The path of electricity in electrical cardioversion, however, does not include the uterus and this procedure has been applied safely in all trimesters of pregnancy.[27]

Lightning

Although the majority of persons struck by lightning are merely stunned and may have transient difficulty moving, lightning-related injuries account for several thousand deaths worldwide each year.[11,28] The overall yearly incidence rate of reported cases ranges from 0.09 to 0.12 per 100 000, with case fatality rate up to 30%.[29,30] Eighty-five percent of all people killed by lightning in the United States are male, with a median age of 26 years (Table 65.1). One-third of all lightning strike-related deaths occur in relation to the victim's occupation.[2,31] The time of injury reaches a peak from 16:00 to 18:00 hours, and most casualties occur between May and September.[28,29,32] Approximately one-third of victims killed were injured on the job.[33] Three-quarters of survivors sustain significant permanent sequelae. Most of these epidemiological data are represen-

tative for the USA; the incidence in other countries may differ owing to different exposure rates and data recording.

Prevention

Technical electricity

Both natural and technical electrocution are avoidable problems. Better understanding of the epidemiology of electrical cardiac arrest may result in improved education and product safety. The public should be made more aware of risk factors for electrical shocks. Risky behavior and misuse, e.g., climbing of utility poles, tampering with electrical installations and equipment by unqualified persons, lack of residual current breakers, and improper handling of electrical equipment, must be avoided.[5,34]

Household current in the United States is 120 volts, whereas many other countries use 220 volts. Although high-voltage electricity is more lethal than low-voltage electricity, most electrical injuries result from standard household and business appliances and the power lines that supply them. High-voltage current, defined as a voltage exceeding 1000 volts, commonly results in severe burns and deep tissue damage. Depending on humidity and electrical conduction of surrounding air, as well as the magnitude of voltage and amperage, arcing current may occur within a certain proximity to the high-voltage source. To avoid harm by step voltage from ground current, rescuers are advised to keep a minimum distance of 10 meters unless the power line has been switched off by expert personnel and is visibly grounded.

When an electrical appliance catches fire, it should be unplugged or turned off from the current fuse box. Only a class C fire extinguisher is adequate, in no case should water be used to extinguish fires.

Household electrical cords are the major electrocution hazard in children younger than 12 years.[23] Oral contact with electrical cords or placing objects in a cord socket are frequent causes of injury in toddlers.[35] Water may contribute to electrocution in up to half of all fatalities, and electric sources in bathrooms remain a constant problem, in particular when house wiring is faulty.[36] After use, electrical appliances should be unplugged and kept out of the reach of small children. Use of electrical safety switches, plug covers, circuit breakers, and immersion detectors should become standard practice in private homes and elsewhere.[21]

All electrical equipment on a construction site must comply with the prescribed standards and be maintained by trained and qualified personnel only. Safety equipment, including portable residual current protective devices, use of adequate protective clothing, ground-fault protection on construction sites and at work places, and compliance with established procedures are mandatory.[13] Preventive measures taken by professional associations have reported successful reduction of the frequency of electrical arc accidents.[37] Electrical safety training should be compulsory for utility and construction workers, and any employees handling electrical equipment. Training should include salvage and self-rescue by disconnection of the power line or intentionally dropping to the ground. A health safety program to provide guidance for safe practice is mandatory.[12,13]

Lightning

Information on lightning prevention is based on experimental findings and empirical data from single fatalities. With respect to evidence-based medicine, we lack randomized study findings to prove the various precautions related to lightning. As lightning is related to conduction between negative and positive electric charges, it may occur within a 15-kilometer radius of the thunderstorm. Threat of lightning injury may occur before the beginning of the storm and continue even when the storm has passed. Occasionally lighting may even strike out of the blue sky.[38] Therefore, people are urged to pay attention to local weather forecasts before undertaking outdoor activities. Lightning-associated injuries most commonly reported from open fields, at swimming pools, and in tents. Accidents are related to work, e.g., on or near docks and during leisure time activities in the open. On the surface below a thunderhead (cumulonimbus), ground charges accumulate on tall objects including telephone poles, electricity poles, and isolated trees and increase the chance of these being hit by a lightning bolt. Taking shelter close to metal pipes, rails, and other metallic paths that can transmit lightning energy from a nearby strike must be avoided.[2,31,32] People should stop outdoor activities, especially swimming, diving, or boating whenever a thunderstorm appears imminent; if persons are caught outdoors in a lightning storm, and feel as if their hair is standing on end or their skin is prickling, they are advised to keep low, squat down, put their feet together, and cover their ears. This is recommended to counteract injuries caused by ground current and shock wave. Proximity to other people of less than 10 m should be avoided.

Although no place in a thunderstorm is absolutely safe, large enclosed structures such as buildings or fully closed and hard-topped metal vehicles provide good shelter from lightning threat. Indoors, people should stay away from doors and windows and avoid elevated locations such as rooftops. Rooms that have excess plumbing, such as kitchens and bathrooms, should be avoided until the storm has passed. In particular, using the telephone, taking a shower, or any contact with conductive surfaces with exposure to the outside should be avoided.[39] About 10% of lightning injuries occur during transport.[40] Whereas lightning remains a potential risk to aircraft passengers, modern airplanes are well equipped to reduce the dangers from accidents due to lightning. Moreover, lightning detection systems help trace early stages of incipient thunderstorms.

Pathophysiology

Technical electricity

Experimental knowledge about the effects of electricity on humans indicates that current flow is directly proportional to tissue damage and systemic effects. Severity of electrical trauma, however, cannot be concluded solely from an electrophysical point of view, e.g., the amperage, voltage, type, duration, and pathway of the electric current.[3,14,41,42] Tissue damage results from conversion of electric energy to heat, on the one hand, and from the direct effect of current on cell membranes and vascular smooth muscle, on the other hand. After brief exposure to potential gradients it is cell membranes that are mainly impaired. Cellular damage results in increased cell permeability, leading to ion leakage, escape of metabolites, cellular edema, and irreversible cellular damage. Leakage of ions leads to an osmotic imbalance which in turn causes a colloidal hemolysis of the red cells. In addition, electrolysis of the blood may cause embolism by formation of gas bubbles and thrombosis. Permeabilization of cell membranes and direct electroconformational denaturation of proteins contributes to further tissue damage.[43,44] Injured tissue

Table 64.2. Expected physiological response in relation to amperage (A) by direct current (DC) and alternating current (AC)

Grade	Amperage (A)		Physiologic response
	DC	AC	
I	< 0.08	0.001 to 0.004	Unpleasant, tingling sensation
		0.01 to 0.02	Tetanic skeletal muscle contractions
II	0.08 to 0.3	0.03 to 0.05	Thoracic muscle tetany, respiratory arrest
		0.05 to 0.08	Brady/tachyarrhythmia, atrial fibrillation
III	0.3 to 8	0.08 to 8	Ventricular fibrillation
IV	> 8	> 8	Thermal damage, ventricular fibrillation or asystole

may be salvageable as long as membrane permeabilization is the primary pathologic condition. Severity of injury is closely related to the magnitude of current passing through the tissues when current is high and exposure time is long.[34] When contact time is long, secondary damage from joule heating can directly affect the whole cell.

Furthermore, the extent of injury depends on the nature of the tissues. Bone and skin are most resistant to the passage of electric current, whereas muscle, blood vessels, and nerves conduct with least resistance. Resistance to current flow varies according to the tissue fluid and electrolyte content and the duration of exposure. In addition, surface moisture, sweat, and ointments reduce the impediment to current flow. In general, the skin of babies and children offers lower dermal resistance. Fetal skin is approximately 200 times less resistant to current flow than is postnatal skin. Further, the hyperemic pregnant uterus and amniotic fluid are excellent conductors of electricity. Together this explains why up to 70% of fetuses die, even if the mother survives an electrical injury.[24]

The area of the contact point and exposure time are important, because it is the amount of energy per unit tissue that determines the extent of injury. A small area of contact usually concentrates electrical energy and leads to serious damage of the skin and underlying tissue, whereas the same current may not cause any visible external damage if applied over a wide surface area. The low cross-sectional area of extremities increases current density.

Alternating current (AC) at 50 to 60 cycles per second is extremely dangerous at even low amperage levels, particularly with prolonged exposure time. The likelihood of ventricular fibrillation increases once exposure continues for a complete cardiac cycle.[25] The heart and diaphragm are most susceptible to frequencies at 50 to 60 hertz; hence respiratory and cardiac arrest are more likely when the current passes directly through the trunk, compared with a straddle or vertical path.[45,46] There is clinical evidence that hand-to-hand (transthoracic) pathways are the most lethal followed by head-to-foot (vertical) pathways. Leg-to-leg pathways may result from ground charge that induces a potential difference between the victim's legs. In comparison, direct current (DC) is generally tolerated at much higher strengths (Table 64.2). Electrocardiogram (ECG) changes and positive MB fraction of creatine phosphokinase (CK-MB) are attributed to the direct effect of current and coronary spasms, which cause patchy damage throughout the myocardium.[47] Although uncommon, true Q wave infarctions have been reported after electrical injury.[48] Finally, conduction disturbances as well as severe dysrhythmias are common after electrical shock, although more benign rhythm disturbances such as atrial fibrillation and sinus tachycardia have been reported as well.[49] Several mechanisms appear to underlie the ability of technical electricity to precipitate sudden death: (*a*) myocardial cell damage from the overwhelming inotropic stimulus; (*b*) direct electrical alteration of cell membrane potential; (*c*) released catecholamines; and (*d*) tissue hypoxia from concurrent apnea. In general, the rhythm on presentation is the worst rhythm; however, there are some reports of life-threatening ventricular arrhythmias occurring up to 12 hours after technical electrocution.[50] Victims often develop hypovolemia and metabolic acidosis secondary to extensive fluid losses from cutaneous and deep tissue damage.

Lightning

Lightning is a transfer of electrical charge within a cloud, between clouds, or between the ground and clouds. Rising air within a thundercloud carries positive charges to the top and leaves negative charges at the bottom layer of the cloud. The electrical potential forces an invisible conductive path between negative charges from the cloud to the positively charged earth and a return charge from the

Table 64.3. Differences between low-volt and high-volt technical electricity and lightning regarding voltage, amperage, duration, common tissue pathway, and injury type

| Characteristic | Technical electricity | | Lightning |
	Low-volt	High-volt	
Type of current	Alternating (AC)	Alternating (AC)	
	Direct (DC)		Electrical impulse
Voltage (V)	< 1000 V	1000 to 380 000 V	up to 1 billion V
Amperage (A)	10 to 15 A	up to 1000 A	> 200 000 A
Duration (s)	Variable	Variable	0.0001 to 0.001 s
Tissue pathway	Superficial tissue	Deep tissue	Skin flashover
Injury type	Cardiac rhythm	Burn, shock	Trauma: blunt, thermal, explosive

earth to the cloud. Contact of charges is followed by a visible surge of electricity. As air is a poor conductor of electricity even when humidity is high, discharge of electrical energy will not occur until a potential difference of 30 000 volts or higher exceeds the inherent resistance of the air.

Once at the surface, lightning can harm people in various ways. A direct strike is the most dangerous type and occurs when the primary contact point is on the victim's body. A splash strike is the most common and occurs when an object such as a tree or car is struck primarily, before the strike enters a person. A ground strike can harm the victim when the lightning bolt has struck the ground and the spreading current makes contact through the feet. Rapid heating of air and explosive expansion of atmospheric gases of the surrounding air create shock waves with the typical "sledgehammer effect" of lightning.[28,51]

The direct current lightning strike differs from the more common alternating current electrocution in several ways (Table 64.3). A single lightning bolt can transfer up to 1 billion volts with 200 000 amperes of current. Because of the short duration of approximately 0.0001 to 0.003 second, the resistance of the skin is protective and a relatively small amount of energy is delivered.[28] In addition, high current tends to travel along the outside of a conductor. Sweat, rainwater and metallic materials in the victim's dress contribute to increased peripheral conductivity. Burns may occur from heated metal objects close to the skin and clothing. The superficial current pathway often resembles a skin flashover, leaving a typically fern leaf-patterned superficial sign. Internal current flow leading to deep tissue necrosis is uncommon and fluid requirements are usually low.[28] Reported blunt injuries include myocardial, pulmonary, and abdominal visceral contusion, tympanic membrane rupture, and orthopedic injury.

Clinical manifestations

Victims of electrical shock can sustain a wide variety of injuries, ranging from a transient unpleasant sensation to cardiac arrest. Respiratory arrest may be caused by electric current passing through the brain, by tetanic contraction during exposure, and by prolonged paralysis of respiratory muscles. The electrically injured patient often presents with multisystem injury, either directly related to the electrical shock or secondary to concurrent trauma.[9] Such injuries include burns, fractures, dislocations, contusions, hemorrhage, visceral injury and neurological injury. Thus, the clinician who evaluates a victim of electrical injury must be highly suspicious of secondary injuries.

Technical electricity

Clinical signs and symptoms after electrical injury to the heart can be atypical, delayed in onset, or obscured by other trauma.[50] The physiological response varies depending on magnitude of amperage and whether current was direct or alternating (Table 65.2). Alternating current at low voltage is frequently associated with arrhythmias, varying from ectopic beats, atrial fibrillation, sinus tachycardia or bradycardia, to ventricular fibrillation and asystole.[52] The underlying cause of cardiac arrhythmia may be direct damage to the myocardial cell, hypoxia secondary to central respiratory arrest, or extensive catecholamine release. Myocardial damage can be caused directly by the current and the heat it produces and indirectly by decreased perfusion secondary to coronary artery spasm or unstable arrhythmias.[53]

High-voltage electric shocks are prone to provoke asystole, but non-specific changes in ECG, including prolongation of the corrected QT interval, transient ST segment inversion or elevation, are observed in up to half of all

patients.[54,55] CK-MB levels may be elevated, but myocardial necrosis is rarely diagnosed.[22,56] In non-survivors, however, histopathologic investigation of the heart may reveal widespread focal necrosis involving the entire myocardium, including the specialized tissue of the sinus and atrioventricular nodes.[57]

Relatively low levels of current across the chest are enough to cause tetanic spasm of the respiratory muscles. Current passing through the brain can directly damage the medullary respiratory center.[43] Consequent respiratory arrest may resolve spontaneously or lead to secondary cardiac arrest due to asphyxia.[54] Cases of pulmonary edema and respiratory distress syndrome have been reported after electrocution.[58]

Transient damage to the nervous system occurs in up to 70% of electrical injuries. Neurological deficits include coma, seizure, blindness, deafness, and aphasia.[59] Delayed and persistent neuropathy is common. High-voltage electrical injury may cause cerebral vein thrombosis with significant early and delayed brain and spinal cord injury. Spinal involvement indicated by ascending paralysis, spastic paraplegia and associated sensory loss has been reported. Patients may suffer from emotional lability, anxiety reactions, loss of appetite and libido, sleep disorders, depression, post-traumatic stress disorder, and psychosis.[10,34,60]

Musculoskeletal and cutaneous injuries dominate the clinical picture. Low-voltage current, especially alternating current, can lead to sustained muscular contractions and subsequent fracture of adjacent bones or dislocation of affected joints. Severe burn injuries are frequently complicated by damaged deep tissues.[61] Extensive myonecrosis, compartment syndrome, thrombosis, may be associated with cyanotic and pulseless limbs. Early radical fasciotomy and debridement may allow better salvage rates of functional limbs and a reduction in systemic effects such as hypotension, infection and sepsis.[5,14,62] Amputation of one or more limbs may be indicated.[63] Massive tissue necrosis leading to rhabdomyolysis and myoglobinuria may cause acute tubular necrosis. Consequent renal shutdown is more likely after volume depletion and prolonged shock.[64]

Lightning

No large series of cases treated by one institution is available to provide sufficient information on the variety of clinical features in lightning victims. There are, however, a few characteristics that appear to be pathognomonic for lightning.[65] Factors that tend to be in the victim's favor are the very short duration of a lightning strike and because the favored pathway for a majority of the current is along the skin on the outside of the body. There are reports of

prolonged, successful cardiopulmonary resuscitation in lightning victims who initially had non-responding cardiac dysrhythmias.[6,10]

Changes in heart rhythm are common, but generally resolve. A direct hit may cause myocardial damage, pericardial effusion, conduction disturbances, or dysrhythmia.[7] The entire myocardium is simultaneously depolarized, and the heart is thrown into a forceful, sustained contraction until current flow ends. In many cases, cardiac automaticity inherent in the myocardium may restore an organized rhythm with spontaneous circulation. Secondary cardiac impairment can occur due to release of catecholamine or autonomic stimulation. ECG may reveal non-specific changes; only direct hits result in a prolonged QT interval or abnormalities revealed by echocardiography. Severely decreased left and right ventricular ejection fraction has been observed, but can be reversible.

Respiratory arrest due to paralysis of the medullary respiratory centers is common. It can outlast the duration of the cardiac arrest and may lead to secondary hypoxic cardiac arrest.[4,30] Contusion of the lungs can occur with pneumothorax or hemothorax. Bronchospasm and pulmonary edema after lightning strike have been reported.[66]

The low resistance of nervous tissue explains its increased vulnerability in lightning strike. Neurological findings vary from short-term loss of consciousness and transient paralysis to coma, seizure, increased intracranial pressure, or even intracranial hemorrhage.[67] Neurological deficits may present as blindness, deafness, and aphasia. Sequelae, e.g., confusion, amnesia, agitation, mood disturbance, sleep disturbance, anxiety attacks, fear, pain syndromes, major depression, and frank psychosis have been reported in victims of lightning strike.[68]

Blunt trauma may be caused by the shock wave produced by lightning. Muscle contractions caused by the current may result in fractures and dislocations.[28,68] Limb paralysis with sensory symptoms, pallor, coolness, and absent pulses may occur from intense vasospasm (keraunoparalysis) due to autonomic nervous system dysfunction. Initially cyanotic and pulseless limbs, however, are prone to revert spontaneously to normal. Delay of fasciotomy for several hours is reasonable.

The gastrointestinal tract can be afflicted with ileus, contusion, or perforation, and the kidneys are susceptible to decreased clearance compounded with a myoglobin load from muscle breakdown.

In victims of lightning strike, burns of any degree can injure the skin, but the extremely short flashover, extensive burns and tissue destruction are uncommon.[69] The external path of the direct current may show an arborizing or fern leaf pattern. Ruptured tympanic membranes from shock

Table 64.4. Distinctions in sequence of resuscitation between low volt, high volt and lightning associated injuries

| Characteristic | Technical electricity | | Lightning |
	Low-volt	High-volt	
Emergency call	Nature and intensity of injury	Nature and intensity of injury Need for expert personnel	Nature and intensity of injury Limit call time by conventional telephone during thunderstorm
Self-protection	Unplugged electrical device Switched-off power line Switched off fuse	Keep minimum distance of 10 m unless power line was switched off by expert personnel and visibly grounded	Avoid locations with high risk of lightning Avoid proximity on site
Triage	Conventional	Conventional	Modified
Spine protection	Immobilization, if indicated	Immobilization mandatory	Immobilization mandatory
External cooling	Not indicated	Cool water on 1° and 2° burn area of less than 30% for up to 10 min Remove smoldering clothes	Not indicated
Airway management	Conventional	Early tracheal intubation and ventilation in orofacial edema	Avoid hypoxic cardiac arrest by early ventilation
IV access	Single peripheral IV access	Multiple large-bore IV lines	Single peripheral IV access
IV fluid administration	IV fluid administration restricted	IV 4–7 ml/kg per day x % burn	IV fluid administration restricted
CPR onset	CPR during extrication	CPR during extrication	Delayed onset after initial ventilation if necessary
CPR termination	Conventional	Conventional	Modified
Referral	Intensive care unit	Trauma/burn center	Trauma center

waves and damage to cornea or retina are common in lightning victims. Cataracts can occur from a few days to several months after the lightning strike.

Clinical case reports suggest that resuscitation may be successful in victims of lightning strike, even when the interval between arrest and therapy is prolonged and refractory rhythms (e.g., asystole) are present.[70] To explain this observation, it was hypothesized that lightning causes cellular metabolism to cease temporarily, thereby delaying the onset of anoxic tissue damage and reducing the potential for irreversible cardiac and cerebral injury. No basic or clinical scientific data are available to validate this assumption.

Resuscitation

Cardiac arrests induced by both natural and technical electricity require special treatment and management of current-induced casualties differs according to whether their injuries are caused by low-voltage, high-voltage, or lightning (Table 65.4). Generally the degree of cardiac and neurological malfunction after primary successful

resuscitation correlates with duration of cardiac arrest time.[71] Special treatment recommendations for lightning and electrical injuries have been based on case reports rather than laboratory and clinical investigations. There are reports supporting the thesis that in victims of electrical injury, resuscitation may be effective even after a prolonged interval between the electrical injury and the resuscitative attempt.[4,6] Because the victims are often young and have no co-morbid diseases, reports that good outcomes may occur after long arrest times are compelling reasons to sustain resuscitation efforts.

Emergency call and response

Information about the likely number of victims and the type of injury must be provided immediately to the dispatch center to ensure early EMS arrival on the scene. If expert personnel are needed in the case of high-voltage accidents it must be recognized early. Furthermore, the dispatch center can give CPR instructions. During a thunderstorm calls by conventional telephone should be kept as short as possible, and only wireless calls by cell phone or radio are regarded as safe.[38] The person calling must stay

on the line with the dispatch center and must not disconnect the line of communication.

Modified triage

Rapid triage and early emergency medical treatment are mandatory if numerous victims have been severely injured following electrocution. Whenever the number of patients exceeds the capacity of rescue personnel, the lowest priority is given to those without a palpable pulse.[72] In lightning, when two or more victims are struck simultaneously, standard triage principles are reversed: highest priority is given to those without a palpable pulse, rather than to victims who are awake but confused.[4] It is unlikely that those who survived the initial injury will develop delayed life-threatening conditions. If there are many injured patients, triage extends to the use of monitoring equipment as well. While pulsoxygraphy is adequate for initial observation of an unconscious patient, ECG may be applied when the patient is awake.

Discontinuing exposure and evacuation

Unlike the victims of lightning strike, patients experiencing technical electrocution should be assumed still to have current flowing through them. The victim may still be gripping the live wire or object because of tetanic spasm of the flexor muscles. For low-voltage electrical injury, electrical sources must be turned off, unplugged, or carefully removed with rubber or wooden instruments before rescue is attempted. If electrical shock occurs in a location that is not readily accessible, such as while the victim is atop a utility pole or is swimming, effective CPR attempts will not be possible until the victim is extricated.[73] The spine should be immobilized and remain so during out-of-hospital emergency treatment as patients frequently fall, resulting in a high incidence of neck trauma.[3,74]

In high-voltage incidents the rescuers must wait at a distance until expert personnel have turned off and visibly grounded the power supply. Unidentified current is regarded as high-voltage unless expert personnel disagree. The recommended safe distance from the electrical transmission lines is at least twice the distance from the insulator to the utility pole, with a minimum of 10 meters.[75]

During a thunderstorm, rescuers are cautioned to minimize their exposure to lightning as much as possible. Victims of lightning carry no electrical charge and can be touched safely immediately after the strike. On the other hand, the lightning strike indicates that the situation might still be dangerous. If providing CPR takes the rescuer to the highest point in the midst of a severe storm, then addi-

tional casualties may occur. In most cases, however, the risk to rescuers in treating the victims of lightning strike is minimal. If the injury occurs on moist ground or in water, it is acceptable to give a few quick breaths before moving the patient to a safer place and starting CPR. A protective layer between patient and ground may diminish the risk of hypothermia. Spinal protection and immobilization should be maintained during extrication and treatment if head or neck trauma appears to be likely.

Cardiopulmonary resuscitation

When cardiac arrest occurs in remote locations that are far from medical care facilities, response times for professional rescue are prolonged. The principles for management of electrically injured victims[76] and victims of lightning[77,78] include ensuring rescuer safety and providing for CPR to be started immediately by bystanders. The goal is to oxygenate the heart and brain adequately until cardiac activity is restored. The sequence of actions follows the International Guidelines for Basic Life Support (BLS) and Advanced Life Support (ALS) with respect to electric shock and lightning strike.[79,80]

BLS

In victims of high-voltage current with first and second degree burns of less than 30% body surface, further extension of thermal injury should be avoided by applying copious amounts of cool water to the burned area. Cold water should not be used as it induces vasoconstriction and consequently increases the afterburn effect. Application is restricted to 10 minutes to avoid further harm from hyper- or hypothermia. Smoldering shoes, belts, and clothes should be removed unless they are stuck to burn lesions. If the victim is not breathing spontaneously, emergency medical service (EMS) system activation, prompt CPR and, if available, use of automated external defibrillator (AED) are initiated by bystanders. Basic life support by mouth-to-mouth ventilation together with cardiac compression in the ratio 2:30 is started. As soon as circulation returns, ventilation should be continued until sufficient spontaneous breathing is restored.

ALS

When advanced life support can be established, the initial cardiac activity is quickly assessed by using defibrillator paddles or self-adhesive electrode pads. The two defibrillator paddles or electrode pads are placed one below the right clavicle and the other at the opposite lateral chest wall with the heart maintained in the center between the two paddle surfaces. The rhythm on the monitor is determined as being

either shockable, e.g., ventricular fibrillation or pulseless ventricular tachycardia, or non-shockable rhythm. With shockable rhythm it has to be ensured that everybody is clear of the patient. A one-shock strategy and immediate resumption of effective chest-compressions after each shock may improve outcome by reducing interruptions of CPR.[80] The total number of countershocks and the power applied should be kept to a minimum because myocardial injury may be cumulative.[81] The chance for successful defibrillation increases when coronary perfusion can be improved prior to defibrillation.[82] When rhythm is non-shockable, CPR is continued and signs of circulation, e.g., palpable carotid pulse, are repeatedly checked for.

Airway management

Patients with insufficient and absent breathing should receive immediate ventilatory support with positive pressure ventilation and a high inspired oxygen concentration, preferably 100%. When administering oxygen on site, a safe distance to burning or hot objects must be maintained. A secure airway is established early, and the gold standard is tracheal intubation. This allows adequate mechanical ventilation and the administration of emergency drugs, with the exception of sodium bicarbonate. A definitive airway is also important in patients with burns of the face, mouth, or neck or whenever inhalation injury is expected. Intubation should be accomplished on an elective basis before signs of airway obstruction become severe. With high-voltage injury, in particular, extensive soft tissue swelling may develop rapidly and compromise the airway and breathing, necessitating emergency cricothyroidotomy or tracheotomy. Airway protection and ventilation are particularly important in lightning victims as the critical factor in mortality from lightning is the duration of respiratory arrest rather than the time of circulatory standstill.[4]

Drug treatment

Drug treatment including vasopressors, inotropic support, and other standard therapies are administered as needed. Close monitoring of patient response is important. Once return of spontaneous circulation has been achieved, further therapies may be started. Dosages and administration schedules do not differ from general recommendations, but it is not clear whether the application of therapies that depend on cardiac electrophysiology, such as antiarrhythmic drugs and cardiac pacing, is altered by the preceding electrical injury.

Venous access

Peripheral venous cannulation, e.g., via the external jugular vein, is usually sufficient to establish vascular access, but central veins are the optimal route for delivering drugs rapidly into the central circulation and for administering infusions. This applies especially to patients with high-voltage injuries, who may have severe burns and significant tissue destruction.

Fluid administration

Vigorous fluid therapy in the early phase of resuscitation with crystalloids (preferably normo-saline solution) is critical to both immediate survival and ultimate outcome. Colloids are not recommended in patients with severe burns unless multiple systems are injured. Colloids potentially increase edema and therefore could add to secondary tissue damage. Fluid requirements are often greater than those estimated by the Parkland formula, because severe burn and extended tissue damage frequently occur together. Infusions should be continued after successful resuscitation at a rate between 4 and 7 ml/kg per % body surface area burned per day.[83]

From emergency medical point of view, this is about 1 l of crystalloids per hour in adults (children: 10 – 15 ml/kg per hour) unless additional injuries other than burns increase the volume demand. Fluid administration should be adequate to maintain diuresis to facilitate excretion of myoglobin, potassium and other by-products of tissue destruction. Lightning victims generally do not require volume expansion, and indeed this can worsen the cerebral edema that commonly accompanies the injury.[4] Once spontaneous circulation is reestablished, intravenous fluid therapy must be restricted.

Prognosis

The various reports of good outcomes even after prolonged arrest times justify early transport and continued CPR en route to the hospital.[6] Heroic therapies such as open chest CPR may be effective in some patients.[84]

Referral and definitive care

Generally, hospitalization is advised for all victims of electrical trauma as the magnitude and severity of internal tissue damage cannot be accurately gauged from external examination alone. Particular attention should be paid to the development of compartment syndrome, hyperkalemia, myoglobinemia and renal injury. Sequelae of internal tissue injury tend to occur along the path of current flow. Furthermore, all victims of electrical injury require a complete neurologic assessment. Delayed neurological injury is common in victims of both lightning and technical electrocution. As soon as the patient's condition has stabilized, smooth and quick transport to the most suitable

intensive care center should be arranged. Victims of high-voltage injury are transferred to the trauma and burn center. Patients who have been struck by lightning are regarded as trauma patients and are transferred to the trauma center. Continuous monitoring of vital signs during transport is mandatory.

Rare syndromes, commotio cordis, sudden death in athletes

Tommaso Pellis[1], Mark Link[2], Charles Antzelevitch[3], and Peter Kohl[4]

Introduction

Athletes deliberately expose themselves to extreme environments (such as high altitude mountaineering and deep-sea diving) and physical challenges (from weight lifting to marathon running), which may give rise to the manifestation of rare cardiac conditions, or cause sudden death (SD). Indeed, the renowned Athenian long distance runner Pheidippides suffered SD in 490 BC after running from the battlefield of Marathon to Athens to announce the great victory of the Greeks over the invaders.

An analysis of the very dissimilar physical and environmental conditions to which athletes are exposed, and related health risks, is beyond the scope of this chapter and will not be conducted. Instead, we will focus on SD from cardiac causes.

Incidence

Sudden cardiac death

It is commonly understood, and substantiated by clinical evidence, that regular moderate physical exercise has beneficial cardiovascular effects.[1] Several prospective epidemiological studies consistently associate exercise with a reduced risk of coronary artery disease (CAD) and sudden cardiac death (SCD).[2,3]

The incidence of SCD in adolescents and young adults (here defined as the age group < 35 years) is about 1 in 100 000 per year;[4] this is 100 times less than in the older population (1 in 1000 per year; Fig. 65.1).[5] Predominant causes of SCD in athletes change with age. In those over

35 years of age, the most common etiology is atherosclerotic CAD, often severe and diffuse, even in individuals without known risk factors or symptoms.[6] In contrast, in younger athletes, a variety of cardiac diseases, largely congenital and often rare, account for the majority of SCD.[4,6–8]

Despite the above-mentioned general health benefit of regular exercise, young athletes can have a *higher* incidence of SD than age-matched non-athletes.[10] Thus, Corrado *et al.*[4] found in the Veneto region of Italy that the SCD incidence in athletes was 2.8 times that of non-athletes (all aged 12–35 years), demonstrating that *competitive sports activity* can actually enhance the risk of SD (Fig. 65.2). Young competitive athletes who died suddenly were primarily affected by silent cardiovascular diseases, predominantly cardiomyopathies, premature CAD, and congenital coronary anomalies (Fig. 65.3). Sports activity, in this context, is therefore not *per se* a cause of the increased mortality; rather, it triggers manifestation of underlying cardiovascular diseases, predisposing athletes to life-threatening ventricular arrhythmias during physical exercise.

In keeping with this view, up to 90% of deaths among young athletes occur during training or competition.[4,7] For this reason, unexplained syncope in young athletes in the context of exercise should be taken very seriously indeed (presuming an "aborted SD"), unless proven otherwise.

Furthermore, current evidence suggests a gender difference of SD in athletes, with a striking male predominance (male-to-female ratio 10:1; Table 65.1).[4,7,11] This predominance of fatal events in male athletes was initially explained by the lower number of females participating in competitive sports. Male gender is in itself a risk factor for sports-related SD, however, as demonstrated by Corrado
Fig. 65.1. Age-related and disease-specific risk for SCD. For the general population (35 years of age and older) the SCD risk is 0.1 to 0.2% per year (1 per 500 to 1000). In adolescents and adults younger than 30 years, the overall risk of SCD is 1 per 100 000, or 0.001% per year. The risk of SCD increases dramatically beyond the age of 35 years and continues to rise. CM = cardiomyopathy; VF = ventricular fibrillation. (With permission from ref. 9.)

et al.[4] Compared to females, male athletes are generally exposed to more intense training and higher levels of intensity during competition, and they have a greater prevalence and/or phenotypic expression of cardiac diseases with risk of arrhythmic cardiac arrest, such as cardiomyopathies[12] and premature CAD in the given age range.[13] Moreover, there appear to be gender differences in mechanisms underlying cardiac electrophysiology, such as a lower level of the transient outward current in females, which could serve to protect them from arrhythmogenic SD linked, for example, to the Brugada syndrome.[14] A role for sex hormones has been conjectured in this and other ion channelopathies.[15]

Based on the Minneapolis Heart Institute Foundation registry, Maron *et al.*[16] report that a majority of athletes who died suddenly of hypertrophic cardiomyopathy (HCM) were African Americans (55%; Fig. 65.4). This predominance is unlikely to be solely attributable to differences in relative rates or types of sports participation compared to other ethnic communities. It is possible that HCM in African Americans represents a more virulent form of the disease, perhaps due to a malignant genetic substrate when associated with exercise,[17] thereby predisposing to SD on the athletic field. In contrast, arrhythmogenic right ventricular cardiomyopathy (ARVC) and aortic valve
Fig. 65.2. Incidence and relative risk (RR) of sudden death (SD) among athletes (solid columns) and non-athletes (open columns) from cardiovascular and non-cardiovascular causes. Athletes had a 2.8 RR of cardiovascular SD (confidence interval [CI] 1.9 to 3.7; $P < 0.001$) compared to 1.7 RR of non-cardiovascular SD (CI 0.3 to 5.7; $P = 0.39$). (With permission from ref. 4.)

stenosis are both significantly more common in white than in African American athletes (Fig. 65.4).[16]

Despite a number of investigations, the *actual* incidence of SCD in adolescents and young adults in

Table 65.1. Characteristics of sudden death victims

	Athletes (*n* = 55)	Non-athletes (*n* = 245)	*P* value
Mean age (yrs)	23.1 ± 7	23.9 ± 9	1.0
Gender			
Males	50	170	0.002
Females	5	75	
Circumstances of death			
Exercise-related	49 (89%)	22 (9%)	< 0.0001
During effort	40	15	
After effort	9	7	
Unrelated to exercise	6 (11%)	225 (91%)	
Medical history			
Familial history of SD	5 (9%)	27 (11%)	0.8
Previous symptoms	18 (32%)	56 (23%)	0.2
ECG abnormalities/ arrhythmias	22 (40%)	36/63 (57%)	0.1

Data are presented as the mean value ± standard deviation or number (%) of subjects. ECG = electrocardiographic; SD = sudden death.

Table 65.2. Causes of sudden death in 387 young athletes in the USA

Cause	Number of athletes	Percent
Hypertrophic cardiomyopathy	102	26.4
Commotio cordis	77	19.9
Coronary-artery anomalies	53	13.7
Left ventricular hypertrophy of indeterminate causation[a]	29	7.5
Myocarditis	20	5.2
Ruptured aortic aneurysm (Marfan's syndrome)	12	3.1
Arrhythmogenic right ventricular cardiomyopathy	11	2.8
Tunneled (bridged) coronary artery[b]	11	2.8
Aortic-valve stenosis	10	2.6
Atherosclerotic coronary artery disease	10	2.6
Dilated cardiomyopathy	9	2.3
Myxomatous mitral-valve degeneration	9	2.3
Asthma (or other pulmonary condition)	8	2.1
Heat stroke	6	1.6
Drug abuse	4	1.0
Other cardiovascular cause	4	1.0
Long-QT syndrome[c]	3	0.8
Cardiac sarcoidosis	3	0.8
Trauma involving structural cardiac injury	3	0.8
Ruptured cerebral artery	3	0.8

Data are from the registry of the Minneapolis Heart Institute Foundation.[16]

[a] Findings at autopsy were suggestive of hypertrophic cardiomyopathy but were insufficient to be diagnostic.

[b] Tunneled coronary artery was deemed the cause in the absence of any other cardiac abnormality.

[c] The long-QT syndrome was documented on clinical evaluation. With permission from ref. 18.

competitive sports remains controversial. The issue has been addressed primarily in the United States (US) and in Italy, two very different countries with dissimilar racial and genetic backgrounds, scope of popular sports activities, screening regulations, and health care provision. The reported annual prevalence of athletic field deaths ranges from 0.5 in 100,000 in US high-school athletes in Minnesota[11] to 2.3 in 100 000 in Northern Italy.[4]

In the majority of US reports that include autopsy data, HCM is the most common underlying disease linked to these deaths (Table 65.2).[6,7] In contrast, HCM is uncommon in Italian studies of SD on the athletic field. A probable reason for this difference is the compulsory pre-participation screening of young athletes, which leads to early exclusion of HCM sufferers from competitive sports. Instead, diseases that are more difficult to screen, such as ARVC, have become the most common causes of SCD in North-Italian athletes (Table 65.3).[4,8]

It is interesting, however, that in spite of the apparently efficient pre-participation screening program, the overall incidence of SCD is higher in Italy than in the US. Among a number of possible explanations are differences in population background (both biological and social), sports participation (range and type of activities), reporting, and others. In addition, a high prevalence of genetic predisposition to ARVC in Italy, particularly in the Veneto region, may play a role, and this clearly warrants further investigation. Another surprising facet is the observation

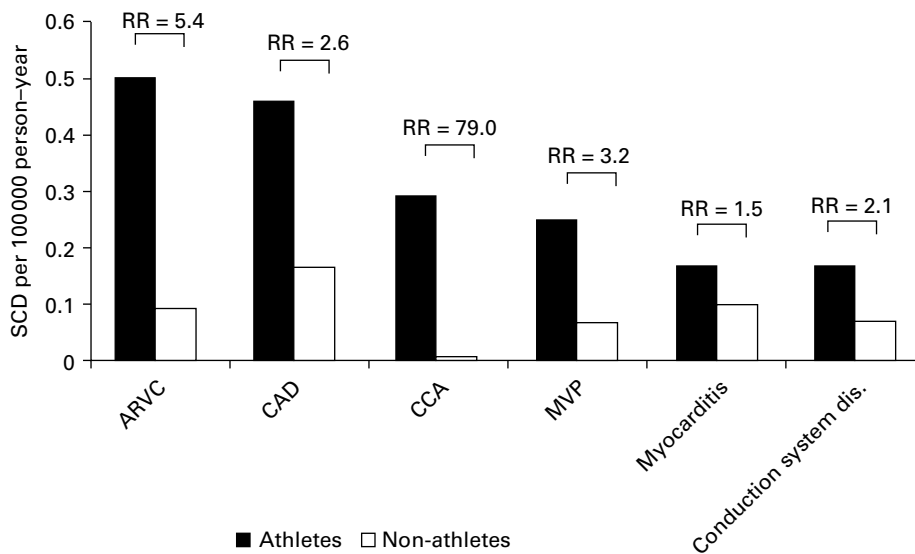
that SD rates in young US athletes are apparently lower than in the age-matched general population (the data collected in the respective studies may be affected by ethnic and socioeconomic differences in the population sampled, e.g., athletes in the Minnesota area may not be representative of the general US population). Equally deserving further investigation is the fact that Italian athletes are at such a relatively high risk, compared to age-matched non-athletes, despite efficient pre-screening for HCM and other cardiovascular conditions (ARVC may


Fig. 65.3. Incidence and relative risk (RR) of sudden cardiac death (SCD) among athletes and non-athletes from: arrhythmogenic right ventricular cardiomyopathy (ARVC), coronary artery disease (CAD), congenital coronary artery anomaly (CCA), mitral valve prolapse (MVP), myocarditis and conduction system disorders. (With permission from ref. 5.)
Fig. 65.4. Impact of race on cardiovascular causes of sudden death. Ao = aorta; ARVC = arrhythmogenic right ventricular cardiomyopathy; CAD = coronary artery disease; HCM hypertrophic cardiomyopathy. (With permission from ref. 16.)

present a particular exercise-induced risk that has yet to be identified).

Before speculating on any of the above differences, it is clear that currently available incidence numbers should be interpreted with care. Thus, Maron *et al.*[11] investigated the annual incidence of SD from undiagnosed cardiovascular disease based on a longstanding insurance program for catastrophic injury or death in Minnesota. The reported incidence of SCD was 1 in 200 000 high-school athletes participating in organized sports. This estimate is based on three episodes of SCD over a 12-year period (with such small case numbers, the actual observation period

Table 65.3. Causes of sudden death in athletes and non-athletes 35 years of age or less in the Veneto region of Italy 1979–1996

Cause	Athletes (N = 49)	Non-athletes (N = 220)	Total (N = 269)
	number (percent)

profoundly affects calculated incidence), and all victims were male (so that the incidence in female athletes remains unknown). Another example of how small numbers may hamper interpretation of SD incidence is the attempt to establish such risk in marathon runners.[19] Out of 215 413 runners who completed the Marine Corps Marathon over a period of 19 years (1976 to 1994) and the Twin Cities Marathon (1982 to 1994), only 4 exercise-related SD occurred. Nonetheless, all deaths were clustered in the last 9 years of observation; thus, if reported during the first 10 years (1976 to 1985) the incidence would have been 0, whereas during the last 10 years it would have almost doubled (compared to the 19 years data).

Assessment of the precise SD frequency in young athletes is further complicated because most previous studies were retrospective. This may have resulted in an underestimation of the true prevalence of sports-related SD, because such studies rely on reporting from individual schools and institutions, or media accounts.[7] Moreover,

limited or missing information on pre-participation screening, and on the number of athletes barred from competition on health grounds, influences outcome.

These limitations were largely avoided in the previously mentioned 21-year prospective cohort study of all inhabitants of Veneto, a region in northeast Italy.[4] According to Italian sports medicine guidelines, athletes aged 12 to 35 years who are participating in organized sports requiring regular training and competition *must* undergo annual screening of their medical history, a physical examination with 12-lead electrocardiogram, and limited exercise testing (as mandated by Italian law).[20] This population, for the 21 years of observation, provided 29 118 600 age-specific person-years. In all cases of SD, an autopsy was carried out (Table 65.4). After excluding non-cardiac causes of death, all hearts were fixed and forwarded to the Referral Center of Pathological Anatomy at the University of Padua for detailed morphologic assessment by a single institution. The subject's clinical history, athletic activity, and circumstances surrounding the cardiac arrest were recorded in each case.[4] The reported annual incidence of all-cause SD of 2.3 per 100 000 athletes, and of 2.1 per 100 000 athletes from cardiovascular diseases[4] will be fairly accurate for the given population, but probably should not be extrapolated to either the whole Italian population, or other countries.

Sudden non-cardiac death

Non-cardiac SD in athletes has been reported from extreme hyperthermia (heat stroke);[21] head and spine trauma (football players, pole vaulters); uncontrolled bronchial asthma;[4] ruptured cerebral artery aneurysm;[4] sickle cell trait;[22] or drug abuse.[16] The incidence of non-cardiac SD is 6% in (prescreened) Italian athletes,[4] and exceeds 33% (198 out of 584) in the US.[16]

Sudden cardiac death involving structural abnormalities

Hypertrophic cardiomyopathy

General

HCM is a complex and relatively common genetic disorder, characterized by an asymmetrically hypertrophied, non-dilated left ventricle, with heterogeneous clinical, morphologic, and genetic expression (Fig. 65.5).[23] The prevalence of phenotypically expressed HCM in the adult general population is about 0.2% (1 in 500).[23] This excludes a probably

substantial proportion of individuals harboring a mutant gene for HCM without clinical symptoms.

HCM is a unique cardiovascular disease with the potential for clinical presentation during any phase of life, from infancy to old age. The clinical course is typically variable and may cause disability or death; indeed, patients may remain stable over long periods of time, with up to 25% of HCM sufferers achieving normal longevity (Fig. 65.6).[25] Nevertheless, HCM is also a prominent cause of SCD in the young, including athletes.[7,26] SCD may actually be the first disease presentation in asymptomatic or mildly symptomatic young people.[7,26,27] Death may occur during mild exertion or sedentary activity including sleep, but it is not infrequently triggered by vigorous physical exertion.[7] Indeed, in the US population, HCM is the most common cause of SCD in young people and competitive athletes (Fig. 65.7).[7]

Although the usual diagnostic criterion for HCM is a maximal left ventricular (LV) wall thickness ≥15 mm, genotype-phenotype correlations have shown that virtually any wall thickness, including values within the normal range, may be associated with presence of an HCM mutant gene.[17] Not all individuals harboring a genetic defect express clinical symptoms, such as abnormal electrocardiogram (ECG) and echocardiography, or impaired cardiac function.[17,30] Most commonly, substantial LV remodeling with spontaneous appearance of hypertrophy occurs with accelerated body growth during adolescence, and morphologic expression is usually complete at physical maturity.[31] In trained athletes, modest segmental wall thickening (13–15 mm) requires differential diagnosis between extreme manifestations of physiologically based "athlete's heart"[32,33] and mild morphologic expressions of HCM,[33] which can usually be conducted non-invasively.[32]

A distinctive clinical observation in some patients with obstructive HCM is the dynamic pressure gradient in the subaortic area that divides the left ventricle into high-pressure (apical) and a low-pressure (subaortic) regions (Fig. 65.8).[34] This form of dynamic subaortic obstruction is typically produced by mitral valve systolic anterior
Fig. 65.5. Gross pathological specimens of the cardiomyopathies. motion and septal contact[35,36] caused by drag effect[36] or possible Venturi phenomenon[35] and is responsible for a loud systolic murmur. Even if this feature attracted much attention, HCM is predominantly expressed as the non-obstructive phenotype (75% of patients show no sizable resting outflow tract gradient).[30,37]

In cases where a subaortic gradient is present, it is now generally accepted that values of ≥30 mm Hg, and associated elevation in LV pressure, reflect a true mechanical impairment to outflow, and are of pathophysiologic and prognostic importance for HCM patients.[28,39] Indeed, outflow obstruction is a strong, independent predictor of disease progression to HCM-related death (relative risk vs. non-obstructed patients: 2.0).[39] Treadmill or bicycle exercise testing in association with Doppler echocardiography has been proposed as the most physiologic and preferred provocative maneuver to identify latent gradients during and/or immediately following exercise for

the purpose of major management decisions, given that HCM-related symptoms are typically elicited with exertion.[40]

Genetics

HCM is an inherited, autosomal dominant trait and is caused by a mutation in any of the more than 10 identified genes encoding for components of thick or thin filaments with contractile, structural or regulatory functions (Fig. 65.9).[17] The close functional association of these proteins has resulted in consideration of diverse HCM spectra as a single disease entity and primary sarcomere disorder. Although DNA analysis for mutant genes is the most definitive method for diagnosing HCM, it is not yet a routine clinical strategy.[17] The substantial genetic heterogeneity, low frequency of individual mutations in the general HCM population, and methodological difficulties associated with identifying single mutations, have all hindered the

translation of genetic research into practical applications and routine clinical strategy, leaving mutation analysis confined to a few research-oriented laboratories.[40]

HCM may be initially suspected because of heart murmur,[7] positive family history, and new symptoms, or abnormal ECG patterns,[8] for example during sports pre-participation examinations.[8] Definite clinical diagnosis of HCM is best established with 2-dimensional echocardiography,[17,23,26] imaging the hypertrophied but non-dilated

LV chamber in the absence of another cardiac or systemic disease capable of producing the observed magnitude of hypertrophy (Fig. 65.10).[41]

Pathogenesis

Microscopic findings in HCM are distinctive, showing disorganized LV myocardial architecture, comprising hypertrophied myocytes with irregular shapes and multiple intercellular connections, often arranged in a chaotic order
Fig. 65.9. Drawing showing components of the sarcomere and mutations in hypertrophic cardiomyopathy. Mutations may impair protein interactions resulting in ineffectual contraction and thereby producing hypertrophy. or aligned at oblique and perpendicular angles, culminating in an irregular pattern (Fig. 65.11).[42] Such cellular disarray may be widely distributed and appears to be most extensive in young victims of the disease (Fig. 65.12(a)).[42] Abnormal intramural coronary arteries, characterized by thickened walls with increased intimal and medial collagen and narrowed lumen, may be regarded as a form of small vessel disease (Fig. 65.12(b)).[43] Such architectural alterations of the microvasculature and the expanded interstitial collagen compartment,[44] as well as mismatch between myocardial mass and coronary circulation are probably responsible for impaired coronary vasculature reserve[45] and bursts of myocardial ischemia,[45] leading to myocyte death and tissue remodelling in the form of patchy or transmural replacement scarring.[46]

Disorganized cellular architecture,[42] myocardial scarring,[46] and expanded matrix[44] probably serve as arrhythmogenic substrates, predisposing to life-threatening electrical instability. This substrate may give rise to primary ventricular tachycardia (VT) and ventricular fib-

rillation (VF), which appear to be the predominant mechanisms of SD.[27]

Life-threatening tachyarrhythmias can be provoked in HCM by a number of variables, either secondary to environmental factors, such as intense physical exertion, or alternatively intrinsic to the disease process. Physical exertion, in particular, can trigger a vicious cycle of increasing myocardial ischemia[45] and diastolic dysfunction,[47] possibly affected by outflow obstruction,[39] systemic arterial hypotension,[48] or supraventricular tachyarrhythmias[49] that lead to a decrease in stroke volume and coronary perfusion.

Moreover, HCM is not infrequently associated with cardiovascular congenital abnormalities which may contribute to, or account *per se* for, SCD. As documented by the Minneapolis Heart Institute Foundation registry, out of 102 athletes who died suddenly with documented HCM, 9 had associated abnormalities that may have contributed to death, including tunneled (bridged) left anterior descending coronary artery ($n = 7$) and coronary artery hypoplasia ($n = 2$).[16]

(With permission from ref. 24.)

Risk stratification

The highest risk for SCD has been associated with the following conditions: (1) prior cardiac arrest or spontaneously occurring and sustained VT;[50] (2) family history of premature HCM-related SD;[30] (3) identification of a high-risk mutant gene;[17] (4) unexplained syncope, particularly in young patients or when exertional or recurrent;[37] (5) nonsustained VT (of 3 beats or more and of at least 120 beats/min) evident on ambulatory (Holter) ECG recordings;[51] (6) abnormal blood pressure response during upright exercise which is attenuated or hypotensive, in patients less than 50 years old;[37,38] and (7) extreme LV hypertrophy with maximum wall thickness of 30 mm or more, particularly in adolescents and young adults.[26] The last mentioned risk factor derives from a continuous, direct relationship between maximum LV wall thickness and SD, which supports the magnitude of LV wall thickness as a determinant of the risk of SCD.[26] Impaired consciousness,

(a)   (b)

such as syncope or near-syncope, is a most striking clinical risk indicator and should never be underestimated.[28]

Finally, variability between ECG leads in measurements of QTc (QTc dispersion) is thought to reflect regional variations in myocardial recovery and excitability.[52] Subjects with HCM have greater QTc dispersion than control subjects,[53] and patients with ventricular arrhythmias have significantly larger QTc dispersion than patients without arrhythmias.[54] Increased QTc dispersion is therefore believed to be an important risk factor for SCD.[53]

Prevention and treatment

Intense physical exertion constitutes a SD trigger in susceptible individuals.[7] Therefore, to reduce risk, disqualification from most competitive sports has been recommended by a number of consensus statements for athletes with unequivocal evidence of HCM.[55,56]

In HCM, treatment strategies to reduce risk for SD have historically relied on drugs such as β-blockers, verapamil, and antiarrhythmic agents (procainamide and amiodarone).[51,57] Nevertheless, there is little evidence[57] that prophylactic pharmacological strategies reduce SD risk. Furthermore, because of its potential toxicity, amiodarone is unlikely to be tolerated throughout the long risk periods of young HCM patients. At present, implantable cardioverter-defibrillators (ICD) appear to be the most effective intervention for high-risk HCM patients.[27] In one multicenter retrospective study, ICD appropriately sensed and automatically aborted potentially lethal ventricular tachyarrhythmias by restoring sinus rhythm in almost 25% of a high-risk cohort, followed for a relatively brief period of 3 years.[27] This is in line with ACC/AHA/NASPE 2002 guidelines that recommend ICD

for primary SCD prevention (class IIb indication), and for secondary prevention after one cardiac arrest (class I indication).[58]

For adults and children with obstructive HCM and severe drug–refractory symptoms, ventricular septal myotomy–myectomy (Morrow procedure) has become an established operation, on the basis of the experience acquired throughout the past 40 years, and is regarded as the standard therapeutic option.[30,37,59] Nevertheless, only a small, though significant, proportion (5%) of the overall HCM population is truly eligible for the procedure.[37]

Arrhythmogenic right-ventricular cardiomyopathy

General

ARVC is a primary myocardial disease, characterized by adipose or fibro-adipose substitution of right ventricular (RV) myocardium. Originally considered a cause of RV failure,[60] ARVC was more recently found to be responsible for severe ventricular arrhythmias in adults[61] and SCD in young persons and athletes (Fig. 65.13(a)).[62] Although initially considered to be strictly confined to the RV, there is growing clinical evidence that, over time, the LV shares RV cardiomyopathic changes;[63] hence the definition of the World Health Organization of a disease "characterized by progressive fibrofatty replacement of RV myocardium, initially with typical regional and later global RV and some LV involvement" (Fig. 65.13).[64]

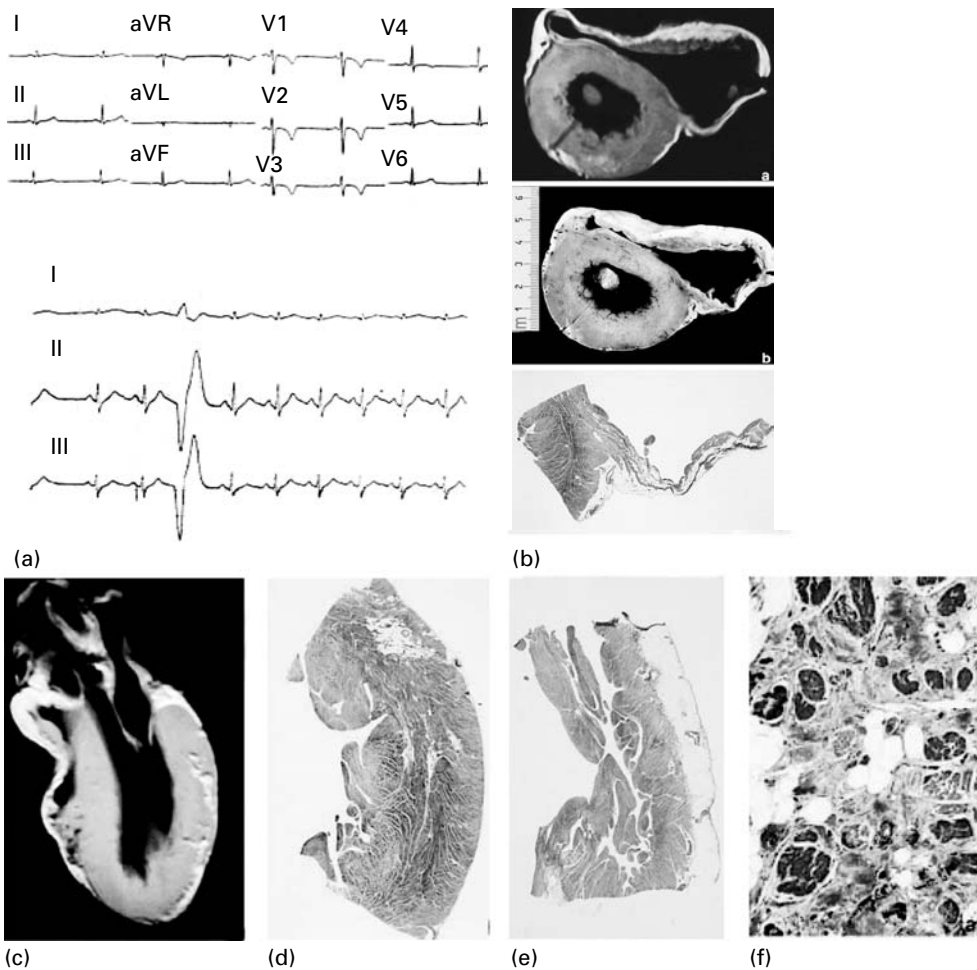
ARVC is associated with a high incidence of ventricular arrhythmias, including polymorphic non-sustained VT and VF, as well as recurrent sustained VT.[66] In a large proportion of victims (up to 80%), the first manifestation of the disease is "unexplained" syncope or SCD.[67]


Fig. 65.13. (a) An asymptomatic 17-year-old boy died suddenly during a soccer game. Retrospectively, the only signs of the disease were basal ECG T-wave inversion in right precordial leads up to V4 and an isolated premature ventricular beat of left bundle-branch block morphology during step test. (b) same case, in vitro NMR cross-sectional view showing a uniformly whitish right ventricular free wall with anterior and inferior aneurysms (note a spotty involvement of the posterolateral wall of the left ventricle); also, corresponding cross section of the heart specimen with infundibular and inferior subtricuspidal aneurysms, and panoramic histological view of the inferior aneurysm showing wall thinning with fibrofatty replacement. (c) in vitro NMR scan in the long-axis view showing extensive involvement of the anterior free wall of the right ventricle and patchy involvement of the posterior wall of the left ventricle; the interventricular septum is spared. (d) corresponding panoramic histological view of the left ventricle showing a spot of fibrofatty replacement of the myocardium. (e) control heart from a 20-year-old man who died in a motor vehicle accident. Panoramic histological view of the lateral free wall of the right ventricle: the fatty tissue is limited to the subepicardium and only slightly infiltrates the myocardium. (f) Myocardial atrophy with fibrous and fatty tissue replacement (Azan stains; original magnification B, D, and E ×2.5, F ×240; (With permission from ref. 65.)

The clinical diagnosis is formulated in patients with ventricular arrhythmias with a left bundle branch configuration,[68] abnormal T wave inversion and epsilon waves in the right precordial leads,[69] increased ventricular volume, localized or diffuse trabecular disarrangement with fibrous or fibrofatty replacement of myocardial tissue on endomyocardial biopsy,[70] and dynamic abnormalities of the RV free wall.[71] The characteristic progres-

sive loss of myocardium coincides with the onset of cardiac electrical instability. Clinicopathological data suggest a wide age range, spanning adolescence to adulthood, during which the disease may become symptomatic and fatal.[65,72] ARVC is diagnosed in 90% of cases after the age of 20 (usually before reaching 50 years), probably because it is concealed during earlier life.[72] Several disease stages have been identified, from an early clinically silent phase with or without minor arrhythmias and with myopathic abnormalities localized only to the RV, during which SD may be the first manifestation of the disease;[62] to an "overt electrical instability" with severe arrhythmias and impending cardiac arrest, characterized by segmental or global RV structural changes;[73] finally followed by "pump failure" characterized by biventricular cardiomyopathy mimicking dilated cardiomyopathy (DCM) with cardiomegaly, congestive heart failure requiring transplantation, and the risk of thromboembolic complications.[74]

It has been proposed that in some young people a sudden change from the subclinical to a clinical stage may produce life-threatening arrhythmias as the first symptom, suggesting that the juvenile form of ARVC is not benign.[75] The experience of SD as first clinical manifestation of ARVC in young people and athletes is in accordance with this hypothesis. In the adult, the disease probably reaches a stable phase in which abrupt changes in electrical instability are less common.

A history of cardiac arrest or VT with hemodynamic compromise, young age, and LV involvement have all been identified as independent predictors of VF.[76] SCD is often exercise-related, and in regions of the world where screening for HCM has excluded the affected athletes from competition, ARVC has emerged as the most common cause of sports-related SCD.[8]

In patients with ARVC, VF has been associated with active phases of myocyte death occurring in younger affected patients with progressive disease, whereas hemodynamically well-tolerated monomorphic VT is caused by a re-entry mechanism around a stable myocardial scar as the result of healing and remodeling processes that occur at a later stage of the disease course.[72] This view is reinforced by the finding that younger age is an independent risk factor for VF.[67]

Macroscopic or histologic LV involvement, or both, can be found in 76% of the hearts analyzed, thus confirming that ARVC affects the LV in the majority of cases. LV changes usually affect both the septum and LV free wall, either diffusely or, more often, regionally (Fig. 65.13(b) and (d)).[67] However, patients with isolated RV changes are younger and more often die suddenly without having

experienced warning symptoms compared to patients with coexistent LV abnormalities.[67]

Genetics

A genetic basis for ARVC is being explored. A large proportion of cases, up to an estimated 30%–50% appear to have a familial distribution.[67,77] The inheritance pattern is autosomal dominant, except for the geographically clustered *Naxos* disease (chromosome 17).[77] Autosomal dominant ARVC has been mapped to eight chromosomal loci on three putative genes. These genes link ARVC to mutations in the *RYR2*-gene[78] which encodes the sarcoplasmic calcium release channel (aka Ryanodine Receptor [RyR]; the same gene is also implicated in familial catecholaminergic polymorphic ventricular tachycardia [CPVT]), and the *DSP* and *JUP*-genes which encode for the cell adhesion proteins desmoplakin and plakoglobin, respectively.[79]

Risk, prevention and treatment

During the concealed phase, affected young persons involved in sports activities are particularly vulnerable to electrical instability with risk of cardiac arrest; early recognition is thus a medical challenge, and exclusion from all sports is mandatory.[65,67]

A large observational study that addressed the clinical impact of ICD therapy on the natural history of patients with ARVC treated for prevention of SD[76] demonstrated that a history of either cardiac arrest or VT with hemodynamic compromise, young age, and LV involvement are independent predictors of potentially lethal ventricular arrhythmias and can help in identifying those ARVC patients who would benefit most from ICD implantation. The major finding was that nearly half the patients ($n = 64$) had at least one episode of ventricular tachyarrhythmia that required ICD intervention despite antiarrhythmic drug therapy over a mean follow-up period of 3.3 years, and 24% experienced VF that, in all likelihood, would have been fatal without termination by the device (Fig 65.14). This high incidence of ICD interventions is in agreement with data from smaller series of patients with ARVC previously reported.[80] Moreover, the majority of appropriate ICD interventions occurred despite concomitant therapy with sotalol, amiodarone, or β-blockers (alone or in combination).[76]

Coronary artery abnormalities

A variety of congenital coronary artery anomalies represent common causes of exercise-related SD in young athletes.[4,8] Corrado *et al*.[4] report 9 out of 55 SD in athletes
Fig. 65.14. Kaplan–Meier analysis of actual survival of ICD-implanted patients, compared with the predicted survival in the same population if no ICD interventions had occurred (assuming that ventricular fibrillation/flutter would, if untreated, have been lethal). Divergence between lines reflects estimated survival benefit of ICD therapy. (With permission from ref. 76.)

Fig. 65.15. Congenital coronary artery anomaly of wrong aortic sinus origin, which may cause SD in young athletes. **Top**, Anomalous origin of the left main coronary artery arising from right (anterior) sinus of *Valsalva*. Note acute leftward bend of left main coronary artery at its origin and its posterior course between aorta and pulmonary artery trunk (Pul. a.). **Bottom**, Normal coronary artery anatomy is shown for comparison. L.A.D. = left anterior descending; L. circ. = left circumflex; L = left sinus; R = right sinus; P = posterior sinus; R.C.A. = right coronary artery. (With permission from ref. 6.)

to be secondary to coronary abnormalities, with 7 due to wrong coronary sinus origin, and the remaining related to myocardial bridging. The mechanism of SD is believed to be episodic myocardial ischemia.[81,82] Diagnosis represents a serious challenge, but is particularly important as surgical correction is feasible.[83] The possibility of a coronary anomaly should always be considered in a young athlete with a history of chest pain or syncope, particularly if the episodes are triggered by exercise.[84] Transthoracic or transesophageal echocardiography and magnetic resonance imaging can be used to diagnose the anomaly,[83] and diagnostic coronary arteriography can ultimately be performed. Patients usually do *not* have abnormalities on 12-lead or even exercise electrocardiograms,[83,85] because the myocardial ischemia is episodic, thereby limiting the value of random screening.

Acquired coronary abnormalities, particularly premature CAD, account for another major substrate for unexpected death in athletes, despite implementation of pre-participation screening programs.[4,8]

Wrong coronary sinus origin

General

Anomalous origin of coronary arteries is a rare congenital disease, found in approximately 0.6% to 1% of all coronary angiograms, and in 0.3% of all autopsies (Fig. 65.15).[86,87] Although an anomalous origin of coronary arteries may have a completely benign and asymptomatic course, it can be a cause for SD in the young, more commonly in competitive athletes than in non-athletes.[4,8]

Risk

Recognized as an important cardiovascular cause of SD on the athletic field (Tables 65.3 and 65.4),[4,8,83] these anomalies may be more common than previously thought.[85]

Left main coronary artery origin from the right aortic sinus of *Valsalva* represents the most serious anomaly, associated with the highest incidence of symptoms and SD.[87] As reported by Taylor *et al.*,[87] in 242 patients with isolated coronary artery anomalies, SD and exercise-related death were most common with origin of the left main coronary artery from the right coronary sinus (57% and 64% of cases, respectively). Anomalous origin of the right coronary artery from the left coronary sinus was also commonly associated with exercise-related SD (46% of cases). High-risk anatomy further involved abnormalities of the initial coronary artery segment, or the coursing of the anomalous artery between the pulmonary artery and aorta. Younger patients (≤30 years old) were significantly more likely to die suddenly than were older patients (62% vs. 12% overall; 40% vs. 2% during exercise).[87] Although the type of malformation may affect life expectancy, this may be less relevant in the elderly as large vessel stiffening may afford some degree of protection, in particular for coronary vessels routed "between" cardiac outflow branches.

Diagnosis

Coronary origin anomalies are rarely suspected and usually first recognized at autopsy, largely because they are not recognized during routine or pre-participation screening, as the affected subjects are often asymptomatic (Fig. 65.16).[8,88]

The available clinical data suggest that myocardial ischemia in young athletes with aortic sinus coronary artery anomalies probably occurs in infrequent bursts, which may be cumulative with time. This view is supported by normal ECG patterns in patients who had *postmortem* pathologic evidence of acute myocardial ischemic damage and/or chronic ischemic injury with replacement-type fibrosis.[83] Thus, repetitive ischemic episodes may result in patchy myocardial necrosis and fibrosis, which could predispose to lethal ventricular tachyarrhythmias by creating an electrically unstable myocardial substrate with increased structural and functional tissue heterogeneity. Considering that trained athletes perform intense physical exercise many times before any fatal event, it is most likely that critical impairment of coronary flow to the myocardium occurs only sporadically.

Pathogenesis

Although the exact pathophysiology of this decreased blood flow is not fully understood, several potential mechanisms have been proposed to explain exercise-related myocardial ischemia and SD in patients with wrong sinus coronary anomalies: the acute take-off angle and kinking or torsion of the coronary artery as it arises from the aorta and passes between the great vessels (Fig. 65.16(b));[89]

(a)   (b)
Fig. 65.16. A 15-year-old male Italian soccer player with a history of exertional syncope 1 year before death, who died suddenly while running during the second half of a game. (a) A 12-lead ECG performed 10 months before death, as part of routine pre-participation screening, is within normal limits. (b) View of the aortic root; the right coronary artery arises normally from the right aortic sinus (arrow), and the left main coronary artery arises anomalously from the right sinus with an acute angle take-off producing a slit-like lumen (arrowhead). (With permission from ref. 83.)

flap-like closure of the abnormal slit-like coronary orifice;[90] compression of the anomalous coronary artery between the aorta and pulmonary trunk (Fig. 65.15),[87] especially during exercise-induced distention of the sinus of *Valsalva*;[91] and spasm of the anomalous coronary artery, possibly as a result of endothelial injury.[92] The consequent myocardial ischemia, exacerbated by increased myocardial oxygen requirements during exertion, in particular in the presence of tissue heterogeneity caused by previous incidents, may trigger and sustain life-threatening ventricular arrhythmias and SD.[86]

Moreover, in some patients the proximal portion of the anomalous coronary artery is essentially intramural (i.e., within the aortic tunica media), which can further aggravate the coronary obstruction, particularly with expansion of the aorta during exercise.[83]

Prevention

A strategy for clinical identification of wrong sinus coronary artery anomalies in young athletes has been proposed.[83] If the index of suspicion is sufficiently high because of the presence of potential clinical markers such as exertional syncope or chest pain, even in the setting of both a normal 12-lead ECG and maximal exercise test, the anatomy of these malformations should be defined non-invasively by transthoracic or transesophageal echocardiography. Pelliccia *et al.*[93] demonstrated that echocardiographic imaging of left and right coronary arteries is feasible and reliable in a substantial proportion of young athletes (~95%). Consistently, identification of coronary artery origins should be generally included as part of any routine

echocardiographic examination.[85] Further anatomic definition, if warranted, may be obtained by coronary angiography or possibly with magnetic resonance imaging[94] or computed tomography.[95]

Myocardial bridging

General

Myocardial bridging (MB) occurs when a band of cardiac muscle overlies a segment of a coronary artery, the 'intramural' segment being referred to as a "tunneled artery." Usually, the coronary vessels course over the epicardial surface of the heart but may dip into the myocardium for varying lengths and then reappear on the heart's surface.[82] The left anterior descending coronary artery is by far the most often bridged vessel; however, diagonal branches are occasionally involved, as well as the posterior descending right coronary artery or marginal branches of the circumflex artery (Fig. 65.17).[82]

Risk

Systolic compression of the left anterior descending coronary artery is a well-recognized angiographic phenomenon.[96] There is, however, a wide discrepancy in pathological data on MB incidence, ranging from 15% to 85% of the population,[97,98] and angiographic observations, from 0.5% to 2.5%.[96,99] This large discordance suggests that only a minor fraction of patients with MB are at risk for clinical symptoms. Moreover, among patients with angiographically documented systolic narrowing of a coronary artery, a substantial percentage (~50%) have

(a)   (b)
Fig. 65.17. Coronary angiogram of a patient with myocardial bridging of the left anterior descending coronary artery in the right anterior oblique position. (a) An absence of constriction during diastole is shown. (b) This depicts the redistribution of blood during systole, also referred to as "milking effect" (arrow). (With permission from ref. 82.)

concomitant LV hypertrophy, HCM, atherosclerotic, or valvular heart disease, which independently affect clinical outcome as well as treatment strategy.[100] Finally, among patients with isolated MB documented at angiography, only about two-thirds exhibit a >50% narrowing of the vessel during systole.[100]

Pathogenesis

The progressive increase in LV wall tension, with maturation may explain, at least in part, why MB – even if present from birth – produces symptoms only later in life.[100] Typically, patients are predominantly male, 5 to 10 years younger than patients with symptomatic coronary disease, and they tend to have severe anginal symptoms.[82] When symptom-limited exercise electrocardiograms are performed, a significant ischemic ST segment depression is identified in 28% to 67% of patients.[82] Consequently, such anomalies may have important clinical implications during intense athletic activity (Fig. 65.18).[82] Indeed, tunneled coronary arteries are occasionally the sole abnormality found at autopsy and are within the most frequent 10 abnormalities responsible for SCD in athletes.[7,18]

MB has been associated with other concomitant cardiovascular abnormalities, in particular HCM.[100] In both con-ditions, myocardial ischemia has been recognized as the predominant arrhythmogenic substrate.[101] MB with compression of an epicardial coronary artery[96] occurs in 30% to 50% of adults who have HCM.[102]

Until recently, visual interpretation of coronary angiograms only revealed systolic narrowing if induced by significant MB of a coronary artery. Coronary flow, however, occurs predominantly during diastole; therefore, it appeared unlikely that this systolic phenomenon would itself cause pronounced myocardial ischemia.

With the advent of quantitative coronary angiography, intravascular ultrasonography, and intracoronary Doppler flow velocity measurements, it has become possible to identify diastolic hemodynamic disturbances in MB patients.[103] There is mounting evidence for a diastolic time-lag during which the previously compressed coronary vessel remains underfilled (30% to 75% of diastole).[81] This prolongation of compression well into diastole is likely to compromise myocardial perfusion, and will have a greater effect in young adults and children, especially during exercise, because their heart rates are faster and diastolic perfusion times are shorter.[81]

Two mechanisms are regarded as responsible for the reduced coronary flow reserve in distal vessels and for

(a)   (b)
Fig. 65.18. Electrocardiogram obtained during exercise testing in a patient with myocardial bridging and induced myocardial ischemia and ventricular arrhythmia. After 9 minutes of a treadmill exercise test, ST segments were normal (Panel (a)) and the patient's heart rate was 131 beats per minute. After 9 minutes and 36 seconds, the patient's heart rate was 141 beats per minute and the electrocardiogram showed acute elevation of the ST segment in lead V1 and depression of the ST segment in leads II, aVF, V5, and V6, followed by rapid ventricular tachycardia and ventricular fibrillation (Panel (b)). (With permission from ref. 81.)
Fig. 65.19. Intracoronary Doppler blood flow velocity profile showing the characteristic "finger-tip"-like flow velocity acceleration during early diastole (single arrow) followed by a plateau phase at mid-to-late diastole (arrows in (a) and (b)). During systole, there is almost no flow within the bridged segment, but a retrograde flow phenomenon occurs at the entry site of the myocardial bridge (horizontal arrows in (a)). During rapid atrial pacing, absolute diastolic flow velocities are increased, and the duration of the plateau phase is reduced owing to shortened diastole (c). (With permission from ref. 104.)

clinical symptoms and signs of myocardial ischemia: (1) a phasic systolic vessel compression with persistent mid-to-late reduction in diameter in diastole and (2) increased intracoronary Doppler flow velocities with abnormal qualitative flow profiles. Qualitative analysis of the Doppler flow profile shows a highly characteristic pattern in approximately 90% of MB patients, with abrupt early diastolic flow acceleration, termed "finger tip" phenomenon (Fig. 65.19).

As an alternative or additional mechanism, vasospastic coronary constriction may be associated with MB.[105] The systolic compression of the vessel may produce endothelial damage, especially at high heart rates, which may stimulate platelet aggregation and enhance coronary vasospasm. These alterations, particularly in association with aggravating factors such as increased heart rate, pressure, and pre-existing coronary vasospasm, may explain the occurrence of symptoms and myocardial ischemia in patients with symptomatic MB.[82]

Myocardial damage resulting from chronic ischemia may cause diffuse fibrosis and increasing disarray of myocardial fibers, which may secondarily create an arrhythmogenic substrate. Yetman *et al.*[81] documented a higher incidence of VT on Holter ambulatory monitoring in MB patients. In addition, ischemic ST segment changes that culminate in VT have been observed in at least one patient with MB (Fig. 65.18). Finally, a greater degree of QTc dispersion is present in patients with MB.[81] These patients have a larger incidence of ischemia, which may lead to an arrhythmogenic substrate in association with abnormal and variable repolarization.

Treatment

Three different treatment strategies are available medical therapy, percutaneous coronary intervention, and direct surgical myotomy or coronary bypass grafting. Medical therapy is the first and principal strategy.[82] It usually includes β-blockers, calcium channel blockers, and antiplatelet agents, with the objective of relieving symptoms and signs of myocardial ischemia and/or protecting against the risk of future coronary events.

Stables *et al.*[106] demonstrated that intracoronary stent implantation can achieve internal stabilization of the coronary artery lumen against external compression by MB. Prior to the availability of coronary stenting, surgical myotomy was regarded as the surgical treatment of choice for patients with persistent symptoms.[82] Alternatively, internal mammary artery anastomosis to the distal vessel segment may be a suitable treatment in patients with unsuccessful coronary stenting or in-stent restenosis.[107]

Atherosclerotic coronary artery disease

General

Several pathological studies have demonstrated that coronary atherosclerotic disease, complicated by thrombosis, is the most common morphological substrate of acute coronary events and SD in adults of the general population.[108,109] In line with this finding, atherosclerotic CAD is the most common cause of SD in athletes >35 years of age.[110,111] In younger subjects, even after stringent pre-participation screening, coronary atherosclerosis is the second most common cause of SCD, accounting for 18% of SD in the athletic population (Table 65.3).[8]

SD due to premature CAD occurs predominantly in the older segment of under 35-year-old athletes, and in non-athletes (29.1 ± 5 years; Table 65.4).[4] Premature CAD is associated with a high risk of sports-related SD (relative risk 2.6; Fig. 65.3).[4]

Pathogenesis

Few studies have addressed the pathological lesions of coronary atherosclerosis and pathophysiological mechanisms of fatal myocardial ischemia in young people.[13] Single-vessel obstructive CAD, mostly affecting the proximal left anterior descending coronary artery, is most commonly observed in young adults and athletes (Fig. 65.20).[4,13] This finding probably reflects early development of CAD, which only later in life will progress and become a more generalized obstructive process. In this context, previous necropsy
Fig. 65.20. Fresh occlusive thrombosis of the proximal anterior descending coronary artery superimposed by an eccentric atheromatous plaque with a large lipid core in a 33-year-old man who died suddenly. Azan stain, original magnification × 25. (With permission from ref. 13.)

studies in adult and elderly victims of sudden coronary death showed a high frequency of multivessel CAD.[108,109]

The increase in myocardial oxygen demand, in the presence of fixed supply, may be the mechanism underlying exercise-induced arrhythmias and SD. The absence of angina pectoris and ECG-documented ischemic changes in the history of the patients suggests that the obstructive coronary plaques, observed at histology, may not be flow-limiting in vivo at rest.[13] The dynamic nature of the pathophysiology of coronary events has led to the recognition that superimposed acute lesions create a setting in which alterations in the metabolic or electrolyte state of the myocardium may lead to disturbed electrical activity.[9] The coexistence of both such factors during, and immediately after, physical exertion could account for the higher incidence of SD in athletes.

A modification in flow dynamics may induce mechanical injury to the vessel wall and explain the propensity for obstructive plaque localization at the proximal tract of the left anterior descending coronary artery, just below the left main coronary artery bifurcation, where flow velocity is critically reduced and wall shear stress is increased.[112] Thus, in subjects from 1 to 20 years of age, the proximal left anterior descending coronary artery is most prone to the formation of fibrocellular intimal thickenings and early non-obstructive coronary plaques,[113] as confirmed by an autopsy study on young trauma victims <35 years old.[114]

In most of the young victims of atherosclerotic CAD-induced SD, obstructive plaques are fibrous, with a stratum of smooth muscle cell hyperplasia occupying up to 46% of the total plaque cross-sectional area (Fig. 65.21).[13] These fibrocellular plaques represent an early stage of mature atheromatous plaques.[115]

Acute thrombosis is present in only 22% of obstructive plaques in athletes and young adult victims of sudden
Fig. 65.21. Proximal left anterior descending coronary artery of a 30-year-old man who died suddenly. (a) Histology showing an obstructive eccentric fibrous plaque at the origin of the first diagonal branch. Note the preserved tunica media. Azan stain, original magnification × 25. (b) Close-up of the boxed area showing a layer of intimal cell hyperplasia. Azan stain, original magnification × 200. (With permission from ref. 13.)

coronary death, a much lower frequency than that observed in older adults, where 73% of plaques are complicated by thrombosis.[13] A normal tunica media and a layer of intimal fibrocellular hyperplasia in the absence of thrombosis may represent the potential substrate accounting for coronary hypervasoreactivity.[13] The normally thick tunica media is an anatomic prerequisite for preserved vasomotor reactivity in the atherosclerotic coronary artery. Constrictive coronary hyperreactivity accompanies both experimental[116] and clinical[117] accelerated atherosclerosis, which shows many similarities to the smooth muscle cell hyperplasia overlying the fibrous plaques observed in the young.

Prevention and treatment

CAD is the primary cause of SCD in the adult; therefore, prevention and treatment are discussed in dedicated chapters. It is less common in the young but the mechanism and therefore the therapeutic approach and prevention strategies are the same.

Coronary vasospasm

General

Coronary vasospasm is a potential trigger of transient myocardial ischemia[118] which, in turn, may precipitate VT/VF and cause SCD (Fig. 65.22).[119]

Risk

Coronary vasospasm is a rare cause of SCD in athletes.[18,120]

Pathophysiology

Coronary artery spasm and modulation of coronary collateral flow may be linked to local endothelial dysfunction, which exposes the myocardium to the double hazard of transient ischemia and reperfusion.[121] Smooth muscle cell hyperplasia has been described as a distinctive feature in coronary plaques retrieved by directional atherectomy from patients with unstable angina, and may provide an alternative mechanism to thrombus formation precipitating myocardial ischemia at rest and during competition.[122] Neurogenic influences are also likely to play a role, but do not appear to be a *sine qua non* factor to trigger spasm. Vessel susceptibility and humoral factors, particularly those related to platelet activation, also appear to be important contributors.[9]

Prevention and treatment

As before, this has been extensively discussed elsewhere in the book. Also, the pathophysiology of this entity is largely speculative, and will not be addressed in detail here.

Valvular heart disease

Aortic stenosis

General

The natural history of aortic stenosis is typically characterized by a long asymptomatic period during which the degree of stenosis increases. In 1968 Ross and Braunwald showed that the risk of SCD is low (3–5%) in asymptomatic patients.[123] More recently, a prospective study showed that SCD did not occur in any of 123 asymptomatic patients followed for 2.5 years.[124] Accordingly, in the absence of cardiac symptoms, survival is excellent without valve replacement.

Risk and diagnosis

The prognostic value of hemodynamic and electrophysiological testing is limited. Clinical manifestations of aortic stenosis include syncope, angina pectoris and/or dyspnea. Both syncope and SCD are exertional in many patients but it is not clear if syncope is a necessary and/or reliable predictor of SCD.[125] The difficulty is to predict the natural history of aortic stenosis in an asymptomatic patient since the risk of SCD is low.[125] The degree of stenosis, amount of calcification and severity of LV hypertrophy can be used to predict the speed of progression of stenosis requiring surgical intervention.[126]

Once symptoms develop, the prognosis worsens dramatically and the incidence of SCD among symptomatic patients rises to 8–34%.[123,126,127] Analysis of Holter ECG in seven patients who died suddenly demonstrated the presence of VT in six patients, while only in one patient was death associated with bradyarrhythmia.[128]

Prevention

Restriction of physical activity should be advised in patients with moderate and especially with severe aortic stenosis.[125] Such a policy resulted in the absence of SCD related to aortic stenosis over 20 years of pre-participation screening in northeast Italy, as demonstrated by Corrado *et al.*[4] In the absence of such screening, aortic stenosis accounts for 2.6% of SCD in athletes.[18] In line with this reasoning the following recommendations for athletic participation have been proposed:[129]

1. Athletes with mild aortic stenosis (<20 mmHg) can participate in all competitive sports.
2. Athletes with mild to moderate aortic stenosis (21 to 40 mmHg) should participate in low or moderate intensity sports only.
3. Athletes with severe aortic stenosis (>40 mmHg) or symptoms should not engage in any competitive sports.
Fig. 65.22. Life-threatening ventricular arrhythmias associated with acute myocardial ischemia related to coronary artery spasm and reperfusion. (a) Continuous lead II electrocardiographic monitor recording during ischemia (time 0 to 55 seconds) caused by spasm of the right coronary artery. There is an abrupt transition (time 56 to 72 seconds) from repetitive ventricular ectopy to a rapid polymorphic, prefibrillatory tachyarrhythmia (time 80 to 130 seconds) associated with nitroglycerin-induced reversal of the spasm. (b) and Closed arrows, site of spasm before and after nitroglycerin; open arrow, lower grade distal lesion. (With permission from ref. 9.)

4. Athletes with bicuspid aortic valve, even without stenosis but with aortic dilatation, can participate in low intensity sports only. Serial 6-monthly echocardiographic monitoring of aortic root and ascending aorta is recommended.

Treatment

Prevention of SCD is one of the goals of surgical treatment of aortic stenosis. If surgery is considered in order to reduce the risk of SCD, however, this risk must outweigh perioperative mortality and known complications of

prosthetic valves.[130] On this ground, surgical intervention is usually deferred until clinical symptoms occur.

Mitral valve prolapse

General

Mitral valve prolapse is equally common in men and women, although men seem to have a higher incidence of complications, including infective endocarditis, severe mitral regurgitation, cerebrovascular ischemic events, and SCD.[131,132] Mitral leaflet thickening greater than 5 mm (that is classic prolapse) is associated with a 14-fold higher risk of complications, including SD.[131]

Risk

The risk of SCD is relatively low (40 in 10 000)[133] – twice the incidence expected in the general population – and the causal relation between mitral valve prolapse and SD is not fully resolved. Nonetheless, increased risk of SD is observed in patients with severe mitral regurgitation and/or severe valvular deformation,[131,133] depressed LV function,[134] QT interval prolongation,[135] and a history of syncope and palpitations. The presence of severe mitral regurgitation with a flail segment appears to carry a particularly high risk of SCD (up to 2% per year).[134]

Prevention and treatment

The mechanism of SD in mitral valve prolapse appears to be linked to the presence of VT. Therefore, it is prudent to disqualify from competitive sports athletes with mitral valve prolapse associated with a history of ventricular arrhythmias.[18,136]

Nevertheless, most patients with mitral valve prolapse have an excellent prognosis with an expected survival similar to that of the general population.[131,132] Indeed, most patients do not develop symptoms or significant echocardiographic abnormalities, and most asymptomatic patients with mitral valve prolapse can be followed conservatively.[132] Neither their activity level nor lifestyle need to be restricted; to the contrary, routine exercise may be preferable.[132]

Marfan syndrome

General

This autosomal dominant disorder is relatively frequent (2–3 per 10 000) and occurs in all races and ethnic groups.[137] Marfan syndrome, with its characteristic phenotype resulting from excessive growth of the long bones and joint laxity, may be underdiagnosed, particularly in populations of elite basketball players.[120] SD in Marfan syndrome is commonly due to aortic dissection.[138] Even with the discovery of the genetic and biochemical basis of the condition, the diagnosis of Marfan syndrome outside families with the classic phenotype remains entirely clinical.[120] Athletes with Marfan syndrome can participate successfully in strenuous competitive sports for many years without experiencing a catastrophic event, presumably before aortic dilatation becomes marked and the predisposition to dissection or rupture increases critically. Treatment with β-blockers is thought to reduce the risk of progressive aortic dilation and SD.[139]

Risk

A large cohort of patients with Marfan syndrome, followed by a single institution to assess long-term outcome, demonstrated a significant incidence of ventricular arrhythmias.[140] Patients were started on medical management early in the course of their disease, mainly β-blockers and angiotensin converting enzyme inhibitor. A high prevalence of LV dilation with associated abnormalities of repolarization was documented. Over an average follow-up period of 24 years, few patients required surgical intervention. The mortality rate from presumed arrhythmogenic death was 4%, exceeding by far the rate of aortic rupture.[140] Such repolarization abnormalities may account for the increased risk of ventricular ectopy and possibly SCD.

Prevention and treatment

Patients with Marfan syndrome and ventricular dysrhythmias may be at particularly high risk for SCD. Accordingly, aggressive treatment modalities including amiodarone or ICDs may be warranted in selected patients.

SCD involving functional abnormalities

About 2% of young athletes who die suddenly have normal cardiac structure at autopsy, and no definitive cause of death can be established.[7,141]

Ion channelopathies

The list of congenital and acquired arrhythmias, secondary to mutations or polymorphisms in genes encoding for cardiac ion channels, has expanded impressively in recent years. These ion channel disorders include long QT syndrome (LQTS), short QT syndrome (SQTS), Brugada syndrome and CPVT, atrial fibrillation (AF), and conduction system disease (Table 65.5). Recent studies have suggested that a small proportion (5–10%) of SD in infants is also

linked to ion channelopathies, including LQTS, SQTS and Brugada syndrome.[142,143]

Clinical diagnosis is generally made by identification of the disease phenotype on standard 12-lead ECG. Some of these cases have previously been classified as idiopathic VF, a category describing syndromes for which a mechanistic understanding is lacking.

Long QT syndrome

General

LQTS is characterized by the appearance of long QT intervals in the ECG, an atypical polymorphic VT known as Torsades de Pointes, and a relatively high risk for SCD.[144] Congenital LQTS is subdivided into seven genotypes, distinguished by mutations in at least six different ion channel genes and a structural anchoring protein located

on chromosomes 3, 4, 7, 11, 17, and 21.[145–147] Timothy syndrome, classified by some as LQT8, is a rare congenital disorder characterized by multiorgan dysfunction, including prolongation of the QT interval, lethal arrhythmias, webbing of fingers and toes, congenital heart disease, immune deficiency, intermittent hypoglycemia, cognitive abnormalities, and autism. Timothy syndrome has been linked to mutations in Ca$_v$1.2, which encodes for a portion of the calcium channel.[148]

The estimated prevalence of this disorder is 1–2:10 000. The ECG diagnosis is based on the presence of prolonged repolarization (QT interval) and abnormal T wave morphology.[149] Cardiac events are often precipitated by physical or emotional stress, but may also occur at rest. The mainstay of therapy is represented by antiadrenergic intervention with β-blockers. For patients unresponsive to this approach, ICD implantation and/or

cardiac sympathetic denervation represent the therapeutic alternative.[150]

Genetics

Two patterns of inheritance have been described: 1) a rare autosomal recessive disease associated with deafness (Jervell and Lang-Nielsen), caused by two genes that encode for the slowly activating delayed rectifier potassium channel (*KCNQ1* and *KCNE1*); and 2) the much more common autosomal dominant form known as the Romano Ward syndrome, caused by mutations in eight different genes, including *KCNQ1* (KvLQT1; LQT1); *KCNH2* (HERG;LQT2); *SCN5A* (Na$_v$1.5; LQT3); *ANKB* (LQT4); *KCNE1* (minK; LQT5); *KCNE2* (MiRP1; LQT6); *KCNJ2*; Kir2.1; (LQT7; Andersen's syndrome) and *CACNA1C* (Ca$_v$1.2; LQT8; Timothy syndrome). Six of the eight genes encode for cardiac potassium channels, one for the cardiac sodium channel (SCN5A) and one for a protein called Ankyrin B, which is involved in anchoring of ion channels to the cellular membrane (ANKB).

Acquired LQTS refers to a syndrome similar to the congenital form, but caused by exposure to drugs that prolong the duration of the ventricular action potential (AP)[151] or QT prolongation secondary to cardiomyopathies such as DCM or HCM, as well as to abnormal QT prolongation associated with bradycardia or electrolyte imbalance.[152]

Pathophysiology

A number of studies point to amplification of spatial dispersion of repolarization within the ventricular myocardium as principal arrhythmogenic substrate in both acquired and congenital LQTS. The accentuation of spatial dispersion, typically secondary to an increase of transmural, trans-septal, or apicobasal dispersion of repolarization, and the development of early afterdepolarization-induced triggered activity underlie the substrate and trigger for the development of Torsades de Pointes arrhythmias observed under LQTS conditions.[153] Models of LQT1, LQT2, and LQT3 have been developed by using the canine arterially perfused LV wedge preparation. These models suggest that in these three forms of LQTS, preferential prolongation of the M cell AP duration (APD) leads to an increase in the QT interval as well as an increase in transmural dispersion of repolarization (TDR), which contributes to the development of spontaneous as well as stimulation-induced Torsades de Pointes.[154]

Genotype-phenotype correlation studies point to major differences among patients with the three most common LQTS loci (LQT1, LQT2, LQT3), which account for approximately 95% of all genotyped patients. Genotype-specific ECG patterns have been identified[155]

and the environmental triggers for cardiac events have been shown to be gene-specific: LQT1 patients experience 97% of cardiac events during physical activity, as opposed to LQT3 patients who present the majority of cardiac events at rest. Moreover, auditory stimuli and arousal have been shown to be relatively specific triggers for LQT2 patients, whereas swimming leads to cardiac events in LQT1 patients.[156]

The response to sympathetic activation displays a very different time-course in LQT1 and LQT2, both in experimental models and in the clinic.[153,157] In LQT1, isoproterenol produces an increase in TDR that is most prominent during the first 2 minutes, but which persists, although to a lesser extent, during the steady-state. Incidence of Torsades de Pointes is enhanced during the initial period as well as during the steady-state. In LQT2, isoproterenol produces only a transient increase in TDR that persists for less than 2 minutes, so that Torsades de Pointes incidence is enhanced only briefly. In LQT3, β-adrenergic stimulation abbreviates APD of all cardiac cell types, reducing TDR and suppressing Torsades de Pointes,[158] thus providing an explanation for the prevalence of cardiac events in LQT3 patients at rest. These observations help to explain the important differences in autonomic activity and other gene-specific triggers that contribute to events in patients with different LQTS genotypes as well as the genotype-specific response to treatment with β-blockers.[159,160]

Prevention and treatment

Because of the great heterogeneity in clinical expression of LQTS, individualized patient management is required. Evaluation is geared toward discerning which asymptomatic family members are affected and who among the affected individuals harbors a "ticking time bomb." Prohibition of competitive sports is one of the biggest issues facing families of children and adolescents diagnosed with LQTS, even though physical activity poses no risk to some patients with this disorder. Unfortunately, clinical testing cannot always accurately determine individuals at risk; while LQT1 and LQT2 patients are universally restricted from high-exertion sports, many LQTS experts support participation in "recreational sports with moderate exertion" in properly treated LQTS patients.

Brugada syndrome

General

The Brugada syndrome, first described in 1992, is characterized by an accentuated coved-type ST segment elevation, or J wave, appearing principally in the right precordial

leads (V1-V3), often followed by a negative T wave, and a high incidence of SCD secondary to a rapid polymorphic VT or VF.[161] The ECG sign of the Brugada syndrome is dynamic and often concealed, but can be unmasked by potent sodium channel blockers such as ajmaline, flecainide, procainamide, disopyramide, propafenone, and pilsicainide.[162] The syndrome may also be unmasked or precipitated by a febrile state, vagotonic agents, α-adrenergic agonists, β-adrenergic blockers, tricyclic or tetracyclic antidepressants, a combination of glucose and insulin, and hypokalemia, as well as by alcohol and cocaine toxicity.[163]

Clinical manifestations of the disease (syncope or cardiac arrest) generally appear in the third to fourth decade of life, although malignant forms with childhood or neonatal onset have been reported.[164] Cardiac events typically occur during sleep or at rest.[165] The disease is inherited as an autosomal dominant trait but there is a striking male to female ratio of 10:1 in the occurrence of clinical manifestations. These gender differences have been attributed to differences in the intensity of the transient outward current (I_{to}).[14]

Genetics

Familial autosomal dominant and sporadic forms have been linked to mutations in the α-subunit of the cardiac sodium channel gene, SCN5A (the same gene responsible for LQT3) in 20% of patients with the Brugada syndrome. Another locus was reported on the short arm of chromosome 3, but no gene has been identified.

Sudden unexplained nocturnal death syndrome, found predominantly in young Southeast Asian males (i.e., from Thailand, Japan, Philippines, and Cambodia), is a disorder causing SD during sleep due to VT/VF. Sudden unexplained nocturnal death and Brugada syndrome have been shown to be phenotypically, genetically, and functionally the same disorder.

Pathophysiology

The arrhythmogenic substrate responsible for the development of extrasystoles and polymorphic VT in the Brugada syndrome is thought to be secondary to amplification of phase 1 (early AP repolarization)-mediated notch in the RV epicardial AP. Rebalancing of the currents active at the end of phase 1 is thought to underlie the accentuation of the AP notch in RV epicardium, which is responsible for the augmented J wave and ST segment elevation associated with the Brugada syndrome (see ref. 166 for details). The ST segment is normally close to isoelectric due to the absence of major transmural voltage gradients at the level of the AP plateau. Accentuation of the RV AP notch under pathophysiologic conditions leads to exag-

geration of transmural voltage gradients and thus to accentuation of the J wave, or to J point elevation. If the epicardial AP continues to repolarize before that of the endocardium, the T wave remains positive, giving rise to a saddleback configuration of the ST segment elevation. Further accentuation of the notch is accompanied by a prolongation of the epicardial AP causing it to repolarize after the endocardium, thus leading to inversion of the T wave.

The down-sloping ST segment elevation, or accentuated J wave, observed in experimental wedge models, often appears as an R', suggesting that the appearance of a right bundle branch block morphology in Brugada patients may be due in large part to early repolarization of RV epicardium, rather than major delays in impulse conduction in the right bundle.[167] Despite the appearance of a typical Brugada sign, accentuation of the RV epicardial AP notch alone does not give rise to an arrhythmogenic substrate. The arrhythmogenic substrate may develop with a further shift in the balance of currents, leading to loss of the AP dome at some epicardial sites but not others. Marked TDR develops as a consequence, creating a vulnerable window, which when captured by a premature extrasystole can trigger a re-entrant arrhythmia. Because loss of the AP dome in epicardium is generally heterogeneous, epicardial dispersion of repolarization develops as well. Conduction of the AP dome from sites at which it is maintained to sites at which it is lost may cause local re-excitation via phase 2 re-entry, leading to the development of a closely coupled extrasystole capable of capturing the vulnerable window across the ventricular wall, thus triggering a circus movement re-entry in the form of VT/VF.[168] Support for these hypotheses derives from experiments involving the arterially perfused RV wedge preparation[168] and from recent studies in which monophasic AP electrodes were positioned on the epicardial and endocardial surfaces of the RV outflow tract in patients with the Brugada syndrome.[169,170]

Prevention and treatment

An ICD is the most widely accepted approach to therapy. ICD implantation is not an appropriate solution for infants and young children, however, or for patients residing in regions of the world where an ICD is out of reach because of economic factors. Although arrhythmias and SCD generally occur during sleep or at rest, associated with slow heart rates, a potential therapeutic role for cardiac pacing remains largely unexplored. A recent report by Haissaguerre and coworkers[171] points to focal radiofrequency ablation as a potentially valuable tool in controlling arrhythmogenesis by focal ablation of the ventricular premature beats that trigger VT/VF in the Brugada syndrome.

Data relative to a cryosurgical approach or the use of ablation therapy are very limited at this time.

A pharmacologic approach to therapy, based on a rebalancing of currents active during the early phases of the epicardial AP in the right ventricle to reduce the AP notch and/or restore the AP dome, has been a focus of basic and clinical research in recent years. Because the presence of a prominent transient outward current, I_{to}, is central to the mechanism underlying the Brugada syndrome, the most rational approach to therapy, regardless of the ionic or genetic basis for the disease, is partial inhibition of I_{to}. Cardioselective and I_{to}-specific blockers are not currently available. The only agent on the market with significant I_{to}-blocking properties is quinidine. It was therefore suggested as a therapeutic approach for treatment of this syndrome.[172] Experimental studies have shown quinidine to be effective in restoring the epicardial AP dome, thus normalizing the ST segment and preventing phase 2 re-entry and polymorphic VT in experimental models of the Brugada syndrome.[168] Clinical evidence of the effectiveness of quinidine in normalizing ST segment elevation in patients with the Brugada syndrome has been reported.[173,174]

The effects of quinidine in preventing inducible and spontaneous VF were recently reported by Belhassen and coworkers[174] in a prospective study of 25 Brugada syndrome patients. These results are consistent with those reported by the same group in prior years[175] and more recently by other investigators.[176,177] The data highlight the need for randomized clinical trials to assess the effectiveness of quinidine, preferably in patients with frequent events who have already received an ICD.

Agents that boost the calcium current, such as β-adrenergic agents like isoproterenol, are useful as well.[166,168,178] Isoproterenol, sometimes in combination with quinidine, has been shown to normalize ST segment elevation in patients with the Brugada syndrome and in controlling "electrical storms," particularly in children.[173,179] A recent addition to the pharmacological armamentarium is the phosphodiesterase III inhibitor, cilostazol,[178] which normalizes the ST segment, most likely by augmenting calcium currents as well as by reducing I_{to} secondary to an increase in heart rate.

Other than isolated anecdotal reports of exertion-induced VT/VF, no data exist concerning the risk of participation in sports. Accordingly, patients with the Brugada syndrome at present are not excluded or restricted from participating in sports. This fact notwithstanding, because bradycardia and increased vagal activity are both known to predispose to the development of ST segment elevation and arrhythmogenesis in Brugada syndrome patients, a case can be made for avoiding these manifestations of a well-trained athlete. Thus, adaptation of the cardiac autonomic nervous system to training, which results in increased vagal activity and/or withdrawal of sympathetic activity, may enhance the propensity of athletes with Brugada syndrome to die suddenly at rest, during sleep, or immediately after exercise.[180]

Short QT syndrome

General
In 2000, Gussak *et al.*[181] proposed SQTS as a new clinical entity. Short-QT syndrome is an inherited syndrome characterized by a QTc ≤ 300 ms and high incidence of VT/VF in infants, children, and young adults.[182] The familial nature of this syndrome was confirmed by Gaita *et al.* in 2003.[183]

Genetics
The first genetic defect (SQT1) responsible for the SQTS, reported by Brugada *et al.* in 2004, involved two different missense mutations (substitution of one amino acid for another) resulting in the same amino acid substitution in HERG (*N588K*), which caused a gain of function in the rapidly activating delayed rectifier channel, I_{Kr}.[184] A second gene (SQT2) was recently reported by Bellocq *et al.*[185] A missense mutation in *KCNQ1* (KvLQT1) was found to cause a gain of function in the slowly activating delayed rectifier potassium current (I_{Ks}). A third gene (SQT3), involving mutations in *KCNJ2*, the gene that encodes for the inward rectifier channel, was found to cause a gain of function in the inwardly rectifying potassium current (I_{K1}), leading to an abbreviation of QT interval. SQT3 is associated with QTc intervals of <330 ms, not quite as short as SQT1, and SQT2.

Pathophysiology
SQTS is also characterized by the appearance of tall peaked symmetrical T waves in the ECG. The augmented T_{peak}–T_{end} interval associated with this electrocardiographic feature of the syndrome suggests that TDR is increased. Recent data collected using a ventricular wedge model of SQTS has provided evidence to support the hypothesis that an increase in outward repolarizing current can preferentially abbreviate endocardial/M cell APD in the left ventricle and this increases TDR and thus creates the substrate for re-entry.[186] The potassium channel opener pinacidil causes heterogeneous APD abbreviation among the different cell types spanning the ventricular wall, thus creating a substrate for VT under conditions associated with short QT intervals. Polymorphic VT could be readily induced with programmed electrical stimulation. The increase in TDR was further accentuated by isoproterenol, leading to easier induction and more persistent VT/VF. The latter is probably

due to the reduction in the wavelength of the re-entrant circuit, which reduces the path-length required for maintenance of re-entry.[186]

Therapy

Because of the recent identification of the short QT syndrome as a new clinical entity, the approach to therapy is still evolving. An ICD is clearly the therapy of choice in patients with syncope and a positive family history of SCD. Nonetheless, ICD therapy in patients with a short QT syndrome has an increased risk for inappropriate shock delivery due to T wave oversensing secondary to the presence of tall peaked T waves. A variety of drugs, including sotalol, ibutilide, flecainide, and quinidine, have been tested in SQT1. Quinidine was the only drug that effectively suppressed the gain-of-function of I_{Kr} leading to a prolongation of the QT interval and rendering VT/VF non-inducible. Quinidine has been proposed as an adjunct to ICD therapy and is a possible alternative treatment, especially for children and newborns.[187] At present there is little evidence on which to base a restriction of activity of patients with SQTS. Events have been reported at rest, during exertion, exercise and during sleep.

Wolff–Parkinson–White syndrome

General

Wolff–Parkinson–White (WPW) syndrome is caused by accessory atrioventricular (AV) connections, bypassing the AV-node and His bundle. WPW is rarely associated with other congenital cardiac anomalies.

Pathophysiology

The short anterograde effective refractory period of the accessory pathway allows extremely rapid ventricular responses during AF, with the risk of deterioration into VF.[188] Anterograde effective refractory periods <250 ms are considered unfavorable in symptomatic patients.[189] Patients with WPW have an SCD risk of less than 1 in 1000 per year of follow-up.[190] Most survivors of SCD have experienced arrhythmias before the event but, in up to 10%, SCD may occur as first manifestation.[191]

Prevention and treatment

For symptomatic patients, catheter ablation is now first-choice therapy with >95% effectiveness.[192] If ineffective, antiarrhythmic drugs prolonging the anterograde effective refractory period of the accessory pathway, or cardiac surgery, are the only alternatives. Consensus remains that in asymptomatic patients catheter ablation is not indicated.[193]

In many cases, the resting ECG shows pre-excitation. The athlete with a WPW pattern on the ECG and no symptoms of palpitations, syncope, or presyncope represents a more difficult problem. It is thought that although these individuals have a lifelong risk of developing arrhythmias, the risk of developing a fatal arrhythmia is quite low; therefore, most experts do not advise routine electrophysiologic testing of these individuals or exclusion from physical activity.[194,195] Electrophysiological testing and ablation therapy is recommended in special circumstances, such as family history of SCD, high risk profession (e.g., pilot), or athletes who may be at higher risk for developing AF.[125]

Catecholaminergic polymorphic ventricular tachycardia

General

In 1975, Coumel *et al.*[196] described four cases of severe ventricular arrhythmias in children with normal QT intervals. VT/VF was reproducibly induced by any form of sympathetic stimulation and termed catecholaminergic polymorphic ventricular tachycardia (CPVT). A remarkable feature of CPVT is its high lethality, demonstrated by the occurrence of 19 juvenile SCD in 10 affected families and by the occurrence of appropriate ICD shocks in 6 of 12 patients implanted with an ICD, over a follow-up period of ∼2 years.[197]

Genetics

The recent identification of mutations of the cardiac ryanodine receptor gene (RyR2), underlying CPVT,[198] lends support to the hypothesis that stress-induced life-threatening arrhythmias, occurring in the structurally intact heart, are phenotypical variants of the same disease. Cardiac ryanodine receptor gene mutations have been identified in a similar proportion of patients with bidirectional VT (36%), polymorphic VT (58%), and catecholaminergic VF (50%), suggesting that the diagnosis of CPVT may extend to all patients with polymorphic VT or VF occurring in the structurally intact heart in the absence of a prolonged QT interval (Fig. 65.23).[197] Mutations of RyR2 have been identified in subjects who had unexplained cardiac arrest during physical or emotional stress, without arrhythmias inducible at exercise stress testing or Holter monitoring.[197]

Pathophysiology

A diagnosis of CPVT should be considered in subjects of all ages with idiopathic polymorphic ventricular arrhythmias occurring during exercise or emotional stress in the absence of structural abnormalities or prolonged QT interval.[197] In athletes with structural heart disease and

Fig. 65.23. Examples of bidirectional (a) and polymorphic ventricular tachycardia (b) degenerating into ventricular fibrillation in patients with catecholaminergic ventricular tachycardia. (With permission from ref. 197.)

syncope, the cause of the syncope should be presumed to be arrhythmic, and athletes should be treated similarly to those who have experienced resuscitated SD, unless another clear diagnosis explains syncope.[199] In athletes without known structural heart disease, syncope during peak exertion should warrant an extensive work-up.

Interestingly, the age of onset of syncope is significantly lower in patients with RyR2 CPVT than in patients with non-genotyped CPVT; however, the mean age of SD among individuals in families with RyR2 CPVT suggests that, if not identified and treated during childhood, the disease becomes lethal in early adulthood.[197] A strong predominance of symptomatic female subjects has been observed among patients with non-genotyped CPVT, whereas male sex appears to be a strong risk factor (relative risk, 4.2) for syncope in patients with RyR2 CPVT.[197] The morphology of the ventricular arrhythmias is independent of the genetic defect, as demonstrated by the presence of discordant phenotypes in individuals with the same mutation.[197]

Prevention and treatment

Analogies may exist between CPVT and LQTS,[197] and further genetic research is required for clarification. CPVT patients must comply with medical therapy, namely β-blockers. ICD treatment may become part of therapy, although attention should be given to the catecholaminergic effects of ICD shock delivery. As in LQTS, ICD should therefore not be implanted without concomitant administration of β-blockers.

Right ventricular outflow tract tachycardia

General

This VT appears to originate from the RV outflow tract and has the characteristic ECG of a left bundle brunch

block contour in V_1 and inferior axis in the frontal plane (Fig. 65.24).

Pathophysiology

Vagal maneuvers, including administration of adenosine, terminate the VT, whereas exercise, stress, isoproterenol infusion, and rapid or premature stimulation can initiate or perpetuate the tachycardia. The mechanism responsible may be cyclic adenosine monophosphate-triggered activity[200] resulting from early or delayed afterdepolarizations. Two types can be distinguished: paroxysmal VT and repetitive monomorphic VT. The paroxysmal type is exercise-induced, whereas the repetitive monomorphic type occurs at rest with sinus beats interposed between runs of non-sustained VT that may be precipitated by transient increases in sympathetic activity unrelated to exertion.

Therapy

Radiofrequency catheter ablation can eliminate tachycardia in 83% to 100% of patients.[201]

Familial atrial fibrillation

AF is the most common sustained arrhythmia encountered in the clinic (in part at least, because in contrast to VF it is compatible with life). AF is usually secondary to ischemic heart disease, hypertension, or congestive heart failure. In a fraction of cases (3–30%) no underlying cardiovascular disease is apparent and in some AF appears to be familial. A locus on chromosome 10, linked to familial AF, was described in 1997, but the specific gene has not yet been identified. More recently, familial AF has been identified as an autosomal dominant trait, linked to mutations in KCNQ1, and associated with LQTS, SQTS, and Brugada syndromes.[203]
Fig. 65.24. Ventricular tachycardia originating from the right ventricular outflow tract. This tachycardia is characterized by a left bundle branch block contour in V1 and an inferior axis. (With permission from ref. 202.)

Conduction system disease

A progressive cardiac conduction defect, also known as Lev-Lenegre disease, is characterized by escalating impairment of conduction in the His-Purkinje system, leading to widening of the QRS complex. Conduction block can give rise to long pauses and/or bradycardia that may cause syncope. Sick sinus syndrome is a disorder phenotypically similar to progressive cardiac conduction defect. Familial occurrence of both syndromes has been reported, with an autosomal dominant pattern of inheritance. An ionchannelopathy in the form of SCN5A mutations is thought to contribute to these defects.

Idiopathic VF

In some patients, neither underlying disease nor distinct electrophysiologic abnormalities or electrolyte or metabolic derangements may be demonstrable. VF in these conditions is referred to as "idiopathic".[204] Idiopathic VF is a diagnosis by exclusion. Therefore, it can only be made when thorough clinical evaluation does not provide evidence for structural heart disease or other known causes of VT/VF. This does not necessarily imply that a patient's heart is completely free of any structural or functional abnormality, but merely that if an abnormal finding (e.g.,

first-degree AV block or AF) is present, it is not considered responsible for the VF episode.[121]

Because idiopathic VF is unlikely to represent a homogeneous disease, future research may identify specific causes in certain subsets, as was the case for LQTS and CPVT. Current consensus is that some minor abnormalities, unknown to be associated with the occurrence of VF, do not rule out the diagnosis. A combined Task Force of the Unexplained Cardiac Arrest Registry of Europe and Idiopathic Ventricular Fibrillation Registry of the US[121] has summarized a variety of minor abnormalities that may be compatible with a diagnosis of idiopathic VF.

Previously, prognosis was considered excellent.[205] There appeared to be agreement that only symptomatic patients with recurrent arrhythmia should be treated. Initially, no particular efforts were directed toward identification of high-risk subgroups or SCD prevention. Data from several more recent studies, however, suggest recurrence rates of VF, syncope, or cardiac arrest varying from 25% to 43% over longer follow-up.[121,205] In the early 1990s, Wever *et al.*[205] were the first to report results of a prospective study on patients with primary electrical disease who survived a VF episode. The major finding was the high recurrence rate of life-threatening events during long-term follow-up, often in young patients (<35 years). In a subsequent study on survivors of out-of-hospital cardiac
Fig. 65.25. Kaplan–Meier curve showing survival free of major events (sudden death, recurrent episodes of syncope, or documented ventricular tachyarrhythmia) of 37 consecutive patients with idiopathic ventricular fibrillation. (With permission from ref. 204.)

arrest due to idiopathic VF, this finding was confirmed.[204] During an average 77 months of follow-up, 43% of patients had recurrent episodes of syncope, documented ventricular tachyarrhythmia, or SCD (Fig. 65.25). Mean age was 35 years and retrospective analysis showed that 9 of 37 patients (24%) could have been classified as having Brugada syndrome.

SCD involving externally caused pathologies

Myocarditis

General
Myocarditis is an insidious disease that is usually asymptomatic; thus, important clues to its epidemiology come from postmortem studies.[206] Such studies suggest that myocarditis is a major cause of SD, accounting for approximately 20% of cases in adults < 40 years of age,[207] including young athletes.[208] In addition, prospective and retrospective studies have identified myocardial inflammation in 1% – 9% of routine postmortem examinations.[209]

Pathophysiology
Initially, selected viruses were implicated by demonstration of rising antibody titers in the serum of patients during acute myocarditis and convalescence.[210] Recently, however, the enterovirus genome has been identified in the myocardium of patients with myocarditis and patients with DCM.[211] Enterovirus and enterovirus-like RNA sequences have also been identified in endomyo-

cardial biopsy specimens from patients with clinically suspected myocarditis and from those with idiopathic DCM.[212]

Prevention and treatment
Myocarditis is difficult to diagnose clinically and may be suggested in the absence of symptoms on the basis of ECG abnormalities alone, which include heart block and ventricular arrhythmias.[213] Reverse-transcriptase–polymerase-chain-reaction assays allow identification of a viral genome in endomyocardial biopsy specimens.[214] Although myocarditis usually has an infectious origin, it can also be a consequence of drug abuse.[215,216]

Bed rest should be considered during viremia, in contrast with non-inflammatory DCM, although this recommendation is based solely on animal studies, and on the observation that myocarditis is often lethal in young athletes.[213]

Commotio cordis

General
Induction of arrhythmias, including SCD, by non-penetrating chest wall impact in the absence of structural injury to the ribs, sternum, and heart is known as *Commotio cordis* (*CC*). First described in the European medical literature during the 19th century,[217–219] *CC* was initially associated with workplace accidents, involving falls or impacts by tools and animal body parts. Since the twentieth century, the focus of *CC* has shifted almost entirely to sporting activities.[220]

The incidence of lethal *CC* in contemporary sports has traditionally been estimated to be < 5 deaths per annum in the US,[220] but under-reporting and misclassification of deaths is likely to occur, and the true number of deaths due to relatively mild chest wall impacts may be significantly higher. Indeed, in the last 5 years, the number of reported *CC* victims has increased in the US to 20 per annum (probably due to better awareness and reporting), with up to 20% of deaths on the athletic field caused by chest wall impact.[18, 221]

Clinical profile
The US *CC* Registry in Minneapolis, established in 1996, has documented in detail more than 170 cases. *CC* victims have a mean age of 14 years (80% ≤ 18 years),[220] and it is thought that young athletes are at particular risk because of their more pliable chest wall that facilitates the transmission of chest impact energy to the myocardium. With age, the thoracic cage stiffens and the chest wall absorbs more of the impact energy. Males comprise 95% of the victims, a proportion seemingly too high to be accounted for solely by the predominance of males in sports.

In the US, the most common sporting activity causing *CC* is baseball (~50%). Other sports include softball, ice hockey, and lacrosse; in each of these sports the impact object is a solid projectile. *CC* is rarely reported after blows from air-filled balls such as used in European soccer and American football. In these sports, *CC* is mostly caused by chest blows with a body part such as a knee, elbow, head, or fist (as in karate).

While organized competitive sports account for about 60% of all *CC* lethalities, some 20% occur in non-competitive recreational athletic activities, often during play with peers. The remainder of events occur during routine activities, parental disciplining, playful boxing, gang rituals, or blows by plastic projectiles or playground swings.

Pathophysiology
Collapse after impact is either immediate (~50%), or occurs following a brief period of consciousness, often marked by extreme lightheadedness. In the 74 cases from the *CC* Registry in which a postcollapse rhythm was documented, 48 showed VF. After prolonged cardiopulmonary resuscitation, asystole is common.[220] In the few survivors, in whom a 12-lead ECG was available, marked ST segment elevation, especially in the anterior leads, was observed, which resolved over time without development of Q-waves or elevation of myocardial enzymes.

Although CC initially was reported to be almost invariably fatal, survival now appears to approach 15%, including some cases with spontaneous resolution (see Fig. 65.26).[221] The greater likelihood of survival is probably related to at least two factors. The first is a reversal of a bias to report only fatal cases: we are becoming aware of many non-fatal cases with either spontaneous or defibrillated recovery. The most important determinant of increased survival is probably due to the better recognition of *CC* in the community, however, which translates into more timely cardiopulmonary resuscitation and defibrillation. Of 78 Registry events in which resuscitation was initiated within 3 minutes, 25% survived (compared to only 8% in which resuscitation was delayed for > 3 minutes).
Fig. 65.26. Number of cases referred to the Commotio Cordis Registry stratified by year of event. Deaths are recorded in hatched bars, and survivors are represented by solid bars. Note the increasing number of reported cases and increasing likelihood of survivors in more recent years, both of which are probably caused by increased awareness of this phenomenon. (With permission from ref. 221.)

Experimental insight

Early experimental efforts generally focused on relatively severe chest wall trauma, such as that typically seen with victims of motor vehicle accidents, falls from heights, and bomb blasts.[217,218] In these models, morphologic cardiac damage was typically produced. Riedinger and Kümmell first distinguished between Cardiac Contusion (in which structural cardiac damage is present) and Commotion (where the heart remains intact).[218] The first systematic experimental insight into *CC* came from Schlomka's extensive experimental research[222] which highlighted the intrinsic cardiac nature of heart rhythm responses to precordial impact, and which suggested coronary vasospasms as a cause of arrhythmia in *CC* (reviewed in detail elsewhere).[219]

This concept had to be revised in recent years, largely as a result of the introduction of a new sophisticated porcine model, developed to clarify the mechanism of *CC*.[223] In this model, ventricular arrhythmias, including VF, can be produced by controlled (timing, location, amplitude) chest wall impact with a baseball in the absence of structural damage to the heart.

When impacts caused VF, this was not preceded by ventricular tachycardia, heart block, or ischemic ST changes (Fig. 65.27). One of the most important determinants of VF is the timing of the chest impact in the cardiac cycle. If a 49 km h^{-1} (30 mi h^{-1}) projectile impact occurs during a 20-ms window on the upslope of the T wave, approximately 30% of strikes will initiate VF. Impacts occurring outside of this narrow window, but still on the upslope of the T-wave, trigger VF only in 5% of cases, while blows at all other times of the cardiac cycle (including the down-slope of the T wave) do not result in VF.[224] Also of note, non-sustained bursts of VF are occasionally induced, as well as transient complete heart block. Non-sustained VF always terminated within 10 s (once it persisted >10 s, defibrillation was required), and heart block was never permanent (usually lasted < 5 beats). These non-sustained arrhythmic episodes may account for cases of *CC* in which collapse after the chest blow is transient, and recovery occurs spontaneously within 10 to 20 s.[220]

Other important variables predisposing to *CC* include the site and velocity of the chest blow. For example, VF will not occur with a chest blow outside of the cardiac silhouette, while impacts at the center of the cardiac silhouette are most likely to provoke VF. Impacts near the base and the apex only occasionally trigger VF; at all other sites on the chest, including the right and left thorax and back, blows will not induce VF.[225] *CC* events occur over a wide range of velocities in humans, ranging from minor blows to impacts from hockey pucks or lacrosse balls, at impact velocities of up to 160 km h^{-1} (100 mi h^{-1}). Of note, in the above porcine model, when the velocity of impacts is increased to 65 km h^{-1} (40 mi h^{-1}), the frequency of VF increases dramatically, up to 70%. On raising impact velocity further to 80–110 km h^{-1} (50–70 mi h^{-1}), however, VF becomes *less* frequent, despite an increased occurrence of cardiac structural damage.[226] The mechanism for decreased vulnerability for *CC* at particularly high impact velocities is unresolved, but it may be related to the requirement for a critical mass of myocardial tissue that is *not* affected by the mechanical stimulus to sustain re-entrant arrhythmias, reduced overall heterogeneity with increasing impact strength, or possibly to critical LV pressure changes produced by the chest wall blow.

Immediately following impact, segmental and transient wall motion abnormalities were observed at the apex, a region distant from the area of precordial impact.[223] Immediate (within 60 s) coronary angiography did not reveal any epicardial coronary artery abnormalities,[223] thereby directly contradicting the "coronary vasospasm" theory of Schlomka.[222]
Fig. 65.27. ECG (lead I, top) and left ventricular pressure recording (LVP, bottom), obtained from an anesthetized pig, subjected to a precordial impact that coincided with the upstroke of the T-wave. Note the swiftness of mechanical induction of VF and loss of contractility (within one cardiac cycle). (With permission from ref. 223.)

Cellular mechanisms of *CC*

In humans and in experimental models it appears that VF, initiated by a chest wall blow, may underlie SCD observed in the context of *CC*. Induction of VF by a chest blow in the absence of structural damage to the heart is a primary electrical event, rather than secondary to other factors such as structural heart block, myocardial ischemia, or hemorrhage. Given the swift electrical response to an impact, *CC* is likely to act via effects on cardiac ion channels.

Myocardial stretch is a probable contributor to the VF in *CC*,[227] potentially mediated via an increase in LV pressure,[225,226] as peak probability of VF was seen at LV pressures between 250 and 450 mmHg. The rapid rise in ventricular pressure observed in this setting may mediate ion channel activation via myocardial stretch, compression, membrane deformation, or possibly by direct action on the ion channels themselves.

Because of certain electrical similarities between *CC* and myocardial ischemia, such as ST segment elevation, a possible contributor is the K^+_{ATP} channel. This is particularly plausible since, on the one hand, K^+_{ATP} channels are understood to be primarily responsible for ST segment elevation and to affect the risk of VF in myocardial ischemia,[228] while the same channel population is also mechanosensitive.[229] Indeed, glibenclamide (a blocker of K^+_{ATP} channels), reduces the magnitude of ST segment elevation with QRS strikes, and the incidence of VF following strikes at the upstroke of the T-wave,[230] suggesting that activation of this channel by chest wall impact is critical for the initiation and/or maintenance of VF in *CC*.

Other channels[231] may be activated by myocardial stretch, and in this way underlie the genesis of ventricular arrhythmias following chest blows. Cation non-selective stretch-activated channels (SAC) in particular would seem to be likely candidates for the initiation of VF with chest wall blows[227] since their activation causes depolarization that may trigger AP in resting cardiomyocytes.[232] This theory has recently been addressed in a randomized and blinded study, with streptomycin, a convenient blocker of SAC in isolated myocytes (at 40 µM; at higher concentrations streptomycin also blocks L-type calcium channels and several potassium channels).[233] In whole animal experiments, streptomycin had no significant effect on the frequency of VF induction, yet the magnitude of ST segment elevation was depressed by the drug.

Interestingly, a recent report highlights the ambiguity of streptomycin effects in native tissue, and suggests that SAC (but not L-type calcium channels) may be protected *in situ* from the blocking effect of streptomycin.[235] An alternative drug to dissect the possible role of SAC *in situ* would be GsMTx-4, a peptide isolated from the Chilean tarantula toxin, which has been shown to be highly selective and efficient in blocking mechanically promoted AF in isolated heart.[236] Its limited availability and exceedingly high cost make whole animal experiments with this drug difficult, but with the emergence of isolated heart models of CC,[234] it is to be hoped that this concern will be addressed in the not too distant future (Fig. 65.28).

Illicit substance abuse

Sudden unexpected death, non-fatal stroke, and acute myocardial infarction in trained athletes have been attributed to the abuse of cocaine, anabolic steroids, and dietary and nutritional supplements.[237,238] Dietary supplements such as ma huang (*Ephedra sinica*), a herbal source of ephedrine, which is a potentially arrhythmogenic cardiac stimulant, are also often taken to enhance athletic performance.[238] Ephedra was initially found in a Neolithic grave in the Middle East, which may indicate that Ephedra was used as a medicine more than 60 000 years ago. In China, Ephedra was the first herbal remedy to yield an active
Fig. 65.28. Guinea pig isolated heart ECG, illustrating the electrophysiological response to left ventricular mechanical impact during the T-wave. The stimulus (arrow) causes a short run of ventricular fibrillation (VF), preceded and followed by normal sinus rhythm (NSR). (With permission, ref. 234.)

constituent, in this case ephedrine. Causal linkage between the use of dietary supplements and cardiovascular events is largely inferential, based on a close temporal relation between the ingestion of the compound and adverse events in otherwise healthy people (see also http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=hstat1a. section.41090).

Cocaine

With more than 30 million Americans having tried cocaine at least once, and with a reported 5 million regular users,[239] a better understanding of the magnitude of this cardiac risk is important from a public health perspective.

Illicit use of cocaine is often associated with acute cardiovascular events, including stroke, myocardial infarction, coronary thrombosis, arrhythmia, and SD.[237] Cocaine induces an increase in the three major determinants of myocardial oxygen demand: heart rate, systemic arterial pressure, and LV contractility. At the same time, the ingestion of even small amounts of the drug causes vasoconstriction of epicardial coronary arteries.[240] Cocaine also increases endothelial production of endothelin[241] and decreases production of nitric oxide[242] – effects that may cause or enhance vasoconstriction.

In addition to vasoconstriction, cocaine may induce thrombus formation in the coronary arteries.[243] Its use is associated with enhanced platelet activation and aggregability[244] as well as increases in the concentration of plasminogen-activator inhibitor,[245] which may contribute to thrombogenesis. Taken together, these concomitant factors explain why cocaine has been associated with an increased risk of a myocardial infarction (24 times) in the first hour after its use in persons who are otherwise at low risk.[246]

Long-term cocaine abuse has been reported to cause LV hypertrophy[247] and systolic dysfunction. Several reports have described DCM in long-term cocaine users, as well as reversible, profound myocardial depression after binge cocaine use.[248] Moreover, chronic cocaine ingestion presents a clinical and pathological profile similar to myocarditis.[18]

The profound repetitive sympathetic stimulation induced by cocaine bears comparison with that observed in patients with pheochromocytoma; both are associated with cardiomyopathy and characteristic microscopic changes of subendocardial contraction band necrosis.[216] Finally, the concomitant administration of drugs and infectious agents may cause myocarditis or endocarditis, which has been seen on occasion in postmortem studies of intravenous cocaine users.[215,249]

Anabolic steroids, dietary and nutritional supplements (particularly ephedrine-containing compounds)

Several reports link the adverse response of ma huang to concurrent use of caffeine, guarana (a source of caffeine and theophylline) or exercise.[238] Moreover, over the last few years, several studies examining substance use patterns, particularly among student populations, have shown an increase in use of steroids abuse.[250,251]

The real incidence of androgenic anabolic steroids is difficult to evaluate, but it has been suggested that more than 1 million Americans are current or former users.[252] Unfavorable cardiovascular events have been linked to both cocaine and anabolic-androgenic steroid abuse in healthy, physically active individuals. Steroid intake has been associated with vascular complications,[253] cardiomyopathy,[254] coronary atherosclerosis,[255] and cardiac hypertrophy,[256] and in several clinical reports, intake was associated with acute myocardial infarction.[257,258]

Despite the above indications, only 9 SCD cases had been examined and confirmed at autopsy by 2001.[259] The mechanism proposed for SCD in athlete consumers of anabolic-androgenic steroids is related to the adrenergic stress imposed to the heart, which is documented by the extensive early contraction band necrosis, triggered by terminal physical efforts.[260]

Athletes taking anabolic steroids tend to have increased QT intervals and an increase in QT dispersion, contributing to an increased risk of arrhythmic events.[261] Moreover, endomyocardial biopsy specimens have revealed increased fibrous tissue and fat droplets in the myocardium of anabolic steroid abusers.[262]

Even if the cause-effect relationship among anabolic-androgenic steroids, body-building, and myocardial infarction currently lacks solid clinical evidence, the concept of cardiac arrest caused by catecholamine myotoxicity, associated with VF, is supported by an experimental study in which anabolic steroids, administered in combination with exercise training, induced degenerative changes within the intracardiac sympathetic neurons of the mouse.[263] It is not surprising, therefore, that concomitant abuse of anabolic steroids and cocaine greatly enhances the risk of cardiovascular events. Indeed, testosterone at concentrations that have no effect on their own can potentiate the cocaine effect on endothelial and platelet functions.[264]

Healthcare implications

Physical inactivity and a sedentary lifestyle have been recognized as risk factors for the development or progression of coronary heart disease and for adverse cardiovascular

and non-cardiovascular events and death.[1,265] Further-more, regular aerobic exercise and fitness have many cardiovascular benefits in both men and women,[266,267] and reduce the risk of fatal or non-fatal myocardial infarction, as well as other coronary events.[1,265] Accordingly, regular exercise is being regarded as a means of primary and secondary prevention of CAD and, consequently, promoted (regardless of age) as a public health goal.[265]

Nonetheless, the consequences of exercise are more complex than they might seem at first, since vigorous physical exertion can be regarded as a two-edged sword.[268] Besides offering protection from coronary events and SCD in those who regularly engage in exercise, it can simultaneously increase the short-term risk of SD or myocardial infarction, particularly in persons who are not accustomed to regular exercise ("weekend warriors").[269,270] Indeed, a case-crossover cohort study confirmed a 17-fold increase in SCD during vigorous exercise, compared to lower levels of activity or inactive states.[268] The absolute risk for events was very low (1 event per 1.5 million exercise sessions), however, and an active lifestyle with habitual vigorous exercise markedly attenuated the risk (probably via blunting the transient risk of SD associated with occasional intense exertion).

A mechanism suggested to underlie the exercise-induced risk is activation of the sympathetic nervous system during physical exertion, which can destabilize vulnerable atherosclerotic plaques or, on the ground of a susceptible myocardium, including exercise-induced rhythm disturbances, trigger fatal arrhythmias.[271]

In contrast, regular modest physical activity enhances myocardial electrical stability by promoting a higher vagal tone, hence raising the threshold of VF (exceptions include Brugada syndrome patients).

Sports participation screening

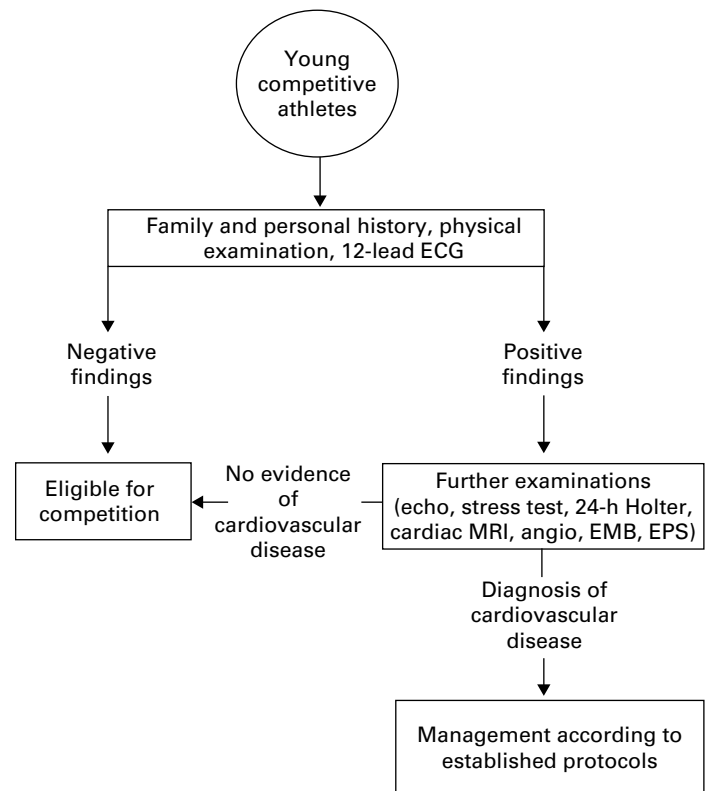
Recently the European Society of Cardiology (ESC) released a consensus statement[56] recommending systematic cardiovascular pre-participation screening of young competitive athletes for the timely detection of cardiovascular abnormalities predisposing to sport-related cardiac death. Following a previous consensus statement from the American Heart Association,[88] the ESC has promoted a standard for medical evaluation of competitive athletes. The recommended protocol for pre-participation cardiovascular screening includes a 12-lead ECG in addition to medical history and physical examination (Fig. 65.29), which is the only screening modality proven to be effective in identifying athletes with HCM, and preventing SD.[4,8]


Fig. 65.29. Flowchart illustrating the screening protocol proposed by the European Society of Cardiology. The initial cardiovascular protocol includes family and personal history, physical examination with determination of blood pressure, and basal 12-lead ECG. Additional tests, such as echocardiography, 24-h Holter monitoring, or stress testing and cardiac MRI are requested only for subjects who had positive findings at the initial evaluation. In uncertain cases, invasive tests such as contrast ventriculography (both right and left), coronary angiography, endomyocardial biopsy, and electrophysiological study may be necessary in order to confirm (or rule out) the diagnosis of cardiovascular disease. Athletes diagnosed with clinically relevant cardiovascular abnormalities are managed according to available guidelines for assessing athletic risk. Angio, angiography EMB, endomyocardial biopsy; EPS, electrophysiological study; MRI, magnetic resonance imaging; SAECG, signal-averaged ECG. (With permission from ref. 56.)

The proposed strategy builds on the Italian experience of mandatory and government-sponsored medical evaluations, in which six million athletes participating in organized sports (~10% of the Italian population) are screened *annually* by specially trained and certified sports medicine physicians.[8,20] This initiative has derived numerous benefits for athletes, including recognition of the additive

Table 65.6. Cardiovascular conditions responsible for disqualification from competitive sports in 621 athletes in Padua, 1979 to 1996

Condition	Number (%)
Rhythm and conduction abnormalities	238 (38.3)
Systemic hypertension	168 (27.1)
Valvular diseases (including mitral-valve prolapse)	133 (21.4)
Hypertrophic cardiomyopathy	22 (3.5)
Others	60 (9.7)

diagnostic power of the ECG in identifying certain cardiac disease risks, particularly HCM.[8] Similar results have also been observed in large populations of young military recruits in Italy with use of the same protocol (with an ECG).[272]

Corrado *et al.*[8] reported the 17-year experience from the Center for Sports Medicine of Padua. During the period of 1979–1996, a consecutive series of 33 735 young athletes (≤35 years) underwent pre-participation cardiovascular evaluation. Of these, 1058 were disqualified for medical reasons: 621 (1.8%) because of clinically relevant cardiovascular abnormalities. The most frequent disqualifying conditions were rhythm and conduction abnormalities (38.3%); hypertension (27%); valvular diseases (21.4%); and HCM (3.6%; Table 65.6). Less frequent reasons for non-eligibility included DCM, congenital and rheumatic heart diseases, and pericarditis.

Of the 33 735 athletes initially screened, 3016 (8.9%) were referred for echocardiographic evaluation because of their family history, abnormal physical findings, or ECG abnormalities.[8] Twenty-two had definite evidence of HCM on echocardiographic examination. No significant differences in the degree of LV hypertrophy were seen before and after deconditioning. None of the 22 athletes who were disqualified because they had HCM died during the follow-up period.

Studies from the US have consistently identified HCM as the most common cause of cardiac arrest in young competitive athletes (up to 30%),[7,273] whereas in the Italian cohort of athletes HCM caused only one death. At the same time, the prevalence of HCM among young non-athletes who died suddenly was comparable between Italy and the US.[8,274] This provides indirect but strong evidence to suggest that screening reduces SD from HCM by reducing the prevalence of HCM among athletes.

Pre-participation cardiovascular screening has traditionally been performed (in the US) by medical history and physical examination, but without 12-lead ECG or other non-invasive testing, which are requested largely at the discretion of the examining physician.[88,275] This screening method has been recommended by the Sudden Death and Congenital Defects Committee of the American Heart Association on the assumption that 12-lead ECG is not cost-effective for screening a large population of young athletes, because of its low specificity.[88] The above screening strategy, however, may have a limited power to detect potentially lethal cardiovascular abnormalities in young athletes. One retrospective analysis of 134 high school and collegiate athletes who died suddenly showed that cardiovascular abnormalities were suspected by standard history and physical examination screening in only 3% of the examined athletes and, eventually, less than 1% received an accurate diagnosis.[7]

The Italian screening modality has proved more sensitive than the current US protocol. Among the 22 Italian athletes (20 males and 2 females, aged 20 ± 4 years) who were identified and disqualified because they had HCM,[8] 82% had shown ECG changes at pre-participation evaluation, which included repolarization abnormalities (87.5%), elevated QRS precordial voltages (69%), and abnormal Q waves (31%). Moreover, premature ventricular beats were recorded in 5 (23%). It is noteworthy that only 5 of these 22 athletes (23%) had a positive family history, a cardiac murmur, or both, at pre-participation evaluation. These findings indicate that the Italian screening modality, including 12-lead ECG, has 77% greater power for detecting HCM, and it is expected to result in a corresponding additional number of lives saved, compared with the AHA-endorsed protocol. Taking into account this difference in diagnostic power, a three times greater cost-effectiveness has been estimated for the Italian screening strategy (compared to the US) for identification and prevention of SD of athletes with HCM alone.[276,277]

On the basis of currently available data, addition of echocardiography would not seem significantly to improve efficacy of the pre-participation screening in identifying HCM. As reported by Pelliccia *et al.*[278] routine echocardiographic examination did not identify any additional HCM case among 4450 athletes previously cleared by ECG at pre-participation evaluation. There are also several limitations that undermine echocardiographic recognition of ARVC, in particular the technical difficulty in visualizing the right ventricle and in assessing its function along with the existence of a wide age range and pathological features including minor and localized structural abnormalities which may nevertheless act as substrate for lethal arrhythmias.[279]

The 12-lead ECG, in contrast, offers the potential to detect, or raise clinical suspicion of, other lethal condi-

tions, such as ARVC, DCM, LQTS, Brugada syndrome, SQTS, and WPW syndrome. Overall, these conditions, including HCM, account for up to 60% of SD in young competitive athletes.[4,7,8,18]

Tools and targets for pre-participation screening will continue to be developed further over time, and their impact on mortality should be reassessed regularly. For example, the Italian screening for ARVC showed that 82% of athletes who died from this disease had a history of syncope, ECG changes consisting of inverted T waves in the right precordial leads, and/or ventricular arrhythmias with a left bundle-branch block pattern.[8] These athletes were not identified at earlier pre-participation screening, however, since ARVC was discovered relatively recently (two decades ago) and remained underdiagnosed or was regarded with skepticism by cardiologists.[280] The number of athletes with ARVC identified and disqualified from active competition significantly increased throughout 1992 to 2001, compared to the previous decade.[277]

Socioeconomic impact

Screening of large athletic populations may have a significant socioeconomic impact. Strategies for implementing the proposed screening program depend on the specific socioeconomic and cultural background as well as on the medical systems in place in different countries. The Italian experience indicates that a comprehensive screening program that includes 12-lead ECG is feasible, with the side effect of reduced cost of 12-lead ECG in a setting of mass screening. The cost of performing a pre-participation cardiac history/physical examination by qualified physicians has been estimated to be 20 Euros per athlete; this rises to 30 Euros per athlete if the 12-lead ECG is added. In Italy, the screening cost is covered by the athlete or by his team, except for athletes under 18 years of age, for whom the expense is sustained by the National Health System. Costs of infrastructure and training courses for pre-participation screening are not included in this calculation, and introducing a comprehensive coverage will increase cost.

Diagnostic challenges: athlete's heart vs. cardiovascular disease

Structural changes

Regular physical training leads to cardiovascular adaptations including both structural and functional changes, which are referred to as "athlete's heart." Modifications include structural remodeling, an increase in LV cavity size

and wall thickness by 10–20%, and an increase in LV mass by up to 45% with preservation of systolic and diastolic function.[281] The abnormal cardiac dimensions associated with athletic training are normally scaled to body-surface area or lean body mass and are usually less pronounced in female athletes.[281,282]

This physiological form of hypertrophy is regarded as a benign adaptation to systematic athletic training, with no overt adverse cardiovascular consequences.[56,283] Other physiological adaptations to training include a variety of abnormal patterns on 12-lead ECG in about 40% of athletes,[284] some of which resemble cardiac diseases, namely increased voltages, Q waves, and repolarization abnormalities.[284]

The magnitude of physiological remodeling may be such that in some highly trained individuals it may pose a challenge for differential diagnosis from cardiac diseases such as HCM and ARVC (Fig. 65.30).[32,281,285] A distinction between physiological adaptation to exertion and cardiac disease is important since in the attempt to minimize the risk of SD, identification of cardiovascular disease translates into disqualification from further competitive sports participation,[56,136] so that both false-positive and false-negative findings are undesirable.

Several studies have evaluated methods to differentiate between HCM and physiological hypertrophy of the athlete's heart,[32] often non-invasively by assessing the reduction of cardiac mass after short periods of deconditioning (usually 3 months),[286,286] or by echocardiographic measurement of diastolic filling.[32] Further support, in particular to avoid false-negative identification of cardiac disease, may come from evaluation of family history.[287] The absence of HCM in relatives does not exclude the diagnosis, however, since the disease may be the result of a *de novo* mutation responsible for the "sporadic" form.[288]

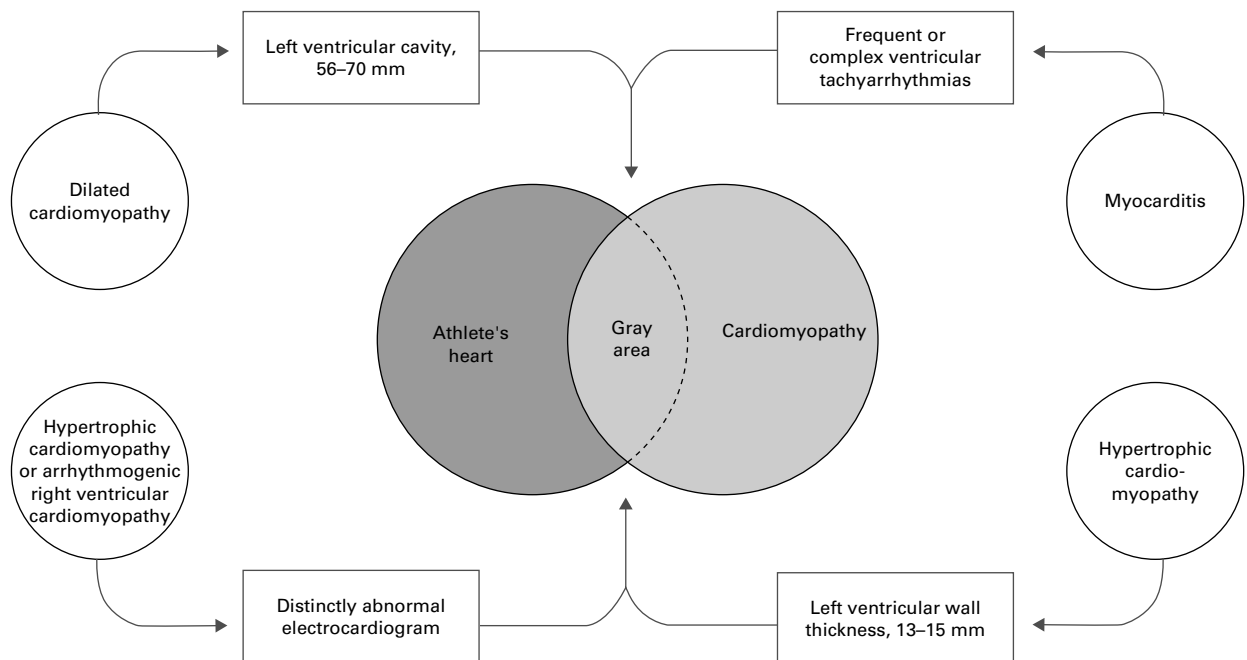
In general, HCM patients have localized hypertrophy with reduced cavity dimensions and evidence of impaired diastolic function, whereas athletes develop symmetric hypertrophy and have normal or slightly increased LV cavity dimensions (Table 65.7). A small LV cavity dimension, enlarged left atrial diameter, abnormal diastolic filling pattern, pathologic Q waves, and ST–T abnormalities on the ECG are suggestive of HCM, whereas supranormal metabolic exercise indices, such as peak oxygen consumption >50 ml/kg per min or >20%, are most likely secondary to physiological hypertrophy.[289] Metabolic indices of exercise provide a useful tool for differentiating between physiologic hypertrophy and HCM since they are abnormal in most patients affected by HCM regardless of the magnitude of hypertrophy.[289]


Fig. 65.30. Gray area of overlap between athlete's heart and cardiomyopathies, including myocarditis, hypertrophic cardiomyopathy and arrhythmogenic right ventricular cardiomyopathy. (With permission from ref. 18.)

Functional changes

Physical activity increases vagal tone.[290] This enhanced parasympathetic activity is held responsible for a variety of arrhythmias and conduction alterations observed in elite athletes, which include premature atrial and ventricular beats, supraventricular tachycardia, junctional rhythm, and first-degree AV block (Mobitz type I). Alternatively, intense endurance training has been shown to shift autonomic modulation from parasympathetic to sympathetic predominance,[291] which may predispose to an electrical instability of the ventricles and eventually trigger ventricular tachyarrhythmias.[292] Several ambulatory Holter studies have shown a higher prevalence of ventricular ectopic beats (70%) and frequent and/or complex forms (25% to 63%), such as non-sustained VT and couplets, in athletic populations.[283,293]

Arrhythmias can be a marker of heart disease and therefore generate appropriate concern when observed in athletes. Indeed, the clinical assessment and interpretation of such arrhythmias may be difficult, since this may be the only expression of potentially lethal cardiac diseases (such as ARVC), myocarditis or even substance abuse.[213,237,283] It has been generally accepted that when frequent and/or complex ventricular ectopic beats are detected in apparently healthy persons who are thoroughly examined

non-invasively and are found free of structural heart disease, it is a benign condition with a favorable prognosis.[293] A large study on almost 16 000 athletes seems confirmatory and extends that observation to extensively trained young adults.[283] Of the 355 athletes who had >3 premature ventricular contractions on 12-lead ECG or a history of palpitations, only 7% harbored structural cardiovascular abnormalities. Nonetheless, structural heart disease was 15 times more frequent in athletes with frequent and complex VT than in those with less severe arrhythmias.

Reversibility

The extreme alterations in cardiac dimensions evident in some athletes have inevitably raised the question of whether such exercise-related adaptations are truly physiological and benign. Reverse LV remodeling is evident after long-term detraining (deconditioning), with significant reduction in cavity size and normalization of wall thickness. Regression in cavity dimension and/or wall thickness typically occurs within weeks to months after cessation of competitive activity.[285] A longitudinal echocardiographic study, however, showed incomplete reversal and substantial residual dilatation of the chambers in 20% of retired, deconditioned athletes.[294] Similarly, LV mass remained

Table 65.7. Echocardiographic features of athlete's heart and HCM

	Athlete's heart	HCM
Maximal left ventricular wall thickness (mm)	< 16	≥ 16
LVH pattern	Concentric	ASH/variable
Left ventricular cavity size	Large	Small
Diastolic function	Normal	Impaired
Left atrial size	Normal	Dilated

ASH, Asymmetrical septal hypertrophy; LVH, left ventricular hypertrophy.

increased in about half of the former athletes.[294] Although firm evidence is lacking, we cannot exclude the possibility that extreme ventricular remodeling associated with intense exercise-related conditioning may represent an irreversible consequence and may have adverse clinical consequences in the long term.[294,295] Unfortunately, detraining is not usually monitored as efficiently as is active athletic performance, which may contribute to incomplete deconditioning and deficient reverse remodeling.

Reversibility of arrhythmias after deconditioning was observed both in athletes with and without cardiovascular abnormalities.[286] Biffi *et al.*[286] assessed the impact of deconditioning on ventricular arrhythmias in 70 athletes who had ≥2000 premature ventricular contractions per day and/or bursts of non-sustained VT on ambulatory ECG recording. After a deconditioning period of at least 3 months, a second 24-h recording demonstrated a clear reduction in arrhythmias for the group overall. Total premature ventricular contraction frequency decreased by 80%, couplets decreased by 80%, and the number of non-sustained VT episodes decreased by 90%. Reversibility of arrhythmia with deconditioning did not, however, always indicate absence of structural heart disease: 26% of patients who showed a clear decrease in ectopy had heart diseases, including mitral valve prolapse, myocarditis, DCM, and ARVC. In athletes with heart disease, resolution of arrhythmias after detraining could explain the mechanism by which the restriction of these athletes from competition may reduce their risk for SCD. Conversely, in athletes without cardiovascular abnormalities, the reversibility of ventricular tachyarrhythmias and the absence of cardiac events in the follow-up period support the benign clinical nature of these arrhythmias as a functional expression of athlete's heart.[286]

Medicolegal implications

Once a cardiovascular abnormality is diagnosed, the recommendations of the 26th Bethesda Conference offer clear criteria by which athletes should be withdrawn from sports competition.[296] The rationale for guidelines on sports eligibility or disqualification is the evidence that intense training and competition increases the risk of SD in those athletes who harbor cardiovascular diseases and, most importantly, that this risk is reduced after withdrawal from athletic competition.[4,8,88,297]

Given the extreme diversity of conditions to which competitive athletes are exposed and the intrinsic variability of each cardiovascular disease, the precise risk of SD to which a single individual is exposed cannot be identified with certainty. Therefore, elite athletes with heart disease may not appreciate the beneficial implications of medical advice, and rather accept the risks than abandon their professional career.[297,298] Also, disqualification of athletes with cardiovascular disease may be difficult to implement.[297–299]

An already difficult medical decision may be further influenced by pressures exerted on the physician by the athletes, their family members, team coaches, and potential sponsors. Athletes may also solicit multiple medical opinions in attempts to regain eligibility (circumventing diagnosis).[299] At the same time, waivers of responsibility that athletes may be willing to sign may not be recognized as ethically and legally binding.[296,297] A precedent for resolving medicolegal disputes comes from the US where an appellate court[297] ruled that guidelines such as the Bethesda Conference report[296] can be used by physicians to formulate appropriate decisions about an athlete's eligibility.

Recommendations for the eligibility of athletes without cardiovascular abnormalities, but with frequent and/or complex ventricular tachyarrhythmias, currently are not available. It is nevertheless common practice to withdraw such athletes for 3 to 6 months and then re-evaluate with ambulatory Holter ECG monitoring. If the frequency of ventricular tachyarrhythmias is significantly reduced or abolished at the end of the detraining period, then athletes are normally allowed to resume training and competition. Close follow-up of such athletes is warranted for the assessment of new symptoms or worsening of arrhythmias.[300]

Conclusions

Regular moderate physical exercise has beneficial cardiovascular effects. Several prospective epidemiological

studies consistently associate exercise with a reduced risk of CAD and SCD. Despite the general health benefit of regular exercise, young athletes can have a higher incidence of SD than age-matched non-athletes. In young athletes, a variety of cardiac diseases, largely congenital and often rare, account for the majority of SCD. Sports activity triggers manifestation of underlying cardiovascular diseases, predisposing athletes to life-threatening ventricular arrhythmias during physical exercise. It is therefore not *per se* a cause of the increased mortality.

In most US reports that include autopsy data, HCM is the most common underlying disease linked to these deaths. In contrast, HCM is uncommon in Italian studies of SD on the athletic field. A probable reason for this difference is the compulsory pre-participation screening of young athletes in Italy, which leads to early exclusion of HCM sufferers from competitive sports. Instead, diseases that are more difficult to screen, such as ARVC, have become most common causes of SCD in North Italian athletes.

About 2% of young athletes who die suddenly have normal cardiac structure at autopsy, and no definitive cause of death can be established. The list of congenital and acquired arrhythmias, secondary to mutations or polymorphisms in genes encoding for cardiac ion channels, has expanded impressively in recent years and may be largely responsible for such unexplained deaths. These ion channel disorders include LQTS, SQTS, Brugada syndrome, CPVT, AF, and conduction system disease. SCD may also be secondary to myocarditis, illicit substance abuse, and direct mechanical insults, i.e., CC.

Provided that efficient health screening is implemented, the impact on recreational and competitive sports can be kept to a minimum. In keeping with this view, the European Society of Cardiology has released a consensus statement recommending systematic cardiovascular pre-participation screening of young competitive athletes. The protocol includes a 12-lead ECG in addition to medical history and physical examination, which is the only screening modality proven to be effective in identifying athletes with HCM, and preventing SD. Given the socioeconomic impact strategies for implementing the proposed screening program, success will depend on the specific socio-economic and cultural background, as well as on the medical systems in place in different countries.

Special issues in resuscitation

The ethics of resuscitation and end of life decisions

Peter Baskett, Arthur B. Sanders and Petter Steen

Stanton St Quentin, Wiltshire, UK, Department of Emergency Medicine, University of Arizona, Tucson, AZ, USA, Oslo, Norway

Introduction

Successful resuscitation attempts have brought extended, useful, and precious life to many, and happiness and relief to their relatives and loved ones. And yet there are occasions when resuscitation attempts have merely prolonged suffering and the process of dying. In a few cases, resuscitation has resulted in the ultimate tragedy – the patient in a persistent vegetative state. It is to be remembered that resuscitation attempts are unsuccessful in 70%–95% of cases and death ultimately is inevitable. All would wish to die with dignity.

A number of ethical decisions are required to ensure that the decisions to attempt or withhold resuscitation are appropriate and the patients and their loved ones are treated with dignity. These decisions may be influenced by individual, international, and local cultural, legal, traditional, religious, social and economic factors.[1–10] Sometimes the decisions can be made in advance, but often they have to be made in a matter of seconds at the time of the emergency. Therefore, it is important that healthcare providers understand the principles involved before they are put in a situation where a resuscitation decision must be made.

This chapter will deal with the following ethical aspects and decisions:
- Advance directives, sometimes known as Living Wills
- When not to start resuscitation attempts
- When to stop resuscitation attempts
- Decision making by non-physicians
- When to withdraw treatment in those in a persistent vegetative state following resuscitation
- Decisions regarding active euthanasia
- Decisions regarding family members or loved ones who wish to be present during resuscitation
- Decisions regarding research and training on the recently dead
- The breaking of bad news to relatives and loved ones
- Staff support.

There are many different schools in medical ethics with emphasis on different principles such as duty (deontology, Kantian ethics), virtue, or the consequences of the decisions (utilitarian). Most common in the Western world today are the four principles of biomedical ethics, first presented by Beauchamp and Childress[11] based upon discussions in a US Presidential commission. The four key principles are *beneficence, non-maleficence, justice, and autonomy*.

Beneficence implies that healthcare attendants must provide benefit while balancing benefit and risks. Commonly, this will involve attempting resuscitation, but on occasion it will mean withholding cardiopulmonary resuscitation. Beneficence may also include responding to the overall needs of the community, such as establishing a program of public access to defibrillation.

Non-maleficence means doing no harm. Resuscitation should not be attempted in futile cases, nor when it is against the patient's wishes (expressed when the individual is in a mentally competent state).

Justice implies a duty to spread benefits and risks equally within a society. If resuscitation is provided, it should be made available to all who will benefit from it within the available resources. Also the needs of others may be compromised if excessive resources are allocated to futile attempts at resuscitation. The ethical principle of justice is independent of legal systems or cultural traditions, but

these two factors will affect how ethical justice is empha-sized within a context.

Autonomy relates to the patients being able to make informed decisions on their own behalf, rather than being subjected to paternalistic decisions being made for them by the medical or nursing professions. This principle was introduced, particularly during the past 30 years, arising from legislature such as the Helsinki Declaration of Human Rights and its subsequent modifications and amend-ments.[12] Autonomy requires that the patient is adequately informed, competent, free from undue pressure, and that there is consistency in the patient's preferences.

Advance Directives

Advance directives have been introduced in many countries emphasizing the importance of patient autonomy. Advance directives are a method of communicating the patient's wishes concerning future care, particularly towards the end of life, and must be expressed while the patient is mentally competent and not under duress. They are likely to specify limitations concerning terminal care, including the with-holding of cardiopulmonary resuscitation (CPR). The term advance directive applies to any expression of patient pref-erences, including mere dialogue between patient and/or close relatives and loved ones and/or medical or nursing attendants. This may help healthcare attendants to assess the patient's wishes in the event of the patient becoming mentally incompetent. Nevertheless, problems can arise. The relative may misinterpret the wishes of the patient, or indeed may have a vested interest in the death (or continued existence) of the patient. Healthcare providers tend to underestimate sick patients' desire to live.

Written directions by the patient, legally administered living wills, or powers of attorney may eliminate some of these problems, but are not without limitations. The patient should describe the situation envisaged when life support should be withheld or discontinued as precisely as possible. This may be aided by a medical adviser. For instance, many would prefer not to undergo the indignity of futile CPR if there was end-stage multiorgan failure with no reversible cause, but would welcome the attempt at resuscitation should ventricular fibrillation occur in asso-ciation with a remediable primary cardiac cause.

In sudden out-of-hospital cardiac arrest the attendants usually do not know the patient's situation and wishes, and an advance directive is often not readily available. Some communities have a standard prehospital advance directive form that will be respected when presented to an emergency healthcare professional. Unless there is a clear advance directive requesting no resuscitation, resuscitation is begun immediately and questions addressed later. There is no ethical objection to stopping the resuscitation attempt that has started if the healthcare providers are later presented with an advance directive limiting care. The family doctor can provide an invaluable link in these situations.

There is considerable international variation in the medical attitude to written advance directives.[1] In some countries the written advanced directive is considered to be legally binding and disobedience is considered to be an assault; in others the advance directive is flagrantly ignored if the doctor does not agree with the contents. In recent years, however, there is a growing tendency towards com-pliance with patient autonomy and a reduction in a patronizing attitude by the medical profession.[1]

When to withhold a resuscitation attempt

Whereas patients have a right to refuse treatment, they do not have an automatic right to demand treatment; they cannot insist that resuscitation must be attempted in any circumstance. A doctor is required only to provide treat-ment that is likely to benefit the patient and is not required to provide treatment that would be futile, although it would be wise to seek a second opinion in making this momentous decision, for fear that his/her own personal values, or the question of available resources, may influ-ence his/her opinion.[13]

The decision to withhold a resuscitation attempt raises a number of ethical and moral questions. What constitutes futility? What exactly is being withheld? Who should decide? Who should be consulted? Who should be informed? Is informed consent required? When should the decision be reviewed? What religious and cultural factors should be taken into consideration?

What constitutes futility?

Futility exists if resuscitation will be of no benefit in terms of prolonging life of acceptable quality. Futility must be discussed in terms of goals or purpose. Some of the con-troversy regarding futility revolves around disagreements on the goals of resuscitation – prolongation of life com-pared with the perceived judgement of meaningful life. It is difficult to evaluate the quality of life of another person and its inclusion can imply value judgements. Futility must also be defined in terms of quantitative aspect – how likely is it that the stated goal can be achieved?[14] What is the threshold of anticipated success for deciding that health care providers will not begin a resuscitation attempt – 10%,

5%, 1%. 0.5%. 0.1%? It is problematic that while predictors for non-survival after attempted resuscitation have been published,[15–18] none has been tested on an independent patient sample with sufficient predictive value, apart from end-stage multiorgan failure with no reversible cause. In addition, studies on resuscitation are particularly dependent on system factors such as time to CPR, time to defibrillation, and others. These may be prolonged in any study, but are not applicable to an individual case. For example, studies may show survival from community cardiac arrest in some large cities is as low as 1%–2%, but does that mean that resuscitation should not be attempted for a patient who arrests outside a hospital with a defibrillator available in a few minutes?

Inevitably, judgements will have to be made, and there will be grey areas where subjective opinions are required in patients with heart failure and severe respiratory compromise, asphyxia, major trauma, head injury, and neurological disease. The age of the patient may feature in the decision but age, itself, is a relatively weak predictor of outcome.[19,20] Nonetheless, age is frequently associated with comorbidity, which has an influence on prognosis. At the other end of the scale, most doctors will err on the side of intervention in children for emotional reasons, even though the overall prognosis is often worse in children than in adults. It is therefore important that clinicians understand the factors that influence success of resuscitation.

What exactly should be withheld?

Do not attempt resuscitation (DNAR) means that in the event of cardiac or respiratory arrest CPR should not be performed – nothing more than that. Other treatment should be continued, especially pain relief and sedation, as required. Ventilation and oxygen therapy, nutrition, antibiotics, fluid and vasopressors, and other interventions should be continued as indicated, if they are considered to be contributing to the quality of life. If not, orders not to continue or initiate any such treatments should be specified independent of DNAR orders.

While DNAR orders for many years in many countries were written by single doctors, often without consulting the patient, relatives, or other health personnel, there are now clear procedural requirements in many countries such as the USA, UK, and Norway.

Who should decide not to attempt resuscitation?

This very grave decision is usually made by the senior doctor in charge of the patient after appropriate consultations. Decisions by committee are impractical and have not been shown to work, and hospital management personnel lack the training and experience on which to base a judgement. Decisions by legal authorities are fraught with delays and uncertainties, especially if there is an adversarial legal system, and should be sought only if there are irreconcilable differences between the parties involved. Such decisions are usually associated with undignified media attention that is not in anyone's interest, especially the patient's. In especially difficult cases, the senior doctor may wish to consult his/her own medical defence society for a legal opinion.

Medical Emergency Teams, acting in response to concern about a patient's condition from ward staff, can assist in initiating the decision-making process concerning DNAR.[21] In addition, some hospitals have Ethics Committees that will provide multidisciplinary consultations and advice to the senior physician before a decision regarding limitation of care is made.

Who should be consulted?

Having stated that the ultimate decision for DNAR should be made by the senior doctor in charge of the patient, he or she would be foolish and arrogant not to consult others in arriving at that decision. Following the principle of patient autonomy, it is prudent, when possible, to ascertain the patient's wishes in regard to a resuscitation attempt. This must be done in advance, when the patient is able to make an informed choice. Opinions vary as to whether such discussions should be a routine matter for every hospital admission (which might cause undue alarm in the majority of cases) or only if the diagnosis of a potentially life-threatening condition is made (when there is a danger that the patient may be too ill to make a balanced judgement). It has been shown that doctors find these discussions difficult and in a review of US institutions only 20%–38% of seriously ill patients had discussed possible resuscitation with their physician.[22] Another report from the UK has indicated that the number of cases designated as DNAR fell significantly when there was a directive that discussion of resuscitation decisions with the patient should be mandatory in all who are compos mentis.[23] In presenting the facts to the patient, the doctor must be as certain as possible of the diagnosis and the prognosis and may seek a second or third medical opinion in this matter. It is vital that the doctor should not allow his/her own life values to distort the discussion – in matters of acceptability of a certain quality of life, the patient's opinion should prevail.

It is considered essential for the doctor to have discussions with close relatives and loved ones if at all possible. Although they may influence the doctor's decision, it

should be made clear to them that the ultimate decision will be that of the doctor. It is unfair and unreasonable to place the burden of decision on the relative.

The doctor would also be wise to discuss the matter with the nursing and junior medical personnel, who are often closer to the patient and more likely to be given personal information. The patient's family doctor may have very close and long-term insight into the patient's wishes and the family relationships based on years of knowledge of the particular situation.

Who should be informed?

Once the decision has been made, it must be communicated clearly to all who may be involved, including patient and relatives. The decision and the reasons for it, and a record of who has been involved in the discussions should be written down – ideally on a special DNAR form that should be placed in a prominent place in the patient's notes – and recorded in the nursing records. Sadly, there is evidence of a reluctance to commit such decisions in writing by doctors in some centers in some countries.[24]

When to abandon the resuscitation attempt

The vast majority of resuscitation attempts do not succeed and have to be abandoned. A number of factors will influence the decision to stop the resuscitative effort. These include the medical history and anticipated prognosis, the period between cardiac arrest and start of CPR, the interval to defibrillation, and the period of advanced life support with continuing asystole and no reversible cause.

In many cases, particularly for out-of-hospital cardiac arrest, the underlying cause of arrest may be unknown or merely surmised and the decision is made to start resuscitation while further information is gathered. If it becomes clear that the underlying cause renders the situation futile, then resuscitation should be abandoned. Information, such as an advance directive, can also become available, which makes discontinuation of the resuscitation attempt ethically correct.

In general, resuscitation should be continued as long as ventricular fibrillation persists. It is generally accepted, however, that ongoing asystole for more than 20 minutes in the absence of a reversible cause, and with all advanced life support measures in place, is justification for abandoning the resuscitation attempt.[25] There are reports of exceptional cases that prove the general rule and each case must be assessed individually.

In out-of-hospital cardiac arrest of cardiac origin, if recovery is going to occur, a return of spontaneous circulation usually takes place on-site. Patients with primary cardiac arrest who require ongoing CPR without any return of a pulse during transport to hospital rarely survive neurologically intact.[26]

Many will persist with the resuscitation attempt for longer if the patient is a child. This decision is not generally justified on scientific grounds, for the prognosis after cardiac arrest in children is certainly no better, and probably worse, than in adults. Nevertheless, the decision to persist in the distressing circumstances of the death of a child is quite understandable and the potential enhanced recruitment of cerebral cells in children after an ischemic insult is an unknown factor to be reckoned with. Similar decisions, based purely on emotion, may occur if the patient is a celebrity or well known to the resuscitating team, such as a member of staff, but purely emotional decisions do not stand up to evidence-based scientific scrutiny.

The decision to abandon the resuscitation attempt is made by the team leader, but after consultation with the other team members, who may have valid points to contribute. Ultimately the decision is based on the clinical judgement that the patient's arrest is unresponsive to advanced life support. In the end, the final conclusion should be reached by the team leader taking all facts and views into consideration and dealing sympathetically, but firmly, with any dissenter.

Decision-making by non-physicians

Many cases of out-of-hospital cardiac arrest are dealt with by emergency medical technicians or paramedics, who face similar dilemmas of when resuscitation is futile and when it should be abandoned. Clearly, resuscitation is futile in cases of cardiac arrest with a mortal injury such as decapitation and hemicorporectomy, known prolonged submersion, incineration, rigor mortis, dependent lividity and fetal maceration. In such cases the non-physician is making a diagnosis of death but is not certifying death (which in most countries can be done only by a physician). In some countries emergency medicine technicians operate under the authority of a base station physician or medical director specific protocols. Consultation with the base hospital physician is strongly advised when the decision is being considered regarding medical futility.

But what of the decision to abandon a resuscitation attempt? Should paramedics trained in, and able to provide, advanced life support in terms of cardiac monitoring, ventilation with oxygen through a secure airway, and appropriate drug administration be able to declare death after 20 minutes of asystole in the absence of

reversible causes – bearing in mind the very negative results achieved with on-going CPR during transport? Opinions vary from country to country.[27] In some countries it is routine, and it is clearly unreasonable to expect paramedics to continue with resuscitation in the precise circumstances where it would be abandoned by a doctor. In making this recommendation it is essential that times are recorded very accurately and written guidelines are provided.[28] The answer would appear to lie in superior training and thereafter confidence in those who have been trained to make the decision.

Similar decisions and a diagnosis of death may have to be made by nurses in nursing homes for the aged and terminally ill without a resident doctor. It is to be hoped that a decision as to the merits of a resuscitation attempt will have been made previously. DNAR consideration should always be addressed for patients in these establishments.

Mitigating circumstances

Certain circumstances such as hypothermia will enhance the chances of recovery without neurological damage. The phrase "not dead until warm and dead" is often cited as a guiding principle to follow, but this only applies to patients with cardiac arrest secondary to hypothermia, not necessarily to other etiologies.

Sedative and analgesic drugs obscure the assessment of the level of consciousness in the patient who has a return of spontaneous circulation.

Withdrawal of treatment after a resuscitation attempt

Assessment of the overall prognosis of the neurological status after resuscitation with a return of spontaneous circulation, but continuing loss of consciousness, is difficult during the first 3 days. During that time, efforts should be made to ensure that blood chemistry and hematology are restored to normal values. There are no specific clinical signs that can predict outcome in the first few hours after the return of spontaneous circulation. Measurement of cerebral spinal fluid creatinine kinase or serum S-100 levels have been found to have a high specificity for determining a poor neurological outcome, but only after about 3 days, and if combined with absent pupillary responses and an absence of motor response to pain and electrophysiological testing, the specificity rises to almost 100%.[29,30] Of note, however, the introduction of therapeutic hypothermia after cardiac arrest appears to have changed the predictive values, and these should be viewed

with caution until new predictive values have been established for these patients.

In a very small number of distressing cases, patients regain spontaneous circulation but remain in a long-term persistent vegetative state. The question may arise as to whether such an existence is in the patient's best interest compared to the alternative of dying. If it is found to be the patient's wish not to continue in this state, the question arises as to whether basic treatment such as food and fluids should be withdrawn to terminate life. Generally there is agreement between relatives and the doctors and nurses as to the path to follow. If that agreement means continuing with basic supportive treatment, then there is usually no problem. Similarly, if there is general agreement that life should be terminated by withdrawing basic treatment this can be done with or without the involvement of legal authorities as required in the country. Difficulties arise if there is a disagreement between the doctors and nurses and the relatives, or between the relatives. The very sad case of Terri Schiavo in the United States in 2005 highlights the extreme protracted legal wrangling and indignity that can be associated with such a situation which attracts the intrusive, and often uninformed, media and internet celebrities and figures to add their gratuitous opinions in a highly charged atmosphere.[31] It is of interest that opinion polls in the US supported the withdrawal of the feeding tube in this case and the majority felt that the wishes of the spouse should be upheld, as opposed to the views expressed by the patient's parents and some politicians, who wished to prolong life regardless.[32] The case has prompted many to make an Advance Directive for the first time. In Europe, although there also may be extreme views supporting either side, it seems that many are content to leave the decision to the family and physicians in private.

Family presence during resuscitation

The question of permitting close family members to be present during a resuscitation attempt, if they so wished, was first raised in the literature during the late 1980s[33] and was a subject of continuing debate during the 1990s.[34] Initial reaction to the suggestion by the medical profession (particularly among internists) was very negative,[35,36] particularly if relatives were uninformed and unsupported and there was a general feeling that the process would be very difficult and stressful for staff.[37] Emergency physicians and pediatricians and the nursing staff were more supportive of this concept. The antagonists cited fears that the procedure would be most distressing for the relative, particularly if defibrillation and very invasive measures

were being performed. Others maintained that the distraught relative might interfere with the resuscitation process or put the rescuers off their prime objective of saving the patient's life. It was thought by some that the presence of a relative would make the decision to abandon the resuscitation attempt very difficult. Some were afraid that medicolegal action might be taken if apparent weaknesses or failures were perceived to have occurred. Public expectation of success rates from resuscitation endeavors as shown on fictional medical series on television (70%–80%) is much higher than occurs in reality (20%–30% at best) .In practice there has been no evidence to support these fears.

Indeed, there has been a continuing flow of papers supporting the concept of family members being present during the resuscitation process, if they wish.[38–45] Many relatives would wish to be present during resuscitation attempts, and of those who have had this experience, over 90% would to do it again. Most parents would expect to be with their child at this time and would not take kindly to being excluded.[46]

Relatives have noted a number of benefits from being permitted to be present.

These include:

- help in coming to terms with the reality of death and easing the bereavement process;
- being able to communicate with, and touch, their loved one in their final moments while they were still warm. Many feel that their loved one appreciated their presence at that moment, and this may be quite possible if consciousness returns during effective CPR (as has been recorded on occasion, especially with mechanical CPR);
- feeling that they had been present during the final moments and that they had been a support to their loved one when they needed it;
- feeling that they had been there to see that everything that could be done, was actually done.

Clearly a number of measures are required to ensure that the experience of the relative is the best under the circumstances.

- The resuscitation should be seen to be conducted competently under good team leadership with an open and welcoming attitude to the relative. "Black humour," so often the saviour of staff working in such stressful situations, should be postponed until afterwards at the staff debriefing session.
- The relatives should be briefed, in terms that they can understand, before entering and offered continual support during the event by a member of staff (usually a nurse) trained in this subject. They should be given to understand that the choice to be present is entirely

theirs, and no feelings of guilt should be provoked, whatever their decision.

- They should be made aware of the procedures they are likely to see and the patient's response (e.g., convulsive movements after defibrillation) and the possible invasive techniques such as tracheal intubation and placement of central venous lines that may be required. The importance of not interfering with any procedures should be emphasized and any dangers of doing so should be explained clearly.
- In the majority of cases it will be necessary to explain that the patient has not responded to the resuscitation attempt and that the attempt has to be abandoned. The decision should be made by the team leader involving the members of the team. The relative should not be burdened with this responsibility. It should be explained to the relative that there may be a brief interval while equipment is removed and that then they will be able to return to be with their loved one at their leisure, alone or supported, as they wish. Certain tubes and cannulae may have to be left in place for medicolegal reasons.
- Finally, there should be an opportunity for the relative to reflect and ask questions about the cause and the process and be given advice about the procedure for registering the death and the support services available.

In the event of an out-of-hospital arrest the relatives may already be present, and possibly performing basic life support. They should be offered the option to stay and may appreciate the opportunity to help and travel in the ambulance to hospital. If death is pronounced at the scene, the relatives should be offered the help and support of their family doctor or community nurse and bereavement councillor.

For resuscitation staff, both in- and out-of-hospital, it is worth offering training on the best way to help relatives who wish to be present. The Resuscitation Council (UK) has designed a program for such a study day.[47]

From increasing experience of family presence during resuscitation attempts, it is clear that problems rarely, if ever, arise. In the majority of instances the relative comes in and stays but a few minutes and then leave – satisfied that they have taken the opportunity to be there to support their loved one and say good bye as they would have wished. Ten years ago most would not have countenanced the presence of relatives being present during resuscitation, but a recent survey has shown an increasingly open and less patronizing attitude and appreciation of the autonomy of both patient and relative.[1] International cultural and social variations still exist, and must be understood and appreciated with sensitivity.

Training and research on the recently dead

Another matter that has raised considerable debate is the ethics, and in some cases the legality, of undertaking training and/or research on the recently dead.

Training

The management of resuscitation can be taught using scenarios with manikins and modern simulators, but training in certain skills required during resuscitation is notoriously difficult. External chest compressions and, to an extent, expired air ventilation, insertion of the oropharyngeal and nasopharyngeal airways can be taught using manikins, but many other skills, needed on a regular basis during resuscitation, can be acquired satisfactorily only through practice on a human subject, dead or alive, even though the design of manikins and simulators improves year by year. These other skills include, for example, central and peripheral venous access, arterial puncture and cannulation, venous cutdown, bag/valve/mask ventilation, tracheal intubation, cricothyrotomy, needle thoracostomy, chest drainage, and open chest cardiac massage. Some of these skills may be practiced during routine clinical work, mostly involving anesthesia, and to some lesser degree, surgery, but others such as cricothyrotomy, needle thoracostomy, and open chest cardiac massage cannot, and are needed only in a life-threatening emergency when it is difficult to justify a teaching exercise. In modern day practice, with practitioners being called increasingly to account and patient autonomy prevailing, it is becoming more and more difficult to obtain permission for student practice of skills in the living. Gone are the days when admission to a "teaching hospital" implied automatic consent for students to practice procedures on patients under supervision as they wished. And yet the public expect, and are entitled to, competent practitioners for generation after generation.

So the question arises – is it ethically and morally appropriate to undertake training and practice on the living – or the dead?

There is a wide diversity of opinion on this matter.[48] Many, particularly those in, but not limited to, the Islamic nations, find the concept of any skills training and practice on the recently dead completely abhorrent because of an innate respect for the dead body. Others will accept the practice of non-invasive procedures that do not leave a mark, such as tracheal intubation. And some are open and frank enough to accept that any procedure may be learned on the dead body with the justification that the learning of skills is paramount for the well-being of future patients. One option is to request informed consent for the procedure from the relative of the deceased. Nevertheless, only some will obtain permission[1,48] and many find this very difficult to do, especially in the harrowing context of breaking bad news to the recently bereaved. As a result, only non-invasive procedures may be practiced, on the basis that distress will not be caused by what is not seen. Clearly, the days of undertaking any procedure without consent are rapidly coming to an end. Perhaps it is now becoming increasingly necessary to mount a publicity campaign to exhort the living to give permission for training on their bodies after death through advance directives, in much the same way as permission for transplant of organs may be given. It is possible that an "opt-out" rather than an "opt-in" arrangement may be adopted, but this will require changes in the law in most countries. It is advised that healthcare professionals learn local and hospital policies regarding this issue and follow the established policy.

Research

There are important ethical issues regarding advancing the quality of resuscitation by performing randomized clinical trials for patients in cardiac arrest who cannot give informed consent to participate in research studies. Progress in improving the dismal rates of successful resuscitation will only come through the advancement of science through clinical studies. The utilitarian concept in ethics looks to the greatest good for the greatest number of people. This must be balanced with respect for patient autonomy in which patients should generally not be enrolled in research studies without their informed consent. Over the past decade, legal directives have been introduced into the United States and the European Union[49,50] that place significant barriers to research in patients during resuscitation unless there is informed consent from the patient or immediate relative. Data show that such regulations deter research progress in resuscitation. It is indeed possible that these directives may in themselves conflict with the basic human right to good medical treatment as set down in the Helsinki Agreement.[12] Research in resuscitation emanating from the United States has fallen dramatically in the last decade,[51] and it appears very likely that the European Union will follow suit as the rules are implemented there. The United States authorities have, to a very limited extent, sought to introduce methods of exemption,[49] but these are still associated with problems and almost insurmountable difficulties.[52]

Research on the recently dead is likely to encounter similar restrictions unless prior permission is granted as part of an advance directive by the patient, or permission can be given there and then by the relative who is next of

kin. Legal ownership of the recently dead is established only in a few countries, but in many countries it is at least tacitly agreed that the body "belongs" to the relatives (unless there are suspicious circumstances or the cause of death is unknown) and permission for any research must be granted by the next of kin unless there is an advance directive giving consent. Obtaining consent from relatives in the stressful circumstances of immediate bereavement is unenviable and potentially damaging to the relationship between doctor and relative. The introduction of these prohibitive directives, as they apply at present, will prevent research in humans into potentially valuable drugs for resuscitation. Research can still be carried out during post-mortem examination, for instance, to study the traumatic damage arising as a result of using specific methods of chest compressions, but all body parts must be returned to the patient unless specific permission is obtained from relatives to do otherwise.

Breaking bad news and bereavement counselling

Breaking news of the death of a patient to a relative is an unenviable task. It is a moment that the relative will remember forever, so it is very important that it be done as correctly and sensitively as possible. It also places a considerable stress on the healthcare provider who has this difficult duty. Both may need support in the ensuing hours and days. It is notable that the breaking of bad news is seldom taught in medical school or at postgraduate level.[1]

Contacting the family in case of death of a relative without the relatives being present

If the relatives are not present when the patient dies, they must be contacted as soon as possible. The caller may not be known to the relative and must take great care to ensure that his or her identity is made quite clear and, in turn, the caller must make sure of the relationship of the call recipient to the deceased. In most cases it is wise not to state on the telephone that the patient has actually died, unless the distance and travel time involved is very long (e.g., the relative is in another country). It may be better to say that the patient is seriously and critically ill or injured and that the relatives should come to hospital immediately. It is wise to ask the relative to ask a friend to drive them to hospital and to state that nothing will be gained by driving at speed. When relatives arrive they should be greeted right away by a competent and knowledgeable member of staff and the situation explained immediately. Delays in being told the facts are agonizing.

Who should break the bad news to the relative?

It is no longer acceptable for the patronizing senior doctor to delegate the breaking of bad news to his junior assistant. Nowadays, it is generally agreed that it is the duty of the senior doctor or the Team Leader to talk to the relatives. Nevertheless, it is wise to be accompanied by an experienced nurse who may be a great comfort for the patient (and indeed the doctor).

Where and how should bad news be given?

The environment where bad news is given is vitally important. There should be a room set aside for relatives of the seriously ill that is tastefully and comfortably furnished, with fresh flowers daily, a television and free access to a telephone. There are some basic principles that should be followed when breaking bad news if grave errors are to be avoided and the relative is not to be discomforted. It is essential to know the facts of the case and to make quite sure that you are talking to the correct relatives.

Body language is vital – always sit at the same level as the patient – do not stand up when they are sitting. Make sure you are cleanly dressed – wearing blood-stained clothing is not good. Do not give the impression that you are busy and in a hurry. Give the news they are anxious to hear immediately using the words "dead" or "has died" – "I am very sorry to have to tell you that your father/husband/son has died." Do not leave any room for doubt by using such phrases as "passed on" or left us" or "gone up above".

Going into the complete medical details at this stage is not helpful – wait until they are asked for. Touching may be appropriate, such as holding hands or placing an arm on the shoulder, but people and customs vary and the doctor needs to be aware of these. Do not be ashamed if you shed a tear yourself. Allow time for the news to be assimilated by the relative. Reactions may vary from relief ("I am so glad his suffering is over" or "He went suddenly – that is what he would have wished"), to anger with the patient (" I told him to stop smoking" or "He was too fat to play squash" or " Look at the mess he has left me in"), to self-guilt ("If only I had not argued with him this morning before he left for work" or "Why did I not tell the doctor he got chest pain"), to anger with the medical system ("Why did the ambulance take so long" or "The doctor was far too young and did not know what he was doing") , to uncontrollable wailing and crying and anguish, to complete expressionless catatonia. It may be useful to reassure the family that they did everything correctly such as calling for help and getting to the hospital; however, in the vast majority of cases health care providers are unable to restart the heart.

Some time may elapse before conversation can resume and at this stage ask the relative if they have any questions about the medical condition and the treatment given. It is wise to be completely open and honest about this, but always say if appropriate "He did not suffer". In the majority of cases the relative will wish to see the body. It is important that the body and bedclothes are clean and all tubes and cannulae are removed, unless these are needed for postmortem examination. The image of the body will leave an impression on the relative that will last forever. A postmortem examination may be required and this should requested with tact and sensitivity by explaining that the procedure will be carried out by a professional pathologist and will help to determine the precise cause of death.

Children

Breaking bad news to children may be perceived to present a special problem but experience seems to indicate that it is better to be quite open and honest with them, so helping to dispel the nightmarish fantasies that children may concoct about death. It is helpful to contact the school so that the teachers and fellow pupils can be prepared to receive the child back into the school environment with support and sensitivity.

Closure

In many cases this will be the relative's first experience of death and help should be offered with the bewildering administration of the official registration of death, funeral arrangements, and socioeconomic support by the hospital or community social worker.

Depending on religious beliefs, the hospital padre or priest may play a vital role. Whenever possible, the family physician should be informed immediately by telephone or e-mail with the essential details of the case so that they can give full support to the relatives. A follow-up telephone call to the relative a day or two later from a member of the hospital staff who was involved, enquiring if they can be of any help, and with an offer to answer any questions that the relative may have forgotten about at the time, is always appreciated.

Staff debrief

Although many members of staff seem, and often are, little affected by death in the course of their work, this should not be assumed. Their sense of accomplishment and job satisfaction may be adversely affected and there may be feelings of guilt, inadequacy, and failure. This may be especially apparent in, but not restricted to, very junior members of staff. A team debrief of the event with positive and constructive critique of techniques should be conducted and personal bereavement counselling offered to those with a particular need. How this is done will vary with the individual and will range from an informal chat in the pub or cafe (which seems to deal effectively with many cases) to professional counselling. It should be explained that distress after a death at work may be a normal reaction to an abnormal situation.

Conclusions

Resuscitation has given many a new lease on life to the delight of patients and their relatives, but has the potential to bring misery to a few. This chapter addresses how that misery can be reduced by not attempting resuscitation in inappropriate circumstances or in patients with a valid advance directive and when to discontinue the resuscitation attempt in cases of futility or persistent vegetative state. Ethical issues such as training and research on the recently dead, and the presence of family members during the resuscitation attempt place further burdens on the medical profession, but must be dealt with sympathetically, and with an appreciation of growing patient autonomy and Human Rights throughout the world. Finally, the breaking of bad news is one of the most difficult tasks to be faced by the medical and nursing professions. It requires time, training, compassion and understanding.

The economics of treating sudden cardiac arrest

Alastair Fischer and Graham Nichol

St George's University of London.
University of Washington-Harborview Center for Prehospital Emergency Care, University of Washington, USA

Introduction

Each year, about 360 000 of about 2.4 million deaths in the USA are caused by sudden cardiac arrest (SCA). Any other cause of death that gives rise to mortality on such a scale (about 15% of all deaths) has seen huge research funding and effort, and funding devoted to finding the cause and successful treatment of the condition. Although much is now known about the cause of sudden cardiac episodes, efforts to apply successful treatment have not received the funding that could be expected of such a large cause of death.

The two main reasons for this are the speed and near-certainty of death. The speed of onset of the condition requires an exceedingly fast response. Successful treatment is available, but it must be applied quickly. Increasing the speed of response of emergency medical services is expensive, and this dominates in the estimation of cost-effectiveness. A fundamental but unresolved question is the extent to which it is worth providing a swift response, and the circumstances in which a society or a health service provider is willing to divert resources from other disease areas, given the uncertainty surrounding the value of the benefits of adding resources to improve the likelihood of success of the treatment. The second reason for the lack of resources is the near certainty of death when the condition strikes. There are relatively few survivors: in most countries, no more than 5% of patients leave hospital alive. Hence, there are few patient support groups to provide a higher profile and act as a lobby group for more effective treatment. There is also a general belief that survivors do not have long to live, whereas the average length of survival is about 6 years, and somewhat longer for those who arrest at a younger age.[1]

But even though sudden cardiac arrest is a common form of death, it is nevertheless a rare event. If the lifetime incidence is 15%, and average life expectancy is 75 years, then there will still only be one sudden cardiac death event every 500 person-years. Once a sudden cardiac arrest (SCA) arrhythmia has become established, the primary means of avoiding death is by defibrillation. Five hundred years is a long time for a defibrillator, if it were to be dedicated to a single person, to have to wait for a single use. Since defibrillators require maintenance, training and retraining of operators, all requiring ongoing costs, it is easy to see why there is not one in every home and on every street corner.

This chapter examines the economics of defibrillation, and tries to generate some general principles. Among other things, the following types of question will be addressed. What is worthwhile doing and what is not? How does the cost of the technology impinge on the total cost of defibrillation? How can training be made less expensive? The chapter also looks more broadly at where there are gaps in knowledge of the cost-effectiveness of combating sudden cardiac death. In particular, modeling will be required to evaluate systems devoted to the treatment of SCA. How could one establish whether emergency service provision in a region requires more or less resources than other uses of resources to maximize the health gain in that community?

The focus of this chapter is the use of automated external defibrillators (AEDs) out of hospital. Implantable defibrillators are not considered except briefly as an alternative therapy and as a potential downstream cost, nor is in-hospital defibrillation. The role of cardiopulmonary resuscitation (CPR) is considered only in passing, but the

model could be extended to assess the incremental cost-effectiveness of community training or other methods of achieving bystander CPR.

Given the cost of defibrillators and their infrequent use, they will not be cost-effective under all circumstances (i.e., they will not be cost-effective if placed in every home and on every street corner); thus, the limits to what circumstances are cost-effective must be determined on a case-by-case basis. In what follows, we assume that the objective of the provider of defibrillators is to use resources in such a way as to maximize the number of quality-adjusted life years gained for the community under consideration.

For this purpose, two strategies are considered:

1. To bring the defibrillator to the patient (via the emergency services: ambulance, fire brigade, police)
2. To site defibrillators where there are large gatherings of people (sporting events, large auditoriums, airports, railway stations and large shopping centers): public access defibrillators (PADs). About 16%–17% of SCA episodes occur in public places.[1]

Beyond this, there are special cases, such as long-distance aircraft and trains, where an offsite defibrillator cannot be transported to the patient without considerable delay, but where the number of people served by the PAD is smaller than in 2 above, yet still moderately large. Moreover, in the case of air and rail travel there are trained "carers" of the traveling public (hostesses and stewards) who know the location of defibrillators and can be trained in their use.

To estimate the relative magnitudes involved in these two strategies, consider 100 cases of out-of-hospital SCA. About 50 incidents are witnessed, of which some 33 would be at home or in places not served by a PAD. Some of the 17 patients who could be covered by PADs will be treated by them, while for the remainder, the emergency service will arrive first. So in round figures, some 40 to 45% of people could expect to be covered by emergency service and some 5 to 10% by PADs;[2] only a very small proportion of the remaining 50% will receive defibrillation in time to prevent premature death. Each implementation of defibrillation in the community has costs and effects.

The main issues in cost-effectiveness analysis

In assessing the costs and effects of an intervention, it is important to determine

- the population under consideration,
- the intervention,
- the comparator or comparators,
- the perspective of the study,

- the effects (benefits), and
- the costs.

Analysis and modeling of the underlying processes involved also generally require some knowledge of factors (or covariates) that determine the costs and outcomes of the intervention.

The first three of these points are straightforward: the population consists of people suffering out-of-hospital SCA, the intervention is an external defibrillator (either carried by a specialized team such as emergency service personnel, or placed as a public access device), and the comparison is with not using a defibrillator. The other three points: perspective, costs, and benefits, require some discussion.

Perspective

The importance of the perspective of a cost-effectiveness study is often underestimated. There are perhaps three main perspectives that can be taken: that of society, that of a health service as a whole (equivalently, a third-party payer perspective), and that of part of the health service such as an emergency service.

If we take a societal perspective, we must ask ourselves what are the total costs of treating a person suffering SCA with a defibrillator, and what are the total costs of treating them without a defibrillator. Without a defibrillator, there will be virtually no survivors, so the costs will be limited in time. With a defibrillator, however, there will be a small proportion of survivors. They will accrue health care costs for the rest of their lives, which may stretch on for years and occasionally for decades. These costs are relevant to the analysis. They include those of long-term care for people with poor neurological outcomes, and implantable defibrillators for those who receive them.

The perspective also helps to determine how the cost-effectiveness analysis will be carried out. From a societal perspective, we may be interested in comparing the effect of using additional resources for treating SCA on the one hand, with anything else, such as education, defense or the environment, or allowing individuals to spend their extra earnings as they wish rather than be collected as taxes, on the other hand. To determine the allocation of resources between such competing uses, we must place a monetary value on benefits as well as on costs, leading to a cost-benefit analysis.

Nevertheless, we may also be concerned with the costs and benefits to society as a whole (that is, take a societal perspective) without wishing to make comparisons outside the health sector. In that case, it is not necessary to go as far as having to convert health benefits into monetary

equivalents. An accepted common currency to compare the full range of health benefits is a quality-adjusted life year (QALY).

To determine how best to spend money within an emergency service, most comparisons can be made by estimating how many seconds can be subtracted from average response time for a given cost of different innovations. The innovation that gives rise to the greatest reduction in average response time for a given cost will in most circumstances be the innovation that gains the most QALYs for a given cost. It is that innovation that should be the first to be adopted. It is only when there is a need to compare spending of additional money within an emergency service with the same money spent elsewhere on health care that recourse to QALYs is required.

The perspective of an economic analysis refers to the group within society that bears the costs and gains the benefits of health care decisions, but the term is also used when examining costs from either an accounting or an economic perspective. Often these perspectives are the same, but sometimes they can be quite different. The accounting approach attributes the cost of a health care worker to the time spent on a task, multiplied by their hourly wage rate. The economic approach attributes the cost of the labor component of making an innovation operational by determining the value of the time spent by looking at what that person would otherwise be doing with the time. In EMS agencies, some of a provider's time is spent waiting for a call to aid, known as on-call time, or using the jargon of linear programming, slack time. If a provider were to be engaged in an activity in place of what would otherwise be slack time, then the so-called "opportunity cost" of their labor will be zero. In other words, it does not cost anything in economic terms if slack time is used for a productive purpose. Conversely, the opportunity cost of delaying an ambulance on its way to defibrillate an SCA victim will be hundreds if not thousands of dollars per minute.

By considering a scenario, we illustrate some of the difficult distinctions that should be made with respect to perspective. Some of these distinctions overlap with decisions about how to deal with costs, and to some degree, the discussion could easily be carried out in the following section on costs.

Suppose that an emergency service with 20 active ambulances carries 1000 people with SCA per year to hospital, where 60 are discharged alive. If SCA patients comprise (say) 1% of all calls, and if they take the same crew-time as a call of average duration, should the SCA calls be debited with 1% of all costs? It is unclear in terms of economic or accounting costs, as there are no theorems to say how joint costs should be apportioned. The decision to allocate costs

as a proportion of resources used is widely utilized as an accounting approach to costs, but is no more than a pragmatic decision.

From an economic perspective, we can gain some idea of how to allocate these costs by supposing that the ambulance service, after pressure from the community, is given resources that would double the number of ambulances from 20 to 40. The service carries no more SCA patients than before (indeed, no more of any sort of patient). Because there are more ambulances than before, response times decrease, and as a result, we suppose that of the 1000 patients with SCA, the number of survivors increases from 60 to 80. The response times for every other sort of patient will also improve. If the active resources have been doubled in order to deal with life-threatening conditions (and for no other reason), however, then the life-threatening conditions alone should be ascribed the cost of the additional ambulances. These costs should not be spread over the people with non-life-threatening conditions who are carried by ambulance. If, perversely, the only people eligible to be carried by an ambulance were those *without* a life-threatening condition, society would probably not provide resources for ambulances at all, and probably rightly so. Notably also, as a consequence of why the ambulances are being provided, ambulances should give priority to people who have life-threatening conditions over those who do not.

So how much of an emergency service's costs should be attributed to SCA patients? Certainly not only the time taken per call. To this must be apportioned on-call time, as a very minimum. But according to the above logic, almost the whole cost of the service should accrue to life-threatening calls, of which SCA calls will be a large portion.

If the perspective is that of the emergency service, we do not need to estimate the cost of postsurvival care for survivors. Find the increased cost of the 10 ambulances, apportion a large chunk (as described above) of this cost to SCA patients, and note that there are 20 additional survivors. If the average number of life-years saved is 6 per survivor, then there would be 2 additional survivors and 12 additional life-years gained per additional ambulance. The cost per life-year saved is thus the cost of the increased number of ambulances divided by 12 if *all* the costs are attributed to SCA, and less if some of the costs are attributed elsewhere (to other life-threatening conditions, and a little to the non-life-threatening conditions carried by the ambulances).

Since we cannot separate the various uses of an ambulance, the most satisfactory solution to this problem of apportionment is to estimate the number of quality-adjusted life-years gained (QALYs) from all uses in aggregate

that would be gained from a given increase in resources. That is, the emergency service has to be evaluated for cost-effectiveness as a whole, and not just for its role in treating/transporting cardiac arrest patients.

Nonetheless, while it might be important within an emergency service to consider only ambulance costs, it is clearly not the case for the health service as a whole. All the costs of treating the survivor, however long he or she may live, and whatever future condition is treated, should be included on a time-discounted basis. (We return later to estimate the cost per life-year saved in an emergency service.) These costs would not accrue if the patient had died of SCA, but would accrue otherwise, so they should be counted. Note that the approach of counting later medical costs of survivors of a condition is not always used in economic evaluation, because it is often too difficult to estimate future costs of what will in many cases be unrelated conditions. Therefore, in the model of an emergency service developed later, we will model scenarios where survivor costs are at first excluded and then included.

From a health service or third-party payer perspective, we do not need to consider the benefit that accrues to people who are able to return to work after an SCA episode. Clearly, however, a societal perspective will include such benefits. What proportion of SCA survivors returns to work? The answer appears to be: 'not many,' as the average age of survivors is typically in the late 60s. Perhaps 20% were working prior to their SCA episode, however, so it is not unreasonable to suggest that perhaps half of these people, or 10% of all SCA survivors, are able to return to work. The gain to society is to be found in the additional product, be it the amount of extra food produced by a farmer-survivor or the amount paid for legal services offered by a lawyer-survivor that would not otherwise be produced. In a society with severe unemployment, the return to work of the survivor may cause a temporary replacement to become unemployed, so no additional product would be forthcoming, and the benefit would be zero. Unemployment on this scale has not been common in industrialized societies since the early 1930s.

The situation with respect to survivors who have retired or who are unable to work after SCA also depends on perspective. In society as a whole, giving a pension paid out of current taxes is merely a transfer payment and is assumed not to involve any change in the amount of work undertaken. Thus from a societal perspective, the payment of a pension is not a cost. It is simply a redistribution of existing resources. From the perspective, not of society, but of a government as a whole, if the budget for the country is of fixed size, then the payment of a pension to a survivor will mean that funds are not available for other purposes, so

the pension payment is a cost. From the perspective of the health service/third-party payer, or the emergency service, which does not pay the pension, a pension payment reverts to not being an economic cost.

Costs

The four main cost components are:
1. cost of device
2. maintenance cost of device
3. training and retraining in the use of CPR and defibrillators
4. costs of subsequent health care for survivors.

The reason costs have been broken into components is to see which costs are important. If costs change in the future due to innovation, what changes in cost effectiveness does this imply? Where should effort be placed to reduce costs? Studies show that the cost of the defibrillator itself is not a major component of total costs. Typical costs of a defibrillator are now about $1000 compared with some $2000–2500 in the early 1990s. Modern defibrillators have relatively low annual maintenance costs, but costs of training (and retraining) in the efficient use of defibrillators are relatively high, because training needs to be given to many people. Typically, therefore, maintenance and training costs of a defibrillator over its lifetime will be several times greater than the initial cost of the device.

The cost per survivor of a defibrillator program depends on whether the defibrillator is a public access device or is carried by an emergency service. For a PAD, relative costs depend on how often the device is used; for an emergency service, relative costs are a trade-off between the number of devices and the speed with which patients can be reached. Subsequent healthcare costs for survivors are also a relatively high proportion of total costs.

Questions must be asked in relation to maintenance and training costs. In settings in which a large proportion of workers' time is on call, the cost of maintaining PADs and of training staff in their use may actually be much lower than costs measured by the time taken to perform them. The real cost of training emergency service officers in the use of defibrillators should be much lower than their accounting cost, apart from instructor time. This is because many such officers have large amounts of slack time. If they were instructed in the use of defibrillators during a time that would otherwise be waiting time, the cost of undertaking the training would be free. If the unit being instructed were called in the middle of training, they would immediately be required to abort the training session to attend the call, and in that case, it would be the time of the instructor that is wasted. If 60% of emergency

service officer time were slack, then the instructor is at best likely to complete only 3 out of every 5 training sessions (the proportion of completions would be lower if slack times were continually interspersed with brief bursts of activity). Thus, in this example, a premium of 1.67 or more would be attached to the instructor's productive time.

The costs of treating an SCA episode are generally not very high, because the vast majority of people die within a short time, and treatment is not prolonged. For the survivors, most leave hospital within a few days or occasionally within several weeks. A small minority has high costs of continued care because of brain damage. For the majority of survivors, the largest costs are usually occasioned by illnesses that they suffer subsequently, and for many of them, the illness will not be of cardiac origin.

Benefits

The benefits of using defibrillators out of hospital are easy to state but uncertain in their extent: they are the sum of the years of additional life gained by survivors discounted by disability and the effluxion of time. The years of extra life can be estimated retrospectively by long-term follow-up of the survivors from about 1970 onwards. As therapy for people with heart conditions improves, however, it is likely that survival from SCA will change. On one hand, it will increase to the extent that follow-up after survival from SCA will improve. On the other hand, it will decrease to the extent that the kind of person having an SCA episode may be older and most probably sicker than those of past years, because of improvements in therapy for people with heart conditions.

Although to be considered with caution, the life expectancy of survivors, even if it changes by 20% up or down, will be relatively well estimated, however. In comparison, estimation of survival *differences* between earlier and later use of defibrillators is fraught with potentially enormous errors.

Cost-effectiveness estimates of PADs from the literature

Several studies have assessed the economics of EMS without focusing on the cost-effectiveness of specific prehospital interventions for cardiac arrest.[3–14] Others have focused on EMS interventions for other disorders.[15,16] We focus here on previous economic evaluations of EMS (Table 67.1) and non-EMS interventions for cardiac arrest (Table 67.2). Estimates published in these articles were converted to US dollars and adjusted for inflation. Since

few of these studies evaluated the incremental cost per QALY, outcomes were expressed as cost per life saved.

The range of incremental costs of EMS or other interventions for out-of-hospital cardiac arrest is highly variable. Comparisons of the incremental cost effectiveness of EMS interventions or lay responder defibrillation for out-of-hospital cardiac arrest are difficult, because of the heterogeneity of interventions considered, completeness of costs, perspective, and the degree to which uncertainty or sensitivity analyses were used to assess the robustness of the economic results. Although it is generally recommended that health economic evaluations express effectiveness in quality-adjusted life–years, and some survivors of cardiac arrest can have reduced quality of life, the majority of previous studies evaluated lives saved. Thus, comparison with other health interventions is difficult. Assuming an average life expectancy of 6 years among survivors, the cost per life–year (without discounting for costs and benefits that occur in the future) will be 1/6 of the cost per life saved.

Cost-effectiveness of defibrillation in an emergency service

We shall now return to examine in more detail the estimation of costs and benefits in an emergency service, where the surrogate for benefit is the reduction in ambulance response time. In a very simple scenario, we described above an emergency service that extended two lives per year from SCA for each additional ambulance added to the fleet. By knowing the cost of running an additional ambulance, we can then estimate the cost per life extended, and by estimating the average additional life expectancy, we can estimate the cost per life–year gained. We said nothing about how one might estimate the number of people saved in this way in the real world.

First, however, let us contrast the economic evaluation of the provision of PADs with that of the provision of an emergency service. The problem of optimal provision of PADs is to place them in those public places where they will be used sufficiently often to justify their provision. This can be judged by estimating the cost per QALY of the provision at different sorts of location. Nevertheless, the optimal provision of defibrillators in an emergency service (assuming that each responder is equipped with a defibrillator) depends on the (incremental) costs and the (incremental) benefits of increasing the number of responders. This research has never apparently been carried out satisfactorily. Two studies go some way towards an answer, but in each case, they look only at comparing different innovations

Table 67.1. Previous economic evaluations of EMS interventions for cardiac arrest

Author (year)	Intervention	Comparator	Perspective	Costs Included	Incremental cost-effectiveness $ per life saved
Nichol (1996) (17)	Reduction in response time: In all-ALS system by adding ALS providers	Existing EMS agency	Society	EMS and initial hospital costs only; not ICD or ambulatory costs	2,627, 000
	In BLS+ALS system by adding defibrillator- capable first responders in fire vehicles				383,500
	by adding defibrillator- capable first responders in EMS vehicles				1,134,400
	Change from all-ALS system to BLS+ALS system				
	by adding defibrillator-capable first responders in fire vehicles				286,900
	by adding defibrillator-capable first responders in EMS vehicles				678,200
Jermyn (2000) (18)	Implementation of first responder defibrillation program	Existing EMS agency	EMS	Training and consumables but not capital equipment	
	In urban setting				7,800
	In rural setting				57,400
Ornato (1988) (19)	Treatment by range of emergency medical technicians (EMT)	Existing EMS agency	EMS	Training costs only	
	EMT				12,900
	Defibrillation-capable				3,600
	EMT				3,800
	Advanced cardiac life support				
Urban (1981) (20)	Advanced cardiac life support	Existing EMS agency	Societal	EMS and initial hospital costs only	91,900
Hallstrom (1981) (21)	Rapid defibrillation by EMTs; rapid defibrillation by EMTs with paramedic backup response.	EMTs without defibrillation	EMS	EMS costs assumed	48,100
					80,900
Valenzuela (1990) (22)	Advanced cardiac life support	Existing EMS agency	EMS	Training, equipment and on-time costs	181,000
Jackobsson (1987) (23)	EMTs	Existing EMS agency	Societal	EMS and hospital only	2,800

within an emergency service system. Nichol *et al.*[17] examined the relative merits of adding single responder units or fully-equipped ambulances, but the study was not designed to find out how many additional such units could be added to an EMS fleet for each successive addition to remain cost-effective. Costs per QALY were obtained for each process, but these would pertain only to the margin, and could not tell us how long we should keep adding units to the fleet.

Table 67.2. Lay responder defibrillation interventions for cardiac arrest

Author (year)	Intervention	Comparator	Perspective	Costs included	Incremental cost-effectiveness, $ per life saved
Forrer (2002) (24)	Police automated defibrillation program in coverage area	Existing EMS agency	EMS	Training and equipment but not medical oversight or quality assurance	84,000
Pell (2002) (25)	Lay responder defibrillation program in all airports, railway and bus stations	Existing EMS agency	Society	EMS, hospital and ambulatory but not ICD costs	1,219,300
Nichol (1998) (26)	Defibrillation by police in coverage area	Standard EMS agency	Society	EMS and hospital but not ambulatory or ICD costs	107,000
	Defibrillation by lay responders in coverage area				190,000
Nichol (2003) (27)	Defibrillation by security guards in casinos	Standard EMS agency	Society	EMS, hospital, ICD and ambulatory costs	183,000
van Alem (2004) (28)	Reduction in time to shock by	Standard EMS agency	Society	EMS, hospital and ambulatory costs to six months but not ICD	
	2 min				23,400
	4 min				19,100
	6 min				17,000

Fischer et al.[29] carried out a somewhat different exercise that also compared the cost-effectiveness of a new practice with that of an existing practice. Although this study looked beyond marginal changes in resources, it was carried out from the perspective of an emergency service (in terms of cost per second of a reduction in response time). It did not compare the cost-effectiveness of an emergency service with that of other parts of a health service or use cost per QALY as a unit of measurement. A third study (the OPALS study)[30] claims that average response times should be lower than present response times (because benefits increase exponentially as response times decrease), but says nothing at all about costs, which increase faster than benefits when response times decrease sufficiently.

The model

We now outline a means of estimating the optimal size of an EMS service. This outline is for demonstration and pedagogical purposes and needs to be adapted to local circumstances before being used to guide decision-making in a EMS agency.

The model used is therefore a simple one. Since most of the estimates were derived from studies in England, the analysis is in pounds sterling (£), for which the current exchange rate is £1 = $US1.75. Since costs will vary from one country to another in ways that are not accounted for by either the official exchange rate or a purchasing power parity exchange rate, the model should use country-specific costs if is to be utilized outside the UK.

The objective is to express, in terms of response time, both the total costs and the total benefits of increasing the size of the emergency service within a given geographical area and with given technology and procedures. From there, we find the range of response times for which an emergency service should be provided, and estimate the response time that maximizes the total net benefits (= total benefits − total cost) of the service.

Estimation of total cost

First, we find an expression for annual total cost of an emergency service in terms of response time, as follows.

We define T to be the time from collapse to defibrillation.

T comprises a lag of "a" minutes from collapse to calling the EMS, plus b minutes of activation time from receipt of call to dispatch of responder, plus t minutes of travel time, plus c minutes from arrival to administration of the first shock.

Thus $T = a + b + t + c$. $\qquad$ (67.1)

Response time $R = b + t$ (i.e., activation time + travel time) $\qquad$ (67.2)

Travel time t depends on the distance travelled by a responder, and we assume direct proportionality between time and distance travelled. The distance travelled will depend on the number of responders and whether they are optimally positioned. In the simplest case, assume that the population is uniformly distributed on an infinite plane and that the ambulances (which are uniformly spaced) travel on a rectangular grid. (Think of the ambulances at the centre of each square on a chess board.) The average distance travelled will be half the distance to the top or bottom of the square, plus half the distance to the left or right boundary. The total distance travelled on average will therefore be the distance from the center of the square to the top or bottom. When there are four times as many ambulances, the average distance will halve; when there are nine times as many ambulances, the average distance travelled will be one-third of the original. Thus, for n on-call ambulances, the average distance will be $1/$(the square root of n) compared with the distance for one ambulance. It is likely that as the number of responders increases and average distances fall, average speeds will also fall marginally, and the centralized dispatcher of vehicle placement will place them less optimally, but in the base case of this model, those factors have been ignored.

Thus $T = a + b + d \cdot n^{-1/2} + c$ $\qquad$ (67.3)

(If the average speed of responders falls and they become less optimally placed as n increases, this may be modeled by changing the exponent on n in the direction of zero. The exponent on n was estimated by Fischer to be -0.37 for the Surrey Ambulance Service, but the magnitude of this exponent estimated by using a different but plausible functional form was -0.43. A reasonable alternative magnitude for sensitivity analysis would therefore be -0.4.)

Since $R = b + t = b + d \cdot n^{-1/2}$, by rearranging, we obtain

$n = (d/(R - b))^2$ $\qquad$ (67.4)

We assume that costs are proportional to the number of ambulance units on duty, which we call $n + n^*$, where n are on-call (and waiting) and n^* are in use.

The total cost of equipping, staffing and operating an ambulance for a year in England is about £300 000 (about \$550 000). Thus the total cost (TC) of running $(n + n^*)$ ambulances is about £300 000 $(n + n^*)$.

Substituting from (67.4) for n yields
TC $= 300\,000\,(d/(R - b)^2 + n^*)$ $\qquad$ (67.5)

Note that this analysis has been carried out from an emergency service perspective, because the cost of hospitalization and future illness costs for survivors have not been included in Equation 67.5. From a societal perspective, we must add to 5 an average hospital cost H and a cost of future illness of F for each of the $N.S$ survivors, where N is the number of patients annually carried to hospital with SCA and where S is the probability of survival for an individual.

We assume that the survival curve T minutes after collapse, derived from the OPALS study,[30] is given by

$S = \exp\,(-0.23T)$ $\qquad$ (67.6)

Since $T = R + a + c$, then

$S = \exp(-0.23(R + a + c))$ $\qquad$ (67.7)

If N people with SCA are carried by the emergency service in a year, the expected number of survivors will be

NS $= N.\exp\,(-0.23(R + a + c))$. $\qquad$ (67.8)

Thus the total cost of current and future illnesses of survivors is

$(H + F)N.\exp(-0.23(R + a + c))$. $\qquad$ (67.9)

Thus from equations 67.5 and 67.9, total societal cost becomes

TC(soc) $= 300\,000((d/(R - b))^2 + n^*) +$
$\qquad (H + F)N.\exp(-0.23(R + a + c))$ $\qquad$ (67.10)

Estimation of total benefits

First, we find the total benefits (TB) for SCA patients in terms of R, from the perspective of the emergency service.

We assume that the NS survivors on average live $Y = 6$ years at a utility value of 0.7 after an SCA episode, and that the value of a life-year saved (at utility $= 0.7$) to the health service/third-party payer is £21 000, equivalent to £30 000 (\$52 500) per QALY. Clearly, the threshold cost per QALY varies from country to country: for the USA, a figure often used is \$100 000; for low-income countries, the figure would be substantially lower.

Thus, using equation (67.8),

$$\text{TB} = 21\,000.\,N.Y.\exp(-0.23(R + a + c))$$
$$= 126\,000.\,N.\exp(-0.23(R + a + c)) \qquad (67.11)$$

From a societal perspective, some survivors will be able to return to work. Compared with being on a state pension, society benefits by the additional production that is measured by their earned income. For the sake of this exercise (as we have no data to inform this scenario), we assume that 10% of survivors work at an annual salary of £20 000 for an additional 5 years, giving an additional benefit of an average of £10 000 per survivor. Thus total societal benefit is given by

$$\text{TB (soc)} = 136\,000.\,N.\exp(-0.23(R + a + c)) \qquad (67.12)$$

Estimation of total net benefit

A **net** benefit is defined as the difference between benefit and cost. If the net benefit is positive, the activity will be worth undertaking; if it is negative, then some combination of other activities will be worth doing instead.

Thus the total net benefit from the perspective of the emergency service, using equations (67.5) and (67.11), is given by

$$\text{TNB} = \text{TB} - \text{TC} \qquad (67.13)$$

Societal net benefit (SNB) is given by equations (67.10) and (67.12) as

$$\text{SNB} = \text{TB(soc)} - \text{TC(soc)} \qquad (67.14)$$

The objects of the exercise are to establish, first, the range of values of R for which TNB > 0, and second, the value of R which maximizes TNB, and then to repeat the exercise by using SNB in place of TNB.

We assume that

- $a + c$ = 4.3 minutes (the sum of the time lag between collapse and contact with the emergency service, plus the lag between arrival of the emergency service and the first shock).

    (The magnitude of the first lag, a, will probably never be known accurately, as it relies on people's notoriously poor recollections, but it is probably approaching 2 minutes. The magnitude of the second lag, c, appears to be at least 2 minutes.[30] The figure of 4.3 minutes makes the data consistent with the OPALS predicted survival curve.)

- b = 1.5 minutes (control room activation time, from receipt of call to the departure of a responder).

    (The literature suggests that this is between 1 and 2 minutes.)

- N = 1100 SCA patients carried in any one year.
- n = 20 (average number of ambulances on call (and not in use).

- n^* = 8 (average number of ambulances in use).
- d = 33 (assuming average response time is 8.9 minutes when n = 20, and using equation (67.4)).

    (N, n, n^* and d are derived from Fischer's study of the Surrey Ambulance Service.[29] The average response time was 8 minutes 52 seconds at the time that the Service was studied. Note that as N, n, n^* and d are all inter-related, it would not be appropriate to change one of these variables without changing the others. A different set of these four variables will pertain to each emergency service.)

- F = £40 000 (= $70 000) of future illness costs for each survivor.
- H = £1700 (= $3000) of hospitalization costs.

    (The values for F and H come from the study of Nichol *et al.* (1998) of emergency services in the USA.[26] They have not been adjusted for inflation, because it is likely that the UK costs would have been a little lower in the first instance.)

Thus $\text{SNB} = [149\,600\,000.\exp(-0.23(R + 4.3))] -$
$$[300\,000((1095/(R - 1.5))^2 + 8) +$$
$$41\,700.\exp(-0.23(R + 4.3))]$$
$$= 107\,900\,000.\exp(-0.23(R + 4.3)) -$$
$$2\,400\,000 - 328\,500\,000/(R - 1.5)^2$$

We show the graphs of total costs and total benefits and the total net benefits from both a societal perspective and an emergency service perspective. The difference between the two results is that the emergency service perspective stops at the hospital door, whereas the societal perspective includes proximate hospital costs and all future health costs of survivors as well as all indirect costs.

According to the assumptions of this model, if the only benefits from operating an emergency service accrue to SCA survivors, and to nobody with other conditions, the service should not be funded, as the net benefits are negative for all response times. This is shown in Fig. 67.1, where the net benefits from an emergency service perspective are maximized at an average response time of 9.2 minutes and a net benefit of −£1.7 million per year. From a societal perspective, the net benefit curve is flat from an average response time of 10 minutes or more, at a value of −£2.8 million per year.

If the benefits of operating an emergency service for other conditions are proportional to those of cardiac arrest for all average response times, and we ascribe a high enough level of benefit to other conditions, then the net benefits of an emergency service become positive for a range of response times. We illustrate this by assuming that all other uses of an emergency service (at each average response time) produce the same net benefits as are gained by people with SCA.
Fig. 67.1. Total net benefits by response time if the only benefits are for SCA.
Fig. 67.2. Total costs and benefits by response time when benefits for other treatments are benefits for SCA.

Figure 67.2 shows how both total costs and total benefits change as R changes. As more resources are made available to the service (that is, as R falls) total benefits at first rise faster than total costs. As response times fall sufficiently, however, total costs begin to rise faster than total benefits. The curves cross twice, and at these points, TC equals TB, and net benefits are zero. Between the two crossing points ($R = 4.7$ minutes and $R = 13.4$ minutes), an emergency service is justified. The greatest net benefit of £7.6 million

per year occurs when $R = 6.5$ minutes, as is shown in Fig. 67.3. From a societal perspective, the two crossing points are at 5.8 minutes and 11.1 minutes, the optimal R is at 7.4 minutes and the maximum benefits are estimated to be £2.2 million per year.

The relationship between 75% response time and average response time was estimated by Fischer[29] to be "75Resp" = $0.136 + 1.163R$, so $R = 6.5$ (the optimum from the emergency service perspective) corresponds to "75Resp" = 7 minutes
Fig. 67.3. Net benefits by response time if benefits for other treatments equal benefits for SCA.

42 seconds. That is, according to this model, the optimal target for emergency services in urban areas in Britain is approximately correct. From the optimal response time, we calculate that optimal value of n will be $n = (33/(6.5 − 1.5))^2$ $= 44$ compared with actual 20, and opt $(n + n^*)$ will be $44 + 8$ $= 52$ instead of $20 + 8 = 28$, a considerable increase. From a societal perspective, opt $R = 7.4$ minutes, and "75Resp" = 8.7 minutes, requiring $n = 31$ ambulances, or $n + n^* = 39$ rather than the actual 28.

The assumption that all calls will have the same average response time is a simplification. To be carried out more realistically, response time should have a distribution and the whole exercise should be done as a Monte Carlo simulation. Since the TC and TB curves are convex to the origin, the optimal response time will be slightly lower than the one calculated in this exercise.

The results would indicate that running an emergency service in a low-income country is probably not a good use of scarce health care resources, because the willingness and/or ability to pay for the service is not likely to be sufficient. In a country that is sufficiently wealthy to afford emergency services, the results depend critically on the extent of benefits from treating and transporting people with conditions other than cardiac arrest.

Discussion

This chapter utilizes some simple economic notions to illustrate how the cost effectiveness of treatments for SCA can be both measured and improved. Among these notions is the idea of opportunity cost applied to otherwise slack time. The

opportunity cost of such time is zero, so the idea should be to pack as much new productive work into that time without losing efficiency in the main task of providing a rapid response to emergencies. The extent to which this is possible in practice may be limited. Nevertheless, opportunities to utilize this time will not be sought if a non-zero price is placed on such time by people charged with examining the cost effectiveness of using slack time more productively. But also important are the ideas of marginal/incremental costs and benefits; of perspective; and of the pitfalls in apportioning costs to a single disorder when the same individuals are on call to treat all disorders. It is relatively easy to estimate average costs and benefits; marginal costs and benefits are often much harder to deal with, as the prototype modeling exercise on the optimal level of resource provision indicates. Yet it is the margin that is relevant when changes to the resource base are proposed. Perspective is also important, because it determines which costs and which benefits to include. At the very least, apportioning costs to life-threatening conditions (or more particularly in the context of this discussion, to SCA) is fraught with difficulties. In the context of the appropriate provision of resources for emergency services, the most appropriate approach is to consider the costs of expanding or contracting the emergency service provider as a whole, and to compare these costs with the estimated benefits of doing so.

So where are the boundaries of cost effectiveness with defibrillators?

The first question is whether resources should be put into PADs or emergency services. The cost-effectiveness of PADs has been examined in rather more detail than that of emergency services, probably because the former estimation is much easier to do. For emergency services, it is difficult both to formulate the problem and to estimate the benefits at the margin. We have provided a prototype model that may be modified in many ways, that attempts to discover the optimal level of emergency service provision given current practice.

Currently, in high-income countries, PADs may be justified in cost-effectiveness terms in places where large numbers of people congregate. How many is the lower boundary of "large" in this context? Other things being equal, it will be:

- smaller in the US than in countries that have lower incomes (and therefore a lower ability to provide health care resources),
- larger, the proportion of the at-risk members of the gathering fitted with an ICD
- smaller, the lower the cost of acquiring a PAD
- larger, the greater the extent of vandalism (this makes the average PAD less effective than otherwise)

- smaller, the lower the training and maintenance costs of PADs
- smaller, utilizing the "slack" time of bystanders as training time
- smaller, making the device easy for amateurs to use
- larger, the greater the presence and efficiency of emergency services.

For airlines, it would appear that PADs can be justified for large planes (200+ passengers) in the US, but not for smaller ones. Clearly, this would change if passengers could be trained in defibrillator use in their waiting (slack) time, provided that the device were simple enough to use without prior hands-on experience, and assuming that there is no "learning-by-doing." This conclusion also ignores diversion costs of airliners and the cost of litigation if PADs are not carried.

The appropriate level of funding of emergency services, has probably never been properly estimated. That in this chapter, a crude illustration of how to go about working out the cost-effectiveness of an emergency service, is apparently as good an estimate as has ever been produced, and shows the rudimentary state of the art in this area. Unlike PADs, which have (arguably) probably been provided up to the limit of their cost-effectiveness, it would seem that in many countries, emergency services have been something of a Cinderella service in health care.

Turning to the model proposed in this chapter, changing the values of each parameter in turn could be used to explore the appropriateness of the model in different circumstances. For example, changing the willingness-to-pay variable (assumed to be £30 000 per QALY in the above) would allow a more appropriate analysis for higher-income countries (USA) and lower-income countries. Changing N would act as a surrogate for lower population density. Changing the different assumed time lags would give an indication of their importance and whether it would be worthwhile reducing them. Estimating the benefits for carriage of people with life-threatening conditions other than SCA is very important, as the size of the total benefit of an emergency service determines whether the service should be provided, and if provided, at which level.

The model could also be extended to include single responders as well as fully equipped ambulances. The optimal mix of these two types of responder could be estimated from such a model.

In most situations, decreasing returns mean that the provision of a resource will be limited, because eventually the costs of a further increase of provision will outweigh its benefits. For emergency services, however, we have shown that benefits may increase faster than costs at certain levels of provision, even though the eventual result will be a limit

in provision. According to the lower curve in Fig. 67.3, the costs of providing a service with an average response time of over about 12 minutes would generally outweigh the benefits of the service (which is why sufficiently remote areas are not served by emergency services). But as the response time dips below 12 minutes, the benefit (per minute of decrease in response time) increases at an increasing rate, as can be seen from the slope of the curve. Nevertheless, the cost of resources that will allow a decrease of a minute of response time will increase as response time decreases. That is because, if there is a four-fold increase in the number of ambulances, the travel time will not on average be one-quarter of the previous time, but one-half. Thus, at first, the cost-effectiveness of ambulances will actually improve as more resources are added, and in countries where this is so, there is added reason for an increase in those resources.

This analysis has several strengths. First, it provides a framework for decision makers to assess the marginal cost of improving response time by addition of emergency response vehicles to an existing EMS system, whereas most previous analyses have considered the incremental cost of improving the skill level of providers in the field. Second, the framework can be adapted to local circumstances by substituting local effectiveness values. Although the overall survival observed in the OPALS study, the basis of this economic analysis, was low, an EMS system staffed by highly trained, experienced EMS providers who treat a high volume of calls and perform a high volume of procedures each year, with independent medical oversight and quality assurance can achieve survival of 15% to 20%[31] (and unpublished data, Seattle Medic One program, August 28, 2005). In Seattle, WA, survival decreased by 3% with every 1-minute delay in CPR and by 4% with every 1-minute delay in defibrillation.[32] Third, the framework can be adapted to local circumstances by comparison to local thresholds for willingness to pay. The latter is important since a society's willingness to expand EMS can depend on the availability of competing alternatives and adequate resources.

This analysis also has weaknesses. First, it provides a point estimate of the incremental cost of improving response time. Since it relies on several assumptions, there is likely to be large uncertainty in this estimate. Future extensions of this model should use Monte Carlo simulation to evaluate this uncertainty. Second, the model assumes that technology and dispatch protocols are constant through time. Response time can be improved by changes in both technology and protocols, however, or location of vehicles closer to where calls are likely to occur. The costs of these alternate interventions were not considered. Third,

this analysis underestimates the incremental cost-effectiveness by assuming no benefit to use of emergency vehicles for other conditions in one case, and by artificially assuming that cardiac benefits are half of all benefits in the other case. Fourth, the use of OPALS data underestimates survival by assuming zero survival once a VF rhythm has ceased. Despite these limitations, we believe that this analysis represents an important advance over previous analyses of the economics of EMS interventions, and should be validated in a variety of settings.

Medicolegal aspects

Richard Pawl

Department of Emergency Medicine, Medical College of Georgia, GA, USA

Part 1:   Introduction

Discussing the law in the context of cardiovascular resuscitation would seem to involve a small number of topics. Most commonly, one might consider the malpractice consequences of negligence in the conduct of medical personnel performing cardiopulmonary resuscitation for a dying patient. Certainly, malpractice law is a legal aspect of cardiopulmonary resuscitation (CPR). Yet, because of the nature of the act of CPR, it rarely, alone, becomes the focus of malpractice litigation. Most commonly, malpractice litigation focuses upon the alleged malpractice that leads up to a patient's resuscitation. However, when the resuscitative efforts of medical professionals are the focus of a malpractice suit, the legal theories may be similar to those one may find in other malpractice litigation (e.g., negligent administration of drugs or negligently performing procedures) to more unique causes of action that arise from the resuscitation of a patient with Do-Not-Resuscitate (DNR) orders, such as the wrongful life legal complaint when the patient designated as a "DNR patient" is successfully resuscitated. Indeed, the more one delves into topics related to the law and CPR, the more one finds that to do adequate justice to the topic one must study the bioethics of death and dying and the evolution of advanced directives and how they apply to all patients – competent and incompetent alike. Because the law relating to death and dying is at the cusp of the interface between bioethics and the law, one must also pursue an understanding of the evolution of our laws as they relate to personhood, self-autonomy, and privacy. The "law of privacy" is still controversial in the United States because the concept of privacy as a "right of privacy" largely became a critical issue in legal cases that involved contraception, sexuality, and abortion.[1] Although readers may disagree about the validity of the evolution of the law as it relates to death, dying, and resuscitation, it is the *law of the land* in the United States, and understanding such law enables one to understand the evolution of this law.

In order to see the relationships between the evolution of the law related to death and dying (and thereby, resuscitation) one must begin with the bioethical philosophies that gave rise to some of the legal concepts that have emerged in the course of litigation and legislation. Nevertheless, it would be naïve to consider that an overview of bioethical considerations could ever do justice to the complexities of the topic. Similarly, it would be naïve to consider that any system of thought could adequately address all of the issues that relate to any particular individual's problems in the course of treating each patient in clinical practice. One can only hope to provide ethical and legal information as tools that the clinician may utilize to solve the ethical and legal dilemmas that confront us in the practice of medicine.

Courts have looked to some principles within their common law and precedents that overlap with bioethical principles, such as the concept of patient autonomy. In the present legal climate, for most scenarios, patient autonomy, the right to self-determination, and the right to privacy have emerged as the leading principles that courts will use in medical decision-making cases. As medicine's capability to preserve life became technologically more advanced over the past 35 years, courts have had to face controversies in patient care decision-making that had previously been non-issues. Although it is not always apparent from reading courts' opinions, judges will often look beyond precedents for guidance for their jurisprudence.

They may delve into bioethical literature, but how judges use that literature may sometimes be in direct conflict with how healthcare providers may apply such literature in treating their patients. In fact, some court decisions regarding issues of patient care and end-of-life decision-making may make sense from a legal point of view, but may seem to be a perverse decision from a healthcare provider's point of view. Nevertheless, parallels between bioethical principles and legal principle may be drawn.

For example, over the last 35 years, medical ethics has been dominated by a body of thought that is often referred to as "principlism" in the bioethics literature. The tenets of principlism may be traced back to *The Belmont Report* that was a product of the National Commission for the Protection of Human Subjects.[2] Created by the National Research Act of 1974 (PL 93-348), the Commission was given the charge to develop ethical guidelines in human research. The four basic principles that were proposed by *The Belmont Report* were autonomy, beneficence, non-maleficence, and justice. Principlism was primarily brought into the mainstream of bioethics by the influence of the authors Tom Beaucamp and James Childress in their publication *Principles of Biomedical Ethics*.[3]

One would think that the legal application of patient autonomy, for example, would merge with the bioethical principles of patient autonomy, and indeed, in some cases they do. The primacy of patient informed consent and informed refusals within medicine arguably were merged from the legal concepts of the same names as they developed within the law. Nevertheless, medicine generally will contend with environments wherein patients and healthcare providers will agree with medical care. That is, patients desire their ability to make autonomous decisions given the appropriate communication with their treating physicians. Courts, on the other hand, must contend with scenarios where providers, their patients, and the patient's surrogates are in conflict. Within those conflicts lies the divergence between principles that seem to be so similar in law and medicine. In some cases, as will be discussed later, a court may actually avoid confronting critically important issues that confront physicians and bioethicists because such issues are far from settled issues for medicine – for example, concepts of futility, ethnocentric issues, and gender issues.

Bioethicists do have the freedom to venture into controversial issues without having to be concerned about the legal concepts with which courts must contend, such as *stare decisis.* Stare decisis represents the legal doctrine of precedent, under which it is necessary for a court to follow earlier judicial decisions within their jurisdiction when the same points arise again within litigation. Additionally,

judges must always be aware that their decisions must be respected by other courts within their jurisdictions under the same doctrine of stare decisis. Bioethicists do not have to follow such doctrine, nor do healthcare providers. Hence, bioethicists may freely criticize that the concepts of principlism represent the bioethics of the privileged patient and fail to take into account the inequities of gender and race. Legal scholars have a similar freedom to criticize judicial decisions as decisions that represent value systems applied by largely male, well-insured judges. Nonetheless, judges must be constrained by the accepted principles of law and the future consequences of their decisions. Additionally, although there are valid legal criticisms that some judges have 'legislated from the bench,' judges must deal with conflicts and controversies within a body of law that must be constrained by the will of the people, and leave making new law to the representatives in the legislatures of our system of government. It is because of some of these legal constraints on the courts that parallel concepts in medicine and the law diverge.

To shed light on the differences between decision-making in medicine versus decision-making in the law, it is useful to discuss some cases. It is an accepted biomedical principle throughout the medical community that the concept of patient autonomy includes the right of a patient to be a fully informed participant in every aspect of the medical decision-making process as well as the right to refuse a prescribed treatment, even if such treatment is life-saving treatment. However, patient autonomy does not give rise to the entitlement to receive inappropriate or futile treatment.[4] "No ethical principle or law has ever required physicians to offer or accede to demands for treatments that are futile. Even civil malpractice standards do not require a physician to render useless interventions."[5] But, in 1991, a Minnesota Probate Court Decision rendered an opinion that forced a patient's healthcare providers to render care that many would consider futile.[6]

In December of 1989, an 86-year-old woman by the name of Helga Wenglie broke her hip.[7] After successful treatment at Hennepin County Medical Center (HCMC), she was sent to a nursing home. A month later, however, she developed respiratory failure, returned to HCMC, and had to be supported with mechanical ventilation.[8] Although conscious and aware of her surroundings, attempts to wean Ms. Wanglie from her ventilator repeatedly failed over the ensuing 5 months.[9]

Subsequently, Ms. Wanglie was transferred to a facility that cared for ventilator-dependent patients. While at this facility she had a cardiopulmonary arrest, was resuscitated, and was transferred to an acute care hospital in St. Paul. Because Ms. Wanglie had suffered brain injury

from oxygen deprivation after the cardiopulmonary arrest, she remained in a persistent vegetative state. Her healthcare providers suggested limiting further life-support treatment and removing her from the ventilator, but her family resisted the suggestion, and had her transferred back to HCMC. However, the healthcare providers at HCMC reached the same conclusion that Ms. Wanglie would remain in a persistent vegetative state and also suggested that Ms. Wanglie be removed from the ventilator. Again, resisting the medical staff's opinion regarding the poor prognosis for Ms. Wanglie, the family believed that only God could take a life, and that allowing the medical staff to remove Ms. Wanglie from her ventilator would be the moral equivalent of playing God.[10]

An HCMC ethics committee reviewed Ms. Wanglie's case and initially advised that the hospital staff should err on the side of continuing treatment while the hospital staff make reasonable attempts to resolve the moral conflicts between the family and the staff. Furthermore, HCMC and the Wanglie family made extensive, unsuccessful efforts to find another provider that would be willing to accept the transfer of Ms. Wanglie to that provider. Ms. Wanglie had become the medical equivalent of a "hot potato."[11]

The hospital turned to the courts to attempt to solve the problem.[12] The hospital first sought the appointment of an independent conservator to decide if the continued use of the mechanical ventilator was beneficial for Ms. Wanglie. Secondarily, if the independent conservator found that the mechanical ventilation was not beneficial, the hospital sought a judgment from the court as to whether the hospital had a duty to continue to provide the ventilator support. Mr. Wanglie filed a motion to be appointed conservator of his wife. After a 4-day trial, Judge Patricia L. Belois found clear and convincing evidence that Mr. Wanglie was the best person to be Mrs. Wanglie's conservator.[13] Judge Belois found that Mr. Wanglie was in the best position "to investigate and act upon Helga Wenglie's conscientious, religious, and moral beliefs" and noted that "[e]xcept with regard to the issue of removing the ventilator, [he] has thoughtfully agreed with the treating physicians about every major decision in his wife's care."[14] Mr. Wanglie then demanded that the hospital continue his wife's death-delaying treatment.[15] After Mr. Wanglie was appointed conservator, the hospital agreed to continue to provide respiratory support to Helga Wanglie, although her physicians deemed such treatment to be non-beneficial because it would not heal her lungs, palliate her suffering, or enable her to experience life.[16] Ironically, Ms. Wanglie died several days after her husband had been appointed her conservator by the court.

Although it was evident in *Wanglie* that the healthcare providers were clearly addressing the concept of the futility of Ms. Wanglie's respiratory support, the court successfully ducked the issue of futility. One can speculate that the court appropriately avoided dealing with that issue because to rule on the futility of Ms. Wanglie's care would be the equivalent of forming a definition of futile care in Minnesota. Under the doctrine of stare decisis, such a decision would have lasting consequences on similar controversies heard by other courts in the jurisdiction. However, the court's decision resulted in forcing the providers for Ms. Wanglie to continue "futile" or "nonbeneficial" care, an act that bioethical principles would generally not support.

Another case that illustrates the divergence between medical ethics and the law can be found in *In re Baby K*.[17] In October of 1992, Baby K was born with anencephaly.[18] She had suffered from breathing difficulties at birth and required mechanical ventilation.[19] Her initial respiratory support gave her physicians time to explain to her mother that babies with anencephaly usually die within a few days from respiratory failure and other complications.[20] Because aggressive treatment would serve no therapeutic or palliative purpose, Baby K's physicians recommended that she should be provided with only supportive care including nutrition, hydration, and warmth.[21] They also discussed the possibility of a Do-Not-Resuscitate (DNR) order for Baby K.

The mother refused to allow the removal of needed respiratory support and refused to allow the DNR order.[22] As a result of the disagreement between the mother and the caretakers, the hospital sought to transfer Baby K to another hospital, but all the hospitals with pediatric intensive care declined to accept the transfer.[23] Like Mrs. Wanglie, Baby K had become a medical hot potato.[24] But, by November 1992, Baby K was able to survive without mechanical ventilation so the hospital arranged to transfer her to a nearby nursing home.[25]

After being transferred to the nursing home, Baby K required three return visits to the acute care hospital wherein she was given respiratory support, stabilization, and a return to the nursing home.[26] After her second admission, the hospital filed an action in a federal district court in the 4th Circuit Court to resolve the issue as to whether it was obligated to provide emergency medical treatment to Baby K that it deemed medically and ethically inappropriate.[27] Note that this case was heard in a federal court because most of the issues that arose giving the court jurisdiction over this case surrounded the Emergency Medical Treatment and Active Labor Act (EMTALA) rather than the futility of providing Baby K with continued medical treatment.[28] The hospital sought a declaratory judgment that it was not obligated under EMTALA to provide treatment other than warmth, nutrition, and

hydration to Baby K.[29] The district federal court held that the hospital was obligated to treat Baby K's breathing difficulty since it qualified as an emergency medical condition, which triggers the hospital's duty under EMTALA to provide stabilizing treatment within their capacity. The hospital appealed to the Fourth Circuit Court of Appeals, which confirmed the district court's decision.

Both courts' decisions hinged on the strict interpretation of EMTALA, which has been the approach the federal courts have generally taken when addressing issues surrounding EMTALA. EMTALA requires a hospital to provide stabilizing treatment within its capabilities to any patient who presents to the hospital with an emergency medical condition.[30] Baby K would present to the hospital filing the appeal from the nursing home with respiratory distress, an emergency medical condition under EMTALA. The hospital argued that (1) the court had previously interpreted EMTALA as only requiring uniform treatment of all patients exhibiting the same condition; (2) that in prohibiting disparate emergency medical treatment Congress did not intend to require physicians to provide treatment outside the prevailing standard of medical care; (3) that an interpretation of EMTALA that requires a hospital to provide respiratory support to an anencephalic infant fails to recognize a physician's ability, under Virginia law, to refuse to provide medical treatment that the physician considers medically or ethically inappropriate; and (4) that EMTALA only applies to patients who are transferred from a hospital in an unstable condition.[31]

The 4th Circuit Court of Appeals rejected all of the hospital's arguments. On the first point, the court determined that the non-discrimination aspect of EMTALA applied to the application of the medical screening exam requirement of EMTALA, pointing out that the statute requires that a hospital must provide stabilizing treatment as required to prevent the material deterioration of a patient's condition.[32] Rejecting the hospital's second argument, the court stated that the plain language of EMTALA included stabilizing treatment to patients with emergency medical conditions and it was outside its "judicial function" to go beyond the statute in considering the issues regarding morally and ethically inappropriate care.[33] The court suggested that the defendants should redress these policy concerns not to the court, but to Congress.[34]

The hospital's third argument was based upon the Virginia Health Care Decisions Act, which recognized that the statute did not expect the doctors in the state to provide treatment they considered to be medically or ethically inappropriate.[35] The Fourth Circuit rejected this argument because of a well-established federal jurisdiction doctrine

of pre-emption. The doctrine requires that when state laws are in direct conflict with laws passed by Congress, the state laws are invalid where the states law conflicts directly with a federal law.[36] The hospital's final argument was also rejected by the court based upon the strict interpretation of EMTALA.

Baby K is illustrative of the courts' restrictions in interpreting moral issues that confront medicine. Federal courts have generally interpreted EMTALA as a strict liability statute (with some exceptions that have not withstood the test of time).[37] From a legal point of view, the court followed *stare decisis* by respecting previous decisions of other federal courts addressing EMTALA. Additionally, this court recognized that its duty was to interpret the law, not to legislate it. By refusing to address policy concerns regarding medically and ethically inappropriate care, the court properly suggested that the venue for addressing policy issues in the law is Congress.

From a moral and ethical point of view, however, the decisions in *Baby K* and *Wanglie* are frustrating to many healthcare providers and bioethicists because, in fact, the courts avoided the bioethical concerns that were at the heart of the provider's concerns. It is important to remember during the course of studying decisions made by courts regarding moral issues that confront medicine that easy and clear solutions may not be forthcoming from our courts. Moral and policy issues in medicine are profoundly more complex than those which we may be able to expect the courts to solve. Certainly, our society has made progress in the arena of patient care decision-making over the last 35 years, but we still have a long way to go.

Part 2:   Advanced directives and the patient self-determination act

Strictly speaking, advanced directives relate to *any* type of document that either empowers someone to act as a surrogate decision-maker in the event of a person's incapacity or any document that provides some guidance of a person's intents and desires in the event of that person's incapacity. *Black's Law Dictionary* includes both a durable power of attorney document as well as the document often referred to as a living will.[1] In other words, advanced directives are . . . "written instructions . . . recognized under state law, relating to the provision of health care when an individual's condition makes him or her unable to express his or her wishes."[2] Since the beginning of the last decade of the twentieth century, all states and the District of Columbia have enacted some form of advanced directive legislation.[3]

Although the concept of a living will was first proposed in the late 1960s as a response to newly developing medical technology that could prolong a patient's life, the discussion was relegated primarily to the medical and legal literature until the story of Karen Ann Quinlan became a "cause celebre" in the mid-1970s.[4] In fact, inquiring about an opinion regarding Karen Ann Quinlan became a popular interview question in the late 70s for prospective medical students.[5]

Karen Ann Quinlan entered into a persistent vegetative state (PVS) after she had ingested some combination of narcotic-based drugs.[6] Although she did exhibit some basic motor reflexes, it was apparent to her doctors that she was unlikely to awaken from her PVS. At some point, Ms. Quinlan's father sought judicial approval to disconnect his daughter from her mechanical ventilator and allow her to die. However, there were no advanced directives that had been executed by this 21-year-old woman. There existed only indirect evidence that she would not have wanted to continue to live in the condition that she was enduring at the time of her father's petition to the court. Having no precedent, the court accepted her alleged casual oral remarks that she would not have wanted to live in her condition and held that Ms. Quinlan's autonomy should not be discarded merely because she could no longer exercise it on her own.[7]

Subsequently, much public debate ensued regarding life-prolonging treatment, extraordinary measures to prolong life, persistent vegetative states, and methodologies to allow patients to exert their rights to self-determination after such patients became incompetent. Living wills became one answer to dealing with an incompetent patient's right to self-determination. Likewise, documents such as durable power of attorney for health were also advocated.[8] It is beyond the scope of this writing to discuss the details of executing advance directives; however, it is prudent to be aware of the Patient Self-Determination Act and its effects, or lack thereof, on the utilization by patients of advance directives.[9]

Although not without criticisms, advance directives became tools that patients could use to direct their own medical care in the event that these patients became incompetent. In an attempt to buttress the use of advance directives, the US Congress enacted the Patient Self-Determination Act of 1990 (PSDA).[10] Applying to all hospitals, skilled nursing facilities, home health agencies, hospice programs, and managed care organizations receiving Medicaid and/or Medicare funding, the PSDA requires providers to maintain written policies and procedures that will educate patients and the public as to their right to execute advance directives and to direct their medical care after the time they may lose their decision-making capacity.[11] The providers must also provide materials that inform all adult individuals receiving medical care of that individual's right under state law to make decisions concerning their medical care, including the right to refuse medical or surgical treatments.[12]

Being another unfunded mandate such as EMTALA, the whole thrust of the PSDA was to alert the public about advance directives with the hope that more individuals would begin to use them.[13] Nonetheless, numerous authors have criticized the PSDA as being an abject failure for numerous reasons.[14] One fairly obvious reason is that few patients being admitted to any of the PSDA-mandated institutions are focused on many of the documents that they are routinely given and asked to sign when they enter into these institutions. Additionally, in the absence of any incentives to do so, little time is taken by the personnel providing the written documentation to explain what the documents actually mean. Physicians have no incentives under the PSDA to spend time with their patients discussing advance directives. Merely being *aware* that one has legal rights is not the equivalent of having the requisite understanding in order to execute documents asserting those rights. Furthermore, without adequate knowledge under the *informed consent* doctrine, one could argue that even executed advance directives may not actually allow patients to exercise their rights of self-determination.

In the end, making patients aware of advance directives will not necessarily encourage our patients to take advantage of them. Many laypersons have insufficient information with which to understand the ramifications of such advance directives in the absence of having advisors who can explain what such documents actually mean. Furthermore, being documents that are executed before a person loses decision-making capacity, healthcare providers, surrogates, and courts may find that a patient's advance directives do not address the healthcare issues that an incompetent patient may actually be facing.

Part 3: Evolution of the law of healthcare decision-making

The legal theories and precedents that are now used in the course of litigation involving healthcare decision-making largely evolved from litigation that occurred in the latter part of the twentieth century. Indeed, most of the hallmark

decisions that delineated the law of healthcare decision-making largely evolved out of constitutional issues that were evaluated by the United Stated Supreme Court (with some exceptions). We must look to the cases of the Supreme Court to understand the evolution of healthcare decision-making. But first, the constitutional concept of *implied fundamental rights* must be introduced.[1]

The United States Constitution protects a number of individual rights. For example, the right to equal protection under the law is an express right granted by the Fourteenth Amendment of the United States Constitution.[2] The right to free speech is an express right that is provided by the First Amendment of the US Constitution.[3] However, many of the Supreme Court decisions rely upon rights that have been defined by the Court as fundamental rights, yet have not clearly been listed in the Constitution. Over the years, the fundamental rights upon which the Supreme Court relied that are not clearly delineated by the Constitution have come to be known as *implied fundamental rights.* One of the frequently used implied fundamental rights in decisions involving healthcare decision-making is the *right to privacy.*

In common law, one can see that early concepts of one's right to freedom from interference with one's person were already expressed in criminal law, namely the tort of battery. Battery is defined as a harmful or offensive contact with a person, resulting from an act intended to cause the plaintiff or a third person to suffer such a contact.[4] A mere touching of an individual against one's will is enough to cause a battery; however, the act must have been intended rather than accidental. It still holds true that if a physician intentionally performs an unwanted touching of a patient, a battery has been committed by that physician. Yet, battery is not a concept that was sufficiently broad to satisfy the complexities of medicolegal jurisprudence.

American law developed throughout its history with the underlying, carefully guarded concept that every person holds the right to be free from unwanted contact from others as well as unwanted restraints by others. Although, at times, the activities of the population in the United States had double standards with regard to this type of personal freedom (e.g., slavery), even in the nineteenth century there were jurists who were protecting such rights. For example, in 1891, the US Supreme Court asserted that

No right is held more sacred, or is more carefully guarded by the common law, than the right of every individual to the possession and control of his own person, free from all restraint or interference of others, unless by clear and unquestionable authority of law.[5]

An early twentieth-century recognition by a court of a person's right to self-determination was uttered by J. Cardozzo in a 1914 decision in *Schlendorf v. Society of N.Y. Hosp.* wherein he stated that "[e]very human being of adult years and sound mind has the right to determine what shall be done with his body."[6] Another early recognition by a court suggesting that a right to privacy existed was described in a dissent by Justice Brandeis in a case decided in 1928 (during Prohibition). The case involved defendants who were convicted of violating the National Prohibition Act with evidence gathered by the new technique of telephone tapping. In dissenting from the conviction, Justice Brandeis asserted that the protection guaranteed by the Amendments (of the United States Constitution)

[I]s much broader in scope. The Makers of our Constitution undertook to secure conditions favorable to the pursuit of happiness. They recognized the significance of man's spiritual nature, of his feelings, of his intellect. They knew that only a part of the pain, pleasure, and satisfactions of life are to be found in material things. They sought to protect Americans in their beliefs, their thoughts, their emotions and their sensations. They conferred, as against the Government, the *right to be let alone* – the most comprehensive of rights and the right most valued by the individual. (*Emphasis by author*)[7]

Privacy and implied fundamental rights

Over time, the judiciary has evolved the concept of implied fundamental rights largely from the "liberty" protected by the due process clause of the Fifth and Fourteenth Amendments of the United States Constitution.[8] In fact, many writers support the approach of deriving implied fundamental rights from the Constitution by pointing out that the Ninth Amendment of the Constitution avers that there exist other valid rights supported by the Constitution that have not been enumerated in the Constitution.[9] Although there are constitutional scholars who debate the validity of implied fundamental rights under our Constitution, the fact of the matter is that the Supreme Court has based many decisions upon the existence of implied fundamental rights. Hence, the right to privacy is here to stay, for now. The debate regarding whether the US Constitution actually accommodated the concept of implied fundamental rights is beyond the scope of this essay.[10]

The right to privacy may be said to have obtained its stature as an established implied fundamental right in a contraception case in the mid-1960s when the Supreme Court heard *Griswold v. Connecticut.*[11] This case involved

a Connecticut statute that prohibited any person from using "any drug, medicinal article, or instrument for the purpose of preventing contraception."[12] Griswold was the Executive Director of the Planned Parenthood League of Connecticut, who was the appellant to the Supreme Court along with Dr. Buxton, who was a licensed physician and a professor at the Yale Medical School who served as the medical director for the League at its Center in New Haven. The appellants had been convicted as accessories to the violation of the Connecticut contraception statute by a married couple whom they advised and who had used contraceptives.

Justice Douglas delivered the opinion of the Court. In the course of his opinion, Justice Douglas evolved the right to privacy in one of the most obscure statements in Supreme Court history. After proceeding past a discussion of various cases involving "rights of assembly," Justice Douglas created the "zone of privacy" right:

The foregoing cases suggest that specific guarantees in the Bill of Rights have penumbras, formed by emanations from those guarantees that help give them life and substance . . . Various guarantees create zones of privacy . . . [t]he present case, then, concerns a relationship lying within the zone of privacy created by several fundamental constitutional guarantees. And it concerns a law which . . . seeks to achieve its goals by means of having a maximum destructive impact upon that relationship. Such a law cannot stand in light of the familiar principle . . . that a governmental purpose to control or prevent activities constitutionally subject to state regulation may not be achieved by means which sweep unnecessarily broadly and thereby invade the area of protected freedoms. NAACP v. Alabama, 377 U.S. 288,307. Would we allow the police to search the sacred precincts of marital bedrooms for telltale signs of the use of contraceptives? The very idea is repulsive to the notions of privacy surrounding the marriage relationship.[13]

Hence, the zone, or the right, of privacy was born from the emanations formed from a penumbra of the Bill of Rights. Many lawyers had to pull out their dictionaries while reading Griswold for the first time.[14] A penumbra is a term that describes the partial shadow in an eclipse or the edge of a sunspot,[15] whereas an emanation is a term for gas created from radioactive decay.[16] Essentially, *Griswold* established the right to privacy for a married couple. In 1972, the Supreme Court considered contraceptives and unmarried couples in *Eisenstadt v. Baird*.[17] Although Justice Brennan, in writing the opinion for the court, did not have to use the marital privacy right discussed in *Griswold* to decide the case, he nevertheless argued for expanding the right to privacy in dicta:

If under *Griswold* the distribution of contraceptives to married persons cannot be prohibited, a ban on distribution to unmarried persons would be equally impermissible. It is true that in *Griswold* the right of privacy in question inherent in the marital relationship. Yet the married couple is not an independent entity with a mind and heart of its own, but an association of two individuals each with a separate intellectual and emotional makeup . . . [i]f the right of privacy means anything, it is the right of the individual, married or single, to be free from unwanted governmental intrusion in to matters so fundamentally affecting a person as the decision whether to bear or beget a child.[18]

Justice Brennan was expanding the right of privacy to apply to begetting and bearing children likely in anticipation of *Roe v. Wade*,[19] which, at the time of *Eisenstadt*, had been argued in front of the Court twice but had not yet been decided.[20] Without going into the controversies involved with the decision in *Roe*, the right to privacy was further delineated by Justice Blackmun in this case:

The Constitution does not explicitly mention any right of privacy. [But], the Court has recognized that a right of personal privacy, or a guarantee of certain areas or zones of privacy, does exist under the Constitution. In varying contexts, the Court or individual Justices have, indeed, found at least the roots of that right in the First Amendment; . . . in the Fourth and Fifth Amendments; in the penumbras of the Bill of Rights, in the Ninth Amendment; or in the concept of liberty guaranteed by the first section of the Fourteenth Amendment. These decisions make it clear that only personal rights that can be deemed "fundamental" or "implicit in the concept of ordered liberty" are included in this guarantee of personal privacy.[21]

Informed consent

As the right to privacy emerged from the basic concept of autonomy in American jurisprudence, so did the doctrines of informed consent and refusal emerge out of American medical malpractice jurisprudence. In the late nineteenth century and early twentieth century, courts were using the general rule that the physician could not treat a patient without his consent.[22] In the late 1950s, however, several courts began to articulate clearly the physician's duty to communicate properly to the patient necessary information with which the patient could make an informed decision about undergoing a proposed course of treatment. In *Salgo v. Leland Stanford Jr. University Board of Trustees*, a California appellate court held that the physician had an affirmative duty to make a "full disclosure of facts necessary to an informed consent."[23] The following year, in *Bang v. Charles T. Miller Hospital*, the Minnesota Supreme Court held a physician liable for failing to disclose information about alternative treatments to the patient undergoing surgery on his

prostate wherein the patient's spermatic cords were severed in the course of the operation.[24]

Generally considered to be the beginning of the contemporary period of the informed consent doctrine, two state supreme courts articulated the parameters of what would be considered the informed consent doctrine. In *Natason v. Kline,* after the plaintiff had sustained injuries she did not expect from radiation treatment after mastectomy, the plaintiff claimed the physician "failed to warn [the patient] the course of treatment which he undertook to administer involved great risk of bodily injury or death."[25] Citing *Salgo,* the court held that the doctor was "obligated to make a reasonable disclosure to the [patient] of the nature and probable consequences of the suggested or recommended cobalt irradiation treatment, and he was also obligated to make a reasonable disclosure of the dangers within his knowledge which were incident to, or possible in, the treatment he proposed to administer . . . in language as simple as necessary . . . [the nature of the ailment, the probability of success, and the alternative methods of treatment]."[26]

Several days later in Missouri, the Missouri Supreme Court decided *Mitchell v. Robinson*.[27] The action was against a physician for negligence arising from the performance of insulin shock and electroshock treatment for the patient's schizophrenia. Along with the negligence action, the patient alleged that he had never been informed of the inherent risk that the convulsions experienced during the treatment could fracture bones. The court held that "considering the nature of Mitchell's illness and this rather new and radical procedure with its rather high incidence of serious and permanent injuries not connected with the illness, the doctors owed their patient in possession of his faculties the duty to inform him generally of the possible serious collateral hazards."[28]

Different jurisdictions will have different standards with regard to what is considered to be reasonable and what a physician is obligated to tell the patient in the process of informed consent. Some courts have held that a physician is obligated to tell a patient the information regarding a course of treatment that a reasonable physician would provide in similar circumstances.[29] This is known as the professional standard of informed consent. This standard has been criticized because it requires the plaintiff to establish that there exists a community standard of informed consent by bringing forth expert witnesses to testify to standard. Other jurisdictions use a layperson's standard of informed consent wherein a physician is obligated to provide information considering a course of proposed treatment that a reasonable layperson would wish to have revealed.[30] Criticisms of this approach include that the decision to disclose is a medical professional's decision

and only the medical professional can judge the patient's health and the psychological impact of a disclosure; and that the lay standard for disclosure would waste a doctor's time in disclosing all the risks and limit the doctor's flexibility in caring for the patient's needs.[31]

Traditionally, an action based upon a lack of informed consent would sound in the intentional tort of battery – unless an effective consent is given to the medical practitioner, an unconsented touching or battery has occurred. As the concept evolved under malpractice law, however, courts determined that a physician owes a duty to a patient to disclose fully all information that is pertinent to the proposed treatment and obtain an informed consent. Failure to perform such duty is considered a breach of a physician's duty to the patient and the action sounds in negligence or the tort of medical malpractice. The generally acceptable elements of informed consent would include a physician's duty to inform the patient of his medical condition, the nature of the proposed treatment for that condition, the benefits reasonably expected from the proposed treatment together with the material risks and dangers of that treatment, as well as treatment alternatives and their risks and benefits.[32]

The most commonly invoked exception to informed consent is the emergency exception. Usually fact-specific, the emergency exception to informed consent may be invoked by the healthcare provider where a delay in treatment in order to inform the patient would be life-threatening. The scenario wherein this condition would be most apparent would be in situations where the patient needs an immediate medical intervention, such as cardioversion. Legal authorities will sometimes define this exception as more of a privilege.[33] Requirements of this privilege include "(a) the patient must be unconscious or without capacity to make a decision, while no one legally authorized to act as an agent for the patient is available, (b) time must be of the essence, in the sense that it must reasonably appear that delay until such time as an effective consent could be obtained would subject the patient to a risk of serious bodily injury or death which prompt action would avoid; and (c) under the circumstances, a reasonable person would consent, and the probabilities are that the patient would consent."[34] However, the emergency exception cannot be invoked when it is known by the healthcare providers that the contemplated intervention, regardless of the consequences, had been previously refused by the competent patient who had been properly informed of the needs of such intervention.

Two other exceptions to informed consent are the therapeutic privilege exception and the patient waiver exception. The therapeutic privilege waiver is rarely invoked but

it allows physicians to withhold information from a patient when a disclosure of that information would cause the patient emotional or physical harm in the determination of the physician. *Canterbury* upheld a therapeutic exception that allowed physicians to withhold disclosure of certain information to a patient when such information posed a threat to the patient's well-being or in the case of an emergency.[35] The therapeutic privilege exception actually undermines the patient-based standard of informed consent by "allowing physicians to employ their professional discretion to withhold information from their patients."[36]

The patient waiver exception to informed consent allows patients to forgo their right to being fully informed about their medical condition and the proposed treatment.[37] Although rarely invoked by patients, a waiver of informed consent would be appealing to those individuals who prefer to trust the provider's professional judgment or who, because of cultural preferences, would prefer to rest medical decision-making with significant others in their family. Healthcare practitioners would be well-advised to obtain such waivers in writing from patients who are competent to provide consent to treatment in the first place.

Negligence

Negligence emerged in the 19th century in the appearance of liability on behalf of certain persons who professed to be competent in certain "public callings."[38] "A carrier, an innkeeper, a blacksmith, or a surgeon, was regarded as holding oneself out to the public as one in whom confidence might be reposed, and hence as assuming an obligation to give proper service, for the breach of which, by any negligent conduct, he might be liable."[39] Intentional torts became more and more grouped together towards criminal liabilities, and negligence became the more dominant cause of actions for accidental and/or unintentional injuries. Negligence is but one kind of conduct. But a cause of action sounding in negligence requires four distinct elements. First, there must be a duty on the part of a defendant, recognized under the law, to provide a certain standard of conduct, for the protection of others against unreasonable risks. For healthcare practitioners, this duty is usually established by the patient–practitioner relationship. Second, the person owing the duty to the other must have failed to perform his duty in a legally recognizable way. Such failure is otherwise known as a breach of duty. Third, there must exist a reasonably close relationship between the breach of the duty owed and the injury sustained by the

other party – known as proximate cause. Finally, there must be a legally measurable injury to the person alleging the breach of duty.

The healthcare provider's duty arises from the patient/provider relationship. The provider begins the duty to the patient usually by initially rendering treatment to that patient. Although this relationship usually ensues with a "person-to-person" contact, some courts have held that if a physician is "on-call" to an emergency department, and contact is made with that on-call physician for the benefit of a patient being attended to in the emergency department, a physician/patient relationship is established even if the on-call physician has refused to see the patient or is not available to attend to the patient.[40]

Once a duty owed is established by the patient/provider relationship, there must be proof that there was a breach of duty of the provider to the patient for a negligence action to occur. Generally, a breach of duty is characterized as conduct that falls below the standard established by law for the protection of others against unreasonable risk of harm.[41] In the case of physicians, the duty of care is the degree of reasonable care and skill expected of members of the medical profession under the same or similar circumstances.[42] The standard of care for the purposes of a negligence action must be established by the testimony of expert witnesses, i.e., other physicians. States have different requirements for the qualifications of expert witnesses, but it is beyond the scope of this writing to go into the nuances of expert witness qualifications in medical malpractice actions.

It is a necessary element of a negligence action to show that the negligence of the physician is the immediate, proximate cause of the patient's injuries. It must be shown that the alleged negligence was a cause, "which in a natural and continuing sequence produced the event or injury, and without which the event or injury would not have occurred".[43] This is sometimes referred to as the "but for" test – that is, but for the negligence of the defendant, the plaintiff's injuries would not have occurred. The plaintiff must also prove under this element of negligence that the event or injury was foreseeable. "Forseeability exists when a physician of ordinary skill, knowledge, care, and prudence, in the exercise of ordinary care, would have been able to reasonably anticipate . . . that the event . . . would have occurred as a natural and probably consequence of his conduct."[44]

Finally, the plaintiff must prove damages – that injuries actually were suffered by the patient as a result of the negligence of the defendant. Additionally, the patient may have incurred recurring medical costs, loss of

income, pain and suffering damages, loss of consortium damages, and so on, which if quantifiable, could be part of the injuries resulting from the breach of duty of the defendant.

Part 4:   Patient care decision-making at the end of life

The body of law that deals with end-of-life decision-making is hardly settled law. Because the welfare of citizens is largely the concern of individual states, judicial decisions regarding end-of-life issues in healthcare vary among the states.[1] The courts of one state have no legal duty to honor the decisions of any other state although jurists may look to other jurisdictions for non-binding guidance on issues that arise before any court. Over time, parallel, though not identical, trends may be perceived between the courts of different states. However, medical advancements in the last quarter of a century created issues in patient care decision-making that courts had not faced prior to the 1960s. Hence, there has been much less time for development of the body of law dealing with end-of-life decision-making than for many other areas within the law. Therefore, it is difficult to make broad generalizations for every issue that one may encounter in patient care decision-making. The following discussion attempts to identify some clear trends in this area of the law as a guide to understanding and contending with end-of-life decision-making. It is essential to advise the readers always to consult experienced attorneys within their own jurisdictions when faced with critical issues regarding end-of-life decision-making.

The competent adult

Legal scholars tend to agree that there are some general principles that generally apply across all jurisdictions.[2] Probably the most well-established general principle that virtually every jurisdiction will follow is that a competent adult patient will always be given the autonomy to control the medical care he or she accepts or refuses. To state this as a principle . . . "[a]n adult patient with decision-making capacity may refuse any treatment unless the refusal will endanger the public health (or in a small minority of jurisdictions and under very narrow circumstances, a dependent or unborn child). The family has no standing to be involved in the decision-making but may be if the patient wishes".[3]

Competent adults have a broad legal prerogative to decide how to respond to medical conditions that threaten their well-being and even their lives. A competent adult has a privacy right to be free from unwanted interventions even if such interventions are meant to maintain that person's life. Such a scenario occurred in *Farrell*.[4] Kathleen Farrell was suffering from amyotrophic lateral sclerosis and was dependent upon a ventilator to keep her breathing. Even though her physician informed her that removing her from the ventilator would cause her death, Ms. Farrell insisted upon having her ventilator turned off. Her husband filed a complaint with the court seeking his appointment as Special Medical Guardian for his wife with specific authority to disconnect her respirator. Although Ms. Farrell had died while still connected to her ventilator by the time the New Jersey Supreme Court heard the case, the court decided nevertheless to hear the case because of the importance of the issues involved.[5] Citing *Quinlan*, the New Jersey Supreme Court asserted that Ms. Farrell, as a competent adult, could assert her right to privacy to refuse mechanical ventilation because her right to privacy was protected in the common law, the state, and federal constitutions.[6]

Another case illustrative of the principle that competent adults have the right to accept or refuse medical care under common law and constitutional law is useful to review because of the personal and social issues that arose that are not actually reflected in the decision of the court. Elizabeth Bouvia was a 28-year-old quadriplegic woman afflicted with cerebral palsy since birth, who was confined to bed in a public hospital who petitioned the court for a writ of mandate to compel the hospital to stop feeding her through a nasogastric tube.[7] She had previously stated that she wished to starve herself to save her from a life she now considered futile and meaningless.[8] Despite her disabilities, Ms. Bouvia had acquired a college degree and had been married,[9] but her fragile life had become unraveled. Her husband left her and she suffered a miscarriage. Her parents, no longer wishing to provide the care that she needed, turned her out of their home. A search for a place for her to live was unsuccessful, necessitating her living in a public hospital for her care.[10] The court, in granting Ms. Bouvia's request to remove her feeding tube asserted that her motive for the removal was irrelevant because no one's approval was needed for her to exercise her right to refuse medical care.[11] This right to refuse medical care was "basic and fundamental" as "part of the right of privacy protected by both the state and federal constitutions."[12] However, 2 years after her successful court battle, she was interviewed by the L.A. Times, stating that . . . "people should have the right . . . to decide if they want to suffer or not."[13] Professor M. R.

Flick points out in describing Ms. Bovia's plight that perhaps she really had not wanted to die, but had wanted to be wanted.[14] This very poignant observation contains a warning to all clinicians to remember to examine a competent patient's true motives for the refusal of medical care before that patient's options are terminated by death.

There exist some cases where a competent adult was denied the ability to refuse medical care when the well-being of the adult's children was threatened. For example, in *Dubreuil*, a Florida court authorized the administration of life-saving blood transfusion required because of uncontrolled bleeding after delivery of her child, despite her objections to receiving the transfusion on religious grounds.[15] The appellate court invoked the state's *parens patriae* interests in the welfare of Ms. Dubreuil's children necessitating the transfusions against her will, because the court found that the patient was the mother of four minor children and there was no evidence that anyone other than Ms. Dubreuil would be available to care for them in the event of her death from exsanguination.[16]

It is generally true that, except where a state finds that the interests and well-being of minors may be affected by a competent adult's decision for forgo life-saving medical care, a competent adult will always have the right to make decisions regarding the medical care he or she will accept or refuse.

Surrogate decision-making in end-of-life decision-making

Generally, incompetent adults and minors require some sort of surrogate medical decision-making. When it comes to minors, the surrogate decision-makers are typically that minor's parents. Previously competent adults may have a surrogate appointed to make decisions for them either by statutory direction or through an advance directive. Unfortunately, many previously competent adults have no advance directives that provide assistance to providers when such patients need a surrogate. Despite public awareness of living wills, it has been estimated that only 10% to 20% of the adult population in the United States has completed a formal advance directive.[17] Never-competent adults typically will have a public guardian appointed by a court who would be responsible for making medical care decisions for them. Typically, such a guardian would be a close relative, but wards of a state would likely have a public guardian appointed. It is very important for clinicians to keep in mind that there exist limitations to surrogate decision-making, and that such limitations may vary depending on the jurisdiction. Hence, despite generalizations that may

be made below, surrogate decision-making, particularly for end-of-life decisions, will be unique to varying degree in every jurisdiction, so it is prudent for clinicians to be familiar with the laws governing the jurisdiction within which they practice.

Minors

A fairly clear trend in the law is that a . . . "parent, or if there is no parent, the legal guardian, may refuse treatment for a minor who is terminally ill or irreversibly unconscious, so long as the minor agrees."[18] There are some limitations concerning such decisions with regard to infants in some states under federal and state child abuse laws.[19] No parent has the right to refuse beneficial medical treatment provided that the treatment is a generally accepted practice in the medical community and that beneficial outcome is expected. "Parents may be free to become martyrs themselves. But it does not follow [that] they are free, in identical circumstances, to make martyrs of their children before they have reached the age of full and legal discretion when they can make that choice for themselves."[20]

On the other hand, when treatment is "futile" based upon the generally accepted standard of care, and the healthcare providers and parents (or guardian) agree, it is legally acceptable to have life-sustaining treatment withheld or withdrawn.[21] "Futile" life-sustaining care may also be withdrawn upon the agreement of parents and providers if the minor is in a persistent vegetative state.[22] If a minor's parents and healthcare providers disagree upon a course of treatment that is subject to differences of opinion within the medical community, it would be advisable for the providers to seek the advice of experienced attorneys in their jurisdiction before contemplating going to court in such situations. As is usually true, provider communication with the parents often surmounts issues that lead to a decisional impasse. Nevertheless, controversial treatments or treatments with which reasonable clinicians may differ could lead to provider liability.

Importantly Congress enacted the Federal Child Abuse Prevention and Treatment Act in 1984 which provided general standards for the care of infants with defective medical conditions when the infant's life is immediately in danger.[23] The Act generally prohibits withholding or withdrawing treatment for infants when such treatment can be reasonably estimated to correct or stabilize a condition that could be life-threatening. Clinicians caring for infants should also be familiar with their state's child abuse statutes as they may apply to newborns and infants with defective medical conditions.

Adults

Surrogate decision-making law for adults is the most variable and lies at the cutting edge of bioethics and the law in some scenarios. It is beyond the scope of this writing to entertain the wide range of opinions in the bioethics and legal literature on this topic. It is hoped that some useful guidelines may be provided within this area of patient care decision-making, but disagreements between parties involved in the care of incompetent patients will still likely end up in court.

Formerly competent adults

Most laws governing surrogate decision-making will respect a formerly competent patient's autonomy interests by requiring a surrogate to follow the course of treatment the patient would presumably want.[24] Such issues are most clear when the formerly competent patient left explicit instructions in an advance directive. When explicit instructions have been left, the surrogate must follow those instructions if they apply to the medical scenario that the incompetent patient is facing, leaving little independent judgment to the surrogate. There is little controversy when the surrogate must decide *in favor* of recommended medical treatment. Indeed, one may say that the surrogate is merely acceding to the supposed wishes of the patient rather than making a decision on behalf of the patient. Additionally, when an advance directive is clear that a patient would refuse certain treatment if certain conditions are present, there is little argument that such treatment can be refused by the surrogate on behalf of the patient without going to court. Unfortunately, because of the uncertainties of medicine and many ambiguities in advance directives as they exist today, advance directives may sometimes be too vague to assist surrogate decision-making effectively.[25]

If a formerly competent patient made an informed decision to reject certain medical care before becoming incompetent, such decisions will generally be given continuing effect as long as the circumstances have not materially changed.[26] For example, in *Yetter*, the now incompetent Ms. Yetter had refused a breast biopsy for a breast mass when she had been hospitalized for schizophrenia.[27] The patient's caseworker testified that at the time of her hospitalization, Ms. Yetter was "lucid, rational, and appeared to understand that the possible consequences of her refusal included death".[28] Later, Ms. Yetter's mental illness became more profound to the point where she was no longer capable of discussing the matter of the breast biopsy.

Although deemed incompetent at the court hearing, the court gave continuing effect to Ms. Yetter's refusal for the breast biopsy. Citing *Roe v. Wade,* the court stated that "the constitutions right of privacy includes the right of a mature competent adult to refuse to accept medical recommendations that may prolong one's life . . . [and] that the right of privacy includes a right to die with which the State should not interfere where there are no minor or unborn children and no clear and present danger to the public health, welfare, or morals."[29]

Although *Yetter* represents only one jurisdiction, it is likely that, if a formerly competent patient made an informed decision to refuse certain medical treatment when that patient was competent, that patient's autonomy interests would be served by giving continuing effect to that decision. As long as the circumstances have not materially changed, it seems likely that such prior decisions would be respected by the courts.[30] Many of the problems with surrogate decision-making for formerly competent patients arise when there exists little or no information available with which a surrogate can make decisions.

When a formerly competent patient expressed no strong preference or written advance directive regarding the refusal of certain treatment prior to that patient's incompetence, a surrogate decision-maker's choices will be more restricted. It seems possible that, in light of the US Supreme Court's decision in *Cruzan*, state courts that have no clear precedent for surrogate decision-making may impose firm restrictions upon surrogate abilities to withdraw treatment in the absence of an incompetent's clearly articulated preferences.[31] In *Cruzan*, the Supreme Court held that the US Constitution does not forbid a state to require clear and convincing evidence of an incompetent's wishes to withdraw life-sustaining treatment.[32] The "clear and convincing" evidentiary standard represents the strictest civil court evidentiary standard. The only standard more strict is the familiar, "beyond a shadow of a doubt" evidentiary standard that is used in criminal law. The "clear and convincing" evidentiary standard is not a *requirement* of the US Constitution. *Cruzan* merely asserts that a state may set its own standards.

Courts are more likely to allow the discontinuation of life-sustaining treatment when it is clear that the patient in question is in a persistent vegetative state or is terminally ill.[33] Yet, when there is absence of a terminal condition, surrogates may have to surmount evidentiary standards of the courts within their jurisdictions. For example, in *Ragona v. Preate*, the court heard a petition from the guardian and husband of a woman who was in a persistent vegetative state, but was not terminal.[34] The petition requested permission to remove Ms. Ragona's

feeding tube. Although the final result of the decision was to allow the removal of the feeding tube the court began its opinion by pointing out that Ms. Ragona's . . . "right to self-determination is [its] guiding principle; the court does not decide whether to withdraw the life-supporting treatment, rather [the court's] role is to determine and effectuate Ruth Ragona's express intent."[35] Citing *Cruzan*, the court stated that Ms. Ragona's intent would have to be proven by clear and convincing evidence and pointed out that . . . "the court must not manage morality or temper theology. Its charge is to examine what law there is and apply it to the facts proven in this cause."[36] The court heard testimony from the treating physician and an independent medical expert to establish that Ms. Ragona was truly in a persistent vegetative state. Subsequently, extensive testimonial evidence was gathered from her husband and her son regarding her previously expressed opinions concerning her wishes. Ms. Ragona had expressed her wishes clearly that she would wish to live in a vegetative state.[37] The court found the evidence to be "highly persuasive" evidence of Ms. Ragona's intent and granted the husband's petition to remove the feeding tube.[38] One can speculate that if there had been less evidence to support Ms. Ragona's opinions regarding the issues faced by the court that the court would have been disinclined to have her feeding tube removed.

Given the evidentiary requirements that courts may apply, courts will certainly be less inclined to allow a surrogate to refuse medical care when the incompetent patient is not terminal or is in something less than a clearly persistent vegetative state. For example, a New Jersey court ordered that an enterostomy tube be inserted to support the life of a patient who was severely debilitated from a stroke, but who was neither terminally ill nor in a persistent vegetative state.[39] In *Clark*, the patient at issue had not executed a living will or healthcare power of attorney document,[40] nor had he ever expressed any desires regarding medical treatment to any known person. Judging that the court had no basis upon which to base a "substituted" judgment on his behalf, the court used an "objective" test to make "[a] determination of whether certain treatment should be provided or withheld . . . strictly on a weighing of the burdens of life with the treatment versus the benefits of that life to the patient."[41] The court held that the burdens of the surgery to insert the enterostomy tube did not outweigh the benefits that the patient derived from life.

In *Wendland v. Superior Court*, an appellate court required the appointment of an independent counsel when the patient's wife sought appointment as his permanent conservator and to have his feeding tube removed.[42]

Mr. Wendland was a 43-year-old man who had been severely impaired as a result of a motor vehicle accident approximately 2½-years earlier. After being comatose for more than a year, he "awoke" and was found to be substantially brain-injured. He was paralyzed on his right side and was able to follow simple commands.[43] His wife, asserting that Mr. Wendland had made statements that he would not want to live in a state of total dependence, was making arrangements to transfer Mr. Wendland to a convalescent hospital where his feeding tube would be removed and he would be allowed to die.[44] This decision had been supported by Mr. Wendland's physicians and the hospital's ethics committee. Mr. Wendland's mother and sister did not agree with this decision, however, and sought the appointment of an independent counsel for Mr. Wendland in the conservatorship proceedings. The appellate court held that Mr. Wendland was entitled to an independent counsel to represent his interests because "his very life was at stake."[45] Citing *Cruzan*, a concurring opinion went on to say that . . . "this much is clear: a person has a constitutional right to refuse unwanted medical procedures, including artificial hydration and nutrition."[46] "There is little doubt that if [Mr. Wendland] were competent, he could refuse further medical treatment. However, in light of his incompetence . . . [Mr. Wendland's] freedom of choice 'is a legal fiction at best' . . . the court must select a conservator who has a broad authority to make decisions regarding treatment, guided by the patient's best interests."[47]

The evaluation of cases dealing with surrogate decision-making provides some guidance to clinicians, though such guidance is less than ideal. In her treatise on healthcare decision-making the author Claire C. Obade summarized the trends for surrogate decision-making at the present time:

A surrogate may authorize, and perhaps compel, the discontinuation of medical treatment for an adult person without decision-making capacity if the patient is terminally ill, or if the proposed treatment will not be of benefit to the patient. However, the surrogate cannot make a decision contrary to the known preferences of the patient, nor can a surrogate refuse medical care which is reasonably likely to be even of limited benefit. The closest relative is presumably the proper surrogate unless there is a court-appointed guardian or the patient has previously designated another decision-maker. State law should be consulted for priority if there is a disagreement among the guardian, designated surrogate and/or close family members".[48]

Although the evidentiary standards differ amongst the states, the vast majority of jurisdictions in the United States have attempted to ascertain the wishes of the formerly competent patient when evaluating surrogates'

requests for or against treatment. The clear and convincing evidentiary standards are applied most vigorously in states such as Missouri and New York.[49] Michigan and Wisconsin apply similar standards for dying patients who still have the capacity to relate to their environment.[50] Fortunately, most states have less rigorous standards for evidentiary proof of a patient's prior intentions.[51] Additionally, courts have the discretion to determine the value of the weight of the evidence they evaluate. Regardless of the evidentiary standards used, the courts will typically attempt to apply a *substituted judgment* on behalf of the previously competent patient. Some courts may use a *best interests* test when previously competent patients have never been found to have expressed their wishes regarding end-of-life issues. The best interests test objective is to treat people the way most people would want to be treated, in other words, evaluating a patient's interests based upon what are believed to be societal standards.

Never-competent adults

Adults who were never competent are considered by the state to be vulnerable constituents whose rights should be carefully guarded. In most scenarios, such incompetent adults should be considered to have the legal status similar to minors. Particularly when such incompetents are wards of the state, regulatory issues must be taken into consideration. The state's mental health statutes may also have a bearing upon the treatment of such individuals. Erring on the side of favoring beneficial treatment is always the preferable rule-of-thumb when providing medical care to these patients. Inevitably, there will arise decision points where it will be necessary to consider the decision to withdraw or withhold treatment for such patients who are in a terminally ill situation or a persistent vegetative state. The prudent clinician should consult with legal counsel familiar with the laws of their jurisdiction whenever considering the withholding or withdrawing of life-saving treatment.

In states where their life-sustaining treatment can only be withdrawn or withheld based upon clear and convincing evidence of the patient's preferences, it is unlikely that a court in such a state would allow the removal or withholding of life-sustaining treatment to a never competent adult. The states that use a "substituted judgment" standard for evaluating the removal of life-sustaining treatment for an incompetent patient may find that the application of this standard to a never-incompetent patient may be stretched and unwieldy.[52] The states that use a "best interests" test in evaluating an incompetent's rights to refuse or withhold medical treatment would probably be in the best position to contend with these issues in their application to a never-competent patient.[53]

Two authors have proposed a statutory theme that, if enacted, could provide an extra-judicial pathway to forgoing life-sustaining treatments for never-competent patients that would protect the interests of public wards.[54] Although specifically limiting the proposal to developmentally disabled persons who have been adjudicated as incompetent to make their own health care decisions, the authors Deborah K. McKnight and Maureen Bellis provide a solid starting place for dealing with the never-competent patient for end-of-life decision-making. The proposal designates a group of decision-makers for the developmentally disabled public ward who together as a unanimous group could decide to withhold or withdraw life-sustaining treatment without seeking judicial review.[55] The group would comprise an "involved guardian," the patient's attending physician, and either two physicians with relevant experience or the endorsement of a prognosis committee.[56] Patient surrogates acting in good faith and physicians exercising reasonable medical judgment would be immune from civil or criminal liability under this proposal.[57] The proposal outlines four situations in which the decision-makers may choose to forgo life-sustaining treatment: (1) the patient has been in a persistent vegetative state for 12 months, (2) the patient has a terminal illness with uncontrolable pain, (3) the patient is in an advanced stage of a terminal illness with severe and permanent deterioration, and (4) if the patient did not fall under any of the other three conditions a decision for treatment withdrawal only could be made after a conscientious effort that the burdens of continuing treatment outweigh the benefits.[58] The decision-makers would then have to agree that a decision to withhold or withdraw life-sustaining treatment would be in the *patient's* best interest with any disputes between the decision-makers requiring court intervention.[59] Finally, palliative care would always have to be provided.[60]

Without some statutory framework for the purpose of making end-of-life decision-making for never-competent patients, it seems unlikely that such decisions can be made without some court supervision. There have been court decisions that have contended with such issues for patients who have never been competent, but they are few.[61] In light of the struggles that courts have had in dealing with formerly-competent patients, it is similarly unlikely that the courts will be the best venues to solve the problems involved inherent to end-of-life decision-making for never-competent patients.

Medical futility and the courts

The bioethical community and legal scholars have written extensively regarding various definitions of medical futility and their applications to end-of-life decision-making. However, it is not the purpose of this essay to provide an overview of such discussions, but rather to discuss the law that has addressed such issues. Some courts, in cases such as *Wanglie* and *In re Baby K,* that have had the opportunity to address futility issues, have rendered opinions that were clearly frustrating to health care providers as well as bioethicists and some legal scholars.[62] To be sure, few courts have actually had to contend with futility issues. Given the moral and ethical controversies involved with the concept of medical futility in the bioethical and legal literature, it seems clear that the courts will struggle with cases that come before them that force them to contend with the issue. *Wanglie* was one of the few cases in which there was an opportunity to address futile care had the judge decided to appoint a neutral guardian for Mrs. Wanglie who was in a persistent vegetative state. Instead, Ms. Wanglie's husband was appointed the guardian and, as guardian, Mr. Wanglie insisted upon the continued life-support of his wife against the opinion of the hospital and healthcare providers that the continued life-support for her was futile.[63] The Fourth Circuit of Appeals ducked the issue of futility completely when it held that a Virginia hospital was required under EMTALA to provide repeated emergency life-saving respiratory support to an anencephalic infant who had to be repeatedly transferred from a nursing facility to the hospital for recurrent respiratory failure.[64] However, there are a few other cases that have dealt with decisions surrounding the withdrawal or withholding of futile care.

In *Causey v. St. Francis Medical Center*, a physician withdrew life-sustaining care to a 31-year-old quadriplegic woman with end-stage renal failure and stage IV coma over the strong objections of the family.[65] The physician had considered the continued life-supporting treatment morally and ethically inappropriate and was supported by the decision of the hospital's Morals and Ethics Board.[66] The patient's husband and son filed an action against the hospital and the physician as an intentional battery claim. Nonetheless, the trial court dismissed the claim as premature because the doctor and hospital "acted in accordance with professional opinions and professional judgment" and under Louisiana's malpractice act therefore this was required to be submitted to a medical review panel prior to being reviewed by the court.[67] The plaintiffs appealed and the Court of Appeal of Louisiana, Second Circuit, heard the appeal. The appellate court first stated that the Louisiana

state legislature had enacted a statute respecting individual autonomy and the right to self-determination by giving a competent, terminally-ill person the right to *refuse* medical treatment.[68] The court went on to say that . . . "the right or autonomy to refuse treatment is simply a severing of the relationship with the physician . . . [i]n this case, however, the patient (through her surrogate) is not severing a relationship, but demanding treatment the physician believes is inappropriate."[69] Holding that the issue was whether the actions of the physician and the hospital met the standard of care of the medical profession, the court held that the issue fell under the Medical Malpractice Act and must first be submitted to a medical review panel.[70] Although the appellate court did not directly confront the issues of futility, it held that such determinations were in the purview of the standard of care.

A Georgia appellate court found that there were factual issues in dispute that would be required to be submitted to a jury in a case where a physician terminated the life-support treatment of a 9-day-old, critically ill infant.[71] The parents had brought a malpractice suit and an intentional tort suit against a physician for terminating the life-support of their daughter. The infant was born at 24 weeks' gestation on the side of the road on the way to the hospital.[72] The infant had been successfully resuscitated in the emergency room of the hospital, but required life-saving care including blood pressure and respiratory support.[73] The attending physician alleged that he had orally obtained the consent of the parents to stop treatment, which the parents disputed. The malpractice claim was dismissed on procedural grounds, but inconsistencies in the facts were such that the appellate court recognized that the parents could have a valid claim for the wrongful death of the infant based upon the reckless disregard of the consequences of the physician's actions or the heedless indifference to the rights and the safety of others.[74] Coupled with a reasonable foresight that injury would occur, the court suggested that if such allegations were proved, such actions would amount to . . . "criminal negligence equivalent to an intentional tort" and sent the case back down to the trial level.[75]

In sum, a healthcare provider treads on thin ice when walking on the surface of the medical futility issues in contravention of a surrogate's wishes. The results of such conflicts, when they reach the courts, are unpredictable and very fact-specific, dependent upon the jurisdiction. Fortunately, most healthcare providers and surrogates agree with the decisions regarding medically futile care. Unfortunately, when disputes are not resolvable through careful communication, consultations with ethics committees, and alternative dispute resolution techniques, submitting the issues to a court will be fraught with uncer-

tainties. There is no clear line of decision-making upon which a provider can rely when acting on an opinion that certain medical care is futile without the consent of a surrogate. It seems that when a provider has made an effort to act carefully within a reasonable standard of care, and with the independent opinions of other physicians or an ethics committee endorsement, courts will give greater deference to a decision to withhold or withdraw care that is considered futile. That being said, the reader must understand that the preceding statement is merely an observational opinion. Providers should consult with attorneys within their jurisdiction for pertinent legal advice.

NOTES

Part 1: Introduction

1. *E.g Griswold v. Connecticut*, 381 U.S. 485(1965) (*J. Douglas' infamous statement evolved the right of privacy from the U.S. Constitution by deriving the right from the Bill of Right's penumbras, formed by emanationsf from those [specific] guarantees [from the Bill of Rights] that help give them life and substance'*; *Roe v. Wade*, 410 U.S 113 (1973) (*J. Blackman finds the right to privacy in the First, Fourth, Fifth and Ninth Amendments and the precedent set forth in Griswold*).

Many states require medical providers to seek transfer of a patient when disputes regarding the care of a patient arise between the patient's providers, the patient, or the patient's surrogates. When disputes rise to the level of court action, particularly cutting-edge public legal and moral issues, other providers and healthcare facilities become reluctant to accept transfer of these 'problem cases.' As a result, the solution for transferring such a patient to another provider willing to care for the patient as the family wishes (as suggested by

courts and state legislation) essentially become an impossibility. These cases are referred to colloquially by some critics as hot potato cases.

Part 3: Evolution of the law of healthcare decision-making

1. Implied fundamental rights are sometimes called substantive due process rights, but the author chooses to use the term implied fundamental rights for the sake of clarity. The "substantive due process rights" appellation is a useful moniker when discussing these rights amongst constitutional scholars.

2. "No State shall make or enforce any law which shall . . . deny to any person within its jurisdiction the equal protection of the laws." 14th Amendment, United States Constitution.

3. "Congress shall make no law . . . abridging the freedom of speech", 1st Amendment, United States Constitution.

4. Prosser and Keeton on Torts, 5th Edition, W. Page Keeton, ed, West Publishing Co. (1984).

5. Union and Pac. R. R. Co. v. Botsford, 141 U.S.250, 251. 11 S. Ct. 1000, 351 L. Ed. 734, 735 (1891).

6. Schloendorff v. Society of N.Y. Hosptitals, 211 N.Y. 125, 105 N.E. 92 (1914).

7. Olmstead v. United States, 277 US 438, 478 (1928)(dissenting opinion).

8. The Fifth Amendment states that no person shall be . . . 'deprived of life, liberty, or property, without due process of law.' The Fourteenth Amendment states that . . . 'no State [shall] deprive any person of life, liberty, or property, without due process of law.'

9. "The enumeration in the Constitution, of certain rights, shall not be construed to deny or disparage others retained by the people." Ninth Amendment, United States Constitution.

10. The reader who may be interested in the debate regarding implied fundamental rights should consider starting with recognized Constitutional law textbooks, such as American Constitutional Law by Laurence Tribe (published by The Foundation Press, Inc.

The near-death experience, long-term psychological outcomes and support of survivors

Sam Parnia, K. Spearpoint, and P.B. Fenwick

Consciousness Research Group, University of Southampton, and
Critical Care Department, Hammersmith Hospitals NHS Trust, London, UK

Since the 1950s and 1960s improvements in resuscitation techniques have led to improved survival for patients following cardiac arrest. Although many studies have focused on prevention and acute medical treatment of cardiac arrest, relatively few have studied cognitive functioning during and after this event. Nevertheless, this is one of the most intriguing aspects of cardiopulmonary resuscitation. Much of the work in this area has evolved from the finding that a proportion of cardiac arrest survivors report thought processes, reasoning, and memory formation that are consistent with previously described near-death experiences. These experiences are reported to have occurred at a time during cardiac arrest when consciousness appears to be absent. The first part of this chapter thus focuses on the history and phenomenology of near-death experiences, their relationship to cardiac arrest and current explanations for the experiences. We then review the longer-term psychological outcomes of surviving a cardiac arrest, as well as the impact of having a near-death experience on long-term quality of life. Finally we review the wider potential philosophical implications of research into near-death experiences during cardiac arrest.

History of near-death experiences

Although modern heart and lung resuscitation methods were established in the 1950s and 1960s, there is a long history, going back centuries, of attempts to resuscitate people after they had become 'lifeless'. These involved using warm ash and hot water, whipping, blowing hot smoke in the mouth and rectum, as well as rolling people back and forth on a wine barrel or a horse to help the chest expand and take air in. The outcome of these methods was understandably poor. Nevertheless despite these primitive methods of resuscitation and the generally poor prognosis of anyone coming close to death there have been many anecdotal reports of unusual experiences during a close brush with death.

The earliest recorded reference to an experience during the dying process is in Plato's Republic.[1] A soldier, Er, suffers a near fatal injury on the battlefield, is revived and describes a journey from darkness to light accompanied by guides, a moment of judgement, feelings of peace and joy, and visions of extraordinary beauty and happiness. Historically, events closely resembling NDEs have been described by Bolivian, Argentinean, and North American Indians, as well as in Buddhist texts, Islamic texts and accounts from China, Siberia and Finland.[2] Two of the most interesting cases are a fifteenth-century painting as well as an eighteenth-century near drowning case. The fifteenth-century painting "ascent to empyrean" by Hieronymus Bosch [Fig. 69.1] depicts a tunnel leading to a bright light and has been found very much to resemble modern descriptions of near-death experiences. An NDE account from Admiral Beaufort, a British admiral who narrowly escaped drowning in Portsmouth harbour in 1795 describes a historical case of what would now be recognized as an archetypal life review.[2]

. . . circumstances minutely associated with home, were the first reflections. Then they took a wider range, our last cruise . . . a former voyage and shipwreck, my school and boyish pursuits and adventures. Thus travelling backwards, every past incident of my life seemed to glance across my recollection in retrograde succession; not however in mere outline, as here stated, but the picture filled up with every minute and collateral feature. In short, the

Fig. 69.1. Ascent to Empyrean. Hieronymus Bosch (1450–1516).

whole period of my existence seemed to be placed before me in a kind of panoramic review, and each of it seemed to be accompanied by a consciousness of right or wrong, or by some reflection on its cause or consequences; indeed many trifling events which had been forgotten then crowded into my imagination, and with the character of recent familiarity.

The first systematic collection of accounts from people who had experienced a close encounter with death were reported by a nineteenth-century Swiss geologist and mountaineer, Albert Heim.[3] Heim had survived a near-fatal mountaineering accident himself and then went on to collect 30 first-hand accounts from other survivors of near-fatal mountaineering accidents, and found that they had had similar experiences.

Modern studies of near-death experiences

Despite these limited reports, it was not really until as late as the 1970s that this subject entered the realms of science,

after Raymond Moody, an American psychiatrist with a background in philosophy, published his best selling book, *Life after Life* in which he had collected the accounts given by 150 survivors of near-death encounters.[4] His series of survivors of near-death encounters was not limited to cardiac arrest, but included reported experiences of people who were considered sufficiently ill to have otherwise died without medical intervention. He found that the survivors who had had experiences described similar phenomena including feelings of peace, a tunnel and a bright light, seeing deceased relatives, a life review, a perception of separation from the body (out of body experience) and entering a heavenly domain.[4] The experiences were usually described as happening when the individual was unconscious and often resulted in a more spiritual and socially orientated outlook and a reduced fear of death. Moody termed these experiences "near-death experiences" (NDE).

Since then it has been found that near-death experiences have been described in many different cultures, including India, China, South America and the Middle East.[2,5,6] Although the central features are universally present, the interpretation of the experience reflects personal religious or cultural views.

Following Moody's work, Sabom,[7] Noyes and Kletti,[8] Ring,[9] and Greyson[10] described and classified the experiences in more detail. A number of actual NDE cases collected by the authors that illustrate some of the typical features are described below. One of the most interesting aspects of these cases is that during the cases many have claimed to have been able to recall very specific details about events that had actually taken place during their experience. One woman explained:

. . . during my operation I was floating around the operating theatre. I could see the surgeon and nurses working on my body, . . . the surgeon said he would leave the wound open to let it drain as the appendix had burst. He then visited me on the ward afterwards to explain what he had done and I already knew as I had heard him. He said I couldn't possibly have heard him and suggested that a nurse had been to my bedside and told me . . . I did not tell him I had seen the operation being performed . . .' [Personal communication to the author]

. . . I can remember so vividly being above and to the right of the bed in the delivery room at the head end in a white-like tunnel, but it was white, absolutely brilliant white . . . I looked down and I could see Dr Gallagher, I could see what he was doing and I saw him run round the bottom end of the delivery bed . . . he must have forgotten [a bucket] was there because I saw him kick it in his haste to get round the other side and he kicked this bucket and it knocked into a trolley with all the instruments on, things like bowls, etc., and that trolley whizzed across the room and hit the wall. It didn't tip right up but you could see things falling off it and he then came round to me on my left-hand side and I saw him

thumping on my chest, thumping and thumping. I heard nothing, I could see nothing, no sound whatsoever, I just saw what he was doing . . . It was peace, it was peace, it was absolute peace . . . I just looked down on myself . . . I could possibly say it was a tunnel where you were looking down [from], but all this light was around you, it was a brilliant light . . . and then there was a noise, a terrible noise . . . I just said, "Let me go back, it was beautiful . . ." The next day I spoke to the doctor and I was telling him what he had done and he was furious and wanted to know which nurse had told me!' [Personal communication to the author]

During the 1980s NDEs were also studied in children. Dr. Melvyn Morse, an American pediatrician, and others found that children's NDEs share many of the same features as those of adults – separating from the body, watching events, feeling peaceful, seeing a bright light and beings of light, but they are often described in children's terminology and during the course of play, sometimes over many months.[11–14]

The following is one case of NDE recalled by a small child that was sent to the authors by his grandmother:

John's heart had stopped . . . . . . they were pressing on his chest and he was lifeless and blue . . .They put him in an ambulance and took him to hospital . . .

[After he had been discharged from hospital] one day, during the course of play, he said, "Grandma, when I died I saw a lady." He was not yet three years old. I asked my daughter if anyone had mentioned anything to John about him dying and she said, "No, absolutely not." But over the course of the next few months he continued to talk about his experience. It was all during the course of play and in a child's vocabulary.

He said, "When I was in the doctor's car the belt came undone and I was looking down from above." He also said, "When you die, it is not the end . . . a lady came to take me . . . There were also many others, who were getting new clothes, but not me, because . . . I was going to come back."

John's parents noticed that he kept on drawing the same picture over and over again. As he got older, it got more complex. When asked what the balloon was, he said, "When you die you see a bright lamp and . . . are connected by a cord" (Fig. 69.2(a), (b)).

Long-term effects of having a near-death experience

One of the aspects of NDE that was first described by Moody, was that NDEs have a long-term positive protective psychological effect. This has been shown in other studies also. Fenwick and Fenwick[15] in a questionnaire survey of 358 people who had had NDEs in widely differing circumstances and who had written in after a television programme about

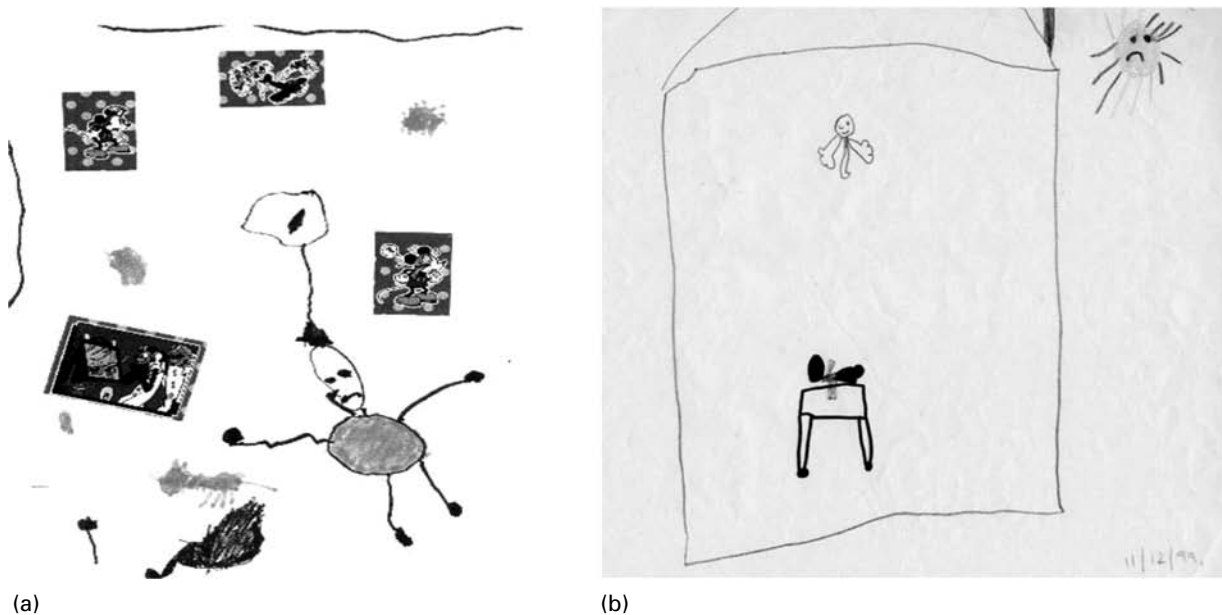
(a)   (b)


Fig. 69.2. Two drawings depicting a NDE experienced by a small child. These are two drawings by John, a child who had a near-death experience when he was less than three years old. His family had at first been concerned because they saw that he kept on drawing the same theme. Here, there is a drawing from when he was younger (a) and one when he had grown a little older (b).

NDEs found that 82% had less fear of death, 42% reported that they were more spiritual, 22% claimed to be a better person and 40% said they were more socially conscious than before. As only 10% of this sample had their NDEs after cardiac arrest, it would appear that simply having an NDE is the positive factor, and the positive changes are not related to the pathology causing the NDE.[15]

Greyson[16] suggested that near-death experiences reportedly foster value transformations and decrease suicidal ideation. Eighty-nine survivors of near-death experiences judged values related to material and social success as less important than did 175 control subjects. The reduction in feelings of personal failures may account for the reported suicide-inhibiting effect.[16] Greyson also studied a group of patients who attempted suicide and found that 26% of them had NDEs.[18] Extending this to other studies on suicide, he found that people who had had an NDE during a suicide attempt were less likely to attempt suicide again.[17,18]

Scientific theories for the causation of NDE

Many theories to account for the occurrence of NDE have been proposed. These include physiological states such as cerebral hypoxia,[19,20] hypercarbia[21] hormone and neurotransmitter release such as endorphins,[22,23] serotonin,[14] and abnormal NMDA receptor activation,[24] abnormal activation of the temporal lobes leading to seizures,[25] or limbic lobe activation.[26–28] Various drugs and, in particular, drugs that are known to cause hallucinations, such as ketamine, which activate the NMDA receptor have been suggested.[24] An alternative view, which is undoubtedly true in a few situations, is that the experience is a psychological response to stress or a form of depersonalization or dissociation in the face of actual or perceived danger or death.[8, 32]

The final moments of the dying process invariably involves a period of hypoxia. Therefore, it has been proposed that hypoxia may lead to overactivity in the visual processing areas of the brain and as there are more cells involved with central vision than peripheral vision, this may therefore create an illusion of seeing a light in the centre that fades out towards the periphery, or in other words a tunnel effect.[19,20] It has also been proposed that hypoxia may induce hyperactivity of the NMDA receptor that may in turn lead to an NDE.[24] Other theories involving other neurotransmitters or hormones such as serotonin and endorphins have also been proposed.[25–27]

More recently some have suggested that out-of-body experiences may be related to a dysfunction at the

temporo-parietal junction.[29–31] It is argued that a multi-sensory disintegration at this area may lead to the disruption of several phenomenological and cognitive aspects of self-processing, causing an illusory reduplication, self-location, and perspective of the self that is experienced as an out-of-body experience.[30,31] This theory has followed from a case report of a single patient who was undergoing evaluation for epilepsy treatment in whom an "out-of-body"-like experience was induced following focal electrical stimulation of the brain's right angular gyrus.[29] Unfortunately this explanation does not take into account the observation that people who have had an out-of-body experience report actually being able to recall specific details of events that had taken place at a time when they had been unconscious. If correct, this would make it unlikely that such experiences are simply illusions, even if the trigger for the experience and hence the neurological intermediary pathway for such an experience may lie in the temporoparietal region of the brain.

In general, all the brain-based and psychological theories for the causation of NDE have proposed possible physical or psychological triggers that may either lead to or mediate the NDE. Although none of the above hypotheses can account for the NDE in its entirety, the NDE is undoubtedly mediated by neuronal intermediaries and may be triggered by either a physical or psychological stimulus. Identifying the neurological changes that mediate an experience, however, cannot identify or determine the "reality" of the experience and this includes near-death experiences. Every subjective experience is mediated by neuronal changes, and is triggered by physical or psychological stimuli, including familiar experiences such as maternal love and compassion; however, identifying the detailed neuronal circuitry that mediates these experiences does not define their "reality." In the same way, eventually identifying the neuronal pathways that mediate NDE cannot determine their "reality." Reality, on the other hand, is socially and not neurologically determined.[33] As explained above, they also do not take into account that people who have had an out of body experience report actually being able to recall specific details of events that had taken place at a time when they had been unconscious, so simply identifying the neurological triggers for the experience may not help determine its reality.

Almost all of our understanding of cognitive neuroscience and its representation in brain structure depends on correlates of cognition. The models of cognition that are built from those data are, however, correlative rather than causative models.

The limitation of early studies

Nevertheless, despite the large number of interesting cases and retrospective studies carried out in the 1970s and 1980s, one of the greatest difficulties in studying these so-called near-death experiences had been the difficulty in defining the actual proximity of the individuals to clinical death. Most cases involving such near-death experiences had not been recorded in conjunction with actual medical data demonstrating objective proximity to death. In some cases, such as the ones illustrated in this text, the patients' own accounts appeared to indicate the existence of a period of cardiac arrest. Therefore because near-death experiences can occur in widely varying circumstances, one of the difficulties in studying them has been the problem of defining the actual proximity of the individuals to clinical death.

The cardiac arrest model of the near-death experience

In clinical practice, death is diagnosed when the heart stops beating, the person stops breathing, and the brainstem and hence the rest of the brain have stopped functioning. The ideal model to study the near-death experience, therefore, is one in which these criteria are met, namely a cardiac arrest.[34]

In this condition patients develop two out of the three criteria of clinical death – no heartbeat, no breathing – and also develop the third – fixed dilated pupils of the eyes* – within a few seconds owing to the loss of brain and, in particular, brainstem function. Secondly, cardiac arrest mimics the initial period of the dying process biologically. Finally, irrespective of the cause of death, the last steps in the dying process are the cessation of breathing and heartbeat – in other words a cardiac arrest. What people experience at that time can provide us with a unique window of understanding into the subjective experiences of the dying process.[34]

In the 1970s Sabom had interviewed a group of cardiac arrest survivors and matched their descriptions of the arrest to the medical notes. He had concluded that patients

---

* In cardiac arrest, drugs may be administered such as epinephrine and atropine that can also make the pupils look fixed and dilated. Other measures of brainstem reflexes such as the gag reflex are also lost, however, indicating that this vital part of the brain does not work.

who had out-of-body experiences were able to describe the resuscitation process as recorded in the medical notes.[35] In 1994, Martens[36] conducted a small retrospective study looking at a group of out-of-hospital cardiac arrest survivors. Since no near-death experiences had been found in this group, it was concluded that this phenomenon must be very rare in cardiac arrest survivors.

The first published prospective study to identify NDE accounts in cardiac arrest survivors was a small 1-year prospective study which showed that 6% of 63 cardiac arrest survivors reported having lucid well-structured thought processes, together with reasoning and memory formation.[34] This study was based upon interviewed accounts obtained within 1 week of the arrest. The experiences recalled were typical of those reported in other studies.

The main features that were recalled were coming to a border of no return, feeling peace, feeling joy, seeing a bright light, losing awareness of the body, and seeing deceased relatives. The authors found no evidence to support a specific role of drugs, hypoxia, hypercarbia, or electrolyte disturbances in the causation of the experiences. This was, however, a small study and therefore the authors concluded that a larger study would be needed. In a larger Dutch study 344 cardiac arrest survivors from 10 hospitals were interviewed over a 2-year period, and 41 (12%) reported experiences similar to those from the British study.[37] Approximately 24% of those who had an NDE also had an out-of-body experience and some reported having been able to watch and recall events from their cardiac arrest.

In one case, a nurse had reported having removed a patient's dentures and placed them in a drawer in a special trolley. Throughout the 1.5 hours of his resuscitation the patient had remained in a coma. One week later he had returned to the same ward where the nurse worked and after seeing her said "Oh, that nurse knows where my dentures are." He went on to describe how she took his dentures out of his mouth and put them into the crash trolley. He added "It had all these bottles on it and there was this sliding drawer underneath and that's where you put my teeth."

The nurse is quoted as saying:

I was especially amazed because I remembered this happening while the man was in a deep coma and in the process of CPR. When asked further, it appeared that the man had seen himself lying in bed and that he had perceived from above how the nurses and doctors had been busy with CPR. He had also been able to describe correctly and in detail the small room in which he had been resuscitated as well as the appearance of those present . . . At the time . . . he had

been very much afraid that we would have to stop CPR and that he would die. And it is true that we had been very negative about his prognosis due to his very poor medical condition when admitted.

The authors found that the occurrence of NDEs was not influenced by the duration of unconsciousness or the type of cardiac arrest, or by medication, but that there were more NDEs in those who had previous CPR, previous NDEs and also in the group of survivors who died shortly after their experience, suggesting that maybe the closer the patients were to death, the more likely they were to get an NDE.

This study also extended and confirmed the findings of the retrospective studies described above that a near-death experience has long-term life-enhancing sequelae. Using a life-change inventory[38] Van Lommel assessed the long-term attitude changes in a subset of his sample. 23 patients with an NDE had a 2- and an 8-year follow-up, and 15 matched patients with no NDE were interviewed at the same time intervals.

The authors found that there were changes in attitude after a cardiac arrest even amongst the people who did not have an NDE, although they were not as marked as those seen in patients who did have such an event. It is clear that a cardiac arrest in itself is a very powerful event and leads to changed attitudes. Both groups became less fearful of death, but interestingly, spirituality decreased in the non-NDE group but increased in the NDE group. They concluded that patients who have an NDE after a cardiac arrest have larger and more positive changes in attitude than those who do not.[37]

Two other studies of NDE in cardiac arrest were published from the USA. One study of 1,595 people who had been admitted to a cardiac unit over a 30-month period, also found that the incidence of NDE increased with the severity of the cardiac disease: only 1% of those admitted with stable cardiac disease reported NDEs; this increased to 10% of those with cardiac arrest. Those who had had an NDE were no different from those who had not in terms of social or demographic variables, cognitive function, or degree of heart disease.[39] Another US study found that 23% of cardiac arrest survivors had an NDE and that again those with NDEs became transformed in a positive manner after 6 months.[40]

It is clear from both retrospective studies and the prospective cardiac arrest studies that having an NDE during a cardiac arrest may have life-enhancing sequelae. In general those with an NDE are happier, more socially orientated, less materialistic, more altruistic and less afraid of death than those who do not have this experience.[4,15,37,40]

Table 69.1. Summary of changes in cardiac arrest survivors at 2-year and 8-year follow-up

Life-change inventory questionnaire	2-year follow-up		8-year follow-up	
	NDE (*n*=23)	no NDE (*n*=15)	NDE (*n*=23)	no NDE (*n*=15)
Social attitude				
Showing own feelings	42	16	78	58
Acceptance of others	42	16	78	41
More loving, empathic	52	25	68	50
Understanding others	36	8	73	75
Involvement in family	47	33	78	58
Religious attitude				
Understand purpose of life	52	33	57	66
Sense inner meaning of life	52	25	57	25
Interest in spirituality	15	−8	42	−41
Attitude to death				
Fear of death	−47	−16	−63	−41
Belief in life after death	36	16	42	16
Others				
Interest in meaning of life	52	33	89	66
Understanding oneself	58	8	63	58
Appreciation of ordinary things	78	41	84	50

NDE = near-death experience. The sums of all individual scores per item are reported in the same 38 patients who had both follow-up interviews.

Participants responded in a five-point scale indicating whether and to what degree they had changed: strongly increased (+2), somewhat increased (+1), no change (0), somewhat decreased (−1), and strongly decreased (−2). Only in the reported 13 (of 34) items in this table were significant differences found in life-change scores in the interview after 2 years.

Consciousness and awareness during cardiac arrest: what can we learn from awareness during anesthesia?

Although the reports of consciousness, thought processes, reasoning and memory formation during cardiac arrest are relatively new, reports of awareness while under general anesthesia have been noted since the introduction of anesthesia in the nineteenth century. In these cases such awareness is usually caused by insufficient anesthesia or by light levels of anesthesia allowed by the use of muscle relaxants. After being aware during general anesthesia, patients report hearing conversations, sensations of paralysis and pain, anxiety, panic, and helplessness.[41] Subsequent psychological sequelae may arise, with sleep disturbances, nightmares, flashbacks and a preoccupation with death.[42] This phenomenon is rare and is thought to arise in less than 1% of patients who undergo general anesthesia, but following its occurrence a longer term post-traumatic stress disorder may also arise.[43]

Four stages of perception during general anesthesia with memory of intraoperative events have been described.[44] At the first stage there is conscious perception with explicit memory. This has been reported in the unfortunate case of those who have been administered a muscular paralytic agent together with inadequate anesthesia and are thus able to feel and perceive events fully but appear completely unconscious. As actual anesthesia is administered and deepened, explicit recall of intraoperative events is lost, but conscious perception remains, such that the apparently anesthetized patient is capable of responding to commands yet appears amnesic of events afterwards. This is the stage of conscious perception without explicit memory (stage 2). There is evidence that with deeper anesthesia there is the possibility of subconscious perception with only implicit memory of intraoperative events (stage 3). A progressive increase in anesthetic concentration leads first to a progressive reduction in working memory, then loss of consciousness and explicit memory, whereas implicit memory of intra-anesthetic events may remain (stage 4). In one study that supports this finding, during anesthesia half of the patients were presented with target words from the category of fruit and colour, whilst the other half had

seaside noises played to them through headphones. Postoperatively no patient had explicit recall of the sounds but the experimental group of patients generated more target words when asked to name the first three fruits and colors that came to mind.[44] At deeper levels of anesthesia there is no perception and no memory.

Using what is understood from awareness during anesthesia it may thus be possible to conclude that perhaps during cardiac arrest there are different levels of consciousness depending on the degree of cerebral depression that occurs as a consequence of reduced cerebral blood flow. Nevertheless, as described later in this chapter much of the evidence regarding cerebral function during cardiac arrest indicates that there is a lack of electrical activity in the brain during cardiac arrest. It has thus been proposed to study the phenomenon of consciousness and its relationship to cerebral function during cardiac arrest by using bispectral EEG monitoring.

Long-term psychological and cognitive effects of surviving a cardiac arrest

It is now widely recognized that severe mental reactions may occur in response to a stressful event and that having a cardiac arrest may be emotionally extremely stressful. In addition, as many patients may have suffered from hypoxic brain injury,[41] and moderate to severe neuropsychological sequelae have been found in approximately 50% of cardiac arrest survivors after 1 year,[45] this has highlighted the significance of studying the long-term psychological effects of surviving a cardiac arrest. Relatively few studies have addressed this issue, nevertheless, sufficient work has been done to show that cardiac arrest survivors enjoy a good overall quality of life, but may suffer from cognitive and emotional impairments. It is not clear whether those who have had an NDE during their cardiac arrest are protected against these effects as no comparative studies have yet been carried out.

Quality of life after cardiac arrest

Granja *et al.*[46] studied the health-related quality of life 6 months after a cardiac arrest using the EQ-5D Generic Quality of Life Instrument, developed by the EuroQol Group. The authors studied all cardiac arrest patients between April 1997 and December 2000 who had been resuscitated after cardiac arrest. These survivors filled in the questionnaire 6 months after discharge. A matched control group consisted of similar aged patients with an

approximately equal Apache II score from randomly selected ICU patients without cardiac resuscitation. This was a small study, as although 36 patients were discharged from hospital, 12 of these died before their 6-month evaluation. A further five were not evaluated. Overall, 19 patients completed the questionnaire, of whom only 8 were working at that time. Eleven patients were retired, however, and 7 of these returned to their previous level of activity. Interestingly, there was no difference on the HR-Qol scores between the survivors of cardiac arrest and those from other ICU patients. The authors comment: "These results agree with previous reports stating that CPR is frequently unsuccessful, but if survival is achieved, a fairly good quality of life can be expected."

Further work by Nichol *et al.*,[47] in a study examining both in-hospital and out-of-hospital cardiac arrest survivors showed that quality of life issues were correlated with clinical parameters. The surviving cohort was followed up for a minimum of 6 months after discharge. From an original group of 126 survivors, 86 patients were interviewed with the Health Utilities Index Mark III used as the quality of life assessment tool. The results indicated that "utilities" were highest in patients with the shortest times to initiation of CPR and that the mean utility scores were lower than those found in the general population or people not limited by chronic disease. Survival was considered to be poor, but most of the survivors retained an acceptable health-related quality of life. With use of the Health Utilities Index Mark III, another study in survivors of out-of-hospital cardiac arrest examined the health-related quality of survival in 268 one-year survivors from an original group of 8091 patients. Scores achieved by these patients compared well with age- and sex-matched members from the general population. Patients aged 80 or more were the most affected and bystander CPR was associated with better health-related quality of life outcomes. The authors concluded, ". . . such survivors have good health-related quality of life and functional status".[48]

Long-term emotional effects and the occurrence of post-traumatic stress disorder after cardiac arrest

Post-traumatic stress disorder (PTSD) is a unique symptom configuration after an extreme event consisting of intrusion re-experiencing (flash-back), avoidance and numbness, and hyperarousal symptoms.[49] Until recently, few studies had examined the occurrence of PTSD in cardiac arrest patients, even though this condition may

potentially be one of the most traumatizing conditions for patients.

In a study aiming to examine the long-term prevalence and emotional disability in cardiac arrest survivors. Ladwig *et al.*[50] conducted follow-up analysis in a group of 21 survivors of out-of-hospital cardiac arrest who had sufficient cerebral performance to enable appropriate psychodiagnostic assessment. A cohort was selected from in-hospital patients who had experienced ventricular tachycardia or fibrillation arrest specifically. These were then compared to a "control" group containing cardiac patients with unstable angina, but who did not suffer cardiac arrest. The results were complex; however, the study group did display healthy levels of emotional stability and had a mean anxiety score lower than did the comparative group (using the Hospital Anxiety and Depression scale). When surveyed via self-assessment, the cardiac arrest group indicated no differences from the angina group with respect to mental condition and their somatic condition or illness-related quality of life issues. The only detectable difference between the two groups concerned ability to concentrate which was more impaired in the cardiac arrest group. Over half of the cardiac arrest group patients stated that having had a cardiac arrest had significantly affected their lives. Identification of a subset of the cardiac arrest patients who had PTSD (identified by the use of Impact of Event scores on intrusive thoughts, avoidance states and increased arousal) showed that patients who had PTSD scored higher for depression and anxiety, which was also seen in the self-assessment results. These patients had a more negative outlook about their disease progression, were less able to concentrate, and were more preoccupied with somatic complaints. An important point is that patients who were sedated at the onset of the events they experienced were five times less likely to develop PTSD.

In another study of 143 cardiac arrest survivors who had been followed up on average 45 months after the arrest, it was found that 27% fulfilled criteria for PTSD according to the Davidson Trauma Score. Patients with PTSD had a significantly lower quality of life. The only independent risk factor for the development of PTSD was younger age. Nonetheless, in this study there was no difference between patients with or without PTSD in use of sedation and analgesia during or after cardiac arrest.[51] In a smaller study comparing 27 patients who had survived an in-hospital cardiac arrest with 27 patients who had a myocardial infarction uncomplicated by cardiac arrest, a similar incidence of PTSD was found. 19% of the cardiac arrest survivors and 7% of the MI survivors fulfilled the DSM-IV criteria for PTSD when assessed by structured clinical interview.[52]

Cognitive and behavioral changes after cardiac arrest

Despite the relatively good quality of life, many studies have indicated that cardiac arrest may be associated with long-term memory impairment in approximately 20%–50% of survivors. In particular, studies have indicated impairment of long-term memory and executive function impairment together with focal cognitive deficits.

Grubb *et al.*[53] found that when assessing cognitive function, between 2 months to 1 year after cardiac arrest, up to 40% of survivors from out-of-hospital cardiac arrest have memory impairment of the ability to "recall" rather than "recognition" memory. It was suggested that this may occur as a consequence of hippocampal damage, as "recall" memory is mediated by the hippocampus. In a further study by the same group which aimed to assess longer-term memory effects of surviving cardiac arrest, 10 of the previously identified survivors of out-of-hospital cardiac arrest were followed up to 3 years after the index event and re-examined for cognitive impairments. These patients were age- and sex-matched with control subjects with myocardial infarction without cardiac arrest. Using the "Rivermead Behavioural Memory test" (RBMT), a test of the ability to extract information from short- to long-term memory and hence a test of memory impairment that may affect everyday activities, as well as the "Doors and People" test, which identifies "recall memory", they were able to show that although the RBMT scores declined in both groups, the cardiac arrest patients were significantly more affected. The DPT scores remained poor in the cardiac arrest group, whereas they were normal in the MI group. This study demonstrated that the memory deficits that take place after a cardiac arrest are persistent and focal, and that "cognitive impairment is a serious and underdiagnosed complication of prolonged cardiac arrest" with considerable effects on normal living activities.[54]

Further work by O'Reilly and colleagues[55] regarding memory impairment compared three groups: in-hospital cardiac arrest survivors, out-of-hospital cardiac arrest survivors and patients with myocardial infarction without cardiac arrest. Four tests were applied to each respective cohort, each consisting of 35 subjects. The tests sought to identify the current state of "affect" (Hospital anxiety and depression scale), premorbid intelligence (National adult reading test), short-term memory (digit span test), and long-term episodic memory (Rivermead behavioural memory test). The in-hospital cardiac arrest survivors displayed higher anxiety levels than did the other two groups, and moderate or severe memory loss was identified in 26% of these patients. The memory impairment in these

patients was not significantly different for the out-of-hospital survivors; however, 38% of them were categorized as moderately or severely impaired. None of the MI group experienced this level of memory impairment. There were no significant differences between the groups with respect to premorbid intelligence and short-term memory tests, with both groups scoring within the normal range expected for unimpaired adults.

Some cognitive defects have been shown to be present soon after cardiac arrest. In one study 60% of patients were found to have moderate to severe cognitive deficits 3 months after cardiac arrest. At 12 months, almost 50% of survivors still had moderate to severe deficits; 45% had evidence of depression and 24% had severe depression.[45]

Nunes[56] studied the long-term effects of surviving a cardiac arrest. Eleven cardiac arrest survivors from the intensive care unit were examined between 1 and 3 years after cardiac arrest. Patients were classified by using the Cerebral Performance Categories (CPC), neurological examination, detailed cognitive testing and computerized tomography (CT) scan with qualitative and quantitative imaging analysis. Six of the 11 patients had good cerebral performance. The verbal and visuospatial short-term memory scores were associated with CPC, such that all patients with at least moderate cerebral disability were found to have abnormal verbal memory test results compared with only one survivor with good CPC score (CPC 1); visuospatial short-term memory was abnormal in four moderately affected survivors and normal in those with good CPC score (CPC 1). CT scan findings correlated with the verbal memory score and the executive functions score, suggesting involvement of different brain areas in these functions. CT imaging revealed atrophy in both qualitative and quantitative analysis, and correlated with impairment in cognitive testing. This was found in the frontal and temporal areas. Another study with MRI has also suggested that memory impairment in cardiac arrest survivors is associated with global cerebral atrophy and not just selective hippocampal damage,[57] which relates to executive and language dysfunction found in affected patients.

Long-term psychological care of cardiac arrest survivors

Although the study of cognition and consciousness during cardiac arrest as well as the longer term psychological outcomes of surviving a cardiac arrest comprise a relatively new area of study, significant advances have been made in this field in the last decade. It has been demonstrated that many cardiac arrest survivors may have cognitive processes during the time of their arrest and anecdotally some have also been able to describe verified events accurately during their arrest, indicating the presence of consciousness. Near-death experiences appear to have a long-term protective psychological effect, even though many studies have shown that a significant proportion of cardiac arrest survivors may suffer from behavioural, cognitive, and emotional disturbances that may begin soon after the cardiac arrest and persist for many years. More work is needed to identify ways of preventing and treating these impairments in cardiac arrest survivors.

To date, there are no standardized programs for the long-term psychological care of cardiac arrest survivors, but as recent studies have indicated that many patients who undergo a cardiac arrest may have long-term psychological outcomes, care should be focused on identifying and appropriately managing patients after the arrest. The authors suggest the establishment of follow-up procedures for cardiac arrest survivors through trained health care professionals who can identify those who may be suffering depression, post-traumatic stress disorder, and emotional or other cognitive effects.

Implications of the study of cognition and consciousness during cardiac arrest

An interesting point that had been raised as a consensus of opinion by the authors of the four published prospective studies of near-death experiences during cardiac arrest, was that the occurrence of lucid well-structured cognitive processes together with memory formation and recall of detailed accounts of events from the period of resuscitation may be a scientific paradox. It has been proposed that this may, in turn, have profound implications for the scientific discovery of the nature of consciousness and its relation with the brain, which is one of the most profound questions facing science today.[58]

The basic scientific problem of consciousness is simple to describe but difficult to answer: how does our sense of self-awareness together with all our subjective thoughts, feelings, and emotions arise from the brain? Traditionally, in philosophical circles this has been referred to as the mind–body problem, and whereas many well-known philosophers including Plato and Descartes have argued that the mind and brain are separate entities, many modern scientists have proposed that the mind is a product of brain activity. The common views for its occurrence can be broadly divided into conventional and nonconventional neurobiological theories. Those in support of the conventional neurobiological theories have commonly

proposed that mind and consciousness are products of neuronal activity and arise as an epiphenomenon from cerebral activity. Conceptually, this is similar to how light arises from a light bulb, but is not the same as the underlying processes within the light bulb. A number of different theories have been proposed to account for this phenomenon, which portray consciousness as an emergent property of neuronal activity in the brain.[59–62] Evidence to support these theories has come from the observation that specific changes in function, such as personality or memory are associated with specific cerebral lesions. In addition, fMRI and PET scanning have also shown a correlation between metabolic activity and different mental states. Although these provide evidence for the role of neuronal networks as an intermediary for the manifestation of thoughts, they do not necessarily imply that those cells also produce the thoughts. Almost all our understanding of cognitive neuroscience and its representation in brain structure depends on correlates of cognition. The models of cognition that are built from these data are correlative rather than causative models. Thus, we proceed with our third-person objective science we cannot get close to subjective experience. This has led to alternative "non-conventional" explanations for consciousness.

It has been proposed that mind and consciousness may arise from quantum processes within neuronal microtubules,[63] or may actually be an irreducible scientific entity in its own right,[64,65] similar to many of the concepts in physics such as mass and gravity, which are also irreducible entities. Consciousness has thus been proposed to be similar to the discovery of electromagnetic phenomena in the nineteenth century, or quantum mechanics in the twentieth century, both of which were inexplicable in terms of previously known principles and were introduced as fundamental entities.[64] Some have argued that this entity is a product of the brain, whereas others, such as the late Nobel laureate Sir John Eccles, have argued that it may be an entirely separate entity not produced by the brain. Furthermore, it has also been proposed that consciousness may be an irreducible scientific entity that is composed of a very subtle type of matter that is still not amenable to measurement by our scientific tools, but is similar in concept to electromagnetic waves, and is governed by precise laws, axioms and theorems.[65]

In spite of obvious interest, no testable, plausible biological mechanism to account for how the brain may give rise to the mind or consciousness has been proposed. Despite a number of theories, progress has been hampered by a lack of experimental models to test such theories. The study of the human mind and consciousness during cardiac arrest has been proposed as a novel and innovative

method that has arisen in the last few years for testing any theory of consciousness.[58]

This is because studies have indicated that during cardiac arrest there is little or no cerebral perfusion and hence no measurable EEG function. Although more accurate studies are needed to verify the occurrence of consciousness and thought processes during the actual process of cardiac arrest, evidence gathered so far appears to indicate that, paradoxically, thought processes with accurate recall of events, reasoning and memory formation may occur during cardiac arrest. Evidence from human and animal studies has shown that there is a loss of global brain function during cardiac arrest. Immediately after a cardiac arrest due to the cessation of the heartbeat, the blood pressure drops to unmeasurable levels. During properly performed chest compressions, the systolic values may rise to sufficient levels, but the diastolic values and hence the mean arterial pressure still remain low.[66,67] The use of vasopressors such as epinephrine and vasopressin has been shown to increase blood pressure, as well as cardiac and cerebral perfusion pressures as compared with chest compressions alone.[68,69] Coronary and cerebral perfusion rely on adequate diastolic pressures and therefore the pressures generated during cardiac arrest with chest compressions and the use of epinephrine, although better than no intervention, are still generally too low for adequate perfusion. Cerebral perfusion pressure (CPP) is determined by the difference between the mean arterial pressure and the intracranial pressure (MAP – ICP). It has been shown that the more prolonged a cardiac arrest, the higher the ICP rises and hence a higher MAP is needed to maintain CPP.[70] Relatively low mean arterial blood pressures are maintained until the resumption of cardiac output despite conventional cardiopulmonary resuscitation.[67–69,71]

In clinical practice the EEG is often used to assess cerebral ischemia during procedures such as cardiac and neurosurgery and to assess cerebral function during cardiac arrest in animals and humans. The data from humans are largely limited to those obtained during defibrillation threshold testing at defibrillator implantation, or individual case reports on patients who had suffered a cardiac arrest while connected to an EEG. In patients with early defibrillated arrhythmias, concurrent EEG monitoring during a cardiac arrest has shown an initial slowing of the EEG, which then progresses to an isoelectric (flat) line within approximately 10–20 seconds and remains flat until the resumption of cardiac output.[71] In cases of prolonged cardiac arrest, however, EEG activity may not return for many tens of minutes after cardiac output has returned.[72] Cerebral blood flow is severely impaired, which leads to a

lack of electrophysiological activity in the cortex, which worsens with the length of the arrest. Animal studies have shown that an absence of cortical EEG activity correlates with an absence or reduction in activity of the deep brain structures as measured by in-dwelling electrodes.[73,74] As a result, consciousness is rapidly lost during a cardiac arrest.

Although there is minimal blood flow to the brain during a cardiac arrest, it has also been shown that, after a cardiac arrest, local cerebral blood flow and hence cerebral perfusion are also severely impaired, despite the restoration of an adequate blood pressure and gross cerebral blood flow rate. This is due to local increases in vasoconstriction, possibly brought about by an imbalance in the local production of vasoconstrictors and vasodilators, which can also explain the observed lack of electrical activity on EEG after the maintenance of adequate blood pressure during the recovery phase of cardiac arrest. The main factor responsible for this reduced cerebral blood flow after a cardiac arrest is the initial period of ischemia before adequate resuscitation.[70] From a clinical point of view these observations are supported by the continued loss of brainstem reflexes such as the gag reflex and continuing unconsciousness. The unconsciousness is due both to reduced cerebral perfusion and to the absence of brainstem function required to maintain cortical activity.

The occurrence of lucid, well-structured cognitive processes such as attention and memory recall of specific events during a cardiac arrest (NDE) raises a number of interesting and perplexing questions. As described above these experiences are reported to be occurring during unconsciousness at a time when cerebral function is severely impaired or absent. Cerebral localization studies have indicated that cognitive processes are mediated through the activation of a number of different cortical areas. Therefore a globally disordered brain will not support lucid thought processes. It has been shown that even relatively minor reductions in blood flow lead to impaired attention.[76] The experiences reported from cardiac arrest are clearly not confusional and occur at a time when consciousness and memory formation should not be possible.

An alternative explanation is that the experiences may actually be arising at a time when consciousness is either being lost or regained, rather than during the cardiac arrest. Experiments during simple fainting episodes have shown that experiences arising during loss of consciousness occur in conjunction with ongoing mental experiences at the beginning of the episode,[77] which is not classically seen in NDEs. EEG data during fainting show a gradual slowing of the cerebral rhythms with the appearance of delta activity before finally, in a minority of cases, the EEG becomes flat.[78] During cardiac arrest, the process

is accelerated, with the EEG showing changes within a few seconds.[79] Cerebral insult leads to a period of both anterograde and retrograde amnesia.[80,81] Memory is a very sensitive indicator of brain injury and the length of these amnesic periods is a measure of the severity of the injury.[82] Therefore, events that occur just before or just after loss of consciousness would not be expected to be recalled, or if they were, the memory would be confusional.[81,82] As described above, cerebral function as measured by EEG may not return until tens of minutes or even a few hours after successful resuscitation. Despite these observations it can still be argued that some of the recalled features may be occurring during the recovery phase, although the patient believes that they occurred during the arrest. The many anecdotal reports of patients being able to "see" and recall specific details relating to the resuscitation period, however, which have been verified by hospital staff, cannot be simply explained in this way and point away from this conclusion. For memory to take place, consciousness would need to be present during the actual cardiac arrest itself.

Studying cognitive function during cardiac arrest allows examination of the relationship between consciousness and brain function. It is perhaps the only clinical situation in which global brain function temporarily ceases, so if consciousness is indeed present, then it clearly cannot be entirely dependent on brain function. The exciting point that we currently face is that for the first time this can now be tested objectively through large studies. It has been proposed to test the claims of "consciousness" and being able to "see" during cardiac arrest objectively by the use of hidden targets that are only visible from a vantage point above the patient and accurately timing these experiences. If it can be proven that this period of consciousness had indeed taken place during cardiac arrest, rather than before or after it, this will have significant implications for science. The study of consciousness has for many years been a neglected area of science, but has now become a significant point of debate in neuroscience. This new approach may provide an insight into this intriguing, yet largely unexplored area of science.

The most important factor in survival from sudden cardiac arrest is the presence of a trained rescuer who is equipped to intervene. The most effective tools of the trained rescuer are CPR and defibrillation. CPR has been taught as a formal program to professionals since the late 1960s and to the lay public since the early 1970s. The program has changed markedly in scope and complexity as well as educational format and philosophy since its inception. Resuscitation councils that promote and teach CPR have sprung up around the world. Yet, despite this long history of the availability of CPR programs and their promotion, most victims of cardiac arrest do not receive bystander CPR.[1–6] Moreover, when CPR is performed, the quality of the CPR is often not ideal.[7,8] Although the development of the automated external defibrillator (AED), its increasing affordability, widespread promotion and availability to non-professionals have all contributed to earlier defibrillation, the number of people who are resuscitated is still limited by the low numbers of people who receive bystander CPR before defibrillation and the often poor quality of CPR when it is provided.

This chapter will address the challenge of teaching CPR effectively in various contexts: to the lay public, to laypersons with a duty to respond (such as police, fire, lifeguards, and airline employees), and to healthcare professionals. It will also discuss advanced educational technologies and present a model for new course development.

Teaching CPR

The lay public

Bystander CPR has consistently been shown to more than double the odds of survival from sudden cardiac arrest (SCA).[9–16] The few communities that have high bystander CPR rates have been effective in communicating the importance of CPR to the general public and have encouraged the whole population to learn CPR, but they have also directed their training efforts toward those people who are most likely to encounter SCA, and have made training readily available through both traditional and innovative means. Offering a variety of CPR courses, using different methods, in different settings, and of variable lengths provides the greatest chance of success in involving the many and diverse individuals who comprise any community.

Whom to teach

The chance that any particular individual in a community will have an opportunity to perform CPR is very small, unless that individual lives or works in a high-risk area or with a high-risk population. Thus, the primary target population for CPR education should be those people who are most likely to encounter a cardiac arrest.[17] This group includes the families of high-risk patients, people who live in retirement communities and people who work in large office buildings, shopping malls, airports, and other similar venues.[18] Nevertheless, even though other individuals are unlikely to encounter SCA, the greater the proportion of the population capable of performing CPR, the greater the chance that SCA victims will receive bystander CPR, so it is important to attract the general public to CPR courses. If there is a social climate of expectation that people should know how to perform CPR, people are more likely to seek out and attend CPR courses. The media has an important role to play in creating this climate of expectation and they should be encouraged to do so with the offer of newsworthy stories of successful resuscitations and the role that bystanders play in the process.[19,20] Public

events and celebrity participation are often helpful as well.[21] CPR awareness campaigns can often reach people through the workplace and through community groups: a co-worker or group member who is a proponent may interest others in participating. Government can assist in creating a climate of expectation and in encouraging CPR proficiency in the general population.

At first glance, instructing schoolchildren in CPR seems like misdirected energy since the likelihood of a schoolchild encountering a cardiac arrest is very small indeed. Instruction of schoolchildren is expected to pay large dividends in future years, however, because it exposes children to the concept and practice of CPR at a stage in their lives when they are best equipped to learn and retain knowledge and skills.[22–27] Research has shown that many adults are reluctant and unprepared to act in an emergency.[28] Teaching children to act in an emergency, before they have been socialized to fear and avoid such situations, makes it more likely that they will be prepared and willing to do so when they become adults.[29] Many communities have successfully incorporated CPR instruction into the standard school curriculum.[22,30,31]

What to teach and how to teach it

Since their inception in the 1960s, CPR courses have undergone regular updates in content, as well as changes in format and scope. Despite this regular renewal, available research suggests that courses are not particularly successful. Learners perform CPR poorly even immediately following their training and, when they are assessed 3 or 6 months later, their performance has further declined. This relative failure of CPR instruction may be due to the structure and content of the CPR courses themselves, teaching methods that are not appropriate to lay persons, the quality of instruction, or inadequate practice time.[32–40]

CPR courses were initially designed by clinicians and, until recently, have not been evaluated to determine how well they accomplish their intended goal of producing CPR proficiency. Feedback over the years has suggested that learners are intimidated by the skill requirements and have often left courses unwilling to perform CPR for fear of doing it incorrectly. This feedback has led to changes in course requirements (learners no longer have to produce a perfect strip on a recording manikin) and to the presentation of material – but courses have not been redesigned completely. Course development should be led by educational specialists and should be evidence-based. The course should be thoroughly tested for educational efficiency prior to its widespread use. A model for new course development is presented later in this chapter.

CPR courses were traditionally led by instructors, beginning with a lecture on theory, followed by a demonstration, and concluding with manikin practice. The ineffectiveness of this model was documented in 1985 and led to video-based skill instruction *(watch-then-practise)* where students were presented with standardized, accurate, and on-message information from an instructional video, with the instructor serving as a facilitator.[41,42] By 1999, *watch-then-practise* was the primary CPR instructional method in the USA. *Video self-instruction* (VSI), or *practise along with the video while you watch,* was developed during 1993–1997 because of limitations in *watch-then-practise* video instruction to produce competent CPR performance.[43–47] VSI is expected to be adopted by the leading US training organizations in 2006. An advantage of the video-based model is that the information and CPR technique that is presented can be standardized and optimized. Regardless of whether the instructor leads or facilitates, immediate hands-on practice (watch-then-practise or practise-while-you-watch) helps to reduce anxiety about skill performance and increases the relevance of oral information, in that answers follow rather than precede questions.

Instruction is always most effective when it is provided in a manner that meets the learner's personal objectives.[48] It is counterproductive to insist on a course duration of 4 hours when many learners want and/or need only an hour or less to learn CPR. Educational principles direct that the course be structured to suit the age and learning style of the group being taught.

Other CPR instructional programs that were video-, television-, CD-software-, and Internet-based were developed during the 1990s for specific populations at risk and were designed to be used at times and locations that were convenient and non-threatening to their target audiences.[36,39,43–47,49–52] The disadvantage of self-instruction is that the learner is unable to ask questions or receive correction of faulty technique, although approaches such as VSI uniformly produce competent CPR technique approaches without intervention from an instructor. For special target audiences, such as the spouses of heart attack patients, specially trained on-scene instructors are needed to address learner fears and to prepare the learner for what to expect. For this reason, families or caregivers of persons at high risk should not rely solely on self-instruction.[36,49,50,53,54]

Some automated external defibrillators (AEDs) include real-time CPR prompting to assist laypersons during training and during actual cardiac arrest situations. The prompting component is currently being evaluated. One obvious question is whether people who follow real-time

instructions can act independently to provide CPR in situations when there is no machine on scene to prompt them – which is the usual real-life situation.

Assessment of a learner's ability to perform CPR is a critical step in determining program success in producing competent CPR performance. Skill assessments performed by instructors of the major US training organizations have traditionally been unreliable, with instructors coaching and cueing learners during testing and/or passing all students, regardless of the quality of CPR performance. Reliable and valid research instruments used for assessing CPR performance should be adapted for use by instructors.[55] Confidence to perform CPR is not a reliable and valid measure of CPR competence, because most learners express confidence at the conclusion of their CPR course, regardless of the quality of their CPR performance. Moreover, learners should understand that they need to review and practise their CPR skills at regular intervals in order to maintain their ability and confidence to perform CPR in real life.[56–60] Training agencies should also understand the importance of reinforcement of skills and knowledge and must work with learners, employers, and the media to ensure that this message is heard.

Summary
The provision of bystander CPR contributes to higher survival rates among victims of sudden cardiac arrest. While proven methods for teaching CPR have been developed, we have not yet succeeded in training a large proportion of the general public to be ready and able to perform CPR proficiently in an emergency.

Lay persons with a duty to respond

A lay person with a duty to respond (hereafter called a "lay responder") is any non-healthcare professional who is responsible for providing CPR or basic first aid skills in a given interior or outdoor environment as part of day-to-day responsibilities. Lay responders range from office workers to flight attendants to security guards to emergency first responders, such as lifeguards, police, and firefighters.

Lay responders face their own set of challenges. They must be prepared to perform CPR on coworkers (people they know and interact with on a daily basis) and on strangers. Since lay responders do not have the knowledge and experience, and hence neither the confidence nor comfort level, of healthcare professionals, it is critical to provide sufficient training and regular reinforcement to build the confidence needed to respond effectively. Feelings of reluctance or embarrassment in dealing intimately with co-workers, and feelings of repulsion or appre-

hension, or fear of being exposed to disease may be partly addressed by training and can be further reduced by the use of mouth-to-mask devices. Training should include precourse preparation, generous skill practice during the course, and reinforcement exercises after the program to assure long-term retention of core skills. The overall training program and response protocols should systematically integrate the specialized knowledge and skills that are peculiar to the work environments within which lay responders will be functioning.

Training lay responders represents one of the most successful strategies for increasing survival from sudden cardiac arrest. Public access defibrillation programs in airports,[61] with police first responders,[62,63] and in casinos[64] have resulted in out-of-hospital survival rates of 49%–60%.

In designing the course curricula to train lay responders, the following questions should be addressed.
1. What is the nature of the environment in which they will respond?
2. What skills do they need to respond effectively in the environment in which they work and what devices or adjuncts, if any, will they be expected to use as part of their response?
3. What is the probable frequency of skill use?
4. What safety issues are important in the environment?

The nature of the environment
The response environments of different categories of lay responders differ dramatically. In any educational program for lay responders, the challenges of their respective environments must be addressed in the training program. For example, flight attendants work in a very compact environment where formal medical back-up may not be available for a long period of time. In an emergency, flight attendants may have to deal with logistical barriers, such as difficult access to the patient (e.g., obese victim in a window seat of an aircraft). In this environment the responder will be faced with some very challenging decisions (e.g., whether to ask that the aircraft be landed urgently) and complicating factors (e.g., CPR may not be possible during the landing of the aircraft). All of these and other issues must be anticipated and addressed during training so that problems do not prevent effective interventions during a real-life emergency. Protocols should be established that clearly delineate the expected actions when an emergency situation arises.

Police and firefighters, on the other hand, work in highly diverse, complex, and sometimes dangerous environments. They confront a great variety of emergencies, including trauma, poisoning, burns, and a host of other life-threatening (to both the victims and themselves) situations. During training, emphasis on scene safety is critical.

The challenges described in these two examples illustrate the need for a systematic analysis of the lay responders' job and the circumstances they will encounter, as part of the planning of an educational program for the selected group. Such analysis can be adequately undertaken only by an individual or team with expertise in the specific environment, as well as expertise in the field of emergency medical education.

Group-specific scenarios should be used to practise the events most likely to be encountered. A sample scenario for a police first responder is illustrated in Box 70.1. This scenario integrates the primary police function of scene safety with the role of CPR/AED responder. Job-specific scenarios are invaluable for illustrating the context in which response takes place; they should be set in the environment of the target audience and simulated through role-playing with hands-on practice.

Box 70.1

Example scenario for police responder
Summary of Scenario: Potentially unsafe scene, VF, 1 Shock conversion
Case History: A 52-year-old male teller collapses following a hold-up at a bank. The dispatcher indicates that the situation is ongoing.
Scene safety: Check the scene before entering bank. The security guard advises you that the suspect has left the scene but the teller has collapsed. Notify dispatch of the status of the scene and respond to the teller.
Victim: Unresponsive, no breathing and no signs of circulation.
Expected Actions: Determine unresponsiveness, notify dispatch that you need an ambulance, apply the AED and leave AED attached.
Outcome: After first shock victim returns regains normal breathing and consciousness.

Skills for lay responders

The skills taught to lay responders can range from CPR and the use of barrier devices to comprehensive CPR, AED, and first aid training for adult and/or pediatric victims. The target population and environment should determine the selection of skills. For example, in a small business where the incidence of trauma is low (i.e., store or office), CPR and use of barrier devices may be sufficient to deal with common medical emergencies such as fainting, stroke, and cardiac arrest. In an industrial environment, additional skills, such as first aid and use of an AED, may be needed. In

addition, there may be national standards that dictate the type of training that is required. In the United States, the US Department of Transportation provides a National Standard Curriculum for Certified First Responders that is routinely used by police and fire organizations.

There are many national programs that can lay the foundation for a well-organized course of instruction. The American Heart Association, the American Red Cross, The National Safety Council, the Heart and Stroke Foundation of Canada, and the American Safety and Health Institute are examples of organizations that provide training and certification in CPR and/or first aid. Before such a program is implemented, emergency medical educators should collaborate with experts from the specific target environment to evaluate the needs of the responders and develop specific objectives, learning activities, skills, and protocols most appropriate to a given training program.

Frequency of skill use and retention of Skills

The retention of skills may well be the most important issue for the lay responder, because most lay responders use these skills infrequently. To this end, the initial training course should be structured to allow the student multiple opportunities to learn, practise skills, and apply critical information. For example, materials such as manuals, reminder cards, interactive CD ROMS, videos, and others, should be provided to the participant well in advance of training to encourage independent acquisition of baseline knowledge. These materials should remain available to the student, so that independent review can be undertaken at any time. A formal strategy for regular reinforcement of skills and review of core knowledge should be included as part of the training program.

An important function of the course itself is to provide maximum opportunity to practise the core skills of CPR, AED, and the use of barrier devices so that the student becomes completely comfortable with the skills. The practice scenarios that use rescuer-specific case examples are critical to the learning process.

Drills can be invaluable for reinforcing skills and knowledge. A properly planned drill can identify flaws in the response system and allow for significant quality improvement. The optimal interval between drills has not been established, but many programs conduct short drills at 6- to 12-month intervals. Complete refresher training should be provided approximately every 2 years or according to local or national standards.

Safety issues

Every response environment represents some risk to the responder. Infection, for example, is a universal risk.

Clearly, issues of safety become more important in response environments that pose greater danger, such as construction sites, industrial settings, at a crime scene or a fire. Scene safety is paramount in these environments and should be emphasized in every aspect of training and protocol development. In some environments, safety protocols may be dictated by national or local standards.

Stress must also be considered. Lay responders who have never dealt with life-threatening emergencies may experience significant stress, both during the emergency and afterward, especially if the outcome is poor. When the victim is a close friend or co-worker of the responder, stress may be intensified. Post-event debriefing by a healthcare professional can reduce inappropriate feelings of guilt or inadequacy and should be routinely arranged as part of the response program. During initial training, it is also important, to set realistic expectations for the responder. Since the survival rate from SCA is only around 5%, responders should understand that positive outcomes in cardiac arrest are the exception rather than the rule.

Summary

The well-trained lay person with a duty to respond represents one of the most successful strategies for increasing survival from cardiac arrest and other life-threatening emergencies.

A training program for this target population should take into account all aspects of the response environment, including specific safety issues, and should provide responders with the skills, knowledge, and confidence they will need to carry out their duties effectively.

Healthcare professionals

Basic life support

Numerous studies have shown that doctors, nurses, and ambulance personnel are generally not proficient in basic life support (BLS) skills, and that their skill retention, while variable, is generally poor.[8,35,65–74] Moreover, many healthcare professionals are reluctant to attend BLS courses, and even more reluctant to attend a refresher course.

BLS training requirements for healthcare professionals vary significantly among countries. Some national organizations, such as the Irish Heart Foundation and the Resuscitation Council of Southern Africa, require formal BLS certification as an entry requirement for advanced life support training (ACLS or pediatric advanced life support, PALS), whereas others, such as the American Heart Association, require only a brief "demonstration of proficiency" in BLS skills at the start of an ALS course. In the UK, hospitals employ dedicated "Resuscitation Officers," who are responsible for the ongoing training and competency of their healthcare professional and auxiliary staff members. Unfortunately, many hospitals do not require their staff to maintain or demonstrate their BLS skills, and many do not provide formal in-service BLS training.

The training of healthcare providers should be tailored to their professional work environment. Performing CPR in the outdoors in all weather, or indoors in limited space hampered by bulky furniture and poor lighting is quite different from performing CPR on a patient lying on an elevated hospital bed, surrounded by monitors and adjunctive equipment. Healthcare professionals must? should? be proficient in performing CPR in a variety of roles: as a single rescuer, as a team member, and as a team leader.

The educational background and personal experiences and responsibilities of doctors, nurses, and ambulance personnel differ significantly. During BLS training, paramedics employed by a busy emergency service or staff based in a large emergency department may demonstrate greater confidence than personnel working in an out-patient or small community facility. Trainers and facilitators (should be aware that) participants may feel intimidated or humiliated by their more confident colleagues. Similarly, sensitivities among different professions, such as the participation of doctors and nurses in the same class, may lead to withdrawal or inhibited behaviour. It takes a skilled educator to maintain a non-threatening and relaxed atmosphere for all participants.

BLS course format, content, and style should be tailored to specific groups of healthcare providers, but core objectives, cognitive and psychomotor skill acquisition should remain constant. The use of computer and video self-instruction is increasing, and may be useful, provided that practical competence is evaluated. Peer instruction (e.g., doctor-to-doctor or nurse-to-nurse) may improve acceptance of BLS training in some environments. Course design and implementation should be based on validated educational principles.[57,75–78]

BLS training should include skills and equipment that the healthcare professional would generally use or have available, including adjunctive equipment such as barrier devices, pocket masks, self-inflating bags, and proficiency in the use of automated external defibrillators (AEDs). Role-plays should involve single and multiple-rescuer settings, with and without adjunctive equipment, and include a variety of special resuscitation situations such as trauma, submersion, and pregnancy. Use of realistic scenarios enhances contextual learning, relevance, and retention when the scenarios are simple in design.

All healthcare providers, undergraduate and post-graduate, should be able to demonstrate practical compe-

tence in the skills of BLS. Refresher programs that evaluate only knowledge retention do not ensure practical ability. Regular re-evaluation of competency is required to asses and reinforce the knowledge and skill retention of healthcare professionals, which have been shown to deteriorate within a few months of initial training.[79]

Advanced life support

As with BLS, knowledge and skill retention after advanced life support (ALS) training is poor.[33,38,80–85] Nevertheless, ALS training has been shown to improve clinical outcomes.[86] A study of anesthetists' management of VF in the operating room showed that ALS training led to significantly better adherence to resuscitation protocols.[87] Before formal ALS training had commenced, the BRESUS study reported overall survival to hospital discharge at 21% for patients requiring defibrillation.[88] At the time of the UK national audit of 1997, when more than 50,000 people had been trained in ALS skills, survival to discharge had increased to 43% for patients requiring defibrillation.[89]

Training programs in ALS skills are well established in many countries.[90] Initially these courses were didactic and lecture-based but, more recently, the emphasis has changed to hands-on, role-playing, and scenario-based learning. Many courses provide combined training of BLS and ALS skills in which CPR is integrated with defibrillation and the use of AEDs.

There are significant international differences in the approaches to teaching advanced skills, ranging from large group lectures to small group skill stations, open and closed group discussions, workshops, tutorials, role-plays, video presentations, and multidisciplinary teamwork training in mock arrest situations ("mega-codes").

Large-group lecture-based teaching is relatively ineffective in changing practice and behavior. Small-group training has many advantages, being more interactive, more personal, and more hands-on, but it is also more time-consuming and instructor-intensive. The optimal size of small groups will depend on the skill being taught, but groups should generally comprise four to eight participants.

Scenario-based teaching allows for useful repetition of sequences and variations on themes, but requires thoughtful preparation, planning and supervision. Although this approach is time-consuming, the value of realism and relevance for healthcare professionals should not be underestimated.

Compared with instructor-directed training, high-fidelity simulation-directed instruction has the advantage of less personal interaction with the instructor and more with the "patient," providing accurate and relevant situations, real-time physiological measurements which add to

the realism, and training that can be adapted to individual participant needs.[91–94] The value of sophisticated simulation is well recognized in aviation and military training programs, although the high cost and time required for this training may well restrict its utility.

Most ALS courses worldwide conclude with written and practical evaluations. An interesting innovation, extensively used by the Resuscitation Council of Southern Africa, is to start each course with the final written evaluation. If candidates fail to achieve 84% for the written test at the start, they may reattempt the test at the end of the course. This method has several educational benefits.

- Instructors know who the weak participants are, and can provide extra attention right from the start. Similarly, instructors immediately know who the knowledgable candidates are, and can ask them more challenging questions, while the weaker participants are given less challenging questions and tasks, building up their confidence as the course progresses.
- The more advanced candidates can be asked to help weaker participants where appropriate, allowing weaker participants to ask questions and read about their uncertainties before the course is completed.
- All those who have passed the test can relax and concentrate on the practical side of the course, knowing that there is no "threat" of a further written test, while those who have failed tend to listen particularly attentively.
- The course does not end in a negative environment (waiting to be tested, waiting for results, wondering if they have passed, upset if they failed, walking out "tail between legs").

In a survey of 3530 participants undertaking PALS Provider courses over a 3-year period (June 2002 to May 2005) at an AHA Training Centre in Johannesburg, South Africa, only 51 participants (1.4%) achieved an initial score of less than 84% on the PALS "final" written evaluation when the evaluation was written at the start of the PALS course. Before starting the course, none of the participants were given, or had access to, any preparatory written evaluations besides the prescribed AHA PALS Provider Manual.[95]

Summary

While healthcare professionals are a natural target audience for BLS and ALS training, course planning for these individuals must be as carefully thought out and organized as it is for the general public and lay responders. Many of the same issues should be addressed: making appropriate courses available, meeting the specific educational needs of the individual learner, and establishing a mechanism to encourage retention of skills.

Simulation in CPR training

Simulation is the use of an artificial environment to mimic appearances and/or behaviours encountered in real life. Simulators and simulation have been used in health care education, if only sporadically, for almost two decades. In acute medicine, most notably in resuscitation and anesthesiology, full-scale simulators (macrosimulators) have been used for many years for problem-based training and education.[91,96–103] Full-scale simulators contribute verisimilitude and standardization to megacode (practice resuscitation) cases, and are also valuable tools for team training, management of crew resources, leadership, and communication.[93,104–106] Smaller scale simulators that run on a personal computer (microsimulators) have extended simulation into a wide variety of problem-based learning areas, and have been successfully sharpened the participants' diagnostic acumen and skills.[107]

Strengths and weaknesses of current simulators

Simulators are either macrosimulators or microsimulators, and each of these can be classified as either simple or complex.[108] Macrosimulators have a physical component, usually a manikin or a part thereof, whereas microsimulators are purely computer-based. Simulators are classified as "simple" or "part-task simulators" if they teach simple algorithms or procedures, involving only a few aspects of a problem. Complex simulators target more complex issues that integrate several aspects of a problem. Note that the classification "simple" or "complex" refers to the complexity of the educational task, and not to the technical complexity of the simulator. There are several technically complex, but educationally simple, macro- and microsimulators. (These four types of simulators have characteristic advantages and disadvantages)

Macrosimulators

Simple macrosimulators range from advanced virtual reality simulators with haptic "force" feedback* for various endoscopic procedures (available from Immersion Medical, Simbionix, Medical Simulation Corporation and others),[109,110] through advanced manikins for difficult airway management (Laerdal AirMan™), to mechanical manikins for the training of chest compression and ventilation (e.g., Ambu® Man or Laerdal™ Resusci®Anne, or the inflatable Laerdal MiniAnne

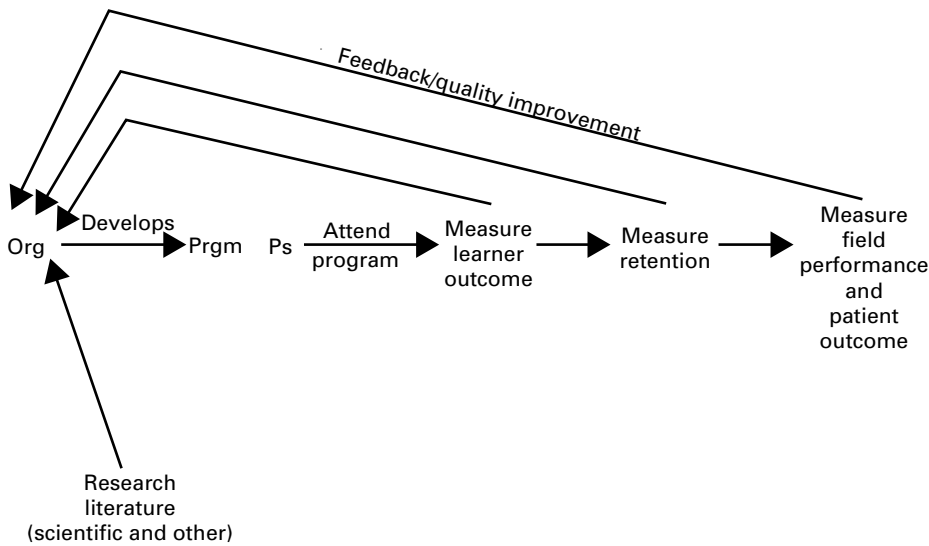
Complex macrosimulators are typically used for anesthesia and for resuscitation training. This category of macrosimulators includes the "Megacode" simulators for Advanced Life Support training (e.g., Ambu Megacode or Laerdal HeartSim 4000) to more complex simulators for trauma and anesthesia/intensive care simulation. (e.g., Meti Human Patient Simulator™ or Laerdal SimMan™). They combine an advanced manikin with a PC or workstation. The manikins simulate palpable pulses, electrocardiograms, spontaneous breathing, airways that can be configured electromechanically to mimic airway problems, and many other clinically relevant responses. In some of the simulators, computer models are used to simulate human physiology/pathophysiology and pharmacokinetics/dynamics, but an operator is required to run the simulator, and several trained participants are needed to complete the elements of a realistic scenario. The main differences between the various macrosimulators are the number of mechanical features in the manikins and differing approaches to the simulation software. Whereas METI is based on physiological models, with particular emphasis on the correct physiological response, the Laerdal SimMan™ models focus on supporting the instructor in running a specific pathophysiological scenario.

Macrosimulators provide the learner with an opportunity to perform manual procedures with or without complex problem-solving activity. They are used for training in specific psychomotor procedures, such as difficult airway management (including intubation, cricoid pressure, tracheotomy, suction and others), insertion of IV lines and chest drains, chest compression and ventilation, defibrillation, drug administration, palpation of pulses and auscultation. Macrosimulators can also reproduce complex situations where several team members have to cooperate to solve the problem. Complex simulators offer a reproducible opportunity for teaching behavioral and interpersonal aspects of performance. They are typically operated by instructors who run both the scenarios and the subsequent debriefing.

Microsimulators

Microsimulators (which run on personal computers and are also called PC simulators) support autonomous, cognitive training. They differ fundamentally from

---

* Roughly speaking, haptics and force feedback are distinct in the use of what is essentially the same technology. A haptic device applies a force in such a way as to allow the user to discern geometry and texture. A force feedback device applies a force to a user holding it, representing the sensation of impact and vibration.


Org = training organization; Prgm = educational program; Ps = program participants

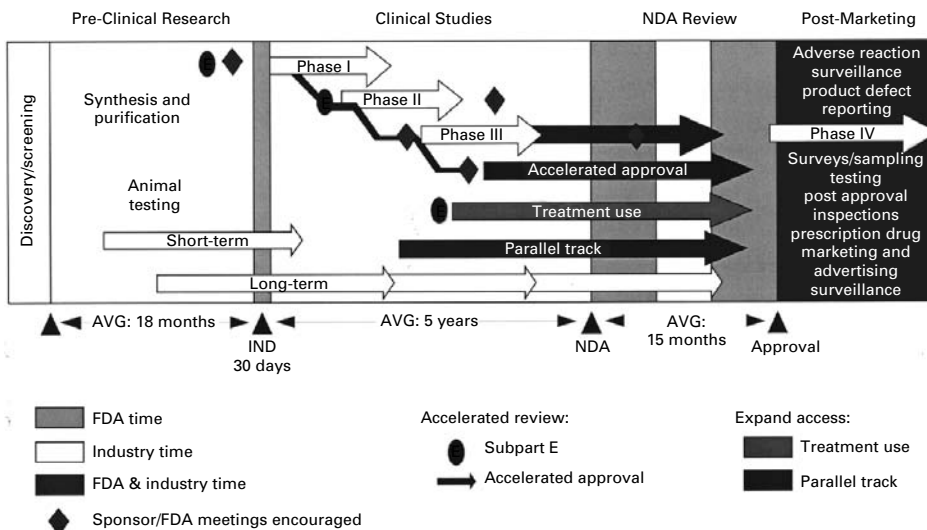
Fig. 70.1. Illustration of educational R&D/QA process


Fig. 70.2. FDA model

macrosimulators in that they do not have a physical component and do not require an operator to run the simulations and to provide educational feedback.

Microsimulators have the clear advantage over macrosimulators of accessibility, as most people have a PC either at work or at home. The programs are relatively inexpensive (US $80–280 for single-user licenses) and can be used informally. Whereas microsimulators cannot address issues at quite the same level of complexity as macrosimulators can, and they cannot train in crew resource management, leadership, or communication, microsimulators can be used to provide systematic learning and practice of a wide range of cognitive issues and problem-solving strategies in many different clinical circumstances. For example, trainees can use simple microsimulators, such as KinView Opioids or GasMan, to experiment with the pharmacokinetics and pharmacodynamics of drugs, or complex microsimulators to run scenarios.

Because microsimulators systematically provide multiple feedback opportunities (high quantity and focus of training) and, since they are easier to access than macrosimulators, they may train the user at a higher level of cognitive complexity than would be achieved with macrosimulator training. It must be emphasized, however, that whereas microsimulation can confidently be used to develop knowledge and problem-solving strategies, it cannot provide practice in manual skills or active role-playing. Moreover, the stress of real-life situations cannot be reproduced in microsimulations.

The ideal complex microsimulator provides credible simulations, followed by intelligent, context-specific evaluation of the user's decision-making during a simulation. Simulation training comes close to the educational principle of "practise by doing" in that well-made simulators give the user a feeling of actively solving the problem. Other training techniques, even if they involve the use of a PC, should not be confused with simulation. Multimedia programs, video teaching, lectures, and printed text tend to stimulate passive acquisition of knowledge and are primarily based on one-way communication of knowledge from the source to the user. The two approaches differ fundamentally in the extent to which the user is involved in the problem solving.

Applied microsimulation

Although the idea of algorithm training on computers is not new, few microsimulators are available for training in advanced life support in anesthesia, intensive care, or emergency medicine either for education of professionals or in basic life support for lay people. A few early microsimulators for anesthesia simulation were made during the late 1980s and 1990s. The ResusSim 98 project was the first to combine advanced PC simulation with elaborate feedback technology.[106] This approach were endorsed by several international authorities, including the European Resuscitation Council, the Australian Resuscitation Council, and the Resuscitation Council of Southern Africa. In 2003, the American Heart Association adopted microsimulation as the basis for their self-directed learning ACLS programme, HeartCode ACLS Anywhere. Successful completion of this programme, including a skills test, qualifies users for renewal of their AHA ACLS provider card (the user interface from HeartCode ACLS Anywhere appears in Fig. 70.4). Since 2000, Red Cross national societies in a number of European countries have used microsimulation as a tool for first aid education. (The user interface from the British Red Cross first aid simulator appears in Fig. 70.3.)

Feedback and debriefing in medical simulation

Macrosimulation and microsimulation differ significantly when it comes to debriefing – the heart of all simulation. In complex full-scale macrosimulation, the participants are typically debriefed by the instructor who has been guiding the scenario, using video and/or printed recordings of the sessions. The major challenge lies in enabling instructors to use a wide range of skills in interpersonal and educational, as well as medical, areas. In microsimulation, the major challenge is to achieve reliable, autonomous performance by the software.

In simple microsimulation, standardized feedback is generated by subtracting the actual performance from a given set of recommendations, producing a banal "error signal." In a more complex microsimulation, focused feedback would optimally evaluate the learner and analyze the entire performance, with reference to timeliness, sequencing, and appropriateness of actions, and indicating whether variances were minor or significant. Focused feedback should assist the trainee in improving subsequent performance.

The technical difficulties in autonomously evaluating individual performance are significant, however. The user often addresses more than one issue concurrently. For example, advanced airway management may be performed concurrently with a specific algorithm for a cardiac condition. Simultaneous approaches present a problem in evaluation, as the user does not clearly mark which action belongs to which strategy. Moreover, several actions may be relevant, but not crucial, to solving the problem, further

Fig. 70.3. In a number of countries, the Red Cross has used microsimulation for first aid education. This example is the Learn First Aid simulator used by British Red Cross.

complicating the debriefing. Optimal feedback technology distinguishes between important and less important actions and mistakes.

In the MicroSim programs (AHA's Heartcode is based on MicroSim), a debriefing technology – artificial intelligence debriefing (AID) – has been used. On the basis of modern research in pattern recognition and educational theory, AID has become an umbrella name for a range of technologies aimed at intelligent debriefing. It is capable, for instance, of detecting different algorithms mixed in a sequence of actions and can assign weight to actions and mistakes. AID can provide feedback on parts of the treatment (e.g., the cardiac treatment algorithm) without being "disturbed" by other actions performed in tandem. The feedback can be presented either in different visual formats or in text.

The relatively low reliance on microsimulators as a training technology may be due to current limitations in feedback technology. As technologies like AID develop and improve, more advanced and relevant microcomputers may play a greater part in resuscitation training

Summary

Simulation provides a uniquely safe and standardized, yet realistic, setting for research into human error. Many of the breaches in protocol made during clinical care result from the practitioner's doubts about which algorithms to follow, errors in drug dosage, and faulty clinical reasoning,[111] and most of these gaps in knowledge and logic can be identified and addressed by the use of simulators.

Simulation achieves interaction with a variety of critical scenarios quickly and allows rare, but time-critical, conditions to be practised and re-played by the user.[112] Simulation should always include a debriefing based on what the learner does during the simulation, to give instant feedback and highlight deficiencies in knowledge. Simulators can also evaluate the knowledge and performance of healthcare personnel, thus completing the educational feedback loop and improving the quality of the education.

CPR course development

Educational research and development/quality assurance model

The following educational R&D/QA model, is based on science-based educational curriculum development, instructional design, and related learning theories (See

Fig. 70.4. Heartcode ACLS interface.

Fig. 70.1).[113–117] The model described in this section is analogous to the US Food and Drug Administration (FDA) process of drug development and testing to determine if a drug is "safe and effective" before approving its entry into the market (see Fig. 70.2). It is a logical model to use for the development of BLS and ACLS programs (and redevelopment/improvement of existing programs) for both providers and instructors. In contrast to many current programs that focus on what the instructor must teach, the design of educational R&D is focused on an in-depth understanding of the target audience and how best to help the audience to achieve specific outcomes related to patient survival.

The model is designed to be used to develop provider and instructor programs. With each program, learner audiences will have different instructional needs and learning styles, and will require unique programs tailored to their specific needs. For example, in BLS or AED training there may be separate R&D processes for school students by age group-

ing, adults by age, paraprofessional providers by level of training and exposure to cardiac emergencies, and professional providers by specialty and exposure to cardiac emergencies. There may also be different instructor materials (and programs) for different BLS or AED instructor audiences, such as teachers, EMS providers who are not credentialed teachers, and community volunteers with no formal training as teachers. The R&D model inventories the learning needs of providers and instructors early in the process.

Programs developed with this model focus on learner competence immediately following training, at a later date, and in actual (or realistically simulated) situations. Ideally, to show full compliance with a training organization's mission, training of significant populations should lead to decreased rates of morbidity and mortality. The model is iterative and linear, with completion of one step before the next; however, it allows for parallel development tracks (e.g., provider level program, testing/evaluation, and instructor program).

Attention to learner outcomes ensures establishment of the first link of the overall public health objectives of BLS and ALS programs (producing competent providers). Positive learner outcomes may not necessarily coincide with traditional indicators of program success, such as the satisfaction of end-users, clients, and instructors. This model ensures that programs meet the learning needs of the participant population. Mismatch of the learner needs and program design occur for a variety of reasons, including repackaging of programs designed for one audience for another (or other) audiences, and development of one program for more than one target-specific audience. Although the use of programs that attempt to meet the needs of multiple audiences with different learning needs may seem efficient, it can seriously undermine program effectiveness.

A scientifically sound development process for all educational programs (providers and instructors) would proceed as follows.

Select R&D team

Because this is an educational development process, the team should primarily comprise education specialists. The team would typically include a project manager, as well as specialists in education research and evaluation, curriculum development, instructional design, media design, learning theory, program evaluation, and public health.

If medical practice guidelines are already established, medical personnel generally should serve as outside consultants as necessary. If development of medical practice guidelines is required, this is not a direct education R&D process and should be completed as a separate process. In developing medical guidelines, education experts should serve as consultants to the medical guidelines committee in order to determine the feasibility of teaching (the "teachability") of various practices for specific target audiences, both professional and lay.

Discussion

The most important and fundamental change to the current process of program development, which will result in the greatest improvement in quality of programs, will be to assign the development of components of the educational agenda to appropriate experts. Educational research and development is a specialized field dedicated to development and delivery of educational interventions that bring about specific learner outcomes. In the cases of BLS and ALS, these specific learner outcomes are directly related to provider behaviors that are associated with saving human lives. The specialty of educational research and development, like specialties in medicine, can only be properly executed by properly trained experts.

Each training organization's BLS and ACLS committee should be made up of two separate committees with different responsibilities and expertise: medical and educational. These are essentially separate teams with separate missions While initial recommendations for changes in medical or educational program development could be generated from either subcommittee, substantive educational recommendations should be formulated only by experts in education. Homogeneous groupings (for example, committees made up of medical scientists, curriculum experts, representatives of the training network, and so on) are inefficient and reduce the quality of any program because they place committee members in a position of influencing work beyond their own expertise.

Conduct a needs assessment and establish the instructional goal

A needs assessment is a critical first step for every program and every major target audience. It documents the need for the program, potential benefits, and probability for success. Then, learning characteristics of the target audience must be ascertained, as well as their existing knowledge and skill sets.

Relevant public health statistics and literature are examined, as well as the success of similar or existing programs, and public health cost-effectiveness, consistent with the mission statement of the training organization (e.g., will AED training or traditional CPR training save more lives?). The process includes identification of a public health problem, specific target audiences that can intercede, and possible programmatic solutions.

The needs assessment is the product of a dynamic process, which begins with discussions and debate by advocates (and also dissenters), followed by several writing and discussion sessions to work towards consensus on the feasibility and justification for moving forward; in other words, the information required to make a "go/no go" decision. If a "go" decision to continue is made, the program's Instructional Goal is outlined. The Instructional Goal is the R&D team's collaborative opinion of what the program will actually accomplish – that is, in general terms what the target audience will be expected to do following exposure to the training program. A question generally asked is "Is the instructional goal feasible for the target audience, and to what extent?" This is answered as part of the target audience analysis.

Conduct a target audience analysis

With the identification of the target audience(s) for the program, the R&D team conducts the in-depth social and learning analysis of the audience. This comprehensive analysis may first study whether or not, or to what extent, members of the target audience are aware of the problem, their perceptions, as well as their potential role in addressing the problem, including their perceptions of participating in such a role, and their motivations for participating in the program. The learning characteristics of the target audiences must be ascertained (e.g., typical methods for self-learning), as well as their existing knowledge and skill sets. This step generally uses several methods including: review of education and psychosocial literature, focus groups, field and case studies, and review of effective educational programs for similar target audiences. The findings of the target audience analysis may also conclude with a "no-go" decision.

Discussion

The target audience analysis is a critical step and is often omitted, directly contributing to inaccurate assumptions about the target audience, and subsequent selection of inappropriate instructional strategies and materials, all contributing to poor learner outcomes.

Many public health papers have been written justifying the need for BLS and ALS in the general population, and suggesting a segment of the population to intercede. For example, public health analyses have suggested that spouses (and other family members) of heart disease patients be taught CPR, because of their obvious likely proximity to these patients if they experience a heart attack or a cardiac arrest. Thus far, however, this strategy remains problematic. The Needs Assessment and Target Audience Analysis are important because they go a step farther by examining the feasibility of utilizing particular audiences to intercede. In order to prioritize options for addressing a public health problem, definitive statements on the rationale for selecting a specific audience, balanced against threats to success, are necessary.

What happens if the Educational Needs Assessment determines that an educational intervention is not feasible or advantageous (e.g., no additional lives will be saved) leading to a "no-go" decision, but the Market Research leads to "go" decision? There are the following possibilities.

- The process is stopped at this phase, or
- An alternative program using a different target audience or technology as a substitute for the target audience is used (e.g., implantable defibrillators), or

- Because the training organization may need revenues to support other programs, the program may proceed (regardless of the program's utility in saving lives).

Develop learning objectives and evaluation instruments

With knowledge of the target audience's characteristics and abilities, the R&D team determines the competencies needed by learners to achieve the program goals efficiently and effectively. The R&D team translates these goals into precise observable learning objectives for the program, and they are also the basis for the development of assessment tools.

The instructional goals are converted into behavioral objectives, and the skills derived from analysis of the instructional goals above are converted into subordinate objectives. The objectives guide the R&D team in the design and development of instruction, especially with selecting content and developing the instructional strategies. Specific, finite, behavioral objectives are formulated from knowledge and understanding of the target audience's learning characteristics and abilities. Requisite entry characteristics and behaviors are also developed (i.e., what competencies participants must already possess before entry into the program).

These learning objectives are also used to construct measures of the learner's accomplishment of the task. Development of assessment tools (e.g., written tests, skill assessments) generally begin at this point and should be performed as a separate and concurrent process by a team of educators with expertise in evaluation. Initially, the assessment tools are tested without participant involvement (e.g., content validity, reading level, expert review), and are "piloted" using subjects with a broad range of the included abilities from novice to expert. Then, like the program itself, the tools are further developed and modified depending on the results of pilot testing, either independently or as part of the pilot testing of the overall program.

The valid and reliable assessment tools serve two purposes: assessment of individual participants during the program and of overall program effectiveness. During the formative stage of program development (i.e., during pilot testing), assessment tools are necessary for providing information about the effectiveness of the instruction (See Step 7, Pilot test program and revise instructional materials). Pretesting of knowledge and experience as entry criteria is important in many programs (in particular, instructor training and advanced classes such as ACLS) to assure that all learners have basic qualifications and

understanding to participate effectively and efficiently in the program and achieve the desired learner outcomes.

Discussion

Learning objectives are the driving force for curriculum development, instructional design, and valid and reliable testing. Historically, developers have not completely recognized the purpose and importance of learning objectives and have assigned this task a low priority to be completed later in the process by a backwards-type logic (i.e., reasoning from the content of the program what the objectives might be), contributing to poor educational programs and poor assessment tools.

Well articulated learning objectives are the key to development of valid tests and measures. Good measures require adequate time for construction. With completion of the learning objectives, test development should begin. Often, test construction is delayed while the precise wordings of final provider materials are awaited. Such delays are not justified, because the structure and content of the test items themselves can be derived from the objectives alone, while wording changes can be made at any point in the process to reflect ongoing development of other materials.

Develop instructional outline (instructional script)

The learning objectives are organized into a logical presentation sequence specifically designed for the target audience. The instructional outline is based on the target audience's experience relative to the subject matter, their learning abilities and motivation, and the required competencies. The instructional outline or script becomes the basic foundation map and script for the program and will be enhanced as other components of the program are developed. The instructional script will also serve a key role in the development of instructor materials.

Select and develop instructional strategies and materials

With the detailed knowledge of the target audience, the specification of learning objectives, and an instructional outline, the R&D team can select and develop instructional strategies and materials. The most appropriate strategies are determined for accomplishing each objective. An instructional strategy is a method or set of methods used to assist a specific target learner audience master a learning objective.

Once the strategy is selected (or conceived), the material (or media) that will best communicate the specific strategy is selected (e.g., video, e-learning, book, instructor, among others). For example, if a visual model is selected as an instructional strategy, specifications for the visual model are first developed, followed by selection of the appropriate material to communicate the instructional strategy to the target learners (e.g., video, instructor demonstration, CD-ROM/DVD, slides, e-learning, interactive simulation, or a combination of materials).

To assist the instructional designer in understanding all the information and concepts that must be communicated through the instructional strategy and materials, traditional developers often begin by producing a self-instructional prototype of the program for themselves. According to Dick and Carey, this activity of putting oneself in the position of the learner forces the instructional designer to confront all the elements of the program that the student must face in mastering the program objectives.[113] When using the self-instructional prototype, the materials alone should permit the participant to acquire the competencies without intervention from an instructor. Once the detailed self-instructional materials are completed, other types of instructional media, specific to the instructional strategies, are considered.

Depending on the types and scope of instructional materials selected, several teams may be needed to complete the development of the instructional materials. Each team needs specific expertise in the (1) type of instructional material (e.g., book or video), (2) content, and (3) specific audience.

Discussion

Selection of instructional strategies as well as instructional materials (media) before fully addressing Steps 1–3 has historically contributed to program development and delivery problems and failures.

The traditional practice of including the instructor as part of the instructional strategy before consideration of other instructional strategies is often used to fill gaps in the materials; this may lead to incoherent program presentation and confusion. This practice allows the designer to avoid having to confront all the learner's challenges, which leads to an incomplete understanding and articulation of the instructional information and strategies, and undermines learning and efforts to control program quality. At the least, in the case of materials developed for a lay audience, research has shown that when considerable latitude is given to instructors, on the theory that they can best tailor the course to the learners, learner outcomes may be less successful. Well-trained educators may have this ability to adapt to learner needs, but the BLS and ALS instructor corps is largely made up of individuals without the appropriate background to do this.

Pilot test program (formative evaluation) and revise instructional materials

Instructional strategies and materials cannot be developed in a vacuum; it is only when materials are tested with learners that informed revisions can be made. The process of pilot testing and revision is ongoing and iterative (i.e., each pilot test brings the R&D team a step closer to an effective instructional program).

Pilot testing takes place at various stages of the ongoing development of instructional materials, often on a small scale with "mini-pilots" involving a few small convenient samples. Revisions are also ongoing, based on the findings of the pilot testing. During initial development of strategies and materials, small numbers of representative learners are asked to respond to sections or components of verbal (written and/or spoken) and visual materials. Findings from pilot tests are used to make decisions, such as program duration, class size, or the need for instructional supplies or equipment. Meaningful data are therefore used to make these decisions versus the tradition of arbitrary decision making.

Before pilot testing, the educational interventions are untested and therefore may be limited in their ability to bring about the expected learning behaviors (e.g., competent CPR performance) because the interventions are based primarily on expert opinion and conjecture and *not* on actual in-class evaluations with the target audiences. Pilot testing typically identifies communications and other instructional problems, and major modifications are often necessary. This trial and error iterative approach is key to the model and can contribute to the success of the final program. Time must be built into the development process for repeated trials and complete redrafting of the program, or sections, if necessary.

Qualitative methods used during pilot testing include videotaping and/or detailed observation of the pilot program, and interviews with all participants, including instructors, if applicable. Prototype learner outcome measures (i.e., assessment tools) are used to determine the extent to which learners are mastering behavioral objectives. In this way, the assessment tools themselves may also be piloted and revised.

Once a prototype instructional program is completed, more formal larger scale formative and summative evaluation, in as realistic a setting as possible, is performed, with learner outcomes as the primary measure of program success. Learner and instructor behaviors are still observed during the final phase of pilot testing. Instructional strategies and materials are modified in accordance with the results of pilot tests and are retested until the course participants master the learning objectives and related competencies.

Discussion

It is during pilot testing that the education developers determine how long it takes participants to master the objectives (i.e., determine program duration). Traditionally, pilot testing has been used to determine how long it takes the instructors to present the material, with lesser regard for how long it actually takes participants to master the objectives. Course length has most often been an arbitrary computation based on course administrative constraints, such as cost or consumer expectations.

External regulations often cause instructional developers to tailor programs to a specific length of time. In such cases, learner competence (i.e., learner outcome) must drive decisions concerning number of course objectives that can realistically be accomplished by learners. Only objectives that can be successfully accomplished within the mandated time frame should be part of the program.

Field test program and modify if necessary

After completion of pilot testing, the program is ready for field-testing (i.e., implementing the program on a limited scale but simulating a full roll-out). The program is tested as it would be delivered in the field.

In a field test setting, as opposed to a pilot test, the delivery simulates program roll-out and uses realistic materials; real-world instructors and participants are involved, who may be unaware that the product is not finalized. This step of product testing is typically focused on the testing of program *delivery,* rather than the *instructional materials* (i.e., what happens when the program reaches the end user). Field testing may uncover the need to change some aspects of the instructional system, such as with non-compliance of instructors. It may also indicate that the user audience does not match the intended target audience. Possible program revisions range from small modifications to comprehensive changes in program design and delivery.

Roll-out program

Following field testing, the program is disseminated to and implemented in the broader target population. Ideally, field testing activities continue throughout the roll-out and implementation of the program.

Establish and implement quality assurance monitoring team and system

The quality assurance monitoring team evaluates the program throughout its life cycle. Their findings, in part, guide the development of the next version of the program, and may inform the development of other BLS and ALS programs. The findings also inform online (i.e., immediate) revisions to the program, if needed.

Quality assurance is a dynamic, ongoing process of monitoring learner outcomes, retention, and field performance after program release, in which findings are used to inform revisions of existing programs and/or the development of new programs. The quality assurance monitoring team is a permanent group composed of experts in education and evaluation who design and monitor the QA system and work with the training organization's field staff and outside evaluators to provide regular evaluation of existing programs. The QA team may become involved with the program during field-testing. The team monitors the progress of the program through its life cycle.

Figure 70.1 presents the cycle of program R&D and QA. Data related to learner outcomes are collected at different time points after instruction, and findings are fed back to the R&D team to inform course revisions.

Monitoring of ongoing courses includes collecting objective, quantitative data, as well as qualitative feedback about the programs, often using the valid and reliable assessment instruments developed earlier by the R&D assessment team. Quantitative data are collected regarding learner outcomes (e.g., skill competencies). Qualitative data can include feedback collected from focus groups and systematic observations of programs. Programs sampled should represent a variety of geographic locales and typical target audiences.

A centralized system for collecting and analyzing data from evaluations should be developed. A reliable feedback mechanism (e.g., reporting of findings) should be in place so that the products of ongoing evaluation are fed back to the R&D group for continual program improvement.

Discussion

Early selection and involvement of the QA team, ideally during the R&D steps, permits QA team members to become familiar with the program and assessment tools and to pilot test aspects of the QA system (e.g., data management, analysis and feedback (to R&D).

Introduction

Clinical guidelines are defined by the Institute of Medicine in the United States as "systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances."[1] The main objective of guidelines is to improve the quality of care received by patients by closing the gap between what clinicians do and what scientific evidence supports. Guidelines provide a point of reference for auditing performance of clinicians or hospitals and may improve effectiveness and efficiency. The development of guidelines requires appropriate resources: expert clinicians, group process leaders, and financial support.[2] All these statements refer to guideline development in general, but they are particularly relevant to the development of resuscitation guidelines that have existed for at least 40 years. The steps involved in the process for developing evidence-based guidelines have been outlined by the Grades of Recommendation Assessment, Development and Evaluation (GRADE) Working Group (Table 71.1).[3]

This chapter will review the history of consensus development in resuscitation, the role of the International Liaison Committee on Resuscitation (ILCOR), the process involved in undertaking a systematic review of resuscitation science, and the writing of clinical guidelines based on a consensus of the science.

The history of international CPR consensus and guideline development

The modern approach to cardiopulmonary resuscitation (CPR) was described in the late 1950s and early 1960s. Although this was undoubtedly the birth of CPR, it was immediately realized that the challenge was to spread the word and educate healthcare workers and laypeople throughout the world. This same challenge faces us today whenever CPR guidelines are modified and updated.

One of the earliest "consensus" decisions on CPR was to agree on the terminology for this new technique (extensive discussions on terminology in resuscitation continue today). The term "cardiopulmonary resuscitation" and the abbreviation "CPR" were proposed first by the American Heart Association (AHA) Ad Hoc Committee on Closed Chest Cardiac Resuscitation in February 1962.[4] Initially, after considerable debate and concern about the risks, the AHA recommended that only doctors should be trained in CPR. It was recommended for rescue groups in April 1962.

In 1966 the National Academy of Sciences' National Research Council convened an ad hoc conference on CPR. This was the first conference to review specifically the evidence and recommend standard CPR techniques; more than 30 national organizations were represented.[5] International awareness was enhanced in the following year, when an International Symposium on Emergency Resuscitation was held in Oslo, Norway; recommendations from this conference were published in 1968.[6] The American Heart Association sponsored subsequent conferences in 1973 and 1979.[7,8] Parallel efforts occurred internationally as other resuscitation organizations faced a growing demand for CPR training.[9,10] Inevitably, variations in resuscitation techniques and training methods began to emerge from individual countries and regions of the world.

Increasing awareness of international variations in resuscitation practices generated interest in the possibility of gathering international experts at a single location with the aim of achieving consensus in resuscitation tech-

Table 71.1. The GRADE Working Group sequence for developing guidelines[3]

First steps

1. Establishing the process, e.g., prioritizing problems, selecting a panel, declaring conflicts of interest, agreeing on group processes.

Preparatory steps

2. Systematic review – identify and critically appraise or prepare systematic reviews of the best available evidence for all important outcomes.

3. Prepare evidence profile for important outcomes – profiles are needed for each subpopulation or risk group, based on the results of systematic reviews, and should include a quality assessment and summary of findings.

Grading quality of evidence and strength of recommendations

4. Quality of evidence for each outcome – judged on information summarized in the evidence profile and based on predefined criteria.

5. Relative importance of outcomes – only important outcomes should be included in the evidence profiles.

6. Overall quality of evidence – judged across outcomes based on the lowest quality of evidence for any of the critical outcomes.

7. Balance of benefits and harms – classified as net benefits, trade-offs, uncertain trade-offs, or no net benefits based on the important health benefits and harms.

8. Balance of net benefits and costs – are incremental benefits worth the costs? Because resources are always limited, it is important to consider costs (resource utilization) when making a recommendation.

9. Strength of recommendation – recommendations should be formulated to reflect their strength – that is, the extent to which one can be confident that adherence will do more good than harm.

Subsequent steps

10. Implementation and evaluation, e.g., using effective implementation strategies that address barriers to change, evaluation of implementation, and keeping up to date.

niques. With this in mind, in 1985, the AHA invited resuscitation leaders from many countries to observe its review of standards and guidelines for CPR and emergency cardiovascular care (ECC).[11] By all accounts, the international guests played a very active role in the discussions![10]

In June 1990, representatives from the AHA, European Resuscitation Council (ERC), Heart and Stroke Foundation of Canada (HSFC), and the Australian Resuscitation Council (ARC) attended a meeting, hosted by the Laerdal Foundation, at Utstein Abbey on the island of Mosteroy, Norway. The purpose of this meeting was to discuss the problems of resuscitation nomenclature and the lack of standardized terminology in reports relating to adult out-of-hospital cardiac arrest. This was the first major collaborative venture involving resuscitation councils from around the world. A follow-up meeting was held in December 1990 in Surrey, England, where the decision was made to adopt the term "Utstein-style" for the uniform reporting of data from out-of-hospital cardiac arrests.[12] Many other 'Utstein-style' international consensus statements have been published over the last 15 years, including the uniform reporting of pediatric advanced life support,[13] laboratory CPR research,[14] in-hospital resuscitation,[15] neonatal life support,[16] drowning,[17] and CPR registers.[18]

The Fifth National Conference on CPR and ECC was held in Dallas, Texas, USA in 1992. More than 40% of the participants were from outside the United States, representing 25 countries and 53 international organizations.[19,20] Three international issues were addressed: the desirability of international support for countries to develop effective ECC; the creation of a permanent infrastructure for international cooperation; the desirability of common international guidelines and an international conference on CPR and ECC. An international CPR and ECC panel discussion, cochaired by Richard Cummins and Douglas Chamberlain, endorsed the need for international cooperation. This would have several advantages: the world's leading experts would achieve constructive communication and cooperation; advice for guidelines would be less likely to be dominated by tradition or peer pressure; guidelines generated in this way would be accepted widely within existing organizations; similar or identical guidelines would be produced by different groups and the potential would exist for eventual universal guidelines.

The International Liaison Committee on Resuscitation (ILCOR)

The first international conference held by the ERC took place in Brighton, England in 1992. At the end of the conference, representatives from the guidelines-producing organizations (AHA, ERC, HSFC, ARC, and the Resuscitation Council of Southern Africa (RCSA)) held the first meeting of the International Liaison Committee.[20] The founding cochairs of this organization were Douglas Chamberlain and Richard Cummins. At its second meeting, held in 1993 in Vienna, Austria, the International Liaison Committee adopted a formal mission statement:

To provide a consensus mechanism by which the international science and knowledge relevant to emergency cardiac care can be identified and reviewed. This consensus mechanism will be used to provide consistent international guidelines on emergency cardiac

care for Basic Life Support (BLS), Paediatric Life Support (PLS) and Advanced Life Support (ALS). While the major focus will be upon treatment guidelines, the steering committee will also address the effectiveness of educational and training approaches and topics related to the organisation and implementation of emergency cardiac care. The Committee will also encourage coordination of dates for guidelines development and conferences by various national resuscitation councils. These international guidelines will aim for a commonality supported by science for BLS, ALS and PLS.

Formal BLS, ALS, and PLS working groups were established and tasked with reviewing scientific data in their respective area of expertise. The name "International Liaison Committee on Resuscitation (ILCOR)" was suggested by Walter Kloeck, the chairman of RCSA, and adopted formally in 1996.[20] The founding organizations were joined in 1997 by the Consejo Latino-Americano de Resuscitatión (which now forms part of the Inter-American Heart Foundation) and in 1998 by the New Zealand Resuscitation Council (joining with the ARC to form the Australia and New Zealand Committee on Resuscitation (ANZCOR)). Since 1999, representatives from Japan, China, Taiwan, Thailand, Malaysia, and Singapore have joined some ILCOR meetings as observers. In 2006, the Resuscitation Council of Asia, which includes representatives from Japan, Korea, Singapore and Taiwan, formally joined ILCOR.

The mission statement of ILCOR was updated in 2005:

The International Liaison Committee on Resuscitation (ILCOR) will provide a mechanism by which the international science and knowledge relevant to cardiopulmonary resuscitation (CPR) and emergency cardiovascular care (ECC) is identified and reviewed. ILCOR will periodically develop and publish a consensus on resuscitation science. When possible, ILCOR will publish treatment recommendations applicable to all member organisations. This consensus mechanism may be used by member organisations to provide consistent guidelines on resuscitation. ILCOR will encourage co-ordination of guideline development and publication by its member organisations. While the major focus will be on evaluation of cardiopulmonary resuscitation and emergency cardiovascular care science, ILCOR will also address the effectiveness of education and training, and approaches to the organisation and implementation of emergency cardiovascular care.

The activities undertaken by ILCOR to achieve the objectives set out in its mission statement are listed in Table 71.2.

By 2005, ILCOR had convened 22 official meetings culminating in the 2005 International Consensus Conference on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science with Treatment Recommendations, held in Dallas, Texas.[20,21] With the benefit of international cooperation, ILCOR has assessed systematically the evidence supporting resuscitation standards and guidelines. Initially, ILCOR experts identified numerous

Table 71.2. The activities undertaken by the International Liaison Committee on Resuscitation

- Provide a forum for discussion and for co-ordination of cardiopulmonary and cerebral resuscitation worldwide.
- Facilitate a process for collecting, reviewing and sharing international scientific data on resuscitation.
- Provide a channel for scientific review and guidance to enable a process of international consensus to be achieved.
- Produce appropriate statements on specific issues related to resuscitation that reflect international consensus.
- Foster scientific research in areas of resuscitation where there is a lack of data or where there is controversy.
- Facilitate a process for dissemination of information on training and education in resuscitation.

national differences in the practices of BLS, ALS, and pediatric and newborn resuscitation. ILCOR has published 18 scientific advisory statements with the goal of explaining, eliminating, or reducing these international variations while endorsing mainly evidence-based resuscitation guidelines.[20,22–29]

The Guidelines 2000 Conference and the goal of universal CPR and ECC guidelines

Early ILCOR meetings were driven by the belief that evaluation of international science by a common group of experts should lead to universal evidence-based resuscitation guidelines and practices. This view was particularly strong leading up to the Guidelines 2000 Conference, the world's first international conference assembled to produce international resuscitation guidelines.[30,31] This was the first major conference to be held under the auspices of ILCOR and it incorporated a sophisticated process for gathering and assessing evidence; this process evolved further in 2005 (see below).[32] Although the output from the Guidelines 2000 Conference was published in both *Circulation*[33] and *Resuscitation*[30] and was subtitled "An International Consensus on Science," the ERC subsequently published its own resuscitation guidelines.[34–39] These included some differences from the "International Guidelines" – the most significant being simpler algorithms and minor differences in recommendations for drug therapy.

What were the reasons for failing to achieve truly universal guidelines? Guidelines cannot be based on data alone – judgment is unavoidable.[40] If our clinical practice was supported entirely by indisputable level 1 evidence, there would be considerably less scope for differences among councils and regions in the translation of science into

guidelines. In reality, much resuscitation practice is supported by lower level evidence or conflicting evidence. This situation can easily be summarized in a consensus on science statement by stating simply that there is no clear evidence for or against a specific therapy or intervention. Nevertheless, clinical guidelines have to be simple and relatively dogmatic – one has to commit to a treatment or technique in preference to another. It will be difficult to reach consensus on the extent to which evidence obtained from selected populations of patients or animal studies can be extrapolated to the general population.[41] The specific endpoint of a given resuscitation intervention that is most relevant (e.g., return of spontaneous circulation, survival to hospital admission, survival to hospital discharge, intact neurological survival, quality of life) will continue to be controversial. By the time educational, cultural, financial, and organizational factors, and differences in drug availability are taken into account, despite consensus on the science, differences in guidelines from one country to another are inevitable.[42] Many problems in resuscitation require local modifications and solutions. The common goals of the resuscitation community are ultimately reducing rates of morbidity and mortality from cardiac arrest.

The Evidence Evaluation Process for the 2005 International Consensus on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science

Evidence-based medicine is now a fundamental component of clinical practice and its principles are well established.[43] The evidence evaluation process used in preparation for the 2005 International Consensus on CPR and ECC Science (C2005) has been described in detail by Morley and Zaritsky, who took the lead in ensuring a high-quality review of the evidence supporting resuscitation.[32] Clinical research in resuscitation is challenging – cardiac arrest is generally an unpredictable event and there are increasing ethical problems associated with enrolling unconscious patients in trials.[44] Inevitably, this means that there are relatively few controlled human studies and in many cases we must rely on animal and manikin studies.

In 2003 and 2004, international experts (worksheet reviewers) were assigned questions to evaluate. With use of a hybrid of a nominal group technique and Delphi survey,[42] the questions for systematic review were refined by each of six ILCOR specialty task forces (BLS, ALS, acute coronary syndromes, PLS, Neonatal Life Support, and interdisciplinary) and from the ILCOR member resuscitation councils and their training networks. Use of the Cochrane

Collaboration PICO system for structuring the question for systematic review was encouraged but was not adopted universally, partly because it applies only to clinical studies. The PICO system structures the question into four components: the patient, population, or problem (P); the intervention or independent variable (I); the comparison (C); and the independent variables or outcome(s) of interest (O).[45] Each structured, evidence-based review was entered onto a standardized worksheet developed specifically for the C2005 Conference (Appendix 1). Two worksheet experts (Morley and Zaritsky) reviewed all submitted worksheets. The steps involved in preparing these worksheets are outlined below.[32]

Step 1. Gathering and selection of the evidence

Reviewers documented their search strategies to ensure reproducibility of the search. The minimum electronic databases to be searched included the Cochrane database for systematic reviews and the Central Register of Controlled Trials [http://www.cochrane.org/], MEDLINE [http://www.ncbi.nlm.nih.gov/PubMed/], EMBASE (www.embase.com), and the EndNote (www.endnote.com) reference library collated by the AHA.

Step 2. Assessing the quality of the evidence

Reviewers determined the level of evidence of relevant studies and assessed their quality. The quality of evidence indicates the extent to which one can be confident that an estimate of effect is correct.[3] There are many established systems for grading the quality of evidence.[3,46] The levels of evidence used for the 2005 consensus process were modified from those used in 2000 (Table 71.3).[30,33] Using predefined criteria, the reviewers assessed the quality of research design and methods and allocated each study to one of five categories: excellent, good, fair, poor, or unsatisfactory. Studies graded as poor or unsatisfactory were excluded from further analysis.

Step 3. Class of recommendation

The strength of recommendation indicates the extent to which one can be confident that adherence to a recommendation will do more good than harm.[3] Unfortunately, there are many systems for grading evidence-based guidelines. The class of recommendation system used in the 2005 AHA Guidelines for CPR and ECC is outlined in Table 71.4.[47] Many of the experts outside the United States did not want to use these classes of recommendation and they

Table 71.3. Levels of evidence used in the C2005 process[52]

Evidence	Definition
Level 1	Randomized clinical trials or meta-analyses of multiple clinical trials with substantial treatment effects
Level 2	Randomized clinical trials with smaller or less significant treatment effects
Level 3	Prospective, controlled, non-randomized cohort studies
Level 4	Historic, non-randomized cohort or case-control studies
Level 5	Case series; patients compiled in serial fashion, control group lacking
Level 6	Animal studies or mechanical model studies
Level 7	Extrapolations from existing data collected for other purposes, theoretical analyses
Level 8	Rational conjecture (common sense); common practices accepted before evidence-based guidelines

do not appear in the ILCOR 2005 Consensus on CPR and ECC Science publication or in the ERC guidelines.[48]

Step 4. Management of conflict of interest

Experts in resuscitation science establish their expertise by undertaking and publishing research and participating in scientific conferences. This work creates potential financial and intellectual conflicts of interest (COI) for the expert.[49,50] Intellectual conflicts of interest include intellectual collaboration or intellectual investment in personal ideas, and long-term research agendas in which investigators have invested a substantial time. A robust COI policy was developed to ensure full disclosure of potential conflicts and to protect the objectivity and credibility of the evidence evaluation and consensus development process.[51]

Step 5. Summary of the science

Worksheet reviewers summarized the science, providing a detailed discussion of the evidence, including the outcomes evaluated and the strengths and limitations of the data.

Consensus on science statements and treatment recommendations were drafted using standardized templates.

Step 6. References

Worksheet reviewers provided an EndNote database file containing the references that were used and these were added to the master reference library collated by the AHA.

Step 7. Posting on the Internet

In December 2004 the completed worksheets, blinded to authorship, were posted on an Internet site (www.C2005.org) that could be accessed by the public for further review and feedback before the 2005 Consensus Conference in Dallas. All individuals making responses or suggestions were required to submit potential or perceived conflict of interest statements.

The 2005 Consensus Conference

A total of 281 experts completed 403 worksheets on 276 topics; 380 people from 18 countries attended the 2005 Consensus Conference (C2005) in January 2005. All C2005 participants received a copy of the worksheets on CD-ROM. Internet access was available to all conference participants during the conference to facilitate real-time verification of the literature.[52] Expert reviewers presented topics in plenary, concurrent, and poster conference sessions. Presenters and participants then debated the evidence, conclusions, and draft summary statements. Each day the most controversial topics from the previous day were presented and debated in one or more additional

Table 71.4. The American Heart Association classes of recommendation[47]

Class 1 Benefit >>> risk	Class IIa Benefit >> risk	Class IIb Benefit ≥ risk	Class III Risk ≥ benefit
Procedure/treatment or diagnostic test/ assessment should be performed/ administered.	It is reasonable to perform procedure/ administer treatment or perform diagnostic test/ assessment.	Procedure/treatment or diagnostic test/ assessment may be considered.	Procedure/treatment or diagnostic test/ assessment should not be performed/ administered. It is not helpful and may be harmful.

sessions. Science statements were drafted to summarize the experts' interpretation of all the relevant data on a specific topic. Draft treatment recommendations were added if a consensus was reached. The 2005 International Consensus on CPR and ECC Science with Treatment Recommendations (CoSTR) was published simultaneously in Resuscitation[21] and Circulation.[53] This consensus on science has provided the evidence from which the latest resuscitation guidelines were derived.

From science to guidelines

The resuscitation organizations forming ILCOR have published individual resuscitation guidelines that are consistent with the science in the 2005 Consensus Conference document. These guidelines are broadly similar, but consideration of geographic, economic, and system differences in practice, and the availability of medical devices and drugs, has inevitably forced some differences. All ILCOR member organizations strive to minimize these international differences in resuscitation practice and to optimize the effectiveness of instructional methods, teaching aids, and training networks.

The recommendations of the 2005 Consensus Conference confirmed the safety, feasibility, and efficacy of some current approaches, acknowledged that other approaches were not optimal, and introduced new treatments resulting from evidence-based evaluation. Whenever guidelines are updated, healthcare providers and laypeople must be assured that it takes time for these changes to permeate down to frontline clinical practice and that, in the meantime, their existing techniques are reasonable and safe. The introduction to the 2005 Consensus Conference document included the statement: "New and revised treatment recommendations do not imply that clinical care that involves the use of previously published guidelines is unsafe."[52] Members of ILCOR considered these new recommendations to be the most effective and easily learned interventions that could be supported by existing knowledge, research, and experience, including the emerging science of ECC education. Treatment changes, such as the compression:ventilation ratio of 30:2 and the single- versus three-shock defibrillation strategy, which were adopted to minimize interruptions to compressions, were often based upon feasibility and teachability, and not on randomized controlled trials. Implications for education and retention were considered carefully when developing the final treatment recommendations.

The 2005 Universal Algorithm

The 2005 Consensus Conference document includes an updated ILCOR Universal Cardiac Arrest Algorithm (Fig. 71.1), which incorporates many of the new treatment recommendations. The algorithm is applicable to attempted resuscitation of infant, child, and adult victims of cardiac arrest (excluding newborns). Every effort was made to keep the algorithm simple yet widely applicable. Resuscitation organizations subsequently based their guidelines on the ILCOR algorithm, although a comparison of the ERC (Fig. 71.2) and AHA ALS (Fig. 71.3) algorithms reveals differences in style.

Implementing guidelines

Failure to translate research findings into daily practice is a well recognized problem.[54] The development of good guidelines does not ensure that they will be adopted in clinical practice and passive methods of disseminating and implementing guidelines (e.g., publication in journals) are unlikely to change professional behavior.[55] Resuscitation organizations have a primary responsibility for disseminating and implementing resuscitation guidelines; this will require significant resources. Summary booklets to supplement the full guidelines will be helpful for busy healthcare personnel. Full use of the Internet to make guidelines freely and easily downloadable is essential: the ERC and the AHA guidelines can be downloaded at www.erc.edu and http://circ.ahajournals.org/content/vol112/24_suppl/, respectively. Resuscitation guidelines can be disseminated effectively through national scientific meetings and by local meetings held in hospitals and in the community. Resuscitation training materials should be updated as rapidly as possible to reflect the new guidelines. The updating of training materials also requires considerable resources and often involves many of the individuals who have been involved in the guideline process. Standardized courses such as the ERC Advanced Life Support Course and the AHA Advanced Cardiac Life Support Course play a crucial role in disseminating resuscitation guidelines. Evaluation and verification of the implementation of new guidelines is achieved through audit.

The future for consensus development in resuscitation

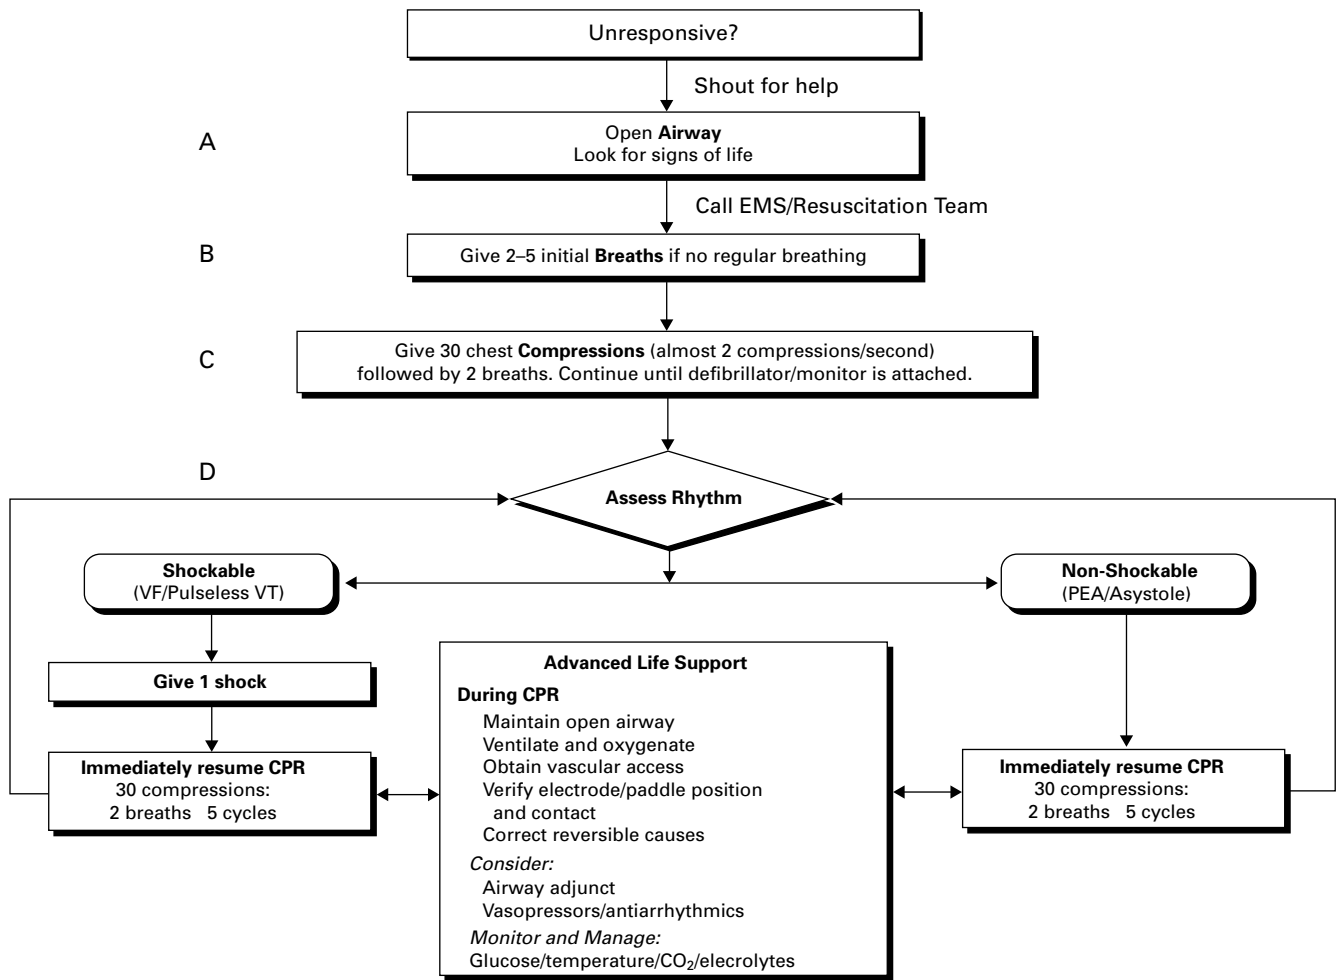
The science of resuscitation is evolving rapidly. It would not be in the best interests of patients if resuscitation


Fig. 71.1. The 2005 ILCOR Universal Algorithm.

experts were to wait five or more years to inform healthcare professionals of therapeutic advances in this field. Some groups have advocated reviewing guidelines as frequently as every two years.[42] Frequent changes in recommendations that do not have a major impact on outcome might undermine the process, however, because teaching and learning new guidelines takes time and resources. New science must be reviewed continually; if major new research evidence is published, groups such as ILCOR should publish interim consensus advisory statements to update treatment guidelines. Large multicentre registries that use Utstein-style consensus definitions of the process of care and outcomes following resuscitation will track the dissemination of new techniques and interventions from science to guidelines and to practice, and lead to further refinements in the guidelines.[18,56,57] Ideally, important interventions and practices could be taught and reviewed rapidly, giving feedback on quality

of performance for all healthcare providers. The interface between resuscitation research and continuous quality improvement (audit) is becoming more blurred. Innovative strategies to improve the process and outcomes of evidence evaluation and resuscitation are being incorporated into the planning for a consensus conference on resuscitation in 2010. Whether this 2010 consensus conference will result in truly universal guidelines has yet to be determined.

Summary

International consensus development in resuscitation has evolved over the last 40 years. Major international reviews of resuscitation science occur every 5 years under the auspices of ILCOR; the result is that CPR guidelines around the world are now broadly similar. Standardized training mate-

rials and courses help to disseminate the guidelines and change the practice of healthcare professionals and first responders.

A statement for healthcare professionals from a Task Force of the American Heart Association, the American College of Emergency Physicians, the American College of Cardiology, the European Resuscitation Council, the Heart and Stroke Foundation of Canada, the Institute of Critical Care Medicine, the Safar Center for Resuscitation Research, and the Society for Academic Emergency Medicine. *Resuscitation* 1996; **33**: 69–84.

15. Cummins, R.O., Chamberlain, D., Hazinski, M.F. *et al.* Recommended guidelines for reviewing, reporting, and conducting research on in-hospital resuscitation: the in-hospital

1
PULSELESS ARREST
- BLS Algorithm: Call for help, give CPR
- Give **oxygen** when available
- Attach monitor/defibrillator when available

2 Check rhythm
Shockable rhythm?

Shockable

Not Shockable

3
VF/VT

9
Asystole/PEA

4
Give 1 shock
- Manual biphasic: device specific (typically 120 to 200 J)
  Note: If unknown, use 200 J
- AED: device specific
- Monophasic: 360 J
Resume CPR immediately

Give 5 cycles of CPR*

5 Check rhythm
Shockable rhythm?

No

Shockable

6
Continue CPR while defibrillator is charging
Give 1 shock
- Manual biphasic: device specific (same as first shock or higher dose)
  Note: If unknown, use 200 J
- AED: device specific
- Monophasic: 360 J
Resume CPR immediately after the shock
when IV/IO available, give vasopressor during CPR (before or after the shock)
- **Epinephrine** 1 mg IV/IO
  Repeat every 3 to 5 min
  or
- May give 1 dose of vasopressin 40 U IV/IO to replace first or second dose of epinephrine

10
Resume CPR immediately after 5 cycles
when IV/IO available, give vasopressor
- Epinephrine 1 mg IV/IO
  repeat every 3 to 5 min

- May give 1 dose of **vasopressin** 40 U IV/IO to replace first or second dose of epinephrine

Consider **atropine** 1 mg IV/IO
  for asystole or slow, PEA rate
  repeat every 3 to 5 min (up to 3 doses)

Give 5 cycles of **CPR**

11 Check rhythm
Shockable rhythm?

Give 5 cycles of CPR*

7 Check rhythm
shockable rhythm?

NO

Shockable

12
- If asystole, go to Box 10
- If electrical activity, check pulse, if no pulse, go to Box 10
- If pulse present, begin postresuscitation care

Not shockable

shockable

13
Go to box 4

8
Continue CPR while defibrillator is charging
Give 1 shock
- Manual biphasic: device specific (same as first shock or higher dose)
  Note: If unknown, use 200 J
- AED: device specific
- Monophasic: 360 J
Resume CPR immediately after the shock
consider **antiarrhythmics**; give during CPR (before or after the shock)
  amiodarone (300 mg IV/IO once), then consider additional 150 mg IV/IO once) or lidocaine (1 to 1.5 mg/kg first dose, then 0.5
Consider **magnesium**, loading dose
  1 to 2 g IV/IO for torsades de pointes
  After 5 cycles of CPR,* go to box 5 above

During CPR

- **Push hard and fast (100/min)**
- **Ensure full chest recoil**
- **Minimize interruptions in chest compressions**
- One cycle of CPR: 30 compressions then 2 breaths; 5 cycles –2 min
- Avoid hyperventilation
- Secure airway and confirm placement

  * After an advanced airway is placed rescuers no longer deliver "cycles" of CPR. Give continous chest compressions without pauses for breaths. Give 8 to 10 breaths/minute. Check rhythm every 2 minutes.

- Rotate compressors every 2 minutes with rhythm checks
- Search for and treat possible contributing factors:
  – Hypovolemia
  – Hypoxia
  – Hydrogen ion (acidosis)
  – Hypo-/hyperkalemia
  – Hypoglycemia
  – Hypothermia
  – Toxins
  – Tamponade, cardiac
  – Tension pneumothorax
  – Thrombosis (coronary or pulmonary)
  – Trauma

ACLS Pulseless Arrest Algorithm.
