Cardiac Arrest

The Science and Practice of
Resuscitation Medicine

Second edition

Cardiac Arrest is the definitive and most comprehensive reference in advanced life support and resuscitation medicine.

This new edition brings the reader completely up-to-date with developments in the field, focusing on practical issues of decision making, clinical management and prevention, as well as providing clear explanations of the science informing the practice. The coverage includes information on the latest pharmacotherapeutic options, the latest chest compression techniques and airway management protocols, all backed by clearly explained, evidence-based scientific research. The content is consistent with the latest guidelines for practice in this area, as detailed by the major international governing organizations.

This volume is essential reading for all those working in the hospital environments of emergency medicine, critical care, cardiology and anesthesia, as well as those providing care in the pre-hospital setting, including paramedics and other staff from the emergency services.

Norman A. Paradis is Adjunct Professor of Surgery, University of Colorado Health Sciences Center.

Henry R. Halperin is Professor of Medicine, Radiology, and Biomedical Engineering at the Johns Hopkins University School of Medicine, Baltimore, USA.

Karl B. Kern is Professor of Medicine at the Sarver Heart Center, University of Arizona, USA.

Volker Wenzel is Associate Professor of Anesthesiology and Critical Care Medicine in the Department of Anesthesiology and Critical Care Medicine of Innsbruck Medical University, Innsbruck, Austria.

Douglas A. Chamberlain CBE is Honorary Professor of Resuscitation Medicine at the School of Medicine, Cardiff University, Wales and Visiting Professor of Cardiology at the University of Brighton, Sussex, UK.

From reviews of the first edition:

. . . It is a tribute to the editors of this book, and the contributors they have selected, that they have managed to produce a book of enormous quality on the science of resuscitation medicine. *The Lancet*

The excellent book, the first of its kind in the field of cardiac arrest, provides a balance of theoretical and clinical information. It achieves a level of authority and sophistication well beyond that of the advanced cardiac life support guidelines and will be of considerable use to all those practicing or teaching clinical resuscitation.

The New England Journal of Medicine

The book has virtually everything one would ever want to know about the causes of cardiac arrest, the applied physiology, and its treatment. Physicians and nurses involved in the management of critically ill or injured patients should have Cardiac Arrest in their personal libraries for ready reference. *Resuscitation*

Foreword

Myron L. Weisfeldt, M.D.

This monograph on cardiac resuscitation medicine is the standard reference in the field. This Second Edition a decade later presents an entirely changed and dynamic field. Advances in resuscitative medicine encompass the basic science understanding of physiology and pathophysiology as well as advances in understanding of the causal mechanisms involved in successful or non-successful resuscitation. There are new programs and approaches at a practical and real-world level that improve survival and the quality of survival from cardiac arrest. I would maintain that these prerequisites relate to the need for this updated monograph. It is important that this text be acquired and used by providers of emergency cardiac care in both the out-of-hospital and in-hospital settings. It will be of value universally in the emergency departments. Clinical investigators will find this text of tremendous value when pursuing the improvement of survival from cardiac arrest, as well as laboratory-based clinical investigators attempting to identify and justify approaches to improving the outcome of cardiac arrest. As the underlying science of resuscitation deepens, basic scientists will value these state-of-the-art discussions. Resuscitation Science has broadened the focus from mechanics to reperfusion injury, post-resuscitation inflammation and programmed cell death.

To substantiate my statements about this update and its value to the medical and resuscitative community, I have identified what I consider to be the eight major advances in resuscitative medicine over the last decade.

1. *The advent of inexpensive, easy-to-use Automatic External Defibrillators (AEDs) for use by the lay public.* Ten years ago, industry was just beginning to produce these revolutionary devices. The FDA considered use of these AEDs by other than physicians, nurses and trained Emergency Medical Technicians (EMTs) as "illegal," off label, over-the-counter use of an approved

device. Ten years ago, only one or two states referred to defibrillation as being covered by the Good Samaritan law. Now all states consider such resuscitative efforts by members of the lay public to be encompassed by the Good Samaritan statutes. Ten years ago there were no convincing data that AEDs are effective in improving the outcome of resuscitation. Perhaps the most remarkable result was in the casinos of Las Vegas where Terry Valenzuela and his colleagues measured time from collapse to defibrillation precisely (on video cameras). Security guards could defibrillate with an average time of 4.4 minutes and survival of 59% in 90 subjects. If defibrillation was performed within 3 minutes ($n = 20$), survival was over 70%. As well, in the Public Access Defibrillation study (PAD), we now have data to support the value of the AEDs in the public arenas when added to CPR instruction. Ten years ago we had no conscientious programs to implement AEDs in full public view in airports and other transportation facilities, on-board airlines, in exercise facilities, or recently by government mandate in large public buildings. Although these programs clearly have had little impact on the overall public health survival rate from cardiac arrest, they have produced some of the most rewarding survivals because of the promptness of resuscitation and the clear ability of those resuscitated very quickly to recover fully and rapidly.

2. *Change in the characteristics of the population suffering cardiac arrest.* Ten years ago, broad population studies showing that 70% or so of people suffering cardiac arrest have ventricular fibrillation (or ventricular tachycardia) as the first documented electrocardiographic rhythm. Now, multiple large population studies note that 20% to 30% of those suffering a cardiac arrest have ventricular tachycardia (VT) or ventricular fibrillation (VF) as their initial rhythm. The majority now have an absence of electrical activity, or occasionally will have electromechanical dissociation. The reason for this major change, one can only speculate. One possibility is that, in fact, modern drug treatment of coronary disease and heart failure combined with implantation of automatic defibrillators in their target population has led to this change. For survivors of cardiac arrest caused by ventricular tachycardia or fibrillation, implantation of defibrillators has provided an increasing standard of care. This is also true for patients with congenitally inherited causes of sudden death, and many individuals with reduced left ventricular function due to previous myocardial infarction or cardiomyopathy. It is possible that we are implanting defibrillators currently at sufficient rate to have an impact in the

United States on the overall public health's incidence of cardiac arrest from these arrhythmias. Drug and procedural treatment strategies for chronic coronary disease and heart failure may also be impacting on the incidence of sudden death from VT/VF. It is very clear that, in these broad populations, beta-blocking agents as well as angiotensin II receptor blockers, and antiplatelet drugs (for coronary disease), and aldosterone antagonist improve survival from these chronic cardiac states. It is less clear that they reduce the incidence of sudden death particularly sudden death from VF or VT. That is a likely possibility. A final speculation is that cardiac arrest in advanced age is more likely not VT/VF. With the striking decline in age-adjusted mortality from cardiovascular disease, we have less incidence of death and perhaps less sudden death from VT/VF in younger individuals on a population basis.

This change in the initial arrhythmia has a number of significant impacts. First, survival of this group of patients who do not have VT/VF is much lower and we know little about what are effective ways of resuscitating this population. We also know less about the long-term management and care of these patients that may result in their survival since it is likely that placing automatic implantable defibrillators in these patients will not improve their long-term outcome even if they survive their initial arrest. These, and a whole host of other theoretical and practical problems, emanate from this change in population suffering cardiac arrest.

3. *In recent years there has been recognition of the need to extend animal data on CPR performance and effectiveness from the laboratory into the clinical arena.* It is very clear from animal studies that all interruptions of chest compressions are detrimental to the hemodynamics of CPR, particularly coronary blood flow. It has long been recognized that indices of coronary blood flow are very closely related to human survival. Interruptions from repeated looks at the electrocardiogram, multiple defibrillation attempts, or procedures such as inefficient intubation, have been minimized on the basis of these data. In addition, it has been demonstrated in animal models very convincingly that hyperventilation or even "usual" ventilation during resuscitation is too much ventilation and is detrimental. Related to these issues, performance of cardiopulmonary resuscitation in the real-world situation, both in the hospital by healthcare professionals and out-of-the-hospital by EMTs, is characterized by multiple, prolonged and repeated interrupts of chest compression and hyperventilation. Monitoring systems, feedback systems, and other systems for controlling or at least documenting the way resuscitation is

performed, are beginning to change the policies and practices of CPR performance. It is very clear that, from point "2" above, we come to the realization that in 70% of arrest in which the initial electrocardiogram is not VT/VF, it is only the quality of CPR and its performance that can lead to return of spontaneous circulation and ultimately the possibility of survival.

4. *In VT/VF Arrest, Dr. Lance Becker and I proposed a three-phase model to integrate and characterize specifically the time relationships of the value of rapid defibrillation, the performance of cardiopulmonary resuscitation, and the need for other measures focused on the metabolic factors that decrease survival after prolonged cardiac arrest.* Phase 1 of the three-phase model identifies the first 4 or 5 minutes as a time when initial defibrillation has a remarkable survival benefit. It next identifies that between 4 minutes and 10 minutes, optimal survival is very poor if there is no CPR performed. Shock at this time may be detrimental in addition to the time wasted. During Phase 2 from 4 to 10 minutes after arrest, it may be critical to perform cardiopulmonary resuscitation to achieve even a 20–30% survival rate. Finally in Phase 3, after 10 minutes without resuscitation, the model identifies the possibility that drugs and pharmacological agents as well as subsequent treatment strategies such as hypothermia may be required to reach reasonable survival.

5. *We are beginning to see devices that may improve perfusion during cardiopulmonary resuscitation and thus may improve survival.* It is understood that the hemodynamics of CPR are not excellent with regard to restoring and maintaining brain and particularly myocardial blood flow. Fluctuating intra-thoracic pressure to a greater degree (both positive during compression or the "systolic" phase of the CPR cycle and increasing negative intra-thoracic pressure during the "diastolic" phase) in animal models seems to show very convincing benefit in improving blood flow as well as animal survival. There are initial studies in man suggesting favorable hemodynamic changes occur. To date, the vest-like devices that increase intra-thoracic pressure during the systolic phase are cumbersome. Motivation to use devices is important. There have been variable results in humans – none that are convincing. A small airway valve device that decreases intra-thoracic pressure between compression cycles improves blood flow in animals and humans. This device is associated with improved short-term survival and we await larger studies which are ongoing to see whether this device will improve long-term and meaningful survival.

6. *Moderate hypothermia may be useful in patients who*

after out-of-hospital cardiac arrest have not awakened when they reach the emergency department. Two studies appear to show benefit of 12 to 24 hours of 32 ° to 33 °C, hypothermia in terms of improving survival and brain function following such episodes of out-of-hospital cardiac arrest. This benefit has been accepted in AHA guidelines, but is not accepted by the FDA. Much is happening in the experimental arena to develop devices that induces easy controllable hypothermia. There are initial studies to potentially bring hypothermia earlier in the course of resuscitation. Again, animal studies suggest that broad implementation of early hypothermia after cardiac arrest may improve survival remarkably.

7. *Registry-based information on in-hospital and out-of-hospital CPR.* Detailed performance data with results are now available for thousands of in-hospital resuscitations. There are also increasing numbers of epidemiological studies and other out-of-hospital registry studies that have identified correlates of survival from cardiac arrest as related to resuscitation strategies, maneuvers and approaches. We are beginning to define "best" practices and (if you will) the "worst" practices.

8. *There is a new horizon of technology that will certainly impact on resuscitation* This technology revolution I predict will include patient sensors that identify futility of cardiac resuscitation. Diagnosis of death is inadequately made in many individuals with current clinical criteria. Perhaps more importantly, we will use sensors that will identify patient status from the point of view of metabolism blood flow and oxygen delivery. They will provide an assessment of the current status of the patient and/or what the resuscitative maneuvers have accomplished. This type of information will dictate care patterns and strategies to improve survival from the point of view of drug administration as well as device and hemodynamic strategies. The strategies are likely to be complex and therefore it is highly likely that devices will integrate the clinical status of the patient with the information obtained with sensors into a care and management. These will emerge particularly as metabolic phase markers lead to specific therapeutic strategies. Information will likely be used at the scene and in the emergency department that is ultimately going to receive the patient. Similar devices and approaches will almost certainly change in-hospital and ED management of the arrest occurring in that circumstance.

9. In summary, this new volume on the science and practice of resuscitative medicine is extraordinarily timely. The depth and breadth of new material and chapters are remarkable and valuable. The new authors include

the current generation of the most contributory and thoughtful leaders of the field. The text should be embraced by a broad and deep audience of those interested in this exciting and forward-moving field and branch of medicine. The worldwide authorship reflects the fact that sudden death is a worldwide problem that is increasingly gaining true worldwide attention!

July 12, 2006

Preface to the first edition

O, that I could but call these dead to life!

King Henry VI
William Shakespeare

There is a no more frightening experience for a clinician than a patient's sudden and complete loss of vital signs. The need to initiate multiple complex therapies, all the while knowing that each minute that passes dramatically decreases the chances for a good outcome, makes sudden death the penultimate medical emergency.

Premature death is the adversary of physicians. For millennia, the loss of life signs was considered the victory of death. Students were taught that once patients had succumbed they were beyond the healing arts. Only relatively recently have physicians regularly attempted to wrest such patients back from death.

Accurate numbers are difficult to obtain. It is said that more than 300,000 persons die each year from sudden cardiac death in the United States alone. Worldwide the figure is in the millions. Sudden death is not, however, caused by coronary artery disease alone. Hemorrhage and asphyxiation, among others, can kill physiologically competent patients without warning. Sudden death is not defined by etiology; it is the circumstance of cardiopulmonary arrest in a person with functional vital organ systems. It is death in the midst of life, and it is always tragic.

We are just beginning to appreciate the magnitude of this problem and the potential for therapy. Just a 5% improvement in outcome – something that could be achieved in many communities by better application of standard care – would save more lives than therapies that have received far more attention. The potential for good is astounding; the relationship of cost to benefit compelling.

Sudden cardiopulmonary arrest is the most difficult disease state to treat. Remarkable improvement in the

quality of care has been achieved in a relatively short time by the American Heart Association's and the European Resuscitation Council's guidelines to therapy. Their efforts define the standard; this text is an attempt to delineate state-of-the-art. Our efforts are complementary. One cannot hope to individualize therapy to the patient's benefit without excellent basic care, and international consensus provides this basis.

Our difficulty in treating cardiopulmonary arrest reflects a limited understanding of the pathophysiology of global ischemia and reperfusion. Physicians are naturally uncomfortable in using therapies that are poorly understood and that have not been clearly demonstrated effective. However, these patients do not allow us the luxury of waiting for more definite knowledge. We must apply all our skill and limited knowledge immediately if persons with "hearts and brains too good to die" are not to be lost forever.

This text is for clinicians who wish to practice both the science and the art of resuscitation. Every physician will at some time attempt to resuscitate a patient from sudden death, but few will have had the opportunity to learn from teachers dedicated to this skill. That is the purpose of this book. In each chapter, a recognized authority has been asked not only to review present knowledge, but also to describe the state of their art. Cardiac arrest patients do not have the luxury of seeking out experts. You must bring that expertise to the bed or curb side.

This is intended to be a comprehensive text incorporating critical analysis of material not readily available elsewhere. The text begins with chapters that place our current knowledge into context, describing the magnitude of the problem. The next two sections describe the basic science of ischemia and reperfusion at the cellular, organ system, and organismal levels and the pathophysiology of cardiopulmonary arrest and resuscitation. The fourth and fifth sections focus on state-of-the-art therapy for cardiopulmonary arrest, first without respect to etiology and then under specific circumstances. Contributors were asked to provide insights that complement widely disseminated guidelines. The sixth section focuses on the pathophysiology and therapy of postresuscitation syndrome, a complex disease state that is increasingly believed to underlie the morbidity and death following resuscitation. The therapy sections conclude with summaries intended to bring together concepts discussed throughout the chapters on cardiopulmonary resuscitation and postreperfusion syndrome.

We are at the beginning of what will be a rapid expansion in our knowledge of the pathophysiology and therapy of sudden death, global ischemia, and reperfusion injury. This text is intended not only to reflect the field, but also to affect it. We hope to convince the reader that there is art even in the management of this, the most dire medical emergency. "Life is short and the art is long." Considering the millions of lives that are cut short and the limits of our knowledge, the art must be very long indeed.

The Editors

Preface to the second edition

O, that I could but call these dead to life!

King Henry VI
William Shakespeare

Death in the midst of life is the adversary of physicians. For millennia the loss of signs of life was considered the victory of death. Students were taught, and people believed, that once patients had succumbed they were beyond the healing arts. On a historical time frame, only relatively recently have physicians regularly attempted to wrest such patients back from death. We believe that the second edition of this text represents yet another step in resuscitative medicine's coming of age.

There is a no more frightening experience for clinicians than a patient's sudden loss of vital signs. The need to initiate multiple complex therapies, knowing that each minute that passes dramatically decreases the chances for a good outcome, makes sudden death the penultimate medical emergency.

It is difficult to obtain accurate numbers, but it is said that more than 300 000 persons die each year from sudden cardiac death in the United States alone. Worldwide the number is in the millions. Sudden death is not, however, caused by coronary artery disease alone. Hemorrhage and asphyxiation, among others, can kill physiologically competent patients without warning. Sudden death is not defined by etiology, but rather by the setting in which it occurs in a person with functional vital organ systems. It is not the natural ending of life, but death in the midst of life, and it is always tragic.

We are just beginning to appreciate the magnitude of this problem and the potential for therapy. Even a small improvement in outcomes of these patients – something that could be achieved in many communities by better application of established interventions-would save more lives than therapies that have received far more attention.

The potential for good is astounding; the relationship of benefit to cost for some interventions is compelling.

If we acknowledge that sudden cardiopulmonary arrest may be among the most difficult conditions that confront rescuers, then remarkable improvement in the standardization of care has been achieved in a relatively short time through the efforts of national organizations which have developed evidence-based guidelines for resuscitative therapy. Their efforts have defined the current standard. This text is an attempt to disseminate the state-of-the-art. We believe that these efforts are complementary, as one cannot hope to enhance therapy to the patient's benefit without international consensus on excellent basic care.

Remarkable progress has been made since the first edition. It has become clear that the treatment of lost hemodynamics is optimized by good and uninterrupted chest compression. A number of studies now indicate that simply removing interruptions can dramatically improve the rate of return of spontaneous circulation. At the same time, it appears that the application of mild hypothermia initiated after restoration of circulation can improve the neurologic outcome of cardiac arrest patients to a degree unanticipated only a few years ago. The combination of the improved chest compression and mild hypothermia has led to preliminary reports of intact survival in more than 50% of patients suffering out-of-hospital sudden death. We must admit that, even as enthusiasts of resuscitation medicine, we did not dream that improvements of this magnitude would occur for decades to come. Confirmation of this improvement in well-controlled clinical trials would mark an important event in medical history.

Our continued difficulty in treating cardiopulmonary arrest reflects ongoing limitations in our understanding of the pathophysiology of global ischemia and reperfusion. Yet the past few years have seen remarkable progress. Better understanding of the reperfusion event, reflected in delineation of phenomena such as programmed cell death, and the genomic and proteomic patterns during reperfusion, can only lead to even greater improvements in outcome. But we really do not understand fully the pathological processes that are taking place in these patients, and physicians are naturally uncomfortable in using therapies that are not fully understood and have not been clearly demonstrated to be effective. Nonetheless, the precarious status of these patients does not allow us the luxury of waiting for more definitive knowledge. We must apply all our skills, and our limited knowledge, immediately if persons with "hearts and brains too good to die" are not to be lost forever.

This text is for clinicians who wish to practice both the science and the art of resuscitation medicine. Every physician will at some time attempt to resuscitate a patient from sudden death, but few will have had the opportunity to learn from teachers dedicated to this skill. That, ultimately, is the purpose of this book. In each chapter, recognized authorities have been asked to review present knowledge, and describe the state of their art. Cardiac arrest patients do not have the luxury of seeking out experts. They must rely on the basic knowledge of all physicians.

This is intended to be a comprehensive text incorporating critical analysis of material not readily available elsewhere. The text begins with chapters that place our current knowledge into context, describing the magnitude of the problem. The next sections describe the basic science of ischemia and reperfusion at the cellular, organ system, and organismal levels and the pathophysiology of cardiopulmonary arrest and resuscitation. The final sections focus on state-of-the-art therapy for cardiopulmonary arrest, first without respect to etiology and then under specific circumstances. Contributors were asked to provide insights that complement widely disseminated guidelines. The last section focuses on the pathophysiology and therapy of postresuscitation syndrome, a complex disease state that underlies much of the morbidity and death in these patients.

The last few years have seen acceleration in publications related to resuscitation. We may be at the end of the beginning of what may be looked back upon as a rapid expansion in our knowledge of sudden death, global ischemia, and reperfusion injury. We hope that the second edition of the text not only accurately reflects the field, but provides a foundation upon which it may advance.

Introduction

A history of cardiopulmonary resuscitation

Mickey S. Eisenberg[1], Peter Baskett[2], and Douglas Chamberlain[3]

[1] Department of Medicine, University of Washington, Seattle, WA, USA
[2] Formerly Department of Anaesthesia, Frenchay Hospital and the Royal Infirmary, Bristol, UK
[3] Prehospital Research Unit, School of Medicine, Cardiff University, UK

For much of recorded history, humans have viewed death as irreversible. For religious and scientific reasons it was considered impossible, or even blasphemous, to attempt to reverse death. It was not until the latter part of the eighteenth century that humans began to believe that resuscitation was possible. Another 200 years passed before the skills for resuscitation were developed to a degree that made the reversibility of cardiac arrest a practical reality in the 1960s. Many important observations and much real progress had nevertheless been made during the intervening years. But the clinical problems were poorly understood, the implications of new discoveries were not always appreciated, single components of life-saving were attempted in isolation, procedures that were potentially effective were often displaced by those of no value, and suitable technology was lacking. Resuscitation had to await its time. Nevertheless, its history is of interest and has important lessons for us today.

The earliest years

The first written account of a resuscitation attempt is that of Elijah the prophet. The story in the Bible tells of a grief-stricken mother who brought her lifeless child to Elijah and begged for help. Elijah stretched himself upon the child three times and, with the assistance of God, brought the child back to life. An even more detailed account of a resuscitation attempt is that of the prophet Elisha, a disciple of Elijah. The child of a Shunemite couple whom Elisha had befriended suffered from a severe headache. He cried out, "*Oh, my head, my head!*" and collapsed. Was this a subarachnoid bleed? The Bible gives no further clues. The boy

died several hours later. The frantic mother found Elisha who entered the house and:

. . . placed himself over the child. He put his mouth on his mouth, his eyes on his eyes, and his hands on his hands, as he bent over him. And the body of the child became warm. He stepped down, walked once up and down the room, then mounted and bent over him. Thereupon, the boy sneezed seven times, and the boy opened his eyes.

Some authorities speculate that the weight of Elisha compressed the child's chest and that Elisha's beard tickled the child's nose and caused subsequent sneezing! Perhaps this is the origin of the phrase "*God bless you*" following a sneeze.[1]

From biblical times until the Middle Ages, several people stand out in the quest to reverse sudden death. Among these is Galen (AD 130 to 200), who lived in Greece. His writings – more than 22 volumes – influenced medicine for the next 1300 years: until the sixteenth century he was considered the final authority on all matters related to health and disease. His experiments, conducted mostly on pigs and monkeys (human vivisection was taboo!), constituted a fund of anatomical and physiological knowledge. Throughout the Middle Ages, there could be no divergence from the "truth of Galen" – however wrong he may have been in some of his writings.[2] Galen taught that the innate heat of life was produced in the furnace of the heart. It was turned on at birth and extinguished at death, never to be lit again. This strongly held belief, passed on through the centuries, is one reason why no one believed that death could be reversed. A non-breathing person was not receiving pneuma; the heart's furnace became permanently cooled.

1530 – Bellows Method

Fireplace bellows first used by the Swiss physician Paracelsus to introduce air into lungs. Variations used in Europe for 300 years.

Fig. 1.1. The bellows method of ventilation (courtesy of the Chicago Museum of Science and Industry).

With the end of the Western Roman Empire in AD 476, Western culture entered a millennium of intellectual stagnation that influenced every aspect of society, including medicine. The first stirring of modern scientific inquiry occurred during the Renaissance and reached fruition in the Enlightenment of the eighteenth century. The work of the two great anatomists of the Renaissance, Andreas Versalius and William Harvey, finally began to erode the inviolable "truth of Galen."

In 1543 Andreas Versalius (1514 to 1564), at 28 years of age, published *De Humani Corporis Fabrica*,[3] a remarkable treatise on human anatomy which began to discard the ancient Galenic superstitions. Versalius' ability to refute the statements of Galen was due largely to the availability of cadavers. The judge of the Padua criminal court became interested in Versalius' early work and in 1539 made the bodies of executed criminals available, apparently delaying executions for his convenience.[4] Although, strictly, he was not the first in the sixteenth century to describe artificial ventilation, he described how the lungs of animals collapsed after the chest was opened and that the heart was then affected.[3] But then:

. . . that life may. . . be restored to the animal, an opening must be attempted in the . . trachea, into which a tube of reed or cane should be put; you will then blow into this, so that the lungs may rise again and the animal take in air. . . I have seen none. . . that has afforded me greater joy!

Versalius must be considered the true father both of modern anatomy and of resuscitation. Sadly, his heterodox views were widely condemned. To avoid execution, allegedly for conducting an autopsy on a nobleman whose heart was seen to be beating, he set out on a pilgrimage to the Holy Land but died before he was able to return.[4–6]

As is so often the case, a new idea emerges almost simultaneously from more than one source. The illustration on the use of bellows for artificial ventilation (Fig. 1.1) is from the frontispiece of the 1974 American Heart Association publication on standards for cardiopulmonary resuscitation;[7] it has a notation that the method dates from 1530. It was in that year, 13 years before the publication of Versalius' great work, that Paracelsus[8] was said to have used the technique in an apnoeic patient. But he, too, was a controversial figure, driven out of Basel to wander through Europe, eventually to meet a violent death.[9,10] He had much less influence on subsequent events than did Versalius. Indeed, no firm evidence exists to confirm the belief that Paracelsus was responsible for the use of bellows for ventilation or indeed wrote on the topic at all![2]

In the following century, the pace of progress quickened. The English physician William Harvey, who had studied in Padua 60 years after Versalius, was the first to provide a definitive description of the circulatory system in *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus*.[11] *De Motu Cordis*, as it is commonly known, wrought a revolution in medicine and biology after it was published in 1628 with only 17 brief chapters and 72 pages. Robert Hooke was among a group of gifted all round British scientists in the latter part of the seventeenth century, which included Robert Boyle, Isaac Newton, Thomas Willis, and Christopher Wren.[12] He was a prominent member and Curator of the Royal Society which had been founded in 1660. In October 1667, Hooke demonstrated to the members of the Society – using a dog – that the movements of the heart and lungs were independent of each other but that the action of the heart was entirely dependent on lung inflation with air.[13] Hooke also experimented with combustion and showed that fresh air was essential for burning charcoal and that "satiated air" would not support combustion. One hundred years before the discovery of oxygen, Hooke drew the analogy between fresh and "satiate" in combustion and in respiration in animals "*who live no longer than they have fresh air to breath.*"[14]

By the eighteenth century, the stage was set for an explosion of experimentation and growth in knowledge about the human body. This burgeoning of scientific discovery and the development of the scientific method occurred during the period known as the Enlightenment. Its leaders claimed that the means to discover truth was through the scientific method. The rise of secularism and the concomitant rise of science allowed the first attempts at resuscitation to be made. In the mid 1700s the four main components of resuscitation (artificial ventilation, artificial circulation, electricity, and emergency medical services) began to emerge. They would eventually develop and coalesce, giving us the ability to reverse death.

The search for artificial ventilation

Deaths during the eighteenth century must be placed in their medical context. People did not generally die from cardiovascular disease; they died principally from accidents, infectious disease, drowning, and smoke inhalation from fires. One of the first accounts of mouth-to-mouth resuscitation appeared in 1744,[15,16] although the event actually took place in 1732. A Scottish surgeon named William Tossach was called to a man overcome by

nauseous steam arising from coals set on fire in the pit. His skin was cold, there was not the least pulse in either heart or arteries and not the least breathing could be observed. I applied my mouth close to his and blew my breath as strong as I could, but having neglected to stop all his nostrils, all the air came out of them, wherefore taking hold of them with one hand . . . I blew again my breath as strong as I could, raising his chest fully with it and immediately I felt six or seven beats of the heart.

Tossach added that the man had walked home 4 hours later. Tossach modestly commented that his technique "*is at least very simple, and absolutely safe, and therefore can at least be no harm, if there is not an advantage in acquainting the publick of it.*" John Fothergill, a London practitioner, did feel when he learned of the incident in 1745[17] that for facts of such great importance it is the duty of everyone "*to render them as extensively public as it is possible.*" And so indeed he did, with a list of indications for its use that included suffocation in water.

Drowning was by then a matter of great and growing concern. Fothergill, together with wealthy and benevolent gentlemen in Holland, was influential in the formation in 1767 of a Society for the Recovery of Drowned Persons in Amsterdam (*Maatschappy tot Redding van Drenkelingen*), later called the Humane Society (Fig. 1.2a). One year after its establishment, magistrates in Milan and Venice began

similar societies. In 1769, the city of Hamburg passed an ordinance providing notices to be read in churches describing assistance to be given to drowned, strangled, and frozen persons and those overcome by noxious gases. Paris began a rescue society in 1771, followed by London (Fig. 1.2b) and St. Petersburg in 1774.[18] Within 4 years of its founding, the society in Amsterdam claimed that 150 persons were saved by their recommendations.[19] The members of the society recommended: (*a*) warming the victim; (*b*) removing swallowed or aspirated water by positioning the victim's head lower than feet, applying manual pressure to the abdomen, and tickling the victim's throat; (*c*) stimulating the victim by such means as rectal and oral fumigation with tobacco smoke; (*d*) using a bellows or mouth-to-mouth method (mouth-to-mouth or mouth-to-nostril respiration is described including the advice that "*a cloth or handkerchief may be used to render the operation less indelicate*"); and (*e*) bloodletting. In general, 6 or more hours were considered a reasonable duration for a resuscitative effort.[19,20]

Unfortunately, mouth-to-mouth ventilation was soon discouraged by the Royal Humane Society of London. This was partly on aesthetic grounds, a consideration even today, but also because Priestley had discovered by 1774 that the composition of expired air was different from that which was inhaled – and therefore "*unfit to enter any lungs again.*"

Although some recommendations for mouth-to-mouth ventilation continued through the nineteenth and early twentieth centuries,[21] it was well out of fashion and virtually forgotten. William Hunter considered it to be "*a method practised by the vulgar.*"[22] So it was that the Royal Humane Society in 1782, less than 10 years after it had been formed, recommended bellows once again in preference to mouth-to-mouth ventilation.[18] By this time, the technique had been developed and refined. In 1776, John Hunter (the brother of William Hunter who guided his early career) had presented to the Society the results of experiments in which bellows were designed to be introduced into one nostril, while at the same time the other nostril and the mouth were occluded. Its mechanism generated both positive and negative pressure.[23] It is noteworthy that John Hunter had also gained considerable experience in humans and made attempts to revive persons who had been hanged as a judicial process.[24]

But using bellows to blow into the nose was clearly not satisfactory, nor universally accepted. The Versalius technique of tracheal intubation was becoming fashionable again, even while bellows and the mouth-to-mouth methods were still in vogue. There were very full details of the technique in a letter from Dr William Cullen[25] dated 1776: "*Dr. Monro informs me, it is very practicable to introduce directly into the glottis and trachea a crooked tube such*

Fig. 1.2. (a) An account of the founding of the Amsterdam Rescue Society in 1767.
(b) Cover of *Royal Humane Society of London Transactions*, showing medals awarded to rescuers (by courtesy of the Society).

as a catheter used for a male adult." Dr. Monro, a professor of anatomy, had other prescient views, for in the same letter we read:

Whether blowing in is done by a person's mouth or by bellows, Dr. Munro opines that the air is ready to pass by the gullet into the stomach, but that this may be prevented by pressing the lower part of the larynx backwards upon the gullet. To persons of little knowledge of anatomy it is to be observed that the pressure should be only on the cricoid cartilage, by which the gullet may be flattened, while the passage through the lungs is not obstructed.

Cricoid pressure became accepted in anesthesia and in resuscitation 185 years later after its description by Sellick,[26] but he and others subsequently became aware of Dr. Munro's earlier recommendation.[27]

Despite all the shortcomings and ill-advised notions on treatment, efforts to prevent death from drowning were nevertheless effective. Herholdt and Rafn[28] reported in a landmark publication of 1796 that 990 lives had been saved by 1793, with a survival rate over the previous 9 years of 50%. The efforts showed commitment and ingenuity. The amphibious craft illustrated in Herholdt and Rafn's book (Fig. 1.3) was used to move quickly over rough ice to reach drowning victims; if the ice gave way, the rescuer himself would not be at risk because he had a safe haven all around him. The value of postural drainage to empty the lungs was, however, more controversial, especially as it was recognized that the lungs even in fatal cases might remain relatively dry.

By this time, interest had been aroused not only in resuscitation but also in the numbers being treated. Charles Kite was an active member of the London Humane Society who wrote an Essay on the Recovery of the Apparently Dead in 1778 describing the epidemiology of drowning for which he

Fig. 1.3. An amphibious rescue craft designed for work on ice.

was awarded the Silver Medal of the Society.[29] He has been described as the father of resuscitation epidemiology.[30] He emphasized the need to keep accurate records and the need for speedy intervention. He advocated artificial ventilation with warm air or "*dephlogisticated air*" (see below) and suggested cricoid pressure and treatment of cardiac arrest with electric shocks. He was a methodical person and designed a pocket resuscitation kit in a case with "*a collection that comprehends every article except an electrical machine*" and also a description of the correct way to use these instruments[31] "*. . .it will prove a very considerable acquisition to the resuscitation air.*" He practiced his theories and describes vividly his experience of a remarkable recovery from drowning in a soldier with a head injury.[32]

At this time, the concepts of fresh and satiated air, set down by Versalius and Hooke two and one centuries earlier, were refined by three scientists working in different countries and more or less independently, although they had some contact. Although the credit for discovering oxygen is usually given to Priestley (1775)[33] from England and Lavoisier from France (1775),[34] it is now agreed that Carl Scheele, a Swedish chemist working in Germany was the first to isolate "*fire air*" in 1772 and 1773. He demonstrated that this was essential for plants to live but could not make an accurate analogy with human respiration. He was slow to publish his findings and his paper of 1777[35] followed that of Priestley who had published his work 2 years earlier in 1775.[33]

Priestley was a Yorkshireman who had trained as a priest and a teacher but had a passion for the composition and chemistry of gases.[36] In 1774, while acting as librarian to the Earl of Sherborne, Priestley had collected a colorless odorless gas from heating red mercuric oxide with sunlight focused through a 12-inch burning lens. He had isolated oxygen but did not call it that – he called it "*dephlogisticated air*" and recorded that it supported combustion vigorously and that a mouse survived in a sealed container filled with this gas for much longer than in atmospheric air. He inhaled the gas himself and "*I fancied that my breast felt peculiarly light and easy for some time afterwards.*"[37]

Lavoisier was born in Paris and studied both law and a wide spectrum of scientific subjects, including geology, mineralogy, electricity, anatomy, biology, chemistry, botany, and weather forecasting.[36] In 1766, he was awarded a Gold Medal by the King for the design of a new form of street lighting for Paris. Lavoisier was aware of the work of Scheele and Priestley but branched out further. He was able to demonstrate that "*air eminently respirable*" or "*fire air*" or "*dephlogisticated air*" was an element, and that when combined with hydrogen it formed water. This newly discovered element was renamed oxygen. He undertook a number of experiments that showed that oxygen was consumed during respiration and carbon dioxide and heat were produced, especially during exercise and after a robust meal.

Both Priestley and Lavoisier were liberals and supported the French Revolution. This was not to stand them in good

stead. Priestley was vilified in England and had to emigrate to the United States where he died in Pennsylvania in 1804. Lavoisier was beheaded in public (immediately after his father-in-law). Joseph-Louis Lagrange is quoted by Wilkinson[36] as having said "*It took only an instant to cut off that head but it is unlikely that a hundred years will suffice to produce a better one.*"

In the middle of the nineteenth century, a major change occurred in artificial respiration. Marshall Hall (1790 – 857), a physician in London, advocated the use of mechanical expansion and compression of the chest wall. In his paper *Asphyxia, its rationale and its remedy* of 1856,[38] he criticized the Royal Humane Society's techniques, and recognized that in a supine position the victim's tongue and larynx fell back and blocked the airway. His method involved repeatedly shifting the victim's position from prone (expiratory) to side (inspiratory) 15 times a minute.[39] Over the next 100 years, dozens of other mechanical methods were promoted. Henry Silvester, a London physician, advocated raising the victim's arms above the head to expand the upper rib cage and then placing them on the chest and applying pressure to cause exhalation.[40] A New York physician, Benjamin Howard, described what he called the direct method in which the victim was placed on his or her back while a bystander held the tip of the tongue.[41] The rescuer knelt astride the patient's hips and pushed into the upper abdomen and squeezed the ribs at a rate of 15 times per minute. In 1890, the Royal Medical and Chirurgical Society in England formed a committee under the chairmanship of Sir Edward Sharpey-Shafer to evaluate current methods but concluded that they were all inadequate.[42] (Schafer has caused confusion by adding Sharpey to his name in honor of his teacher in anatomy and physiology, William Sharpey.) Although essentially an histologist and the author of the standard textbook of the time, *Essentials of Histology*, which had appeared in 1899 and continued through 17 editions until 1953,[43] Shafer also had a profound interest in artificial respiration. He developed a new method[44] with intermittent pressure on the back of the prone victim which he believed not only achieved adequate gas exchange, but also maintained an open airway, allowed water and mucus to drain away, posed no other risk to other organs, was easy to learn, and could be performed without fatigue. Schafer did comparative experiments on his laboratory assistant using each of the methods devised by Hall, Silvester, Howard, and himself and claimed that his own method produced by far the best expired minute volumes (6.76 L). Although this method faced considerable opposition (and some said that perhaps Schafer's laboratory assistant was too keen to please his professor[45]), it gradually became a standard, both throughout much of Europe and in the United States, and

was not dropped from the First Aid Textbook of the American Red Cross until 1959 when the whispers of its detractors rose to a clamor.[46]

The methods used for mechanical artificial respiration did vary, however, on a geographical basis. Silvester's method was followed in Germany,[47] Holland, and Russia, whereas Schafer's method was followed in the United States, England, France, and Belgium.[48] Colonel Holger Nielsen, in Denmark, believed that the best solution to the controversy was to develop yet another method that combined the best features of both the popular techniques. His original plan was to have two rescuers: one was to perform prone pressure on the lower back to cause exhalation, whilst the other rescuer was to lift the arms above the victim to facilitate inhalation. The Danish Red Cross rejected this proposal in 1930 because it could not be performed by a single person. Nielsen went back to the drawing board. Apparently, his breakthrough came when he visited a masseur for relief from rheumatic pains in his shoulders. Nielsen noticed that when the masseur pressed down on his shoulder blades he experienced a forceful expiration. This personal experience led him to suggest in 1932 that a single rescuer be positioned at the head of the victim, alternating pressure on the upper back for expiration with arm lifting for inhalation. He presented physiological data to support the superiority of his prone back pressure–arm lift method over Schafer's or Silvester's techniques. Acceptance of Nielsen's method by Red Cross societies was rapid. Instruction in the new artificial respiration spread throughout Europe and to the United States.[48]

Frank Eve, a physician who practiced in Hull in Yorkshire, adopted a different approach.[49] He regarded the thorax as a cylinder with a piston, the diaphragm. He noted that the cylinder wall is often rigid, especially in elderly men and in victims of drowning. He believed it was better to exploit the piston element

Essentially the method consists of laying the patient on a stretcher which is pivoted about its middle on a trestle and rocking up and down rhythmically so that the weight of the viscera pushes the flaccid diaphragm up and down.

Eve produced case reports in 1932[50] to support his rocking method and experimental evidence in 1933[51] claiming tidal volumes of 650 ml – much greater than the various chest compression and arm lift methods. His technique was officially adopted and endorsed in the United Kingdom by the Royal Navy during the Second World War, before being superseded by the expired air method.

In 1949, Archer S. Gordon began evaluating different methods of artificial respiration to determine which was most effective. Gordon's research included measurements

on fresh corpses from the adult wards of Cook County Hospital in Chicago. With no research funds available at first, Gordon worked with no salary and, since he was on-call 24 hours, slept in his supervisor's office. He later recalled: *"When I received a call that a patient had expired, I rushed across the street, got my cart of equipment, rushed to the ward, moved the corpse to a secluded examining room, and proceeded with my studies."* Gordon would insert a tube into the trachea and connect it to a respirometer; it was long before the days of sophisticated electronic measurement devices. He measured the results of his experiments on the smoked drums of a kymograph. Not only did he smoke the paper for the drums himself, but also after each case he would shellac the tracing in order to preserve the record. Gordon's early results were published in 1950.[52]

Meanwhile, the US Defense Department became interested in his work; some form of manual resuscitation might help soldiers stricken by nerve gas. At the instigation of the military, Gordon began working with live subjects. He anesthetized medical student volunteers and paralyzed them with curare in order to carry out procedures similar to those used on corpses. By 1951, his considerable bank of data had shown that a modified Holger Nielsen method of manual respiration surpassed all others that he had tested, in terms of efficacy and ease of performance learning. In a subsequent paper,[53] Gordon alluded to mouth-to-mouth and mouth-to-nose artificial respiration, but stated that because of the "*difficulties involved in studying and teaching the method, it has not been included in these tests.*" It was a missed opportunity. Had Gordon included mouth-to-mouth ventilation in his tests, he would have found it to be far superior to any of the manual methods.

Gordon's research came after 200 years of experiments in artificial respiration. In 1953, Karpovich was able to list 105 published methods recommended for adults and 12 for infants.[1] With the cacophony caused by the advocates of so many methods, and with none being truly effective, it is no wonder that confusion, argument, and controversy ruled. Many of the experiments by Gordon and others were done with tracheal tubes in place, thanks to the inventiveness of Kuhn,[54] Magill,[55,56] and Mackintosh[57] and thus the problem of obstructed airway was never taken into account. Even if the airway was not obstructed, these techniques resulted in air exchanges well below that which was needed to sustain life. In the early 1950s, the world awaited a better method.

The kiss of life

James Elam was the first contemporary investigator to prove that expired air was sufficient to maintain adequate oxygenation, when he used mouth-to-nose breathing on patients with acute poliomyelitis paralysis during an epidemic in Minnesota in 1946.[58] These episodes invariably occurred at times of equipment failure or when patients arrived in the hospital with acute respiratory paralysis.

Elam chose mouth-to-nose ventilation because he believed it was the obvious thing to do in such emergencies. He described his first experience in detail:[59]

I had just gotten to Minneapolis . . . and I was browsing around to get acquainted with the ward when along the corridor came a gurney racing – a nurse pulling it and two orderlies pushing it and the kid on it was blue. I went into total reflex behavior. I stepped out in the middle of the corridor, stopped the gurney, grabbed the sheet, wiped the copious mucous [sic] off his mouth and face, tilted his head back, took a big breath, sealed my lips around his nose, and inflated his lungs. In four breaths. I kept on because they had to do a tracheostomy. He was just totally unable to swallow; he had bulbar polio.

With a zealot's passion he spoke of the value of mouth-to-nose ventilation whenever he could, drawing attention to the ineffectiveness of the Holger Nielsen method. To prove that exhaled air was adequate to oxygenate a non-breathing person, Elam obtained permission to do studies on postoperative surgical patients before they recovered from ether anesthesia. The tracheal tube was left in place and succinyl choline was continued as a drip. Elam found by blowing into the tube with his expired air that normal arterial oxygen saturation could be maintained in the patients. After he had published his results in 1954,[60] the US Army Chemical Center in Edgewood, Maryland, recognized the potential value of Elam's findings as a method for ventilating victims of nerve gas (anticholinesterase) poisoning. Although impressed by a successful technique that required no respiration equipment, the Army could not endorse the technique without the blessing of the National Research Council. The Red Cross, meanwhile, was unconvinced that expired air resuscitation was superior to other techniques: manual methods continued to prevail.[61]

By good fortune, Peter Safar joined James Elam on a long car journey from an anesthesia meeting in Kansas City to their homes in Baltimore in October 1956; their 2 days together led to a collaboration that was to change resuscitation practice for ever. Safar was stimulated to become involved in resuscitation research and began a series of experiments on curarized volunteers to see if mouth-to-mouth artificial respiration was effective. By the spring of 1957, he had proved conclusively three essential points in relation to artificial ventilation:[62] first, simply tilting a person's head backward would usually open the airway; second, most existing manual ventilation techniques provided little air, whereas mouth-to-mouth provided

excellent artificial ventilation; third, mouth-to-mouth resuscitation could be performed easily and effectively.

Review (ethics) committees did not exist at the time of Safar's experiments on human subjects; the chief investigator was responsible for ensuring the safety of subjects and for the ethical conduct of research. Safar was well aware of the potential risks. He went to great lengths to explain the experiment to the subjects, instituted multiple safeguards to ensure their safety, and supervised each experiment himself. The volunteers were heavily sedated and thus were not conscious of their paralysis, which generally lasted 1 to 3 hours. All subjects breathed a combination of 50% oxygen and 50% nitrous oxide and were closely monitored. No one was allowed to remain in a non-breathing state for more than 90 seconds, and the high oxygen content of the blood (from breathing 50% oxygen) made this safe.[62]

Within a year, Elam, Safar, and Gordon convinced the world to switch from manual to mouth-to-mouth methods.[63] A 1958 issue of *J. Am. Med. Assoc.* contains the following endorsement:[64]

Skilful performance of expired air breathing is an easily learned, lifesaving procedure. It has revived many victims unresponsive to other methods and has been proved in real emergencies under field conditions. Information about expired air breathing should be disseminated as widely as possible.

The invention of the self-inflating bag valve mask by Ruben in 1957 provided a key advance in artificial ventilation that was independent of compressed gas and the aesthetic drawbacks of the mouth to mouth method.[65,66] It became, and remains, the optimal method for healthcare professionals to provide artificial ventilation in the emergency situation.

The search for artificial circulation

Probably the first mention of chest compression to treat cardiac arrest appeared in a dental journal – written by John Hill, an English surgeon, in 1868.[67] He treated patients aged 72, 12, and 8 – all of whom were recognized as having lost both respiration and circulation as a result of chloroform. The front of the chest was compressed forcibly three times each 15 seconds, and the inspiration that followed a rapid release was used to administer ammonia (now known to be a potent venoconstrictor!). All survived; the younger child regained a pulse only after 15 minutes of treatment and relapsed once – but nevertheless made a slow recovery over several days. Better known is the 1883 recommendation of Professor Franz Koenig to use

sternal compression for artificial ventilation.[68] Eight years later, Dr. Friedrich Maass, one of his assistants, performed compressions in two patients intentionally to counter chloroform-induced cardiac arrest.[69] One case involved an 18-year-old man who had lost his pulse during induction of anesthesia and was regarded as dead. Maass initially tried a slow rate of chest compressions to simulate respirations, but, when the situation did not improve, he increased the rate to 120 compressions per minute and noted a carotid pulse. Within 25 minutes the patient achieved a spontaneous pulse and blood pressure. After the man recovered Maass operated on him without complications. Maass concluded: "*So long as compression is applied at the speed of the patient's breathing, slow deterioration. When compression is speeded up, gradual improvement follows. . .*" Maass later described his technique thus:

One steps to the left side of the patient facing his head, and presses deep in the heart region with strong movements . . . The frequency of compression is 120 or more per minute. The effectiveness of the efforts is recognized from the artificially produced carotid pulse and the constriction of the pupils.

External chest compressions survived, predominantly in Germany, for several more decades,[70] but it was used in association with the inefficient methods of artificial ventilation by then in vogue and failed to become well established. Case reports were not widely available because they were published only in German or French, but more importantly the technique could not be successful in most cases of cardiac arrest until defibrillation was developed. No therapy, regardless how innovative, was likely to gain widespread acceptance if it rarely or ever succeeded. Moreover, the relationship between heart disease, ventricular fibrillation, and sudden death was not appreciated until well into the twentieth century. As a result, the role of chest compression to support an artificial circulation was largely ignored until it was rediscovered in 1960.

Open chest cardiac massage was also introduced relatively late, despite the cardiac arrests that occurred during anesthesia. Although Moritz Schiff had practiced and described the technique under experimental conditions and chloroform anesthesia in 1874,[71,72] the first recorded attempt in man was by Niehans in Berne – recorded by a colleague in 1903.[73] But the first definite success had occurred 2 years earlier in Tromsø: it was described only after Igelsrud told a colleague of it when he visited the USA.[74] Interest in open cardiac massage continued for a while. Green in 1906[75] described 40 cases that were by then in the literature, of which nine had been "entirely successful" and eight others had shown transient recovery of pulse and respiration. But

it was never a procedure that, by itself, would have a high success rate, nor could it be widely applied.

The accidental rediscovery of artificial circulation occurred in William Kouwenhoven's laboratory at Johns Hopkins University in Baltimore.[76] Kouwenhoven and Guy Knickerbocker were studying fibrillation in the hearts of anesthetized dogs. In one series of experiments they wanted to determine how long they could leave a dog's heart fibrillating and still achieve defibrillation successfully. On this particular occasion they had taken an anesthetized dog and inserted a catheter into the femoral artery to measure its arterial blood pressure. While observing the dog's fallen arterial pressure, Knickerbocker applied the defibrillator's paddles to the animal. He noticed a blip on the blood pressure indicator. The force of the application of the paddles to the dog's chest had caused a pulsation of blood and a momentary increase in arterial pressure apparently. Knickerbocker called Kouwenhoven over, and they both observed the phenomenon. By repeatedly applying the paddles, they were able to extend the period of time the dog's heart was in fibrillation from approximately 1 minute to several minutes and still successfully achieve defibrillation.

Several weeks after the initial observation, James Jude, a surgical resident at the time, joined the team. All three soon realized that they could use their hands to apply pressure to the chest and achieve artificial circulation. At first it was not at all evident where to compress the chest. Should it be side to side? front to back? on the upper chest? lower chest? Through a series of experiments in late 1958 the team discovered that the best procedure was to apply rhythmic pressure on the lower part of the sternum and press straight down using the heel of the hand. Other locations led to higher rates of complications, including lacerations of the liver, stomach, or lungs. They repeatedly measured actual arterial pressures and through trial and error discovered that the optimal depth of compression should be 1 to 2 inches and the best rate of compression was approximately 60 to 80 per minute.[61] Their success with dogs led the three experimenters to consider trying the technique on humans. Jude and other residents began applying the experimental results to living patients. The first person to have this lifesaving procedure, recalled Jude, was described as follows:[77,78]

. . . rather an obese female who was having a cholecystectomy and was being held in the emergency room just before surgery. The patient went into cardiac arrest as a result of fluothane anesthetic . . . This woman had no blood pressure, no pulse, and ordinarily we would have opened up her chest and done direct cardiac massage. Instead, since we weren't in the operating room, we applied external cardiac massage and they immediately switched back to

straight oxygen in ventilation. Her blood pressure and pulse came back at once. We didn't have to open up her chest. They went ahead and did the operation on her, and she recovered completely.

In 1960 the three investigators reported their findings on 20 cases of in-hospital cardiac arrest.[76,79] Fourteen of the 20 patients (70%) survived and were discharged from the hospital. Many of the patients were in cardiac arrest as a result of anesthesia. Three patients were documented to be in ventricular fibrillation. The duration of chest compression varied from less than 1 minute to 65 minutes. The article was very clear: chest compression buys time until the external defibrillator arrives on the scene. As the authors write in the article: "*Anyone, anywhere, can now initiate cardiac resuscitative procedures. All that is needed is two hands.*" However, respiration or ventilation received relatively little attention in the 1960 article. Many of the patients had been intubated. Soon, however, chest compression formally 'married' mouth-to-mouth ventilation: the couple's new name was CPR.

The birth of cardiopulmonary resuscitation

Ventilation and compression combined

Between 1958 and 1961 artificial respiration was combined with artificial circulation to create CPR. The period began with demonstrations that mouth-to-mouth ventilation was effective for artificial respiration and chest compression was effective for artificial circulation. Now all that was needed was the formal connection of the two techniques to create CPR as it is practiced today. And that took place at the scientific level when Safar, Hackett, Jude, and Kouwenhoven presented their findings at the Maryland Medical Society meeting held on September 16, 1960 in Ocean City. In the opening remarks the moderator said: "*Our purpose today is to bring to you, then, this new idea.*" It was so new that it was still without a name. The moderator stated that the two techniques "*cannot be considered any longer as separate units, but as parts of a whole and complete approach to resuscitation.*"[80] In his remarks Safar stressed the importance of combining ventilation and circulation. He presented convincing data that chest compression alone did not provide effective ventilation; that required mouth-to-mouth respiration.

To promote CPR, Jude, Knickerbocker, and Safar began a world speaking tour. In 1962 Gordon, along with David Adams, produced a 27-minute training film called *The Pulse of Life*. The film was used in CPR classes and viewed by millions of students. For the film, Gordon and Adams devised the easy to remember mnemonic of A, B, and

C standing for the sequence of steps in CPR: airway, breathing, circulation. In 1963, the American Heart Association formally endorsed CPR. Three years later, the National Research Council of the National Academy of Sciences convened an *ad hoc* conference on cardiopulmonary resuscitation. The conference was the direct result of requests from the American National Red Cross and other agencies to establish standardized training and performance standards for CPR. Over 30 national organizations were represented at the conference; its recommendations were reported in *J. Am. Med. Assoc.*[81]

From electrical therapy to defibrillation

The discovery of electricity is obscured by antiquity, but the ancient Greek and Chinese civilizations were aware of magnetic properties of lodestones. But for 2000 years no progress occurred in the understanding of magnetism or electricity. Superstition and the occult ruled. The Renaissance allowed scientific inquiry to begin, and superstitions slowly began to crumble. William Gilbert (1544 to 1603), physician to Queen Elizabeth I, performed the first experiments that clarified the properties of magnets and electrostatic charges and published *De Magnete* in 1600.[82] Gilbert gave us the word electricity.

By the middle of the eighteenth century, electricity was thought to be so pervasive that it was considered to be the fifth element after fire, water, earth, and air. In 1743, Johann Gottlob Kruger who was Professor of Medicine at the University of Halle wrote omnisciently: ". . . .*through electrification, changes in the deepest regions of the human body can be brought forth.*" Electricity, he claimed, would be *"a new kind of cur,"* and he called for experiments to demonstrate its effect on life. Kruger predicted a benefit of electricity in the treatment of paralyzed limbs. Electricity would function "*just as one uses flagellation with nettles to restore sensation and reestablish the power of motion.*" Kruger's lecture and subsequent publication on the application of electricity to medicine earned him the title of founding father of electrotherapy.[83]

Kruger's contemporaries soon began to recommend electricity for many different ailments. A student of Kruger's named Christian Gottlieb Kratzenstein reported the successful use of electrotherapy in paralysis in 1744. He wrote of "*a woman who lost the paralysis in her small finger within one quarter of an hour by electrification.*"[84] This unknown woman may have been the first person to benefit from electrotherapy. It was a humble beginning to a journey that would culminate 200 years later in Cleveland, Ohio, with the first successful defibrillation of a human heart.

An account of what was purported to be a human resuscitation by electricity had already been described in 1774 in the Register of the Royal Humane Society of London in relation to a child who had fallen out of a window and appeared to be dead:[85]

Mr. Squires tried the effects of electricity. Twenty minutes elapsed before he could apply the shock, which he gave to various parts of the body in vain; but, upon transmitting a few shocks through the thorax, he perceived a small pulsation; in a few minutes the child began to breathe with great difficulty. . .

Kite provides an illustration of the device likely to have been used by Mr. Squire to resuscitate the child (Fig. 1.4).[86] Kite's device may properly be called a proto-defibrillator. All of the elements of a modern defibrillator are there: it had a source of energy in a Leyden jar that served as a capacitor; an electrometer functioned as the energy setting; brass knobs served as the electrodes; metallic strings were equivalent to the cables; and glass or wooden tubes served as insulators to prevent the operator from being shocked. Or as Kite so delicately put it, "*In this manner, shocks may be sent through any part of the body . . . without a probability of the assistants receiving any inconvenience.*" But with the delays that had occurred and the nature of the event, it is hard to credit that fibrillation and defibrillation had occurred in this instance.

The history of true defibrillation may well go back to 1775, the year after Dr. Squires's experience. Abildgaard, a remarkable Danish veterinarian does not seem to be well known and deserves better recognition. An excellent account of his role in defibrillation and a translation from Latin of his relevant writings were published to commemorate the bicentennial of his experiments.[87] He wrote:

I took a hen, which I knocked down with the first shock directed to the head. . . it lay without feeling as if completely dead and was unable to be aroused by any stimulus. . . I tried an electric shock directed through the chest to the spine . . . it rose up and, set loose on the ground, walked about quietly on its feet. . . after the experiment was repeated rather often, the hen was completely stunned, walked with some difficulty, and did not eat for a day and night; then later it was very well and even laid an egg.

Why did he do such an experiment, and indeed was the hen really dead? His two further quotes seem to address these questions satisfactorily:

. . . all reports of men, slain by a bolt of lightning, state that nothing in such bodies, when dissected, was found which was sufficient to be called the cause of death. . . I took a different hen, along with the same cock, upon which I had conducted the second experiment. I left both on the ground. . . made lifeless by one shock. . . But on the next morning I found them completely dead and very cold, and I

was unable to revive them with the electrical machine with any amount of trying.

It is noteworthy that, while the capacitor discharge to the head was capable of killing a chicken, revival needed a discharge across the thorax. His work did not go unnoticed at the time, with at least two subsequent references in the literature including an anonymous comment in 1779[88] that was particularly prescient: that Dr. Abidgaard's experiments may lead to conjectures "*as to the cause of death from lightning, but also, perhaps, to important discoveries with respect to the means of recovery in such a case.*"

The potential of capacitors is limited. But in 1799, Alessandro Volta, Professor of Physics at the University of Pavia, used the principle of two dissimilar metals to generate electricity by creating the world's first electrochemical battery.[89] This followed from Galvani's discovery that the leg of a frog twitched when in contact with both iron and brass.[90]

Galvani's work made it obvious that electricity led to muscle contractions. Starting a stilled heart with electricity became an important goal of medical science. Physicians still had little understanding of the heart's electrical conduction system, but they knew it was a muscle. What was not clear, however, was whether an arrested heart could be restarted. The ability to restart a non-beating heart was essential if death were to be reversed. Many studies took place at the beginning of the 19th century, but the results

were contradictory and inconclusive. During the French Revolution, the French anatomist and physiologist, Xavier Bichat, realized the advantages of studying the issues of electricity and the heart on the bodies of victims of the guillotine. Bichat received permission from the revolutionary authorities to conduct electrical experiments on freshly decapitated bodies. He tried to stimulate the muscles and the heart using galvanism and chemical stimulants. He concluded that the heart could be excited reliably only by direct contact with electric stimulation.[82] Other French scientists performed similar experiments and reached somewhat contradictory conclusions. The time interval from death to the performing of the experiments, which was the most important factor explaining the heart's responsiveness, was often not taken into account. The importance of time was intensively studied in a special commission formed by the Academy of Turin in Italy. The conclusion of the committee was that the heart lost its ability to contract in response to electrostimulation 40 minutes after death.[82]

In 1804, Aldini, who was Galvani's nephew, wrote about the need to integrate artificial respiration and electric therapy. According to Aldini, electricity should be used immediately and not after a long period of artificial ventilation, the sequence recommended by most other scientists. Aldini wrote: "*Artificial respiration ought to be attempted but it should be accompanied by the application of Galvanic power externally to the diaphragm and to the region of the heart.*" He may thus have been the first to advocate a

combination that presaged modern CPR and defibrillation. Aldini freely admitted to ignorance about how electricity affects the heart, but "*. . that it does affect (the heart) has, I trust, been sufficiently demonstrated by experiments.*"[91]

The use of electricity for resuscitation and the need to apply it rapidly were evident in the advice of Richard Reece, a London physician. In *The Medical Guide* in 1820,[92] Reece described the optimal means of resuscitation. He wrote:

In cases of suspended animation what is necessary to be done should be done quickly; therefore, on the first alarm of any person being drowned or suffocated, while the body is searching for, or conveying to the nearest house, the following articles should be got ready: viz. warm blankets, flannels, a large furnace of warm water, heated bricks, a pair of bellows, warming-pan, sal volatile, clyster pipes, and an electrifying machine.

His book provides an example of such an electric machine and a description of the device by its inventor, de Sanctis. The device, called a *reanimation chair*, consists of a voltaic battery, a bellows to ventilate the lungs and a metal tube to be inserted in the esophagus for delivery of stimulating vapors. The three resuscitation items were packaged in a carrying case and available for purchase in a medical supply store in London. The bellows was to be inserted in the mouth and the nose clamped shut. An assistant was to press on the ribs to cause expiration after each ventilation with the bellows. The voltaic pile was to be suspended from a hook attached to the back of a chair. One wire from the battery was attached to the metal tube in the oesophagus, and the second wire was to be successively touched to "*the regions of the heart, the diaphragm and the stomach . . .*"[92] There is no record of anyone being resuscitated successfully by use of the reanimation chair. Nevertheless, the pathway of electric stimulation advocated by de Sanctis was not totally bizarre. Stimulation with an esophageal electrode was explored in 1956 as a means of achieving cardiac pacing; and in 1979 the first automatic external defibrillator was designed with a posterior pharynx–anterior chest pathway of current flow.[93]

Which route of electricity – chest, neck, or total body stimulation – was best for treating heart conditions provided a common source for debate in the nineteenth century. Many scientists and physicians claimed that total body electrification was most beneficial for cardiovascular disease and gave names to these types of therapy that sounded more scientific than they were. Electrohydriatics or electrobalneotherapy referred to immersion in a tub of electrified water. For a static bath with cephalic douche the patient sat in a dry tub with sparks applied to the head. Autoconduction, also known as inductothermia, involved standing inside a large circular solenoid cage, which used a high-frequency electricity of several hundred thousand oscillations per second. According to the inventor of such a device, "*These currents can be very powerful. They produce no pain or conscious phenomenon in the person treated. The current, nevertheless, acts very energetically on the tissues.*"[92] This treatment was similar in principle to microwaving the entire body! High-frequency treatments were especially popular in France from 1890 to 1930 and were used to treat diabetes, gout, obesity, and many other conditions.[82] Virtually every disease and malady, according to some authority, could benefit from electricity.

Little progress could be made in using electricity to counter sudden death until the most frequent underlying cause had been discovered. A lethal arrhythmia that we now know as ventricular fibrillation was first described in 1850 by Hoffa and Ludwig in Germany.[94] They demonstrated that strong galvanic or faradic currents applied directly to the ventricles of a dog's heart caused a disordered and ineffective action. This was given a variety of names: tremulations fibrillaires, delirium cordis, intervermiform (wormlike) movements, fibrillar contractions, herz-delirium, undulatory movements, and intervermicular actions. Ludwig was also known for his development of the kymograph (which became the direct precursor of the electrocardiogram), although he did not specifically use his kymograph to record ventricular fibrillation. It was considered only a curiosity with little relevance to humans.

John MacWilliam in a series of articles from 1887 to 1889 published in the *British Medical Journal*, made the first detailed descriptions of ventricular fibrillation. Until that time, it had been assumed that sudden cardiac failure took the form of quiet standstill. Experiments that MacWilliam performed on dogs refuted this idea. He described how tumultuous activity could have an effect similar to that of a motionless heart:[95]

In many of these cases the fatal issue is determined or ensured by the occurrence of fibrillar contraction in the ventricles. . . . A sudden, unexpected, and irretrievable cardiac failure may, even in the absence of any prominent exciting cause, present itself in the form of an abrupt onset of fibrillar contraction (ventricular delirium). The cardiac pump is thrown out of gear, and the last of its vital energy is dissipated in a violent and prolonged turmoil of fruitless activity in the ventricular walls.

McWilliam[96] was the first to speculate that fibrillation is the most common mode of sudden death in humans, including those induced by anesthetics. No one picked up on his theory until 1913, when Levy showed convincingly the relationship between chloroform and fibrillation.[82] He was also aware that defibrillation is more difficult to induce in a healthy heart than in a diseased or weakened heart.

McWilliam never investigated the effect of electricity to stop the fibrillations of a heart muscle, nor is it certain that he even thought of this possibility. He did, however, appreciate the value of electrical pacing. The concept was not new. Steiner[97] had successfully paced a variety of animals with chloroform-arrested hearts using direct current via needles thrust into the heart, and even tried it in a patient! Green[98] was later successful in man using hand-held external electrodes, whilst McWilliam[99] described a path from the back to over the cardiac apex. But we had to wait until 1952 for external pacing to be accepted[100] and until 1959[101] for acceptable intracardiac pacing.

It was not anesthesia, which could cause all forms of cardiac arrest, but rather accidental electrocutions, that led to further work on ventricular fibrillation. Many Western nations began to use electricity during the last two decades of the nineteenth century, and accidental deaths from electrocution entered the scientific community's consciousness. Investigators in the 1880s believed that death from electrocution was caused by respiratory paralysis secondary to overwhelming trauma to the central nervous system: "*. . .the condition after the shock is merely one of suspended animation in which respiratory function is suspended.*"[82]

Final proof that electrocution caused ventricular fibrillation came at the turn of the century. Jean Louis Prevost and Frederic Battelli, both physiologists, reported in the year 1899[102] that a weak current passed through the heart or through the intact chest fibrillated the heart. But their interest was not only in the induction of fibrillation: crucially, they also took a major interest in the restoration of the heart beat by electricity and were the first to show unequivocally that it was possible:

. . . we asked ourselves what would be the effect of applying a high voltage current on a dog whose heart had just been put into a state of ventricular tremulation. We worked on 6 dogs, in three of which we noticed that the heart that had been paralysed with ventricular tremulation started to beat again and the pressure rose and stayed up after the application for 1–2 s of a 4800 volt current applied from the head to the feet.

It does seem, however, that they did not appreciate the importance of their findings in relation to sudden death, despite McWilliam's earlier speculations. Three decades passed before others came to appreciate the significance of Prevost and Battelli's work and its relevance to humans.

Even when the problem of ventricular fibrillation was widely understood, no one believed that anything could be done to alleviate it. In 1913 the Electric Light Association of Chicago commissioned a report addressing resuscitation from electric shock. The report acknowledged ventricular fibrillation as a cause of death in linemen but stated "*a*

solution of the problem in a manner permitting the life of the individual to continue may be impracticable."[103]

During the first two decades of the twentieth century, researchers pursued non-electrical interests related to chemical fibrillation when the real solution should have been within their grasp. Chemical defibrillation was investigated in the hope that a regular heartbeat would resume or could be started with another chemical agent. It was also advocated erroneously to stop defibrillation so that heart massage could be more effective. Salts of potassium chloride were the most common agents used for chemical defibrillation, but calcium chloride was also used to start an arrested heart.[104] The connection between electricity and defibrillation was picked up again in 1926, when the Consolidated Electric Company of New York City sought advice from the Rockefeller Institute on how to deal with the alarming number of fatal electric accidents among its workers. The institute in turn funded research at several universities, including Johns Hopkins University, which was also supported later by the New York Edison Power Company.

In 1930, Donald Hooker, William Kouwenhoven, and Orthello Langworthy, with funding from Edison Power, began to study the direct effects of electricity on the heart.[105] They confirmed that electric shocks, even small ones, could induce ventricular fibrillation in the heart and that more powerful shocks could eliminate the fibrillation. Moreover, after inducing ventricular fibrillation in dogs they were then able to defibrillate the heart without opening the chest.[106] Their closed-chest defibrillation was effective only if the fibrillatory contractions were vigorous and the period of absent circulation or breathing did not exceed several minutes: longer periods required open-heart massage for electric shocks to be successful. Since an initial shock was required to place the heart in ventricular fibrillation, it was only logical to call the subsequent shock that defibrillated the heart the countershock. The term *countershock* was used synonymously for many years to mean attempted defibrillation. They were by then close to developing effective defibrillation in humans.

But it was a surgeon who achieved this breakthrough. Claude Beck had worked for years in Cleveland, Ohio on a technique for defibrillation of the human heart. He witnessed a cardiac arrest while an intern in 1922: the anesthetist announced that the patient's heart had stopped during a urological procedure. To the amazement of Beck, the surgical resident removed his gloves and went to a telephone in a corner of the room and called the fire department.[107] He remained in total bewilderment as the fire department rescue squad rushed into the operating room 15 minutes later and applied oxygen-powered

resuscitators to the patient's face. The patient died, but the episode left an indelible impression on Beck. Twenty years later he wrote, "... *surgeons should not turn these emergencies over to the care of the fire department. We should take care of them ourselves... And so I prepared myself to handle it.*"[108] Beck would go on to develop techniques to take back the management of cardiac arrest from the fire department and place it in the hands of surgeons. Ironically, 20 years after his accomplishment the management of most cardiac arrests in the USA once again returned to the fire department.

Cardiac surgeons during the 1930s were well aware that ventricular fibrillation, when it occurred during an operation, was fatal. Beck and his colleague Mautz[109] quoted case reports, but believed that drugs together with electricity could potentially stop ventricular fibrillation in man as had been shown in dogs. They believed that "surgeons should be equipped to use this method." But 10 more years were to pass before long-term success was achieved.

On the basis of the work of Hooker and Kouwenhoven, Beck decided to construct an alternating current (AC) internal defibrillator. He achieved his first successful resuscitation in 1947.[110] A 14-year-old boy was undergoing surgery for a severe congenital funnel chest. The 3-hour operation was uneventful except for a 45-minute period of a rapid heart rate of 160 beats/min for which digitalis was used. During the closure of the large incision in the chest, the pulse suddenly stopped and the blood pressure fell to zero. The boy had gone into cardiac arrest. Dr. Beck immediately reopened the chest and began manual heart massage that was continued for 35 minutes. Another 10 minutes passed before the defibrillator arrived in the operating room. The first shock using electrode paddles placed directly on the sides of the heart was unsuccessful. Beck gave a second successful shock after administering procainamide, and in a very few seconds a feeble, regular, and fast contraction of the heart occurred. The blood pressure rose from zero to 50 mm Hg. Twenty minutes after the successful defibrillation, the chest wound was closed. After 3 hours the child awoke and was able to answer questions. He suffered no neurological damage and his exercise tolerance was considerably improved. What started as a straightforward operation led to 45 minutes of cardiac arrest before resuscitation with the first successful defibrillation in a human. Beck thus earned a place in medical history.

Eight years later, in 1955, another medical "first" was achieved when an out-of-hospital cardiac arrest, that occurred just outside the door of the University Hospital in Cleveland, was treated successfully.[111] Dr. Albert T. Ransone – who was 65 – had had an ECG taken in the hospital following chest pain the night before. As he was leaving, he collapsed and was rushed to the emergency department, pulseless, cyanotic, and with dilated pupils. A subsequent review of the cardiogram revealed an acute posterolateral myocardial infarction. Beck and his colleague David Leighninger immediately opened his chest, not even delaying to remove his shirt or prepare the skin. They compressed his heart by hand for 25 minutes until the electrical defibrillator, which was located in a laboratory far distant from the emergency department, was brought. Defibrillation was achieved after the third AC shock of 3 A lasting 2 full seconds. Ransone left the hospital 11 days later and returned to practice before retiring in Florida. He died in February 1984 at 93 years of age. Beck's defibrillator added 28 years of life to someone whose heart "*was too good to die,*" a phrase that was first used in relation to this case.[112]

Although Kouwenhoven's paper mentioned the ability to defibrillate the heart internally, no one at that time, including Kouwenhoven, pursued the possibility of closed-chest defibrillation in humans. The work of his group had been brought to a halt by the Second World War. The research resumed afterwards under the sponsorship of the Department of Surgery at Johns Hopkins and again was funded by the Edison Electric Institute, which had not given up hope that a means of closed-chest defibrillation could be developed for accidental electrocution of linemen.[113] They built a device that was to evolve into the Hopkins AC defibrillator[114] which underwent a long series of tests in dogs. After 52 successful tests, Kouwenhoven, who was an engineer without medical qualifications, approached Dr Blalock with whom he was cooperating but was frustrated to be told that this was not enough: he should run additional tests. While the tests were under way, Kouwenhoven visited Dr Paul Zoll in Boston who was also developing a closed-chest defibrillator.

For Paul Zoll the development of an external defibrillator was a natural extension of his earlier work with an external cardiac pacemaker. Like the other researchers in the field, Zoll had spent several years perfecting the procedure in a series of animal experiments and by 1955 he was ready to try it on humans. On August 22 of that year a 64-year-old woman admitted 5 days earlier for a serious heart attack collapsed with ventricular fibrillation. Zoll and his colleagues applied a single 360-volt countershock using electrodes across the woman's chest.[115] The ventricular fibrillation stopped at once, but her heart did not start beating normally and she died. The next two patients also died following successful external defibrillation, but Zoll remained undaunted. Finally, on November 17, a 67-year-old man survived several episodes of ventricular fibrillation after treatment with Zoll's external defibrillator, and was discharged a month later. Over a period of 4 months,

Zoll had treated ventricular fibrillation 11 times successfully in four different patients. The energy required ranged from 240 to 720 volts. Zoll had worried about the potential damage such high energy could cause but was able later to write: "*The complete recovery in Case 4 after repeated countershock indicates that external defibrillation can be accomplished without ill effect to the patient.*"

The defibrillator Zoll designed, as well as earlier versions invented by Kouwenhoven and Beck, used AC and were run from line (mains) current, the electricity from the wall sockets. These AC defibrillators were very large and heavy, mainly because they contained a transformer to step up the line current from 110 volts to approximately 1000 volts, which was required to defibrillate the heart. The major limitation of AC defibrillators thus was their lack of portability. They could be packaged in a large cabinet, and wheels attached to the bottom would allow some maneuverability, but basically it was difficult to bring them to the patient. Even in the hospital this was time-consuming, and the possibility of transportation to a patient's home was out of the question. Not many lives would be saved unless the inherent non-portability of AC defibrillators could be solved.

Bernard Lown is credited with solving the portability problem in the 1960s. Years later he would win the Nobel Prize for Peace, but another major contribution to humanity was the development of a defibrillator that used DC instead of AC; this allowed battery operation and eliminated the need for a heavy transformer.[116] A capacitor could store energy until it was released in one massive jolt to the chest wall.

In recent years, biphasic waveforms have been shown to have advantages over the simpler monophasic shocks. They could have been available much earlier. Kouwenhoven, Becker, and Knickerbocker had produced a portable defibrillator in 1963 that used a discharge that had been derived by progressively reducing the number of cycles of alternating current until it became "diphasic" – or biphasic as we would now call it. It could be operated using 6- or 12-volt dry batteries. Again this group was well ahead, but had the frustration once more that their progress had escaped wide medical notice, possibly because the device was described only in an engineering journal (Fig. 1.5).[117]

With the development of portable DC defibrillators, prehospital resuscitation had become a practical possibility. Not only could a defibrillator reach a patient more rapidly, but mouth-to-mouth ventilation and chest compression were now available to buy precious minutes of time.

Prehospital resuscitation

The concept of using ambulances to bring aid to the victim rather than the other way around emerged during the Napoleonic war, and the honor of developing the first emergency medical service probably belongs to Baron Dominique-Jean Larrey. In 1792, the Baron – Napoleon's
Fig. 1.5. Kouwenhoven's "Mine" biphasic portable defibrillator of 1963.

chief army surgeon – devised the first ambulance service to bring aid directly to the injured soldier. When Larrey first entered the military, the only medical care was well to the rear of the army. After the fighting was over, fallen soldiers would be picked up, and those still alive were taken to field hospitals. Larrey was shocked by the delays in providing even minimal care to soldiers. His indignation led him to design a lightweight, two-wheeled ambulance that allowed the surgeon to be mobile and work directly on the battlefield. The vehicles were called *voitures d'ambulance* because they travelled with the "flying artillery" on the field of battle.[118,119] The term "ambulance" referred at the time to a hospital, not a vehicle, but no doubt it was from this that the more familiar use of the word derives. Civilians were not to benefit from ambulances for many years, although the need had been recognized – especially during times of plague so that "*all possible care should be taken to provide such means of conveyance for the sick that they may receive no injury.*"[120]

Urban ambulance services for civilians first appeared in Cincinnati (in 1865 and in New York City in 1866). Within 15 years every urban area in the USA had some form of ambulance service.[121] Other countries lagged behind. In 1881 a volunteer ambulance service was set up in Vienna after a disastrous fire in a theatre[121a] and Dr. James Cantlie, who had written one of the first English books on first aid, gave a public demonstration that was attended by physicians from Germany, Spain, and Russia – leading to the introduction of civilian ambulances in those countries. In the same year, Reginald Harrison from Liverpool visited the USA to investigate the services and subsequently set up a horse-drawn ambulance managed by the police. In 1903, a steam ambulance was available in London and 1905 a motor ambulance was established in Scotland.[122]

For civilians, ambulance services were for many years merely a means to bring the patient to the hospital but provided no medical care at the scene. In 1914 Cantlie set up a College in London to train attendants with considerable initial success:[123] 14 000 students attended in the first 3 years. But the initiative was not well supported and the College closed in 1923. During the 1930s and 1940s municipal fire departments in some cities of the USA (including Los Angeles, Columbus, Baltimore, and Seattle) began to provide rescue, first aid, and resuscitation care. In 1966 the United States National Academy of Sciences and the President's Commission on Highway Safety issued reports decrying the unevenness of ambulance personnel competency and the lack of standard procedures. The commission described the carnage resulting from traffic accidents as the neglected disease of society. The subsequent National Highway Safety and Traffic Act of 1966[124] authorized the Department of Transportation to establish a national curriculum for prehospital personnel, which led to the training of emergency medical technicians. In the same year, a similar scheme for advanced first aid training began in the UK.[125] But nowhere in the West was there any definitive treatment for prehospital cardiac arrest.

In 1965 Frank Pantridge turned his attention to this vexing problem of heart attacks and sudden cardiac death. His sensitivity to the problem came from two sources. First, personnel in the emergency department of the Royal Victoria Hospital in Belfast frequently commented on the number of patients who were dead on arrival. Second, Pantridge was aware of an epidemiological study in Belfast that indicated that, among middle-aged or younger men with acute myocardial infarction, more that 60% died within 1 hour of the onset of symptoms.[126] Thus the problem of death from acute MI had to be solved outside the hospital, not in the emergency room or the coronary care unit. He wrote:

The majority of deaths from coronary attacks were occurring outside the hospital, and nothing whatever was being done about them. It became very clear to me that a coronary care unit confined to the hospital would have a minimal impact on mortality.

He wanted his coronary care unit in the community.

Pantridge's solution was to develop the world's first mobile coronary care unit, or MCCU. He staffed it with an ambulance driver, a junior physician, and a nurse. Pantridge encountered several obstacles to the creation of the MCCU. He dealt with them in his typical fashion: head-on, with bulldog determination to succeed and transparent contempt for politicians and other authorities who opposed him. A modest grant was obtained, and an old disused ambulance was resuscitated. There were, of course, various other problems. *"My non-cardiological medical colleagues in the hospital were totally unconvinced and totally uncooperative,"* Pantridge said. *"It was considered unorthodox, if not illegal, to send junior hospital personnel, doctors, and nurses outside the hospital."* But despite all obstacles, Pantridge's new programme began service on January 1, 1966.

Of ground-breaking importance in the 1967 *Lancet* publication by Pantridge and Geddes[127] was the reported outcome in ten patients who had cardiac arrest. All had ventricular fibrillation; six arrests occurred after the arrival of the MCCU, and four occurred before arrival of the ambulance. All ten patients were resuscitated and admitted to the hospital. Five were subsequently discharged. But the system reacted too slowly to resuscitate persons who fibrillated before a call was placed.

When the unit was established, it was assumed that most sudden cardiac deaths in the community were the result of

acute myocardial infarction. It was not appreciated that ventricular fibrillation can occur without new infarction and with only seconds of warning – or none at all. Today we know that the mechanisms of sudden death in the community are diverse and complex. The Belfast system was ideal for patients whose hearts fibrillated after the ambulance was at the scene or *en route*. But the article has historical importance because it served to stimulate prehospital emergency cardiac care programs throughout the world. It is noteworthy that August 1967 is 200 years to the month from the founding of the Amsterdam Rescue Society.

Although the concept of mobile coronary care was introduced only in the 1960s, the concept that the doctor should go out to the patient was not new for victims of trauma. Kirschner in Germany had recommended this practice as early as 1938.[128] By 1957 there was a mobile operating unit in Heidelberg with another well equipped system in Cologne.

Paramedic-staffed mobile intensive care units

The extensive international readership of the *Lancet* helps explain why Pantridge's idea spread so rapidly to other countries. Within 2 years, similar programs that included physicians in the MCCU began in Australia and Europe. The first programme in the USA was started in 1968 by William Grace at St. Vincent's Hospital in Greenwich Village in New York City. It was soon followed by a programme in Charlottesville, Virginia, begun by Richard Crampton. Both programs were models of the Belfast programme. They used specially equipped ambulances and placed physicians on board to provide advanced resuscitation care directly at the scene of cardiac emergencies.

William Grace had visited Pantridge in Belfast and spent 10 days learning about the program. Shortly after returning to New York City, Grace set about establishing an MCCU patterned after the Belfast unit. The ambulance operated in the catchment area of a large area in the lower west side of Manhattan. Calls for medical emergencies in which chest pain was a complaint were passed on from the police emergency call number to the hospital. Among the first group of patients seen by the MCCU were three patients treated for ventricular fibrillation of whom one survived.[129]

Like the Belfast program, the St. Vincent's MCCU was not established to provide primary response for sudden cardiac arrest, but rather was designed to treat the early period of acute MI. Ventricular fibrillation, if it occurred after arrival, could be managed, but patients suffering ventricular fibrillation before the MCCU's arrival could seldom be resuscitated. Although the first in the USA to

bring advanced resuscitation directly to the scene of a life-threatening emergency, it was nevertheless limited in vision and was not nationally applicable. An evolution in prehospital emergency care was needed. Pantridge and Geddes had broken the conceptual block that resuscitation was restricted to hospitals. Now someone had to break a conceptual block that kept resuscitation in the hands of physicians. This happened in the USA and in Ireland but with different international impact.

The evolution from physician-staffed mobile intensive care units to paramedic-staffed units in the USA occurred independently and almost simultaneously in six communities. The innovators were Eugene Nagel in Miami, Leonard Cobb in Seattle, Leonard Rose in Portland, Michael Criley in Los Angeles, James Warren in Columbus Ohio, and Costas Lambrew in Nassau County New York. These six programs took a different approach to the problem of cardiac emergencies. Not only were paramedics used instead of physicians, but also from their inception the programs were established to deal with the problem of sudden cardiac arrest that may have already occurred before a call for help was received. Four of the six programs had a strong base of a fire department ambulance service in their communities. Thus it was fire fighters who took on the additional role of paramedics.

Nagel understood that the model of the physician-staffed prehospital MCCU could never become accepted in the USA. Physicians were too expensive to await calls in fire stations, and help would take too long to arrive on scene if they had to be picked up from hospitals. But he moved incrementally, taking radio and telemetry as his first step. Before he could sell the need for defibrillation and medications, he had to prove that not only was ventricular fibrillation a major prehospital problem, but also that the ECG signal could be sent from the field to the hospital. The decision to use telemetry was, however, more than a proving exercise and scientific data gathering. For Nagel it was the Trojan horse that gained him access through the legal impediments that were stopping fire fighters from defibrillating patients and administering medications. He hoped to find support for his innovative approach from the medical community; instead he only encountered discouragement. Nagel recalled this opposition:

It was a rare doctor that favored us doing any of this stuff – very rare. We had incidents in the street when we were just sending an EKG, where doctors on the scene would tell the firemen to quit fooling around and haul the victim in. There were some strange orders out in the field from doctors on the scene. The second big force against our doing anything was from emergency department nurses.[130]

Eventually, opposition was overcome and paramedics were given permission to undertake some emergency procedures without radio contact. Nagel vividly recalled the first save of the Miami paramedic program.

There was a guy named Dan Jones who was then about 60 years old, who was a wino who lived in a fleabag in the bad part of town. Jones was well known to rescue. In June of '69 they got a call – man down – it was Jones. They put the paddles on him, he was in VF, started CPR, zapped him, he came back to sinus rhythm, brought him in to ER and three days later he was out and walking around. In gratitude, about a week later, he came down to Station 1, which he had never done before, and he said he would like to talk to the man who saved his life. They told me they had never seen Dan Jones in a clean shirt and sober, both of which he was that day. He would periodically come to the fire house and just say hello and he seemed to be sober. In my talks in those days I said this was the new cure for alcoholism. That was our first true save.[130]

Pantridge's article also motivated Leonard Cobb in Seattle. He knew the Seattle Fire Department was already involved in first aid and therefore approached the Fire Chief, Gordon Vickery, to propose a new training program to treat cardiac arrest. The fire department already had one of the first computerized systems in the USA for documenting first aid runs. Cobb realized that this system could provide scientific documentation for the efficacy (or lack thereof) of Pantridge's suggestions and suggested to Vickery that they pool their knowledge and resources. Cobb and his colleagues then provided instruction and training in cardiac emergencies including cardiac arrest to volunteer fire fighters. The program became operational in March 1970, 9 months after Nagel's first save in Miami. The mobile unit – and there was only one at first – was stationed outside the Harborview Hospital emergency department. As Cobb himself points out, the mobile unit was not the real innovation. Rather, it was the concept of a tiered response to medical emergencies. The idea was "*that we would get someone out there quickly*" – via the fire department's already existing mobile first aid units – "*and then a secondary response would come from the mobile intensive coronary care unit.*" The beauty of the tiered response system was the efficient use of fire department personnel, which allowed aid personnel to reach the scene quickly (on an average of 3 minutes) to start CPR. Then a few minutes later the paramedics arrived to provide more definitive care such as defibrillation. In this way the brain could be kept alive until the electric shock converted the heart to a normal rhythm. After stabilization the paramedics would transport the patient to the hospital.

The Seattle paramedic program did more than pioneer paramedics and develop a tiered response system. It was the first program in the world to make citizens part of the emergency system. Cobb knew from data the program had collected that the sooner CPR was started, the better the chances of survival. He reasoned that the best way to ensure early initiation of CPR was to train the bystanders. Thus Cobb, with the support of Vickery, began a program in 1972 called Medic 2. Its goal was to train over 100 000 people in Seattle how to do CPR. Cobb recalled how the idea was first proposed:

One day he [Vickery] said, "Look, if it's so important to get CPR started quickly and if firemen come around to do it, it can't be that complicated that other folks couldn't also learn – firemen are not created by God to do CPR. You could train the public." I said, "That sounds like a very good idea." Shortly afterwards things started.[130]

By the twentieth anniversary of the Medic 2 program, over half a million people in Seattle and the surrounding suburbs had received training in CPR in a course of approximately 3 hours. But some people were sceptical about mass citizen training in CPR; indeed, many felt the potential for harm was too great to allow such a procedure in the hands of laypersons. The sceptics also had the support of national medical organizations. The alarmist voices were stilled by some fortunate saves. Cobb recalled one resuscitation soon after the Medic 2 program began involving a man who was indeed in ventricular fibrillation:

In March 1973 there were these kids playing golf at Jackson Park. They came across a victim a quarter of a mile from the clubhouse. But these kids had taken the CPR course over at the local high school. Two or three of them started doing CPR and the other kid ran off and phoned the fire department. Shortly they came with the aid car and Medic 1 screaming over the fairways. They got him started up again. He survived; he's alive today (1990). That was a very convincing story. I didn't mind it being written up in the *Reader's Digest*.[130]

In early 1969 Michael Criley wondered if Nagel's scheme could be set up in the Los Angeles area using the services of existing Fire Department rescue squads, which were, as Criley later put it, *"busy doing things like rescuing cats from trees."* The mobile units began responding to emergency calls in August1969, 2 months after the units in Miami. Leonard Rose in Portland developed a slightly different system, one that used private ambulance drivers as paramedics. Having overcome legal difficulties in relation to training, the unit was working by September 1969. In Columbus, Ohio, Warren had long been interested in the problem of sudden cardiac death and had set up the region's first in-hospital cardiac care unit in 1955. He had been deeply impressed by Pantridge's work and, in association with Richard Lewis, set up a scheme with the Fire Department that became operational in October 1969. The

Nassau County program was unique in that police officers were trained as paramedics. A police department-based paramedic service also began in Grand Rapids, Michigan, although this model was not widely imitated. Thus, the decade of the 1960s that had started with the development of CPR had, by its end, effective paramedic programs in six major American cities.

The American systems were not, however, the first to have non-medical personnel using defibrillators for prehospital cardiac arrest. It was the Irish Heart Foundation that led the way,[131] although their pioneering work went largely unnoticed. Two private ambulances in Dublin were equipped with defibrillators and the ambulance staff were trained to use them. From December 1967 to November 1971, 20 patients who suffered a cardiac arrest either immediately before, or after, the arrival of an ambulance were defibrillated by ambulance staff; 11 survived to hospital discharge.

Other schemes were set up in the UK independently of events elsewhere, but were operational effectively only after those in Ireland and the USA. In 1968, encouraged by the success of the Belfast mobile coronary care unit, a pilot coronary ambulance scheme was set up in Brighton under the direction of William Parker, the local Medical Officer of Health. It relied on general practitioners and medical staff from one of the hospitals to provide medical expertise. It responded to few calls, usually without the promised medical cover, and the specialized equipment was rarely used. After one unsuccessful attempt at defibrillation – due primarily to equipment failure – the decision was made to train ambulance personnel who manned the ordinary emergency ambulances. These were operational from 1971 and by the end of the following decade over 40 patients per year were being discharged alive after prehospital cardiac arrest from a population of 300 000.[132] A second initiative was set up in Gloucester and Bristol in the South West of England providing a service from 1972.[133] Originally the emphasis was on effective pain control and ventilation, but soon ambulances were available that were manned by paramedics equipped with mechanical ventilators, intravenous fluids, electrocardiographs with telemetry, and defibrillators. The success of these schemes in Brighton and the South West of England led eventually to a national system of paramedics within the UK.

In mainland Europe, the same motivation to bring treatment to patients with cardiac arrest of life-threatening conditions took a different path. In most countries, the decision was made to have mobile intensive care units that were manned by physicians. The differences between the systems in the USA and the UK on the one hand and France and Germany (with most of Europe) have been described by Dick.[128]

The quest continues

By the early 1970s, CPR, defibrillation, and a rapid means to provide prehospital care were all in place. The structure to resuscitate sudden death victims had been built and was proving successful. That most of the world did not have this structure in place in the 1970s was largely due to lack of diffusion and spread of the ideas, combined with reactionary local inertia, rather than the impossibility of carrying them out.

However, the story of resuscitation does not stop with paramedic defibrillation. By 1975, Diack had already realized that electronic pattern recognition of the waveforms of ventricular fibrillation could be used in the logic of a defibrillator to permit or withhold the electrical discharge.[93] The human role could therefore be reduced to the simple task of recognizing the possible need for defibrillation, applying electrodes, and activating the machine. The first automated unit was used successfully by paramedics in Brighton in 1980,[134] and the first successful randomized trial of their efficacy was published from Seattle in 1989.[135] The introduction of AEDs expanded the possibility for prehospital resuscitation from cardiac arrest enormously, because defibrillation could now be undertaken by laypersons with modest or even no training. They have proved successful when used in fixed sites where cardiac arrest might be expected[136,137] or where access to conventional help is unavailable as in aircraft.[138] They are also being used within the community in so-called first responder schemes[139] and within the homes of vulnerable patients.[140]

Provision of speedy defibrillation was, however, recognized to be only part of the answer in the battle against unexpected sudden cardiac death. Whilst community instruction in CPR can reach many citizens and thus widen the time frame for successful defibrillation, inevitably many calls for help will come from individuals who have not been instructed or lack the confidence to perform poorly remembered skills. There is a role for providing instruction during the emergency itself. In 1981 a programme to provide telephone instructions in CPR began in King County, Washington. This programme used the emergency dispatchers to give instant directions while the fire department EMT personnel were *en route* to the scene.[141] This demonstration project increased the rate of bystander-provided CPR by 50%. Dispatcher-assisted CPR is now standard care for dispatcher centers in many parts of the world.

Guidelines for best practice techniques in basic and advanced life support have been produced by the American Heart Association, the European Resuscitation

Council, and by Resuscitation Councils in other parts of the world. Increasingly, cooperation between organizations and individuals proved valuable. The International Liaison Committee on Resuscitation (ILCOR) was set up in 1992,[142] and now provides a forum for a consensus on the science of resuscitation that permits identical or similar evidence-based practices to be used the world over.

Nonetheless, the last 20 years have not seen a fundamental breakthrough. CPR is basically unchanged since it was first integrated into an effective system in 1960. Defibrillation is also largely unchanged, although further sophistication over and above those of waveform analysis can be expected. The pharmacological management of cardiac arrest has not demonstrated real progress over several decades, and emergency medical services in the twenty-first century are similar to those of the 1970s. The quest to reverse sudden death has not stopped, but it has also not led to a new scientific or historical breakthrough. Increasingly, it must be accepted that cardiac arrest that occurs in the community is a community problem and that emergency services cannot usually be available in time to provide successful definitive treatment. Wider involvement of responders within the community has to be a key strategy. Other significant advances are likely to require a more complete understanding of heart and brain physiology, and perhaps one day we will be able to counter very much more effectively than at present both ischemic heart disease and sudden cardiac death. Future chapters are still to be written.

The epidemiology of sudden death

Graham Nichol and David Baker

University of Washington Clinical Trial Center, Seattle, WA, USA

Epidemiology is the study of the distribution and determinants of health-related states or events in specified populations and the application of this study to the control of health problems.[1] Although much has been learned from epidemiologic studies of cardiac arrest, this broad definition should be tempered by the recognition that death can be deferred but not prevented.

Epidemiology and the study of cardiac arrest

Much of what we understand today about the basic pathophysiology of cardiac arrest has been gained through observational rather than randomized studies of patients at risk for or in a state of cardiac arrest. This is only natural since sudden death is a relatively unpredictable event that usually occurs out-of-hospital and the victim is initially treated by emergency medical services providers, then transported to hospital for further triage and treatment in the emergency department. The epidemiologic study of cardiac arrest not only provides information about risk factors for the onset of arrest, the current status of treatment of the condition, but also suggests how to improve treatment and directs physicians toward future studies of resuscitation.

In broad terms, epidemiologic data are used to identify cellular (e.g., gene mutations that predispose to arrhythmias), environmental, social, educational, behavioral (e.g., activity level, smoking), clinical (e.g., atherosclerosis, reduced ventricular function, diabetes), or health system risk factors that predispose individuals to cardiac arrest or particular outcomes after its onset. By identifying risk factors that are amenable to modification, such as diet or smoking, physicians have attempted to improve survival through prevention. By identifying favorable interventional factors for survival, such as early cardiopulmonary resuscitation (CPR), physicians have improved the acute treatment of sudden death. By identifying individuals who have survived cardiac arrest, physicians have improved secondary prevention by implanting devices to treat recurrent events. The declining rates of cardiovascular disease observed in high-income countries[2–4] suggests that there has been some success in applying these strategies but that there is still a long way to go.

This chapter considers the definition, the nature, and magnitude of cardiac arrest. It describes some of the methods used to study cardiac arrest, incidence and survival statistics, as well as particular concepts important to understanding the literature in this field.

Definition of sudden death

An international consensus workshop classified cardiac arrest as the "cessation of cardiac mechanical activity, as confirmed by the absence of signs of circulation."[5] This definition emphasizes that cardiac arrest is a clinical syndrome that involves the sudden (usually less than 1 hour from onset of first symptoms until death) loss of detectable pulse, or cessation of spontaneous breathing. If an EMS provider or physician did not witness the event, then it may be uncertain as to whether a cardiac arrest has occurred. The World Health Organization proposed an alternate definition that acknowledges that many cardiac arrests are not witnessed: for those patients without an identifiable non-cardiac etiology, sudden cardiac death includes death

within 1 hour of symptom onset for witnessed events or within 24 hours of having been observed alive and symptom-free for unwitnessed events.[6]

Such definitions have several limitations despite their widespread use. First, "presumed cardiac etiology" is frequently used as an inclusion or a priori subgroup criterion, but can only accurately be determined by conducting a postmortem examination. Since it is impractical to perform an autopsy on every fatal arrest, classification must rely on limited information that is available to emergency providers in the out-of-hospital setting or physicians in the emergency room.[7] It is frequently difficult for emergency providers to ascertain whether and how long the patient had symptoms beforehand when they are trying to provide acute resuscitation in the field. In the absence of precise definitions, use of the etiology of arrest as an inclusion criterion will create bias. Therefore, episodes should be included in epidemiologic studies regardless of their etiology.

Since the likelihood of underlying disease is uncertain, many studies presume that an arrest is of cardiac origin unless there is another obvious cause: specifically, unless the episode is known or likely to have been caused by trauma, submersion, drug overdose, asphyxia, exsanguinations, or any other non-cardiac cause as determined by the rescuers.(5) Such classifications are important especially for out-of-hospital cardiac arrest studies, but remain inexact because they are subject to ascertainment bias due to incomplete assessment on the basis of information at the scene, or toxicology tests ordered selectively on patients successfully transferred to hospital, and the frequent lack of autopsy data.

Second, many epidemiologic studies of cardiac arrest use emergency medical services as the sampling frame, so unwitnessed deaths that did not result in a call for aid are difficult to ascertain and therefore are not included. The exclusion of such patients from a study would underestimate episode incidence and overestimate survival compared to a study that included them.

Third, there is geographic variation in the frequency of "do not attempt resuscitation" declarations by individuals and family members and whether EMS providers can choose not to initiate or to cease efforts in the field. The inclusion or exclusion of such patients in different epidemiologic studies makes it difficult to compare the incidence and outcome of cardiac arrest in different jurisdictions.

Reasonable alternative definitions that address these limitations are unexpected cardiac death without any reference to duration of symptoms, and EMS-treated cardiac arrest. The latter might include any persons evaluated by organized EMS personnel who: a) receive attempts at external defibrillation (by lay responders or emergency personnel), or receive chest compressions by organized EMS personnel; or b) are pulseless but do not receive attempts to defibrillate or CPR by EMS personnel. This would include those with "do not attempt resuscitation" directives, a history of terminal illness or intractable disease, or a request from the patient's family to "not treat."

Unexpected cardiac death generally occurs in persons with known or previously unrecognized ischemic heart disease.[8,9] Other causes of sudden death include non-ischemic heart disease (especially arrhythmic including ventricular fibrillation, Wolff-Parkinson-White syndrome, long QT syndrome, Brugada syndrome, short-coupled torsade de pointes and catecholamine-induced polymorphic ventricular tachyarrhythmia), pulmonary diseases including embolus, cerebral nervous system disease, vascular catastrophes including ruptured aneurysms, as well as drugs and poisons. Patients without identifiable abnormalities are categorized as idiopathic. Although routine cardiac imaging may seem normal in such patients, discrete genetic or anatomic abnormalities are sometimes identified by more sophisticated tools such as magnetic resonance imaging, positron emission tomography, or genetic testing. Traumatic sudden death is usually considered separately from unexpected cardiac death, because the treatment and prognosis of traumatic and non-traumatic arrest differ so much from each other.

Global burden of illness

Globally, cardiovascular disease contributes 30.9% of global mortality and 10.3% of the global burden of disease.[10–12] It is responsible for more deaths than any other disease in industrialized countries, and three-quarters of mortality due to non-communicable diseases in developing countries. Eighty percent of deaths due to cardiovascular disease occur in low- and middle-income countries.

In the United States, cardiovascular disease is the leading cause of death among individuals aged greater than 65 years, the second leading cause of death among individuals aged 0 to 14 years and 45 to 64 years, and the fourth leading cause of death among individuals aged 15 to 24 years (www.americanheart.org/downloadable/heart/1103834819155FS23LCD5.pdf accessed on March 2, 2005). Cardiovascular disease is estimated to have cost $368 billion in the United States in 2004 (http://nhlbi.nih.gov/about/03factbka.pdf accessed on October 22, 2004).

About half of coronary heart deaths are sudden.[13] Since there were 7.2 million coronary heart deaths worldwide in

2002.(http://www3.who.int/whosis/ accessed on August 28, 2005), this implies there were 3.6 million unexpected cardiac arrests. About 2/3 of these occur without prior recognition of cardiac disease.[14] About 60% of unexpected cardiac deaths may be treated by EMS.[15] Although the proportion of those treated by EMS is likely less in those countries that have limited access to emergency services, this implies that as many as 2.2 million cardiac arrests are treated by EMS worldwide annually.

Incidence vs. survival

The wide variation in incidence and outcome after unexpected cardiac death is attributable in part to several factors in addition to differences in clinical risk factors and EMS care. Considering some of these factors requires clarification of some epidemiologic concepts.

First, it is important to distinguish between two common epidemiologic measures: incidence and survival rate. The incidence of cardiac arrest is the attack rate of cardiac arrest in the community. Risk factors for increased incidence of cardiac arrest include previous health, age, race, and gender. Early identification of modifiable risk factors can reduce an individual's risk of cardiac arrest.

The survival rate is the complement of the case-fatality rate, and is defined as the number of survivors divided by the number of individuals who experienced unexpected cardiac death. The latter requires a specific and measurable definition.[16] For example, subjects who inadvertently are treated in the field, such as a person with syncope who receives bystander CPR, should not be included. Stratification of the denominator for a survival calculation can distort an assessment of the quality of a community's EMS system. For example, survival can be expressed relative to the total number of deaths in a community, the number of 911 dispatch calls to the area, or those who received field interventions such as CPR or defibrillation. Each of these groups has a particular sensitivity and specificity for detecting true cardiac arrest. If a surveillance system reports as cardiac arrest an episode that was not, then incidence and survival are overestimated (the latter only if the patient lives). If the system misses a true cardiac arrest, then incidence and survival are underestimated (the latter if the patient dies.) Therefore, a surveillance system must assess all events in a consistent and comprehensive manner. EMS systems that habitually monitor their episodes sometimes utilize multiple methods of ascertainment to do so. A process of adjudication is useful to differentiate possible cardiac arrest from definite cases.

By changing the definition of a "case," the denominator is adjusted, thereby altering the apparent survival rate. For example, Eisenberg et al. demonstrated a two-fold range in survival rates in the same population depending on the subgroup or denominator chosen.[17] Therefore, studies should clearly state the criteria for inclusion in the study or registry. An alternate approach in settings where complete ascertainment of episodes is likely to be challenging is to compare the absolute number of survivors rather than the proportion of survivors.[16]

The risk factors for survival (or mortality) after a person has suffered a cardiac arrest can be considered separately from those affecting incidence. These factors become important for predicting and improving survival. Many of these factors relate to the timeliness[18,19] and quality of resuscitation at the scene of arrest.[20] Some confusion between incidence and survival is understandable, because some, but not all, factors that affect incidence also affect survival. Other factors that increase incidence, however, may not affect survival. For example, male sex is a risk factor for incidence of sudden death, but survival rates for men and women are similar. The following section explores factors that influence the *incidence* of sudden death, and those that predict *survival* from cardiac arrest.

Data sources

Data to describe out-of-hospital cardiac arrest can be obtained from a variety of sources, each of which has particular advantages and disadvantages. Some population-based studies use death certificates or International Classification of Diseases (ICD) coded hospital discharge data. Such data are frequently accessible from a central location or computer. Moreover, such data are quite complete since a death certificate is filed for all deaths. Nonetheless, assignment of causation is inaccurate on death certificates for several reasons. Many patients are classified as having cardiac arrest for lack of a better diagnosis. Certificates can be completed hours to days after the event, by a physician not in attendance at the time of death. Confounding diseases, such as stroke or drug intoxications, present much like cardiac arrest and are likely to be misclassified. Estimates of the incidence of unexpected cardiac death that are based on death certificates overestimate the true incidence by as much as 47%.[21]

Hospital discharge data are another inaccurate method of estimating cardiac arrest because there is no specific ICD code for cardiac arrest. Instead, several non-specific cardiac codes are combined (e.g., ICD-9 code 390 to 398, 402, or 404 to 429) and it is assumed that these cases represented sudden cardiac arrest if the death was reported as

occurring out of hospital or in the emergency room or as "dead on arrival."[22] Such an approach has good sensitivity (most people dying from "cardiac arrest" will have ceased cardiac mechanical activity!) but poor specificity (not every person reported as dying from "cardiac arrest" actually died *primarily* from cardiac arrest).

An alternate approach to studying cardiac arrest relies on data collated from EMS patient care records. Such databases usually have a more precise description of what happened to the patient immediately before and after the onset of the episode and consequently may be more accurate than death certificates. EMS databases accumulate large numbers of patients in relatively short time periods because they usually encompass the entire community, thus covering a larger population than patients presenting to a single hospital. One weakness as a data source, however, is that they do not necessarily identify all victims of cardiac arrest. They may miss patients treated by other EMS providers, or not treated by EMS, or those who are transported by the family or suffer cardiac arrest in the emergency department or elsewhere in the hospital.

The study of in-hospital cardiac arrest has some advantages over that of out-of-hospital arrest.[23] There is usually a shorter response interval until treatment, more highly trained providers able to respond in a timely manner, better information about events leading to the arrest, and more complete follow-up. Critics of in-hospital studies, however, argue that because of co-morbid illness and other factors, the in-hospital setting fails to simulate the out-of-hospital patient experience. To the extent that these patients were sick enough to require hospital admission, any cardiopulmonary arrest may not be sudden and hence not classifiable as sudden death.

Some countries or regions have developed registries that include detailed information on cardiac arrest victims. For example, Sweden,[24] Norway, Scotland,[25] and Western Australia have large registries of cardiac arrest data. Recently a pilot study demonstrated the feasibility of collating process and outcome data related to consecutive cases of out-of-hospital cardiac arrest in multiple countries by using secure and confidential web-based methods.[26] Also, the American Heart Association and National Institutes of Health are supporting an out-of-hospital cardiac arrest registry in the catchment areas of EMS agencies that are participating in the Resuscitation Outcomes Consortium (www.uwctc.org accessed on September 16, 2005). Collectively, these large registries will contribute to a better understanding of the incidence and outcome of unexpected cardiac death especially if they are able to migrate towards using common definitions of eligibility and covariates.

Accuracy of data

Epidemiologists' ability to interpret research results is limited by the accuracy of the data collected. It is unfortunate that although the technology now exists to collect accurate information, these methods have generally not been incorporated into EMS care and research. Time is the most critical factor during cardiac arrest treatment, yet determining accurate times remains a serious obstacle. Accurate assessment of the duration of time since the onset of arrest has taken on increased importance since the recognition that therapy may need to be tailored to the duration of this interval.[27] A few studies have determined the moment of cardiac arrest or collapse with precision by video recording of public-use areas[28] or telemetry monitoring integrated into a defibrillator.[29] Estimates of the time of onset of cardiac arrest are used[30,31] but are subject to bias.[32] An alternate approach to increasing the accuracy of response time intervals is to synchronize all EMS-related time pieces to an atomic clock.[33]

The time of the call to 911 and the time rescuers get to the victim's address are standard time points in most systems, because these are collected by a central dispatcher rather than estimated by the rescuers. Although some dispatch centers interpret the time of call to be the time the call was received at the dispatch center, some interpret it as the time the call was answered, and others interpret it as the time that EMS providers were sent to respond. Another potential cause of variation in dispatch times is that some EMS agencies use a single dispatch center, whereas others use an initial public safety answering point that then transfers medical calls to an EMS dispatch center for disposition. Although response time intervals are not always included in resuscitation registries,[5] epidemiologic studies that assess these intervals should ensure that they are measured in a consistent manner within each EMS agency. The length of time for rescuers to get from the vehicle to each patient's side can be an additional source of uncertainty and delay in some systems.[34,35] The interval from call to EMS until defibrillation may be a better measure of the performance of EMS systems when compared to the interval from call to arrival on scene.[35] Few studies have accurately recorded the moment of all treatment time points, including defibrillation, intubation, and drug administration.

Technological solutions avoid some of these problems. Monitor/defibrillators can record time and treatments with precision to the second. Audio or ECG recordings of the actual arrest can be reviewed after the event to relate the process of care to timing intervals.[36,37] Electronic patient records can capture field data and transmit it to a central receiving station for verification, analysis, and

interpretation. These methods may increase the accuracy of measurements of response time intervals.

The physiologic characteristics of a patient in cardiac arrest may also be used to estimate time or response to treatment. Ventricular fibrillation has an underlying organized rhythm that is influenced by the underlying mechanism of arrhythmia[38] and predicts the duration of VF as well as the response to treatment.[39] Various morphologic characteristics of ventricular fibrillation correlate with successful defibrillation in animal models[40–42] and observational human data.[42–44] To date, there are no prospective or controlled studies that demonstrate that defibrillation guided by waveform characteristics improves outcomes.

Elevation of the level of carbon dioxide in tissue or exhaled air is another possible marker of duration or severity of circulatory shock.[45–47] An important limitation of using end-tidal carbon dioxide, however, is that it correlates poorly with tissue levels in the absence of cardiac output. To date, there are no published prospective or controlled studies that demonstrate that resuscitation guided by carbon dioxide levels improves outcomes.

Another source of potential inaccuracy is the interpretation of the initial recorded rhythm. One study found that paramedics could reliably differentiate large-amplitude VF from flat-line asystole, but were not consistent in differentiating fine VF from coarse asystole.[48] Another identified errors in rhythm analysis by automated external defibrillators.[49] Such inconsistencies may affect survival rates by significantly changing the subgroup identified as having VF and hence changing the denominator, as well as by changing the likelihood of successful resuscitation. In summary, accurate data collection during a cardiac arrest is not a trivial matter, and development and implementation of newer methods will be crucial to future studies.

Incidence of cardiac arrest

The true incidence of out-of-hospital cardiac arrest is unknown. Its reported incidence in the United States is 1.9/1000 person years among those aged 50 to 79 years.[14] Since the US population aged 50 to 79 is 67 667 031 (http://www.census.gov/ accessed on Aug 28 2005), this implies 130 000 out-of-hospital cardiac arrests. The reported incidence of EMS-treated cardiac arrest is 36/100 000 to 81/100 000 total population.[15,50] Since the total US population is 297 227 385 (http://www.census.gov/ accessed on Sep 21 2005), this implies 107 000 to 240 000 treated arrests occur in the United States annually. Of these, 20 to 38% have ventricular fibrillation or ventricular tachycardia as the first recorded rhythm.[14,50] This implies

21 000 to 91 000 treated ventricular fibrillation arrests annually.

The reported incidence of unexpected cardiac arrest in Europe is 1/1000 population.[51] Since the European population is 455 489 113 (http://www.populationdata.net/ accessed on Aug 28 2005), this implies 450 000 out-of-hospital arrests occur annually in Europe.

During the early twentieth century, the incidence of coronary artery disease in the United States and other high-income countries increased dramatically. In the 1940s, cardiovascular disease became the leading cause of death, overtaking deaths caused by infectious agents. In the early twenty-first century, cardiovascular disease has become a ubiquitous cause of morbidity in most countries.[52] This epidemiologic transition reflects increased longevity in low and middle income countries, and thereby increased exposure to cardiovascular risk factors. It also reflects adverse lifestyle changes, including increased inactivity, obesity, tobacco use, and consumption of fats. Nonetheless, there has been a steady decline in morbidity and mortality from most cardiovascular diseases in high-income countries over the last 30 years.[2–4] Much of this reduction has been attributed to modification of risk factors.[53] Although the incidence of ventricular fibrillation and cardiac arrest with any first initial rhythm is decreasing over time,[50] there has been little improvement in survival from cardiac arrest.[54,55]

Unexpected cardiac death in children

Unexpected cardiac death in children merits special consideration in the field of acute resuscitation, because its incidence, etiology, prognosis, and treatment differ from those of out-of-hospital adult episodes. The reported incidence of out-of-hospital pediatric unexpected cardiac death is 2.6 to 19.7 annual cases per 100 000.[56] Unexpected death in the pediatric patient is usually due to trauma, sudden infant death syndrome, respiratory causes or submersion,[57] but ventricular fibrillation is still commonly observed.[58] The reported average survival to discharge is 6.7%. Children with submersion or traumatic injury have a poorer prognosis.

Unexpected cardiac death in hospital

Unexpected cardiac death in hospital also merits special consideration because of its unique characteristics. A large multicenter cohort study of in-hospital cardiopulmonary arrest events excluded events that occur out-of-hospital to avoid double counting.[59] For adults, the reported

incidence of unexpected cardiac death in hospital was 0.174 ± 0.087 per bed per year. The commonest causes of these events were arrhythmia, respiratory distress, hypotension, or myocardial infarction. The average survival to discharge was 17%.

High-risk subgroups

The patients at highest risk for cardiac arrest account for only a small portion of arrests in the community.[60] The largest number of cardiac arrests in the community occur in the low-risk general public simply because there are so many more of these individuals than those in the high-risk subgroups.

Witnessed VF is commonly used to assess the efficacy of an EMS agency, because it provides a homogeneous population for analysis that is readily responsive to timely intervention.[61] It is to be hoped that survival figures may become more closely comparable among communities by use of such a definition; but this may not be true because VF is correlated with response time.[62] A potential limitation to this approach is that as the subgroup becomes smaller, the results become less applicable to the larger population. Also, focusing on a subgroup of patients with a particular initial rhythm rather than all treated cardiac arrests may give a biased sense of outcomes. By considering only patients with ventricular fibrillation, one may underestimate the burden of illness and improvements in treatment, because the incidence has decreased and rates of survival to hospital admission or discharge have been static over time for ventricular fibrillation but not pulseless electrical activity or asystole.[50] The updated Utstein template and recommendations offer some logical guidelines for investigators reporting on subgroups.[5]

Calculating incidence of cardiac arrest

Incidence is the occurrence rate per year for a disease within a population at risk. It is usually calculated by taking a ratio of the number of persons developing a disease each year divided by the population at risk. This "simple" measurement becomes quite complicated when applied to cardiac arrest because of the effect of age on the incidence. Many cardiac arrest studies reported incidence as the number of cardiac arrests per year divided by the population within the region. If we use Seattle with a census population of 460 000 aged 20 years or older as an example, there were 372 cardiac arrests within the metropolitan area during 2000, an incidence of 372/460 000/yr or 0.81 cardiac arrests/1000/yr. Focusing on the adult population in this manner is common, and underestimates the total number of arrests slightly, but not the incidence since cardiac arrest is uncommon in the pediatric population.

A separate but related issue is that incidence rates are usually based on the census population of the catchment area of the EMS agency even though the number of individuals fluctuates by time of day and day of week. A city that has a large population ingress during the working week may appear falsely to have an elevated rate of unexpected cardiac death.

If large unaccountable differences in incidence are present, there are important public health questions that require investigation and may prove critical for efforts to improve survival. Likewise, this information may be useful for comparing survival statistics from different communities. Therefore incidence should be routinely reported in cardiac arrest studies.

Risk factors for incidence of cardiac arrest

Despite considerable study, the real causes of sudden death remain obscure. Predicting how a complex system with multiple interrelated elements responds to a variation in an individual component is a general problem in systems biology. Atherosclerosis is likely a factor in the majority of cases; structural and congenital abnormalities, fibrosis, and conditions such as myocarditis contribute to most of the rest.[15] Many risk factors for cardiac arrest, such as hypertension and hypercholesterolemia, are present for long periods of time and are likely to be identified any time an individual is evaluated. Others are evanescent, difficult to document, and less understood. Here, risk factors are classified as cellular, phenotypic, environmental, social, educational, behavioral, clinical, or health system risk factors. A combination of these factors is usually present. In each group, risk factors can be divided into those that are fixed (so-called "fate" factors) and those that can be modified to some extent. The latter may evolve over time or be transient. Evolving factors that may modify the risk of lethal arrhythmia include cell membrane levels of polyunsaturated fatty acids,[63] ion channel function,[64] and local or systemic inflammation.[65] Transient factors that may suddenly trigger a lethal arrhythmia include transient ischemia and reperfusion, transient systemic factors, transient autonomic and neurohumoral factors, and toxic/proarrhythmic effects.[13] The interplay of these factors is complex, as socioeconomic gradients exist in some circulating factors that are not fully explained by health-related behaviors or risk factors for coronary heart disease.[66] Efforts should be

made to modify risk whenever feasible. A caveat to this approach is that population stratification approaches, such risk factors derived from the Framingham Heart Study, predict well the risk of events in large community groups, but less well the risk of specific asymptomatic individuals.

Cellular

Animal experimental, cell biology, genetic, nutritional, and epidemiologic studies demonstrate that cellular constituents such as cell membrane and free fatty acid levels of n-3 polyunsaturated fatty acids (PUFAs) alter cardiac ion channel function, modify cardiac action potential and reduce myocardial vulnerability to ventricular fibrillation.[67] These findings have important clinical and public health implications, because n-3 PUFA levels can be altered by inexpensive changes in dietary intake. Specifically, ingestion of one fatty fish meal a week is associated with a marked reduction in sudden cardiac death.

Elevations in plasma non-esterified fatty acid (NEFA) levels[68] and high-sensitivity C-reactive protein (CRP) levels[65] or decreased long-chain n-3 fatty acid levels are independently associated with elevated risk of unexpected cardiac death. It remains unclear whether elevation of CRP indicates an underlying inflammatory pathological process or whether it is directly proarrhythmic.

Genetically based risk factors for cardiac arrest may include factors that facilitate the onset of ischemia and infarction, including activators of plaque rupture and thrombogenesis; alterations in neuroendocrine signaling, including differences in transmitter pathways that contribute to sympathetic–parasympathetic imbalance; and potential triggers or attenuators of cardiocyte membrane excitability and transcellular conduction.[69,70] Molecular genetic analysis has identified an inherited disease and likely cause of death in 40% of families with at least one member who had unexplained cardiac death at age 40 years or less.[71] A caveat to the potential role of genetic screening to identify mutations that predispose to arrhythmia is that familial clustering of cardiac death may reflect shared environmental or genetically transmittable abnormalities. Regardless of which of these is correct, familial risks for sudden death are separable from familial risks for myocardial infarction.[68,72]

Identification of cellular and genetic risk factors for cardiac arrest may have therapeutic implications. For example, KvLTQ1 gene mutations are predisposed to arrhythmias that may be more responsive to beta-blockers;[73] carriers of SCN5A gene mutations are predisposed to arrhythmias that may be more responsive to electrical defibrillation.[74]

Environment

The incidence and outcome of cardiac arrest vary by time of day, day of week, or season.[75–80] Data from the Framingham study show that the highest risk for MI is on awakening and it decreases progressively during the day. Various physiologic processes have been considered to explain this phenomenon, such as increased clotting or increased parasympathetic instability. Some researchers have suggested that part of the morning peak in cardiac arrest may be due to a reporting artifact (i.e., the patients really die during the night but are not discovered until early morning). Potential interventions to reduce periodic variation in unexpected cardiac death include resource allocation of EMS and hospital resources to match anticipated need.

Social

Disparities in incidence of cardiac arrest are observed across socioeconomic gradients as well as across geographic region.[81–87] Cardiovascular disease is the leading cause of income-related differences in premature mortality in the United States,[88] and Canada.[89] Non-hispanic blacks bear a disproportionate burden of morbidity and mortality due to cardiovascular disease.[90] These disparities may be caused by differences in genetic risk, health behaviors, educational attainment, socioeconomic disadvantage, access to preventive care, or other yet to be identified variables. As understanding of the magnitude and cause of these disparities increases, potential interventions include culturally appropriate public health initiatives, community support, and equitable access to quality care.

Behavioral

Cigarette smoking is thought to be the single most important cause of preventable death in the United States. An estimated 438 000 persons in the United States die prematurely each year due to exposure to tobacco smoke.[91] The deleterious effects of smoking may be mediated through increased plasma catecholamines, heart rate, and arterial blood pressure; production of coronary spasm; and increases in myocardial work and oxygen demand with concomitant reduction in oxygen supply.[92] Collectively, these effects lower ventricular fibrillation thresholds. In patients who successfully quit smoking, rates of sudden death return to near normal over time. Of great concern is the effect of "passive smoking," which has been associated with an increase in smoking-related disease, primarily heart disease.[93]

Exercise, much like weight loss, can be both good and bad. Persons who exercise regularly have a decreased incidence of coronary artery disease compared to persons who are sedentary,[94] and decreased mortality in those with that disease who exercise compared to those who do not.[95] Nevertheless, the heavy exertion with exercise is associated with an increase in acute events, such as MI. A period of strenuous activity was associated with a temporary increase in the risk of having an MI for about 1 hour after the exertion.[96] Heavy exertion in persons who do not exercise regularly was associated with the highest risk.

Use of street drugs is associated with unexpected cardiac death. Cocaine use is associated with severe and catastrophic heart disease in many individuals. It increases adrenergic stimulation by blocking the presynaptic reuptake of norepinephrine and dopamine, thus causing an increased sensitivity to catecholamines. The combined effect of cocaine and cigarette smoke is worse than either one alone.[97] Opioids are also associated with cardiac arrest.[98] Both cocaine and methadone prolong QT intervals, predisposing to ventricular arrhythmias.[99]

Moderate alcohol intake is associated with reduced cardiovascular mortality compared to no alcohol intake, although the mechanisms by which alcohol is protective remain unclear. This effect is thought to be mediated through increased levels of HDL.[100] Nevertheless, heavy consumption is associated with increased mortality, an effect sometimes referred to as "holiday heart" because it is often associated with binge drinking in otherwise healthy people during weekends.[101] In the Physicians' Health Study, after controlling for multiple confounders, men who consumed two to six drinks per week had a 60 to 80% reduced risk of unexpected cardiac death compared to those who rarely or never consumed alcohol.[102] In the British Regional Heart Study, the relative risk of unexpected cardiac death in those who drank more than six drinks per day was twice as high as occasional or light drinkers.[103]

Emotional factors influence the occurrence of cardiac disease. Characteristics such as anger, chronic stress, aggressiveness, anxiety, and hostility are difficult to measure objectively, however, and there are many confounding issues. Educational attainment moderates the risk of acute infarction due to anger.[104] Studies have yet to confirm a definite relationship between emotional factors and cardiac arrest.

Clinical

Sudden death has been associated with all forms of cardiac disease. The rates of sudden death parallel the prevalence of risk factors for coronary artery disease. Known coronary artery disease or a previous episode of sudden death remains the greatest risk factor for sudden death.

Cardiac arrest is particularly common in patients with established cardiovascular disease. Patients with acute coronary syndromes (ACS) or myocardial infarction (MI) are at high risk of dying (i.e., >5%) within 30 days of presentation, regardless of whether ST-segment elevation is present or absent.[105] The risk of death remains elevated for at least 6 months in patients with ACS,[106] and for at least 1 year in patients with MI.[107] Patients with ventricular dysfunction are at higher risk than those without.[108] At least one-half of these deaths are suspected to have an arrhythmic mechanism.[109] Several non-invasive diagnostic tests may identify patients who are at high risk of cardiac arrest, but have low sensitivity and specificity,[110] and are generally available only in tertiary care centers. More than 1 000 000 patients are discharged with MI, and more than 780 000 patients are discharged with a primary diagnosis of ACS in the United States each year. (http://www.cdc.gov/nchs, accessed on June 9, 2002) Since more than 16% of these have a left ventricular ejection fraction (EF) < 40%,[111] thousands of individuals are annually at increased risk of cardiac arrest.

Ischemia and reperfusion, which occur commonly during the early phases of MI, are clearly associated with arrhythmias. Because only 20% of sudden cardiac death victims have acute infarction, it is assumed that transient ischemia rather than infarction has a major role in triggering sudden death. Transient systemic factors, such as hypoxia, hypotension, acidosis, or electrolyte abnormalities, can affect electrophysiologic stability and susceptibility to arrhythmias. A vigilant search should be made for an underlying cause of arrhythmia even in the setting of electrolyte abnormalities, however, as hypokalemia may be a cause or consequence of cardiac arrest.[112]

Congenital or acquired arrhythmias are a known risk factor for cardiac arrest. Unfortunately, the severity of risk is not well defined because of the many associated factors that may confound evaluation of a particular patient. Deaths in athletes have drawn considerable public interest to this problem. Although known arrhythmias increase the chance of cardiac arrest, the degree to which various arrhythmias increase the chance of cardiac arrest is difficult to predict precisely. Screening of athletes for risk of arrhythmia lacks sensitivity and specificity.[113]

The rate of cardiac arrest increases exponentially with increasing age. The rates for cardiac arrest are substantially higher at any given age for men than for women. Since more women in the population are older than men, the overall incidence by gender are similar, although women are at less risk at any particular age.

Race is an important risk factor for many cardiovascular diseases. Blacks have a higher rate of hypertension, left ventricular hypertrophy, renal disease, and diabetes compared to whites. As a consequence of these differences in the distribution of risk factors, the incidence of cardiac arrest is significantly higher in blacks than in whites.[81]

Hypertension predisposes patients to develop CAD, cardiac hypertrophy, congestive heart failure, stroke, renal disease, and sudden death. The risk is continuous, without evidence of a threshold, down to blood pressures as low as 115/75.[114] Twofold to threefold increases in CAD are seen in patients with systolic blood pressure above 160 or diastolic blood pressures above 95.[115] Hypertension affects about 65 million persons in the United States,[116] and may affect more than 90% of individuals during their lifetime.[117] As many as two-thirds of affected Americans are untreated or undertreated.[118] This care gap has important public health implications since randomized trials have definitively shown that treatment of hypertension reduces the risk of cardiovascular events and mortality.[119]

Elevations of serum cholesterol and triglycerides are known risk factors for cardiac death. The risk of CAD increases as total cholesterol increases, with low-density lipoprotein (LDL) cholesterol associated with elevated risk and high-density lipoprotein (HDL) cholesterol associated with decreased risk.[120] Elevated triglycerides are especially of concern for women.[121] The levels of lipids are thought to be mediated through an unclear combination of hereditary predisposition and diet. Strict control of diet (less than 10 g of fat per day) can even cause regression of preexisting CAD.[122] Reduction of dietary saturated fat and partial replacement by unsaturates for at least 2 years reduces cardiovascular events, and cardiovascular and all-cause mortality.[123]

Obesity is an independent risk factor for cardiac disease. The prevalence of obesity among adults aged 20 to 74 years has risen from 13% to 31% during the past 25 years,[124–126] despite a decrease in the prevalence of all other risk factors except diabetes over time across all body mass index groups in the United States.[127] Similar increases in obesity have been observed in other high-income countries.

Diabetes is associated with increased CAD. The prevalence of diabetes is increasing over time in the United States.[128] About 10% of the population have diagnosed or undiagnosed diabetes. Diet, exercise, and tighter control over glucose levels may lower the increased risk of CAD associated with diabetes. Since diabetics have an elevated incidence of hypertension, control of blood pressure will also reduce the risk of CAD and renal failure. Renal failure is associated with an increased incidence of cardiac arrest.[129]

Male patients presenting with impotence related to vascular disease are at high risk for sudden death.[130] More than two-thirds of males admitted with acute MI were found to have had significant complaints of sexual dysfunction before infarction.[131] Therefore physicians evaluating patients with non-cardiac vascular disease should ensure that these patients are evaluated for cardiac risk as well.

Health system

There is incontrovertible evidence that implantable cardioverter defibrillators reduce the risk of unexpected cardiac death in those with elevated risk of arrest or those who have survived an initial event.[132] Implantation of these devices shortly after an acute cardiovascular event is deleterious,[133] but non-invasive alternatives exist.[134] Nonetheless, antiarrhythmic devices are potentially underutilized in some settings.[135]

A variety of prescription and non-prescription pharmaceutical agents increase or decrease the risk of arrhythmia or cardiac arrest (Table 2.1). Drugs that have the most significant impact on mortality due to cardiac arrest lack direct electrophysiological effects on myocardial excitability.[136] This implies that these agents act on proximate events that can predispose to lethal arrhythmias (e.g., ischemia, fibrosis). Other agents decrease cardiovascular or all-cause mortality, but have not been demonstrated to decrease cardiac arrest. The latter outcome likely reflects lack of statistical power to detect a difference in an event that is infrequent compared with events or mortality. Nevertheless, lack of demonstrated benefit specific to cardiac arrest should not be interpreted as lack of need to prescribe agents that are otherwise effective in those with cardiovascular disease.

Pharmaceutical agents act via diverse mechanisms to modify the risk of arrhythmia or arrhythmic death. Angiotensin-converting enzyme (ACE) inhibitors decrease the incidence of ventricular tachycardia independent of changes in ejection fraction in humans with heart failure.[137] ACE inhibitors may block remodeling by cardiac myocytes,[138] or reduce ventricular fibrillation in the setting of acute coronary occlusion and reperfusion.[139] Randomized trials demonstrate that ACE inhibitors reduce the risk of sudden cardiac death by 20% in patients after myocardial infarction.[140] Aldosterone antagonists decrease cardiac deaths including those due to sudden events in patients with heart failure, perhaps due to blunting of myocardial fibrosis and hypokalemia that predispose to arrhythmias.[141] Beta-blockers attenuate the toxic effects of norepinephrine upon cardiac myocytes,[142]

Table 2.1. Effect of drugs on long-term risk of cardiovascular death and cardiac arrest

Drug	Effect on Cardiovascular Mortality	Effect on Cardiac Arrest Mortality
Angiotensin-converting enzyme inhibitors	−	−
Aldosterone antagonist	−	−
Beta-blockers	−	−
HMB coreductase inhibitors	−	−
Amiodarone	−	−
Angiotensin-receptor blockers	±	±
Thrombolytic therapy	−	−
Low molecular weight heparin	±	±
Iib/IIIa receptor antagonists	±	±
Clopidogrel	−	±
ASA	−	±
Warfarin	−	±
Digoxin	±	±
Drugs that prolong QT interval[a]	±	+
Vaughan-Williams Class IC[b]	+	+
Vaughan-Williams Class III[c]	+	+
Inotropes	+	+
Cyclooxygenase inhibitors	+	+

[a] Includes, but not limited to: selected antiarrhythmic agents, terfenadine, astemizole, cocaine, methadone.

[b] Flecainide, Encainide.

[c] D-Sotalol, dofetilide.

improve systolic function and reverse statistics,[143] and reduce death due to cardiac arrest in patients with heart failure.[144–148]

Disorders of endothelial function, inflammatory responses, plaque stability, and thrombus formation predispose to cardiovascular events.[149–151] Statins reduce serum cholesterol but also modify these factors. Randomized trials have demonstrated that statins reduce all-cause mortality and sudden cardiac death in those with and without coronary artery disease.[152,153] Although there is some evidence that elevated cholesterol is not an independent risk factor for cardiac death,[65] "statin" inhibitors of hydroxyglutaryl-CoA reductase reduce CRP expression levels.

Although observational studies suggested that digoxin was associated with increased risk of cardiac arrest,[154] a large randomized trial demonstrated that digoxin therapy does not increase this risk in patients with symptomatic heart failure and reduced ventricular function.[155]

To date, all drugs that enhance cardiac contractility, regardless of mechanism, have been shown to increase mortality among those with symptomatic heart failure and decreased ventricular function.[156–159] This increased mortality is attributable to sudden death, presumably due to lethal ventricular arrhythmias. Class IC antiarrhythmic agents (e.g., flecainide, encainide, and moricizine) suppress ventricular arrhythmias but are associated with increased mortality due to cardiac arrest.[160,161] Pure class III agents have also been evaluated as antiarrhythmic agents. D-Sotalol was associated with significantly increased mortality and sudden arrhythmic death compared to placebo.[162] Dofetilide reduced atrial fibrillation, but not total mortality, ventricular tachycardia, or ventricular fibrillation in patients with heart failure and reduced ventricular function, and was associated with a 3% incidence of torsade de pointes.[163]

Amiodarone has little proarrhythmic effect and does not worsen heart failure.[164,165] It reduces modestly arrhythmic death in patients with heart failure or previous myocardial infarction.[166–171] Amiodarone reduced the composite cardiovascular endpoint of death, recurrent ventricular tachycardia or fibrillation, or syncopal ICD shocks by 44% compared to conventional therapy guided by electrophysiological testing or Holter monitoring in survivors of ventricular fibrillation.[172] There was an important but non-significant reduction in recurrence of potentially lethal arrhythmia after 2 years of therapy. The lack of a placebo arm in this trial limits its generalizability, as it is

unclear whether the benefit is due to amiodarone or the harmful effects of conventional antiarrhythmic drugs (mainly class I agents in this case.)

Angiotensin receptor blocker agents (ARBs) decrease serum inflammatory markers[173] and decrease thrombosis via increased tissue-plasminogen activator (t-PA) and decreased plasminogen activator inhibitor-1 (PAI-1)[174] in patients with heart failure. Randomized trials of ARBs have demonstrated heterogeneous effects on reduction of all-cause mortality and sudden cardiac death compared to captopril in patients with heart failure or acute infarction.[175–177]

Coronary plaque rupture precipitates thrombosis, infarction, and thereby sudden death. Successful reperfusion on an infarct-related artery increases electrical stability at the edge of the infarcted area, and reduces the subsequent risk of ventricular arrhythmias.[178] Thrombolytic therapy reduces the risk of all-cause mortality and to a variable degree sudden cardiac death in patients with acute myocardial infarction.[179] There are inconclusive trial data regarding the effect of low-molecular weight heparin,[180] platelet glycoprotein IIb/IIIa receptor antagonists,[181] or clopidogrel[182] upon all-cause mortality and unexpected cardiac death in patients with acute infarction or acute coronary syndromes. Chronic antiplatelet therapy with aspirin reduces the odds of vascular death in high-risk individuals, but the benefit is smaller and not significant in low-risk individuals.[183] Warfarin reduces all-cause mortality in patients with coronary artery disease but is associated with increased risk of bleeding.[184]

Drugs such as quinidine, erythromycin, psychotropic drugs, cocaine, and terfenadine that produce proarrhythmic side effects can be associated with prolongation of the Q-T interval and an increased risk of sudden death.

Variation in process and outcome after unexpected cardiac death

There is a wide geographic variation in outcomes after the onset of cardiac arrest.[185,186] This is attributable in part to regional differences in the availability of out-of-hospital and hospital-based emergency cardiac care.[185] Potential interventions for out-of-hospital cardiac arrest include: bystander CPR, lay responder defibrillation programs,[187] experienced EMS providers,[188] and interventions provided by EMS providers[189,190] or at receiving hospitals.[191,192] Only lay responder defibrillation and therapeutic hypothermia, however, have been shown in randomized trials to improve significantly outcomes to hospital discharge after cardiac arrest.

Also there is regional variation in EMS processes such as EMS service level provided, number of EMS providers responding, use of procedures or drugs in the field, training, quality assurance/feedback, and response time intervals. Some of these factors have been associated with differences in survival or quality of life after resuscitation,[186,193–196] although no analysis has had adequate power to detect independent effects of all factors.

The median reported rate of survival to discharge after out-of-hospital unexpected cardiac death with any first recorded rhythm is only 6.4%.[186] It is likely that this overestimates the actual rate of survival in many communities because of publication bias. In many large urban areas the rate is less than 2%,[34,197,198] and it is even lower in some cities and rural areas. Most communities are not aware of their own survival rates as cardiac arrest data are not routinely tracked. Yet a city with an organized emergency medical service (EMS) system and dedicated quality assurance can achieve survival of 15 to 20%[50] (and Unpublished data, Seattle Medic One program, August 28, 2005). If the average survival could be improved from 5 to 20% by optimizing the chain of survival, the premature deaths of 16 000 to 36 000 in North America, or 67 500 in Europe could be prevented each year.

There are several challenges to improving survival from cardiac arrest. Successful treatment depends more on when treatment is done than on what is done. The most crucial treatment takes place outside the hospital by citizens and trained rescuers. Treatment crosses medical disciplines, with EMS providers, emergency physicians, cardiologists, anesthesiologists, critical care physicians, and primary care physicians all involved in delivering care and contributing to research. Treatments are relatively standardized, but what generates considerable controversy is the timely delivery of care. The latter depends on the implementation and maintenance of an integrated, community-wide, emergency cardiac care system that has been referred to as the chain of survival.[199,200]

The chain includes early access, early CPR, early defibrillation, and early ACLS. The strength of the chain of survival is the strongest predictor of survival for victims of cardiac arrest. It is not measured directly in studies as a single variable because it includes many interlinked factors. During treatment of cardiac arrest, single factors are less important than how and how quickly all the treatments are put together. Communities that have effective chains of survival will have good survival rates; conversely, communities that have even one weak link in the chain will suffer poor survival rates.

Identification, monitoring, and comparison of outcomes after EMS care among communities is desirable

because it aids development of better systems. Since treatment of cardiac arrest is generally initiated by the EMS system, it is crucial for system managers to make decisions about what system or set of protocols works best. Difficulties in reporting survival rates and comparing results among communities make it difficult to determine how much survival benefit can be obtained from a particular intervention, such as upgrading equipment or changing the CPR protocol. The Utstein guidelines are an important step to improving uniformity in reporting survival rates. These guidelines aim for use of clear standardized definitions in an effort to facilitate comparison of community survival rates and logical subgroup analysis.

As already indicated, the primary obstacle to effective treatment is time. Whereas it is relatively easy to know the best treatment for victims of cardiac arrest, the difficulty lies in providing that treatment rapidly. It is the extended time until defibrillation and treatment that is responsible for most deaths from cardiac arrest. Since time relates primarily to the structure of the emergency cardiac care system within the community, changes that reduce the response time intervals should improve survival.

The multiple factors that affect survival after cardiac arrest are described below: risk factors are classified as social, educational, behavioral, clinical, or health system risk factors.

Risk factors affecting survival from sudden death

Social

Socioeconomic status is an important factor in predicting survival from cardiac arrest.[201] In Seattle, high socioeconomic status estimated was associated with a 1.6-fold increase in survival rate, after adjustments for age, witnessed collapse, bystander-initiated cardiopulmonary resuscitation, time from call to paramedic arrival, activity, location of collapse, and chronic morbidity. Part of the challenge of separating socioeconomic status from associated factors (e.g., race or geography) is the need to assess the validity of the surrogate estimate of socioeconomic status. It is unclear whether a single value (the socioeconomic status surrogate) reflects an individual's cumulative lifetime experience with the health care system, diet, exercise, smoking, stress, and the factors thought to be mediators of socioeconomic status. Determining the role of socioeconomic status in incidence and survival from cardiac arrest is a worthy but complex analytic task.

Location

A large proportion of cardiac arrests occur in the patient's home.[24,202] Such patients are older, less often witnessed, less often receive bystander CPR, and have a longer interval between collapse and the arrival of EMS providers.[203,204] Even when these factors are accounted for, arrest in the home is an independent predictor of adverse outcomes. Persons who venture into public places are unlikely to be healthy.

Witnessed cardiac arrest

Witnessed cardiac arrest has been consistently observed to be an important predictor of successful resuscitation.[205] It is only logical that people who suffer unwitnessed cardiac arrest will not fare well. Those with witnessed arrest who are treated promptly have a particularly good prognosis. Extended resuscitation efforts on some of these individuals may be futile.[206–208] Criteria exist for field termination of resuscitation, as ongoing efforts may not be justifiable in those who do not achieve restoration of circulation, because of the cost and risks of speeding ambulances to both rescuers and citizens. Yet successful resuscitation is occasionally observed after prolonged CPR.[209,210–213] These discordant results reflect a need to tailor therapy to the duration of time since the onset of arrest.[27]

Clinical

Initial cardiac rhythm

Which cardiac rhythm is present upon arrival of EMS providers is an important predictor of outcome. The likelihood that the initial recorded rhythm will be ventricular fibrillation depends on the time interval since the onset of arrest.[62] Patients in VT or VF are several times more likely to survive than are patients with asystole and PEA. But patients who are not in ventricular fibrillation are indeed resuscitated with ACLS treatment. For example, 13% of those who survived cardiac arrest in Seattle, WA in 1999–2000 were initially in one of the poor prognostic rhythms (asystole or PEA).[50] Although the rate of survival to discharge remains low in these latter groups, the proportion of patients admitted to hospital has increased over time. Thus, resuscitation attempts and further research are warranted for these patients.

Age

Age is an independent factor in survival from cardiac arrest, but is not as strong a predictor as many other

factors. Although some controversy exists with respect to resuscitation in elderly persons, studies so far show that many older persons do quite well after cardiac arrest. Nevertheless, elderly patients have lower survival and quality of life after resuscitation compared to the non-elderly.[214] Some of these differences reflect the presence or absence of prior comorbid illness.[215] A 10-year increase in age resulted in a decrease in survival rate of 10 to 50%.[81,201]

Gender

The effect of gender upon outcomes after cardiac arrest is unclear. A single-center observational study suggested that survival to discharge rates for women and men are about the same.[216] However a large community-based cohort study suggested that women had markedly reduced rates of ventricular fibrillation (VF), slightly older age, fewer witnessed arrests, and fewer arrests in public locations than men.[217] Unadjusted survival rates were lower in women than in men (11% vs. 15%, $P<0.0001$). Women had similar survival after adjustment for VF (OR, 0.97; 95% CI, 0.85 to 1.11) and after adjustment for VF plus additional factors (OR, 1.09; 95% CI, 0.93 to 1.27).

Race

Race is an significant and important independent predictor for survival from cardiac arrest.[81,218] In Chicago, the survival rate for blacks was 0.8% compared to 2.6% for whites. Blacks were found to have significantly fewer witnessed cardiac arrests or favorable initial rhythms, were less likely to receive bystander CPR, and to be admitted to the hospital. When they were admitted, blacks were half as likely to survive. There was no important difference in the response time for EMS. In Seattle, the initial resuscitation rate was low in black victims (17.1% vs. 40.7%), and rates of survival to hospital discharge were also lower in blacks (9.4% vs 17.1%). The differences in outcomes were not fully explained by features of the collapse or relevant EMS factors. Possible explanations for the racial gap in outcomes after cardiac arrest include less bystander-initiated cardiopulmonary resuscitation, poorer levels of health, and differences in the underlying cardiac disorders. Improving survival for blacks could be accomplished by a general strengthening of the chain of survival for all citizens. In addition, problems in the chain of survival specific to the black community need to be sought and targeted for improvement.

Health system

Bystander cardiopulmonary resuscitation

Since its rediscovery by Kouwenhoven, Jude, and Knickerbocker in 1954,[219] external chest compressions coupled with ventilation (CPR) have been shown to be life-saving, in numerous studies conferring a twofold to three-fold increase in survival rate.[205,220,221] Despite such benefit, many members of the general public are not well trained in this technique. The elderly and minorities are less likely to be trained, to be familiar with what CPR is or how to be trained to perform it,[222] and less likely to perform it at the time of arrest.[81,82] Teaching CPR to citizens can be substantially improved. An effective program for training older people, who are more likely to be present at an arrest, to perform CPR has not been developed. Most communities have rates of bystander CPR around 20 to 30% of arrests. Short video-based, self-instruction programs of CPR training, however, have achieved initial competency equivalent to standard CPR.[223] Broad implementation of such programs may improve the likelihood of bystander CPR in the next decade.

Lay responder defibrillation

Lay responder or public access defibrillation is a strategy that consists of training and equipping lay volunteers to use defibrillation while awaiting arrival of emergency medical services (EMS) providers. A large randomized trial evaluated the effectiveness of public access defibrillation.[224] Participating sites were communities served by EMS systems that provided advanced life support. Each site identified distinct units within their service area (e.g., office buildings, public areas). Volunteer lay responders in both control and intervention units were trained to: (a) recognize cardiac arrest, (b) dial 911, and (c) perform CPR. Units randomized to intervention also received training in application of an AED. The intervention was designed to place a trained lay responder, with an AED in CPR+AED units, at the side of an individual experiencing arrest within 3 minutes of event identification.

The study population comprised individuals with out-of-hospital sudden cardiac arrest. More than 19 000 volunteer responders in 24 North American regions participated. There were more survivors to hospital discharge in the units assigned to have volunteers trained in CPR plus the use of AEDs (30 survivors among 128 arrests) than there were in the units assigned to have volunteers trained only in CPR (15 among 107; $P=0.03$; relative risk, 2.0; 95 percent

confidence interval, 1.07 to 3.77); there were only two survivors in residential complexes. This trial confirmed that training and equipping volunteers to attempt early defibrillation within a structured response system can increase the number of survivors to hospital discharge after out-of-hospital cardiac arrest in public locations. Trained laypersons can use AEDs safely and effectively.

Paramedic-witnessed cardiac arrest

Cardiac arrest witnessed by paramedics deserves special attention. This includes all patients who suffer arrest after the arrival of rescuers; they or others have called for help from 911 before arrest, usually for chest pain or shortness of breath.[225] They account for less than 15% of cardiac arrests in most series. These patients may have an underlying pathologic condition that is somewhat different from that in sudden death since they have symptoms longer (and are able to call for help). Of note, not all of these patients have an initial recorded rhythm of ventricular fibrillation or ventricular tachycardia. In addition, because their cardiac arrest has occurred in the presence of paramedics, they may provide a better indication of how well the EMS performs than the overall community-wide survival rate. Patients who are witnessed by paramedics have a two- to threefold increase in survival rate compared with those not witnessed by paramedics.

Short treatment intervals

The chance of survival diminishes with each passing minute without CPR, defibrillation, or advanced cardiac life support.[186,205,226,227] In an EMS system staffed by highly trained, experienced EMS providers who treat a high volume of calls and perform a high volume of procedures each year, with independent medical oversight and quality assurance in Seattle, WA, survival was predicted by time to CPR and defibrillation.[205] In patients with witnessed ventricular fibrillation before EMS arrival, survival decreased by 3% with each minute until CPR was started, and by 4% with each minute to first shock after CPR has been started. In a similar mature EMS system in King County, Washington, survival was predicted by three time intervals: time to CPR, defibrillation, and advanced cardiac life support (ACLS) care.[226] In patients with witnessed ventricular fibrillation before EMS arrival, survival decreased by 3% for each minute to first shock after CPR has been started, and by 2% for each minute to advanced care after the first shock. Although not all communities have these exact findings, modeling survival provides the best data currently available on the effect of interventions such as CPR or defibrillation. In other EMS systems staffed by less experienced EMS providers who have a lower call volume each year, provision of CPR and defibrillation, but not advanced cardiac life support, significantly improved survival to discharge.[135] Collectively, these studies emphasize the importance of timely intervention and of considering differences in EMS structure and function when comparing results across EMS systems.

Rescuer performance

The training and performance of rescuers in the EMS predicts outcome after cardiac arrest.[188] Physician involvement in training, supervision, evaluation, and leadership is likely to be a substantial ingredient of successful systems and is currently not measured.[228] The use of quality assurance in EMS is infrequent and immature, but can have significant and important effects on outcome. When quality assurance is performed, it sometimes assesses factors such as education rather than performance or outcome indicators. Recent studies have demonstrated that CPR is frequently not performed according to evidence-based guidelines in the out-of-hospital and in-hospital setting.[37,229,230] Although these studies lacked power to detect a significant relationship between CPR process and patient outcome, a related study demonstrated that a greater rate of chest compressions was associated with a greater likelihood of achieving restoration of spontaneous circulation.[231] Collectively, these studies reemphasize the importance of medical oversight to assure and improve the quality of prehospital emergency care.

Future directions

In the future, significant changes in resuscitation are likely to occur. Observational studies will continue to improve the field of resuscitation. New epidemiologic data are desperately needed to answer the following questions:

- What is the current incidence and survival rate of out-of-hospital cardiac arrest? Why has the survival rate after cardiac arrest remained static?
- Can the proportion of cases that receive bystander CPR be increased?
- Can outcomes be improved by broad implementation of quality assurance of EMS care?
- Is training and equipping family members of those at risk for cardiac arrest an effective method of reducing time to defibrillation and increasing survival?

• Can differences in incidence and survival according to race and socioeconomic status be reduced?

To find answers to these questions and to test future therapies, more accurate and larger quantities of data are needed than are currently available. National or international databases offer the best opportunities to do so. Data accuracy must be improved so that real verifiable time intervals can be measured. A critical step towards improving outcomes is for every community to monitor and improve its rate of survival after out-of-hospital cardiac arrest. Finally, new therapies must be developed to improve treatment.

Basic science

Global cellular ischemia/reperfusion during cardiac arrest: critical stress responses and the postresuscitation syndrome

Kimm Hamann, Dave Beiser, and Terry L. Vanden Hoek

Department of Emergency Medicine, University of Chicago, USA

Cardiac arrest is the most lethal disease of ischemia/reperfusion (I/R) with only 5%–7% of out-of-hospital cardiac arrest (OHCA) victims surviving to hospital discharge.[1] Why a patient passes from full human function to "death" within minutes to hours, often despite an initially successful resuscitation and restoration of normal vital signs, is unclear. Certainly compared with the focal tissue ischemia of stroke or myocardial infarction the ischemic interval of cardiac arrest is measured in minutes rather than hours; yet, the establishment of reperfusion following cardiac arrest resuscitation, unlike that following focal ischemia, cannot be considered definitive therapy. Indeed, out of every 100 cardiac arrest victims, about 30 will achieve return of spontaneous circulation (ROSC) but only 5 survive the postresuscitation period to hospital discharge.[1–6] Thus, postresuscitation deaths contribute significantly to overall out-of-hospital cardiac arrest mortality as most patients who are initially "saved" die during a lethal post-resuscitation syndrome often during the first 24–72 hours, characterized by early cardiovascular collapse with multi-organ failure [7–9] *and* subsequent *failure of central nervous system recovery*.[10–12] If we could successfully treat or prevent reperfusion injury it would result in an estimated 6–10 fold improvement in survival following cardiac arrest. Efforts to improve post-resuscitation care are well justified since 75% of patients who are discharged alive return to their communities with intact neurological function and a good quality of life.[13–15]

The extent of such post-resuscitation injury is likely to be associated with the time of ischemia. Weisfeldt and Becker proposed a "three-phase time-sensitive" model of cardiac arrest highlighting the need for different treatments at specific ischemia times of cardiac arrest.[16] The model suggests optimal treatment of cardiac arrest should be phase-specific: (1) the electrical phase (from onset to ~4 minutes), where ideal treatment is defibrillation; (2) the circulatory phase (from ~4 to ~10 minutes), which requires high quality CPR prior to defibrillation; and (3) the metabolic phase (after ~10 minutes of ischemia), which likely requires therapies directed at the modulation of oxidants, immune system mediators, microvascular injury, apoptosis, and energy substrate depletion.[7,9,17–21] This chapter will focus on events likely to occur with greatest severity in those cardiac arrest patients resuscitated from the metabolic phase.

The post-resuscitation period represents a critical therapeutic window for improving outcomes through interruption of death pathways and abrogation of ongoing end-organ ischemic injury. Proof of this assertion comes from recent clinical studies demonstrating that therapeutic hypothermia, induced during the immediate post-resuscitation period, significantly improves clinical outcomes.[22–25] Unfortunately, hypothermia is one of the only examples of an effective post-resuscitation intervention. It also stands out as particularly non-specific therapy that is likely to act in a somewhat "global" fashion to modulate entire classes of fundamental intracellular processes mediating post-resuscitation disease. A deeper understanding of the cellular mechanisms of post-resuscitation injury, through the development of new clinical biomarkers and measures, is vital to optimizing the delivery of therapeutic hypothermia and developing therapies targeted at specific pathways or subclasses of cardiac arrest patients. In addition, similarities between the post-resuscitation and sepsis syndromes[20,26] suggest opportunities for the development of new therapies targeted at specific mediators of post-resuscitation injury. Hypothermia, and the achievement of

core body temperature goals, might simply be one component of a larger protocol of "early-goal-directed therapy"[27] directed at the molecular level toward modulating critical post-resuscitation events.

This chapter reviews the clinical and basic science features of the post-resuscitation syndrome, with particular focus on the cardiovascular system, cellular stress-responses, and mechanisms of cell injury and death following cardiac arrest and resuscitation. In particular, the role of oxidants and critical stress responses including inflammation, apoptosis, and death pathways will be highlighted. An improved understanding of these cellular mechanisms will likely be vital to optimizing the clinical application of therapeutic hypothermia. In addition, new therapies targeted at modulation of cytokines and oxidants have great promise for the treatment of cardiac arrest. Similar to the treatment of electrical phase patients by using defibrillation, such therapies could some day routinely resuscitate patients in the metabolic phase – the sickest of cardiac arrest patients – back to previous human function.

The post-resuscitation syndrome

The post-resuscitation syndrome is characterized by systemic inflammation, myocardial dysfunction,[7,9,17,18] circulatory collapse and multi-organ failure leading often to either death during the first 24–72 hours or subsequent failure of central nervous system recovery.[10–12] The post-resuscitation and sepsis syndromes share many similar features including endothelial dysfunction, thrombosis, impairment of fibrinolysis, marked elevation of inflammatory mediators, and mild hyperthermia.[20,25,28–30] Recent clinical studies have noted the appearance of peripheral markers of this inflammatory cascade such as cytokines/chemokines (e.g., IL-1ra, IL-6, IL-8, IL-10) and other inflammatory mediators including activated polymorphonuclear leukocytes, endothelial adhesion molecules, and complement following out-of-hospital cardiac arrest (OHCA) – findings similar to those seen during sepsis.[20,31–35] In cardiac arrest patients, non-survivors demonstrate plasma IL-6 concentrations that are 20-fold greater than these of survivors, and approximately 50-fold greater than baseline values from normal humans.[20,36]

Why a sepsis-like syndrome would be seen in the context of a non-infectious disease is intriguing. Cardiac arrest involves sudden, global, multi-organ ischemia. Reperfusion occurs during cardiopulmonary resuscitation (CPR) and more fully at return of spontaneous circulation (ROSC). The changes in oxidant stress and redox state associated with these critical transitions during whole-body ischemia/reperfusion likely activate a host of cellular stress responses at the transcription and protein level. These critical stress responses throughout multiple organs could explain the simultaneous triggering of cytokines, chemokines, activated complement and polymorphonuclear leukocytes, and endothelial cell adhesion molecules. Interestingly, such stress responses could be quite adaptive when localized to tissue injured by trauma or microbial invasion, local events that can also cause localized changes in oxidant stress and altered redox state. When they become simultaneously global throughout the body as may occur during cardiac arrest, however, these same stress responses could become overly amplified with devastating and lethal consequences.

Regarding post-resuscitation myocardial injury, while much work has focused on neurological injury after resuscitation, less is known about the earlier cardiovascular injury and collapse that is often seen in these patients. In a small clinical study of post-resuscitation hemodynamic instability, survivors of out-of-hospital cardiac arrest usually demonstrated improvement of cardiac index (CI) by 24 hours, with persistently low CI at 72 hours associated with death by multi-organ failure.[9] Nevertheless, this study did not include those patients who died early after ROSC prior to reaching the cardiac catheterization laboratory; that is, those exhibiting the most acute and severe postresuscitation cardiovascular injury. Postresuscitation cardiac dysfunction has been associated with elevated plasma TNF-alpha levels in swine models.[37] In addition, TNF-alpha-induced caspase-3 activation has been shown to mediate cardiac dysfunction in response to endotoxin challenge in mice.[38] Understanding such cardiovascular post-resuscitation injury is important as it represents the most accelerated and lethal form of three distinct post-resuscitation phenotypes: intact survival, neurological impairment, or in-hospital death due to cardiovascular collapse.

Redox-mediated intracellular stress responses

The list of potential mediators of post-resuscitation injury is legion and includes both the intracellular and extracellular expression of multiple reactive oxidant species; pro-inflammatory mediators of the innate immune system such as cytokines/chemokines (e.g., IL-6, IL-8), endothelial adhesion factors, activated complement and leukocytes; and other pro-apoptotic signaling molecules. We will begin by discussing the intracellular mechanisms of redox-signaling.

During the global ischemia of cardiac arrest, the myocardial intracellular environment is characterized by striking

changes in myocardial oxygen tension (PO_2), carbon dioxide tension (PCO_2), and pH. Following the onset of ventricular fibrillation, intramyocardial PO_2 levels rapidly plummet, while PCO_2 and hydrogen ion concentrations increase.[39–41] After only 4 minutes of ventricular fibrillation in swine, myocardial PCO_2 may increase to well over 200 torr with a corresponding drop in pH to 6.0 and below.[41] Indeed, increased myocardial CO_2 during cardiac arrest may negatively affect the heart's ability to be successfully defibrillated.[42] Furthermore, hypercarbic acidosis has been shown to worsen myocardial contractility in an isolated rat heart preparation[43] and worsen outcomes in a swine model of cardiac arrest.[44] The myocardial intracellular environment undergoes another transformation as these trends are reversed with the initiation of effective cardiopulmonary resuscitation (i.e., partial-flow reperfusion). Finally, upon return of spontaneous circulation, the myocardium undergoes a third transition as reperfusion leads to the rapid normalization of these parameters within 30 minutes post-resuscitation.[40,41]

These striking shifts in the cellular microenvironment have the potential for radical alteration of the potential for oxidant signaling, ROS-mediated damage, and eventual cell dysfunction or death. Oxygen, for example, is essential for life; as an acceptor of electrons from the mitochondrial electron transport chain it allows concurrent synthesis of adenosine triphosphate (ATP) through oxidative phosphorylation. Control of oxygen delivery at the tissue and cellular level thus is critical for survival. Changes in redox state precipitated by sudden drops in tissue O_2 tension can trigger adaptive oxidant signaling responses that attempt to restore metabolic homeostasis. Although there are numerous sources of oxidant signaling molecules in the cardiovascular system, mitochondria appear to be critical oxygen biosensors capable of acting as first responders to the PO_2 changes associated with cardiac arrest.[45–49]

Our own studies of I/R in cardiomyocytes suggest that oxidant stress is generated within seconds to minutes of ischemia onset. This increase in oxidant stress is seen both at the cardiomyocyte level[45] and at a systemic level within minutes of CPR in swine models of cardiac arrest.[50,51] Prolonged ischemia can induce superoxide generation and lipid peroxidation; alter cardiolipin and affect the integrity of the mitochondrial electron transport chain. Reducing equivalents present at the time of resuscitation fuel a burst of lethal oxidant generation as a result of electron transfer from complexes I and II into the intermitochondrial membrane space via complex III, with subsequent cytochrome c release and apoptosis.[48]

Recent work demonstrates the existence of a "pH paradox," a worsening of cardiomyocyte survival after ischemia despite rapid normalization of pH during reperfusion. Acidotic reperfusion of ischemic cardiomyocytes by using hypercarbia has been reported to improve cell survival.[52] The mechanism of this protective effect is not entirely clear, however. Hypercarbia may act as a mitochondrial inhibitor; indeed, recently researchers from our laboratory have demonstrated that a brief transient period of mitochondrial inhibition during the reperfusion of chick cardiomyocytes *in vitro* abrogated the generation of ROS and improved cell survival through a mitochondrial complex III-dependent mechanism.[53] Thus, even though the rapid normalization of O_2, CO_2, and pH is an implied intermediate goal of CPR, an uncontrolled overly rapid transition might worsen mitochondrial recovery and post-resuscitation oxidant injury. The conditions for a more controlled reperfusion (e.g., temperature, transitions in tissue O_2 and CO_2) that minimize post-resuscitation injury are not known, but likely vary depending on time of ischemia (i.e., they are phase specific).

The type of oxidant species generated in the heart during cardiac arrest and reperfusion likely are numerous, with many species (particularly superoxide, H_2O_2, and nitric oxide) capable of both good and bad effects depending upon redox state, tissue CO_2 levels and pH, and other species present. The formation of intracellular ROS and that of nitric oxide are interrelated, with one species affecting and regulating the other.[54] We have previously utilized a nitric oxide synthase inhibitor (NOS), NG-nitro-L-arginine methyl ester (L-NAME), to block the formation of nitric oxide in our cardiomyocyte model during conditions of hypoxia,[55] supporting the notion that cardiac cells can generate significant amounts of NO within minutes of onset of cardiac arrest-like conditions. In turn NO can interact with superoxide to form peroxynitrite, with concurrent oxidant damage. Indeed, inhibition of NOS has been shown to reduce myocardial O_2 consumption in an intact dog preparation and improve coronary perfusion pressure and rate of ROSC in a swine model of cardiac arrest.[56,57] While NO can play a deleterious role in reperfusion injury, depending upon timing and concurrent generation of other oxidants, it can also exert highly protective effects.[54]

Other oxidase systems such as NADPH oxidase, xanthine oxidase, and cytochrome P450 systems would likely be affected by this initial oxidant stress response by mitochondria and could further amplify oxidant stress via increased generation of ROS. The underlying mechanism of oxygen sensing by mitochondria may involve redox regulation of nitrite and nitric oxide homeostasis in the inner mitochondrial membrane[58], with inhibition of cytochrome c oxidase by nitric oxide as well as superoxide

generation from complex III.[59] In addition, mitochondrial membrane and cell membrane anion channels may be sensitive to redox state and control the release of superoxide into the cytosol and possibly the extracellular space.[45]

The oxidant tipping point

Such oxidant and inflammatory stress responses can play both adaptive and deleterious roles in the organism, depending upon the threshold that is reached during conditions of ischemia/reperfusion. Indeed, the importance of oxidant stress for adaptive cardiovascular responses is suggested by recent findings that high-dose antioxidants taken chronically may actually increase cardiovascular disease mortality.[60] Although such stress responses are necessary for survival against local traumatic injury or infection, when quickly generalized to a multi-organ level during cardiac arrest, these same critical stress responses could result in amplification of oxidant and inflammatory stress that shifts the balance from survival to activation of the death pathway.

Such an oxidant "tipping point" may be seen at the molecular level. For example, Stamler and Hausladen have proposed a continuum of nitric oxide- and ROS-mediated Cys-SH oxidant modifications that progresses from SNO (S-nitrosylation) to SOH (sulfenic acid), disulfide (SS), sulfinic (SO_2^-), and sulfonic (SO_3^-) acids.[61] This continuum may define how a cell or tissue "ramps up" its response to changes in redox state, eventually crossing the oxidant stress threshold from adaptive signaling to irreversible damage. In addition, the timing of adaptive oxidant modifications of Cys-SH is important, such that adaptive oxidation to disulfide linkages can protect against subsequent oxidant damage by more lethal oxidants if induced early. Protective strategies such as intra-ischemic hypothermia could conceivably be mediated by such oxidant modulation, with induction of protein protection prior to the increased oxidant stress of ROSC.

Circulating messengers of I/R injury: extracellular oxidants and cytokines/chemokines

Extracellular expression of pro-inflammatory and oxidant molecules amplifies the magnitude and local extent of the original I/R injury through both autocrine and paracrine effects, which promote increased oxidant production and release of cytokines/chemokines.[62–64] For example, both serum and tissue levels of the oxidant stress marker F2-isoprostane increase significantly within minutes of cardiopulmonary resuscitation after swine cardiac arrest,

reaching a peak within 30 minutes after ROSC.[50,51,65] Such molecules also play an important role in communicating the original insult to distal/remote tissues by promoting microvascular injury through the recruitment, activation and/or diapedesis of a variety of circulating cell types (e.g., leukocytes, platelets); and increased fibrin clot formation with decreased fibrinolysis,[30] the end result being poor capillary tissue perfusion, tissue ischemia and multi-organ dysfunction.[62–64] Evidence for such distal amplification of injury through microvascular injury comes from several mouse models of I/R injury of gut or liver. Such models can generate significant injury "at a distance," with splanchnic organ ischemia producing increased pulmonary sequestration of circulating leukocytes, increased levels of pulmonary tissue in chemokines related to human IL-8 such as MIP-2 and KC, and microvascular permeability.[66–68] Cardiac arrest conceivably amplifies this "injury at a distance" many fold, since multiple organs experience I/R conditions simultaneously.

I/R-induced oxidant and inflammatory protein signaling pathways have been shown to have an impact on distal tissues through direct endocrine pathways as well.[63] These direct endocrine pathways may initially represent adaptive homeostatic responses to I/R that then become amplified in a maladaptive manner long after the initial injury.[63] Such a direct oxidant pathway has been postulated in part to mediate post-ischemic myocardial stunning.[64] Isolated hepatic I/R injury has been shown to inactivate mitochondrial superoxide dismutase (MnSOD), a mitochondrial antioxidant enzyme, within pulmonary endothelial cells.[69] Pro-inflammatory cytokines, such as TNF-alpha, have also been shown to have direct negative inotropic effects on myocardium.[70] In a murine model of resuscitated hemorrhagic shock (a related state of global I/R,[71]) infusion of a soluble TNF-alpha receptor antagonist (etaneracept) significantly attenuates post-resuscitation LV dysfunction.[72] Another example of direct organ–organ communication of I/R injury comes from recent work in a model of focal intestinal I/R.[73] In this model, *Tnfrsf1a*–/– mice showed decreased pulmonary infiltration of polymorphonuclear cells, decreased NF-kB activation and decreased mRNA expression in several NF-kB target genes encoding pro-inflammatory cytokines/chemokines.

Transcriptional pathways of critical stress response

As noted in the above mouse model, I/R can alter gene expression.[73] A recent transcriptome analysis of rat myocardium after focal I/R demonstrated increased

expression of mRNA of pro-inflammatory proteins such as IL-6 and IL-18 at 2 days post-reperfusion with later transcription of genes encoding pro-apoptotic caspases.[74] Such transcriptional alterations may be triggered by changes in oxidant stress and redox state via stress-sensitive transcription factors such as NF-kB.[75,76]

Similar transcriptional stress responses are likely to occur following global I/R. For example, in murine models of unresuscitated hemorrhagic shock (HS), a brief, but profound, period of HS rapidly leads to hepatic NF-kB activation, TNF-alpha mRNA expression, as well as increases in plasma TNF-alpha concentration.[77,78] In a separate murine model, unresuscitated HS leads to upregulation of NF-kB gene expression at 1 hour and an associated sustained NF-kB activation lasting 24 hours, suggesting the possibility of a sustained period of pro-inflammatory transcription.[79] Such rapid and sustained activation of NF-kB-mediated responses, in contrast to episodic activation and spontaneous resolution, has been associated with induction of cell death pathways.[80]

Reperfusion during resuscitation also appears to trigger activation of transcription factors and early gene-expression of cytokines/chemokines and prostaglandins within multiple vital organs, including the liver, spleen, lung, and muscle after whole-body ischemia due to hemorrhagic shock.[81] Such transcriptional changes appear to be modulated by the severity of hemorrhage and the timing and choice of therapeutic intervention.[82–84]

Such a rapid multi-organ activation of innate immune response by NF-kB signaling has already been modeled in non-cardiac arrest patients exposed to non-toxic doses of endotoxin.[85] Genomic systems biology approaches suggest that innate immune responses in humans evolve quickly, and the stress responses seen within 4–6 hours of initiation may be critical for successful return to a normal human phenotype.[85] Factors that both initiate and limit innate immune responses evolve significantly between time of onset and at 4–6 hours, with their balance and trend likely to be critical for successful resolution of both "pro-inflammatory" and "counter-inflammatory" stress response phases.

Post-resuscitation syndrome: the connection among oxidant stress, inflammation, and apoptosis

In addition to microvascular and direct inhibitory effects, oxidant stress and inflammation are thought to trigger pro-apoptotic pathways. For example, I/R has been shown to trigger apoptotic cell death through the Fas/Fas ligand pathway leading to caspase activation.[48,86] Fas (also known as CD95) is a membrane-bound receptor in the tumor necrosis family expressed in a variety of cells including heart and lung. Researchers from our laboratory have demonstrated the expression of both Fas and FasL in human epithelium.[87] Cytokines may play an important role in activating metalloproteinases which can cleave membrane-bound Fas and FasL to its soluble form that then can be released into the circulation.[88] Although the role of apoptosis following cardiac arrest is not entirely known, it is conceivable that such high circulating levels of cytokines could induce myocardial apoptosis and play an important role in cardiovascular dysfunction and collapse. This notion is consistent with some pathology studies involving heart tissue from cardiac arrest patients. A case series of pathology specimens taken from postmortem heart tissue showed widespread uptake of apoptosis markers throughout the myocardium of patients after sudden death.[89]

Programmed cell death in the heart

If injury to a cell is too great, or if its "usefulness" has expired, a cell or neighboring cells may signal its removal. Physiological removal of cells has been termed programmed cell death (PCD) because a genetic program consisting of a sequence of molecular signaling and biochemical events is initiated to dismantle the affected cell. Apoptosis, a specialized form of cell death, was originally equated with PCD; however, it is becoming clear that there are many forms of PCD and that even necrotic cell death may be regulated in many tissues,[90] including the heart,[91] particularly after ischemic injury.[92,93]

Necrosis/oncosis

The terms "necrosis" or "oncosis" traditionally have been used to refer to an unregulated cell death morphologically typified by cellular swelling and plasma membrane rupture. While historically viewed as a pathological or "accidental" form of cell death resulting from acute cellular injury, or as a result of bioenergetic catastrophe,[94,95] recent evidence suggests that necrosis/oncosis may be a substitute, or alternate pathway, for myocardial cell death and loss of cardiac function,[91] – particularly when apoptosis is blocked, for example, by caspase inhibition.[96,97] Regulated or "programmed" forms of necrosis have been described recently in a number of cell types (see reviews[90,95,98]), and may involve a number of molecular mediators or regulators normally associated with apoptosis, such as certain members of the Bcl-2 family (see below). Such regulated

forms of necrosis have not yet been described specifically in cardiac arrest, but in light of the numerous descriptions of "necrotic," "oncotic," or generally "non-apoptotic" cell death in the heart, it is likely that continued dissection of death mechanisms in the heart after arrest or infarction will elucidate such mechanisms and their potential role in myocardial damage. Interestingly, an atypical pathway of cardiomyocyte cell death caused by hypoxia and acidosis has recently been described, which seems to involve a combination of features of apoptosis and necrosis.[99] A pro-apoptotic member of the Bcl-2 family (see below), BNip3, and its actions on the mitochondrial permeability pore were implicated in this death mechanism, but activation of the apoptotic proteases, caspases, was not. On the other hand, the involvement of specific caspases in additional, perhaps intermediate, forms of cell death, have been linked to non-apoptotic forms of PCD recently termed "paraptosis" and "pyroptosis."

Paraptosis and pyroptosis – caspase-associated non-apoptotic cell death

Another form of PCD distinct from apoptosis has been termed paraptosis (for "next to" or "related to" apoptosis) and is characterized morphologically by cytoplasmic vacuolation and late mitochondrial swelling.[100] Although this death is not blocked by either the anti-apoptotic protein, Bcl-x_L, or by certain caspase inhibitors, this form of cell death is driven by an alternative activity of caspase-9, perhaps related to phosphorylation of caspase-9 by specific kinases.[101] Caspase-9 has been associated with ischemia/reperfusion (I/R)-induced cell death in a number of models of cardiomyocyte injury,[102–104] but the potential role of paraptosis-like cell death in myocardial injury is unknown.

Recently, the term pyroptosis (for "fire or fever," Greek) was proposed to describe a cell death that is uniquely dependent on caspase-1. Although caspase-1 is classified as a member of the inflammatory caspase subfamily (see below) and has been dissociated from certain physiological pathways of apoptosis[105,106] recent evidence suggests that caspase-1 can interact with multiple pathways of both inflammation and cell death.[107,108] Of particular note are recent descriptions of key roles for caspase-1 in ischemia-induced cell death.[108–110] In a murine model of myocardial ischemia, caspase-1 acts in synergy with hypoxia to stimulate caspase-3-mediated apoptosis[108] and inhibition of caspase-1 in a suprafused human myocardium model of I/R reduced ischemia dysfunction at least in part by inhibiting proinflammatory cytokines, IL-18 and IL-1β.[111]

The latter study is particularly interesting in light of the previously discussed connection between post-resuscitation disease and the sepsis syndrome.[20,26]

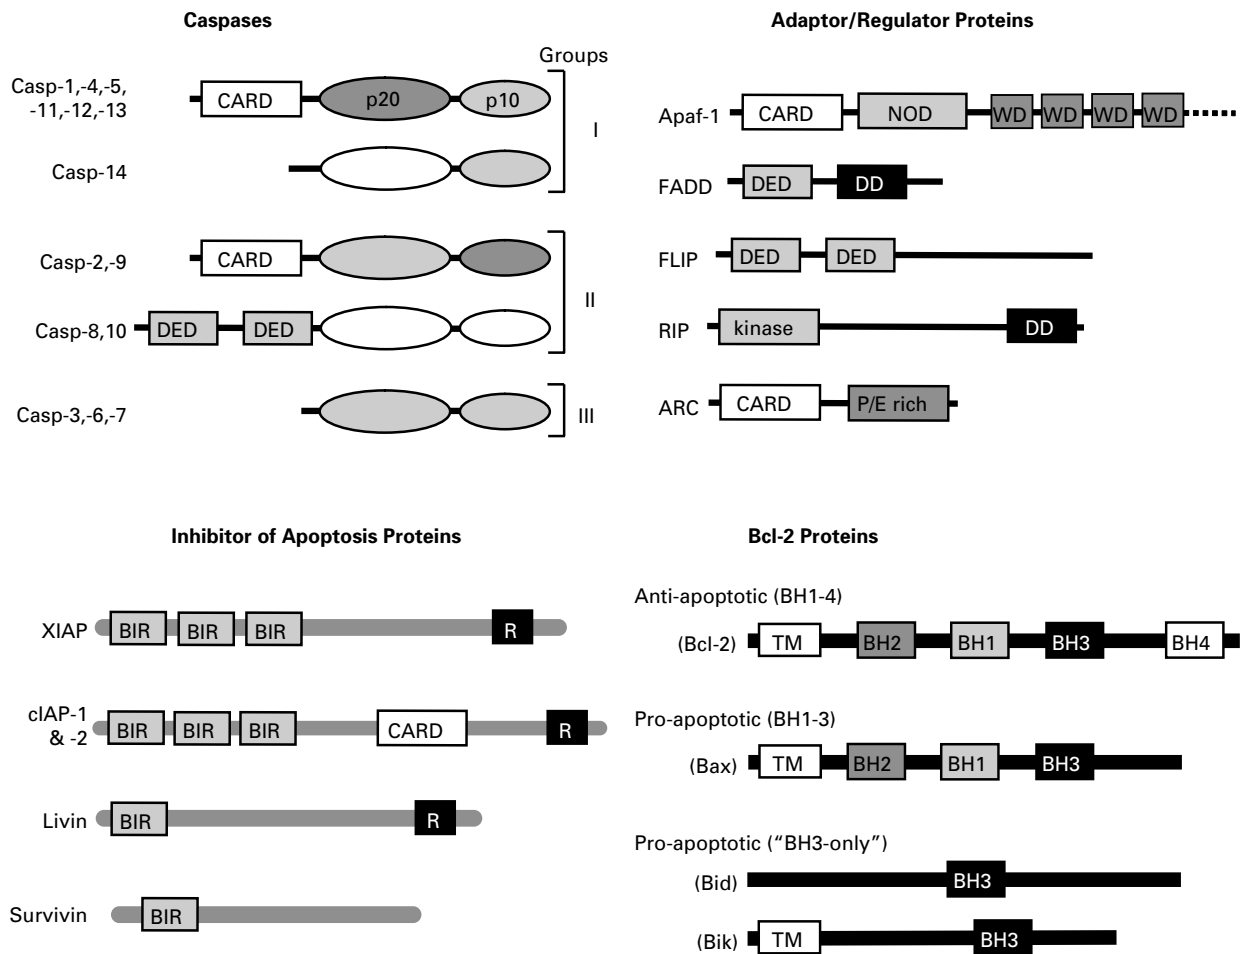
Whereas pyroposis as originally described[112] may be a novel form of cell death induced by infection with *Salmonella* and *Shigella* species, pyroptosis as a process likely plays a physiological role in a variety of tissues,[113] and growing evidence of the participation of caspase-1 and inflammation in the post-ischemic myocardium suggests that this pathway is important in cardiac arrest. Like the involvement of the extrinsic apoptotic pathway described below, thus far the participation of caspase-1 has been examined specifically in cardiac arrest from a perspective of global ischemia and damage to "outlying" tissues such as the brain.[114] Nonetheless, the significance of caspase-1 activation to potential inflammatory or "pyroptosis-like" responses following cardiac arrest in either the brain or heart remains to be more thoroughly investigated.

Autophagy

Before we consider apoptosis and several of its well-characterized molecular mediators and regulators, another potential form of cell death has attracted a great deal of attention for its role in physiological homeostatic processes, including processes of cell death and survival in the myocardium.[115] Autophagy ("to eat oneself," Greek) is a regulated process by which a cell carries out lysosomal degradation of its own constituents, including cytoplasm (microautophagy) and larger cytoplasmic proteins and organelles such as mitochondria (macroautophagy). Chaperone-mediated autophagy is a third form of the process largely confined to mammalian systems, involving the formation of a complex between cytosolic protein substrates and protein chaperones and subsequent translocation into the lysosome. There is some disagreement as to whether autophagy truly represents an initiated form of cell death or a cellular response to stress from which a cell may or may not recover. It is clear that autophagic processes can occur in the heart, however, and (macro)autophagy has been described recently in the chronically ischemic myocardium.[116] In the latter study, autophagy was hypothesized as a homeostatic process utilized for the turnover of unnecessary or dysfunctional organelles and cytoplasmic proteins in the ischemic myocardium, which could protect against further ischemia.[116] Recently, in a murine model of autophagy[117] the pro-death function of autophagy was examined in mouse heart muscle.[118] Transgenic expression of cardiac Bcl-2 (and its subsequent interaction with the autophagy

protein, Beclin-1) helped maintain levels of autophagy that were compatible with cell survival, rather than cell death.[118] Selective or preferential autophagy of the mitochondria has been termed mitophagy,[119] and is thought to occur as a process of mitochondrial quality control, or as a cellular response to overwhelming numbers of damaged mitochondria.[120] In I/R injury, oxidative damage to mitochondrial membrane proteins can lead to opening of the mitochondrial permeability transition (MPT) pore.[121] At one extreme, MPT opening can lead to necrosis through ATP depletion or to apoptosis via cytochrome c release (see below) and cell death.[119] MPT pore formation under less severe stress can promote autophagy, however, or more specifically mitophagy, and the removal of ROS-producing mitochondria may be a survival mechanism.[119] Thus, a greater understanding of the occurrence and extent of autophagy in the stressed myocardium will be important in considering future therapeutic approaches to the management and treatment of cardiac disease,[115] and post-resuscitation survival.

Apoptosis

Of the known forms of PCD, apoptosis is by far the best characterized at the molecular level. Morphologically, apoptosis is characterized by nuclear condensation and fragmentation and by cell shrinkage. Indeed, J.F.R Kerr, the originator of the term "apoptosis,"[122] initially described this cell death as "shrinkage necrosis."[123] DNA fragmentation or "laddering" is another characteristic of apoptosis, and this, along with many of the morphological aspects, is due a subclass of proteases called caspases (*cy*steinyl *asp*artate-specific prote*ases*), although there are now recognized forms of apoptosis that may be caspase-independent processes.


A number of excellent reviews of apoptosis in the heart exist[124–128] and the reader is referred to these and others for more comprehensive and detailed reviews of molecular mechanisms of apoptotic pathways of cell death in cardiomyocytes. Here, we will briefly consider the major pathways and molecular participants of apoptosis and the evidence for their involvement in I/R-induced injury in the myocardium, particularly with regard to the involvement of the mitochondria. Recently, there has been recognition that apoptosis of cardiomyocytes (and perhaps other cell types, such as endothelial cells[129,130]) can occur in various pathologies of the human heart, including heart failure,[131,132] I/R injury in myocardial infarction,[133,134] and in ischemic injury during cardiosurgical procedures.[135,136] Most recently, evidence of apoptotic death of cardiomyocytes in the global

I/R following cardiac arrest and resuscitation has been studied and related directly to cardiac function and survival.

Caspases

As implied above, caspases are central to the dismantling of a cell via the major pathways of apoptosis (discussed below). Fourteen mammalian caspases have been identified to date,[137] and the apoptotic caspases can be grouped into two general categories: (i) initiator or "upstream" caspases, including caspases-2, -8, -9, and -10, and (ii) "executioner" or apoptosis effectors, caspases-3, -6 and –7 (Fig.3.1). The remaining caspases make up a third group and are often referred to as "inflammatory" caspases. These are involved in the maturation of certain cytokines, such as IL-1β. All caspases exist as zymogens or "procaspases" and generally are activated by proteolytic cleavage, either through autolytic cleavage or activation via induced proximity or dimerization/oligomerization[138–140] or, for the executioner caspases, by cleavage by other (upstream) caspases. The initiator caspases possess specialized prodomains (CARD = *ca*spase *r*ecruitment *d*omain or DED = *d*eath *e*ffector *d*omain) involved in their activation, and generally speaking, once activated, these initiator caspases activate the effector caspases via cleavage of their pro-forms (e.g., procaspase-3). On the basis of specific sequence preferences, caspases perform distinct roles in the apoptotic process, although in caspase-deficient cells, one or more caspases may substitute for the missing caspase.[125] Literally hundreds of caspase substrates have been identified, and these include major structural elements of the cell, cell cycle proteins, protein kinases and phosphatases, transcription factors, and components of the DNA repair machinery, as well as apoptotic regulators, such as members of the Bcl-2 family.[141,142] As outlined below, the activation of several different caspases has been observed in I/R-induced apoptosis in isolated cardiomyocytes and in intact myocardium.

In addition to control of initiating events of apoptosis pathways discussed below, regulation of caspase activity also is accomplished directly via endogenous inhibitors of the caspases known as inhibitors of apoptosis proteins (IAPs) (Fig. 3.1) An extended discussion of IAPs is not possible here, and the reader is referred to several recent reviews of this protein family.[143–146] Briefly, IAPs were first identified in baculoviruses, (see reviews[143,147]); and in mammals there are at least seven IAP family members, each of which contains one or more baculoviral repeat (BIR) domains, through which they interact with certain caspases. Specific interactions between caspases and BIR

Fig. 3.1. Primary structures and diverse interacting domains of major protein groups associated with apoptosis. Examples in each of the major families and groups of apoptotic proteins and regulators are shown, including critical functional and interacting domains: CARD = caspase recruitment domain; p20 = large caspase subunit; plO = small caspase subunit; DED = death effector domain; BIR = Baculovirus IAP domain; R = Ring zinc finger domain; NOD = nucleotide-binding oligomerization or "ATPase" domain; P/E-rich = proline/glutamine-rich domain; WD = tryptophan-aspartate repeats; DD = death domain; TM = transmembrane domain; BH1-4 = Bel-2 homology domains 1–4. Mammalian caspases have been organized into three major groups: group I containing the inflammatory or "cytokine maturation" caspases; group II comprised of initiators of apoptosis containing CARD or DED prodomains; and group III containing the effector caspases. (Caspases -11 and -12 are of mouse origin; caspase-13 described from bovine cells {Shi, 2002 #1943}) The Bcl-2 protein family has also been subdivided into three major groups, including the anti-apoptotic proteins, such as Bcl-2 and BCI-XL, which act to block the release of cytochrome c and other apoptogenic mitochondrial proteins. The proapoptotic members of the family are further divided into two subfamilies: the multi-domain proapoptotic proteins, represented by Bax and Bak; and the BH3-only subfamily containing at least 10 members. The WD domains in Apaf-1 are thought to be responsible for binding cytochrome c, while the NOD domains are involved in binding ATP/dATP and analogs driving conformational changes, which are critical for apoptosome formation (see Fig. 3.2, text and cited reviews for additional details regarding these and other molecular interactions).

domains have been elucidated recently, and XIAP (the most studied of the IAPs), inhibits the effector caspases-3 and -7 and the initiator caspase-9 through BIR2 and BIR3 regions, respectively.[148,149] These caspase inhibitors can be inhibited themselves by the mitochondrial proteins Smac/DIABLO (second mitochondria-derived activator of caspase/direct IAP-binding protein with low pI)[150,151] and Omi/HtrA2.[152–154] The involvement of IAPs, Smac, and Omi in I/R-induced apoptosis is not well studied, particularly in the heart, but recently a deficiency of XIAP expression was
Fig. 3.2. Diagrammatic summary of the two major pathways of apoptosis in mammalian cells. The extrinsic pathway is initiated by the binding of a death ligand/cytokine trimer such as FasL (Fas ligand) to its trimerized receptor (here, Fas/CD95). This leads to the recruitment of adaptors such as FADD and, in turn, procaspase-8 (or-10). Oligomerization of these proteins comprises the death-inducing signaling complex (DISC) and leads to the activation of caspase-8. Caspase-8 initiates the caspase cascade and/or cleaves Bid (to truncated or "tBid") for cross-talk to the mitochondrial pathway. The mitochondrial or intrinsic pathway can be initiated by a number of stress factors, including ischemia/reperfusion, and may involve caspase-2 activation and direct effects on the mitochondria and/or activation of pro-apoptotic Bcl-2 proteins, such as Bax and Bak. Details of these mitochondrial interactions and models of cytochrome c (and other apoptogenic proteins, e.g., Smac/DIABLO, Omi/HtrAl, AIF, & EndoG) release are summarized in Fig. 3.3. Cytochrome c forms a complex with Apaf-1, which in the presence of ATP/dATP, induces formation of a heptameric, wheel-like structure to which procaspase-9 molecules are recruited. Activation of caspase-9 leads to initiation of the caspase cascade involving effector caspases-3, -7 and -6, and to DNA fragmentation and caspase-mediated dismantling of the cell.

found in post-infarction hearts in a murine model,[155] and increased ratios of XIAP to Smac were associated with minocycline-induced cardioprotection in a rat model of I/R injury.[156] A novel "CARD-carrying" caspase inhibitor (see Fig. 3.1), ARC (*a*poptosis *r*epressor with *C*ARD domain) has been identified recently, which interacts with at least two initiator caspases, caspases-2 and -8.[157] ARC appears to be expressed primarily in skeletal and cardiac muscle cells, and recent evidence indicates that ARC can protect a myogenic cell line from oxidant stress by preserving mitochondrial function.[158] This protection is likely a result, at least in part, of ARC's ability to interact with and prevent the activation of the pro-apoptotic Bax protein[159]

(see below). In addition, the calcium-binding activity of ARC also has been implicated in its anti-apoptotic activities.[160]

Pathways of caspase activation

There are two major pathways of caspase activation in mammalian cells: the "extrinsic" or death receptor-mediated pathway and the "intrinsic" or mitochondria-mediated pathway (Fig. 3.2). The extrinsic pathway is mediated by specific membrane receptors, primarily of the tumor necrosis factor receptor (TNFR) superfamily, and

the most well -characterized death receptor besides TNFR itself, is Fas (CD95). The binding of the death ligand trimer, FasL, to the preformed Fas surface receptor homotrimer results in the formation of a death-inducing signaling complex (DISC), involving the adaptor protein FADD (*Fas-a*sscocated protein with a *d*eath *d*omain), which is recruited via its death domain (DD), and in turn recruits procaspase-8 (or-10) via death effector domains (DED), resulting in activation of caspase-8 (see review[161]). If only small amounts of caspase-8 are activated, the pathway may proceed through the cleavage of Bid and the pro-apoptotic effects of truncated Bid (tBid) on the mitochondria. Direct activation of caspase-3 by larger amounts of DISC formation and active caspase-8, however, can bypass the mitochondria to lead directly to the caspase cascade and apoptotic death (Fig. 2).[162] FADD and RIP (*r*eceptor-*i*nteracting *p*rotein) levels are increased in hearts of TNF-? transgenic mice,[163] whereas the levels of another protein, FLIP (*FL*ICE (caspase-8)-*i*nhibitor *p*rotein), are decreased in rat cardiomyoctes following hypoxia.[164] Both conditions can sensitize cardiomyocytes and other myocardial cells to death receptor-mediated killing. FADD and RIP have also been associated with innate immunity,[165,166] and in light of the potential role of such responses in post-resuscitation disease, future investigations of these molecules may have important implications beyond their roles in apoptosis. There are several recent reports of Fas/caspase-8 involvement in I/R-induced apoptosis in myocardium, mostly from isolated cells or isolated heart models of myocardial infarction.[167–170] These reports also suggest that a significant portion of the infarct is due to activation of the Fas-mediated pathway, but that blockade of the pathway in Fas-deficient mice,[167,170] or in cells expressing a dominant negative FADD,[168] only partially reduced infarct size. These data suggest that the initiating infarct persists, and that initiation of the injury is Fas-independent. It is possible, therefore, that the mitochondrial pathway plays a critical role in the early stages of I/R injury. Indeed, our data[102,103] and those of others[171] support an initiating role for the mitochondrial pathway in I/R injury and place Fas/caspase-8 activation downstream in amplification or post-infarction roles.[172]

As the name suggests, the mitochondrial or intrinsic pathway centers on the mitochondria and mitochondrial proteins, but can involve other organelles as well.[173] Details of this pathway of apoptosis in cardiomyocytes have been reviewed recently and elegantly[126,127] and because of space restrictions, we will limit our discussion to a brief consideration of critical pathway mechanisms and what is known about the major players in I/R-induced injury in the heart. As mentioned above, several studies have implicated mito-

chondria in the initiation of I/R-induced apoptosis (see recent review[174]). Mitochondria in cardiomyocytes depolarize during ischemia and a central role for generation of mitochondrial reactive oxygen species (ROS) has been implicated in this depolarization.[175] At reperfusion, a burst of ROS production can lead to the release of cytochrome c from the mitochondria, which in turn initiates formation of the wheel-like, heptad structure known as the apoptosome, ultimately resulting in the activation of caspase-9 and the caspase cascade (Fig. 3.2). Release of cytochrome c, and perhaps other apoptogenic molecules such as Smac/DIABLO, Omi/HtrA2, as well as AIF (*a*poptosis-*i*nducing *f*actor) and Endo G (*endo*nuclease *G*) (see below), involves the permeabilization of the outer mitochondrial membrane. There have been several mechanistic models of this permeabilization (see reviews[126,176,177]), and while still poorly understood, most include critical roles for the Bcl-2 family of proteins (see Fig. 3.3).[126,178,179] Recent demonstrations of potential roles of Bcl-2 family proteins in the regulation of ROS production[180] strengthens this association and generates numerous important questions on the specific roles of Bcl-2 proteins in I/R-induced apoptosis.

The Bcl-2 family

The Bcl-2 family of proteins includes more than 20 members all of which share at least one of four conserved Bcl-2 homology (BH) domains (Fig. 3.1). These proteins are grouped into at least three different interacting classes or subfamilies: (1) the anti-apoptoptic proteins, including Bcl-2, Bcl-x$_L$ and at least two others, (2) the pro-apoptotic proteins, which include Bax and Bak as the most characterized members, and (3) the so-called "BH3-only" proteins, including Bid, Bad, Bim, BNip3, PUMA and Noxa, among others. The interactions among these proteins can modulate critical steps early in the sequence of apoptotic events through their initimate associations with the mitochondria. Regulation of the activity of many Bcl-2 proteins is posttranslational, and both cleavage and conformational changes are among such regulatory mechanisms.[181–183] Regulation of mitochondrial permeabilization by homo- and heterotypic interactions between Bcl-2 proteins is importantly, but not exclusively, involved in I/R-induced apoptosis.[127] Direct interactions of Bcl-2 proteins with the outer mitochondrial membrane and disruption of normal mitochondrial respiratory function appear to be key to the intrinsic pathway.[127]

Of the Bcl-2 family members, Bid and Bax are two pro-apoptotic members, which have been centers of attention with regard to ischemia-induced cell death in the heart.
Fig. 3.3. Simplified diagram of apoptotic mitochondrial events.(a) Following an apoptotic insult, the activation of BH3-only proteins leads to the release of cytochrome c (cyto c), as well as LAP inhibitors, Smac/DIABLO and Omi/HtrA2 (b), from the inner membrane and intermembrane space. BH3 proteins may directly activate Bax and Bak or inactivate their antagonists, the anti-apoptotic proteins, such as Bcl-2 and BCI-XL. Bax is cytosolic and must translocate to the mitochondrial to exert its effects, while Bak possesses a transmembrane domain (see Fig. 3.l) and is normally found in the outer mitochondrial membrane. In one model, following an apoptotic signal, Bax and/or Bak can oligomerize and may form channels large enough for cyto c and other proteins to escape into the cytosol. As shown in Fig. 3.2, cyto c induces the formation of the apoptosome, initiating the caspase cascade. (c) Two other mitochondrial proteins, AIF and EndoG, can also be released. While their release from the mitochondria may be associated with caspase activity in some cells, their direct participation in DNA degradation appears to be caspase-independent (d). Another model of apoptogenic protein release involve the putative mitochondrial permeability transition (MPT) pore thought to consist of the adenine nucleotide translocase (ANT), the voltage-dependent anion channel (VDAC) and other unknown constituents. This model also involves Bax (or Bak) and proposes that Bax binds VDAC, inducing conformational changes which permit apoptogenic protein release.

For example, through the use of Bax knockout mice, the participation of Bax in I/R injury in isolated murine hearts also was elucidated recently; functional and apoptotic parameters examined in this study showed reduced damage in the Bax-/- hearts and moderate levels of damage markers in the heterozygote (Bax+/−) mice.[184] In healthy cells, Bid is located in the cytosol; it has been well studied as a "cross-talker" between the death receptor (e.g., Fas)/caspase-8 pathway and the mitochondrial pathway via caspase-8 cleavage to truncated Bid (tBid)[185] (see Fig. 3.2) Caspase-8-mediated Bid processing was recently observed (only during reperfusion) in a model of I/R-induced apoptosis in rat cardiomyocytes.[169] A role for Bid in I/R injury was also demonstrated in additional rat and rabbit models.[186,187] While a detailed discussion is beyond the scope of this chapter, there are several other BH3 proteins, such as BNip3, Bad, and Puma, for which there is also now evidence supporting roles in I/R injury in the heart.[188–193]

AIF and EndoG – caspase-independent apoptosis?

Although caspases have been traditionally associated with apoptosis as initiators, there are at least two factors released by the permeabilized mitochondrion, namely AIF and Endo G, which translocate to the nucleus (Fig. 3.3) and

may separately or in conjunction[194] initiate chromatin condensation and DNA fragmentation, two hallmarks of apoptosis. Mammalian AIF is a flavoprotein with an oxidoreductase domain, and overexpression of AIF can cause caspase-independent cell death in some systems.[195] There is some evidence, however, that endogenous AIF release from the mitochondria requires caspase activity,[196] and this represents a requirement for caspase-2 activity, which has been shown to act on the mitochondria following certain apoptogenic stimulation of some cells,[197–199] including I/R induction of cardiomyocytes.[103] Both EndoG and AIF are expressed in the mammalian heart,[200–202] but their roles in ischemic injury to the myocardium, particularly during and after cardiac arrest, are not yet clear. Nevertheless, there is evidence of AIF participation in experimental infarcts in rat hearts,[203] and protective treatments in perfused hearts blocked the I/R-induced release of AIF.[204] On the other hand, AIF has also been shown to have a potential *anti*-apoptotic role through its activity as a free radical scavenger.[205] Furthermore, recent evidence shows that AIF may function as a vital mitochondrial respiratory enzyme in the myocardium[206] and that its loss may lead to oxidative stress in the myocardium and the development of mitochondrial dysfunction, dilated cardiomyopathy, and heart failure.[207,208] Much work remains to be done before we understand the mechanistic and, in some cases dualistic, roles of apoptotic molecules in I/R-injury in general, and in the post-arrest heart in particular.

Apoptosis as an anti-inflammatory strategy

One major feature of apoptotic removal of damaged cells is the avoidance of inflammation, but apoptosis may also function to resolve ongoing inflammation. In light of the recent view that the resuscitated, post-arrest condition is similar to one of sepsis or inflammation,[209] this potential anti-inflammatory role for apoptosis takes on new meaning and significance. I/R injury can activate the transcription factor NF-kB, and although this factor can regulate the transcription of protective, anti-apoptotic genes, it also initiates gene programs leading to innate immune responses and the promotion of inflammation (see review[210]). Recent data suggest that the innate immune system may play an important role in cardiovascular diseases,[211] including ischemic injury in which these responses may be beneficial in the short term, but maladaptive if not resolved.[212] The extent and duration of the innate immune response is regulated by factors such as cytokines, which help limit and resolve the response. One such cytokine, IL-6, recently has been identified as a critical factor in resolving innate immune responses (see

review[213]). In general, resolution of inflammation is thought to involve apoptosis of inflammatory leukocytes,[214,215] and IL-6 may be intimately involved in this process.[213] Much of the activity of IL-6 in resolution of inflammatory leukocytes can be attributed to signaling through an endogenous soluble IL-6 receptor (sIL-6R), a process referred to as IL-6 trans-signaling. While certain cell types can be rescued *in vitro* by IL-6,[216,217] IL-6 trans-signaling promotes caspase-3-mediated apoptosis of neutrophils.[218] The precise regulation of these IL-6 activities is not clear, but the data support a central role for this cytokine and its effects on apoptosis of inflammatory cells in the induction and control or limitation of the innate response, such as that seen following cardiac arrest and resuscitation.[209,219]

Conclusion

Developing a better understanding of the molecular pathophysiology of the post-resuscitation injury phenotype – ranging from early cardiovascular collapse and death, to minimal cardiovascular dysfunction, to neurological impairment at hospital discharge – is the first step towards developing other post-resuscitation therapies beyond therapeutic hypothermia. Common cell responses throughout the body (i.e., global responses) that occur during the ischemia of cardiac arrest and the reperfusion of CPR and ROSC likely involve oxidant stress and inflammation. Both can be highly adaptive and protective in moderation, but when a threshold of oxidant injury and circulating inflammatory mediators is surpassed, post-resuscitation injury ensues. Apoptosis plays a critical dual role in both containing inflammation (i.e., apoptosis of leukocytes) and amplifying injury (e.g., apoptosis of cardiac myocytes and other vital tissue). Treating these critical events by using new cytokine, oxidant and apoptosis modulation strategies will be necessary to resuscitate patients fully from the Metabolic Phase of cardiac arrest.

Introduction

Sudden cardiac death (SCD) is an enigma: despite an overall decrease in cardiac mortality, SCD rates appear to be rising along with the concomitant increase in prevalence of coronary disease and heart failure. Even with decades of research, the underlying cellular mechanisms and stimulus/triggers are not well understood. This chapter addresses the application of large scale "omic" strategies to this critical clinical problem. First, is a discussion of the steps currently underway using genetic strategies to characterize several inherited arrhythmogenic diseases. The final two sections focus on two newer strategies, the technologies of genomics and proteomics.

Genetics, genomics and proteomics are complementary technologies. Figure 4.1 shows the flow from genes to proteins and emphasizes the increasing complexity at each step. Genetics strategies concentrate on identifying and characterizing a small number of candidate genes, informed by our understanding of the relevant biology, and are largely focused on analyzing sequence variants. Genomics looks more globally, with new approaches using unbiased whole-genome scans to examine both sequence variants and other genomic alterations, such as copy number polymorphism. Analysis of expressed genes, mRNA, is performed using the technologies of transcriptomics. Finally, the expressed proteins are studied using proteomics. This includes potential mutations (seen as amino acid changes) as well as post-translational modification (such as glycosylation or phosphorylation). It is only through the combined application of these technologies that we will be able to elucidate the underlying mechanisms of SCD, with the ultimate goal of both predicting individual risk and improving therapeutic intervention.

Genetics of cardiac ion channel diseases causing sudden death

Introduction

The inherited diseases of the heart occurring in the absence of structural abnormalities are the so-called "primary electrical disorders" or "inherited arrhythmogenic diseases." They typically manifest with peculiar electrocardiographic features, syncope and sudden death in young, otherwise healthy, individuals. The common denominator of these disorders is the abnormality of proteins controlling the excitability of myocardial cells and their response, but the spectrum of genes and mechanisms underlying these disorders is remarkable and progressively expanding.

This section will summarize current understanding of the genetic determinants of cardiac instability and the abnormalities predisposing to sudden cardiac death in the absence of structural cardiac abnormalities. We will also briefly review the role of molecular genetics for management and risk stratification.

Strategies for genetic analysis

The common denominator of all Mendelian (monogenic) disorders associated with a risk of cardiac arrhythmia and sudden death is the remarkable genetic heterogeneity. With the exception of a few mutational hot spots
Fig. 4.1. Genetics, genomics, transcriptomics and proteomics. DNA can contain a variety of mutations and/or SNPs, that have the potential to be correlated to disease phenotypes. Such mutations may or may not be passed on to the mRNA during transcription; they can be left out either if they are not present in the transcribed region of the gene or by alternate splicing of the mRNA. The mRNA is then translated into proteins whose amino acid sequences could be affected by the original DNA mutation. Proteins often undergo post-translational modifications (PTMs), resulting in even greater complexity. Combining genetic, genomic and proteomic data allows for the examination of all the steps along the way to the final cellular makeup.

identified in long QT syndrome, the vast majority of probands carry a private (i.e., nonrecurrent) mutation. Obviously, this has profound impact on the choice of strategies for testing, because it implies that the screening for known mutations is not feasible. Systematic screening of the complete open reading frame (ORF) of known genes by denaturing high-performance liquid chromatography (DHPLC) (or similar techniques allowing detection of PCR fragment mobility anomalies) with subsequent DNA sequencing of the abnormal migration patterns, is the most widely used approach. Other laboratories perform direct ORF sequencing. At present there are no robust sensitivity analyses performed to suggest which approach is superior.

The success rate of genetic testing varies greatly according to the different diseases. Approximately 70% of clinically affected patients are successfully genotyped for long QT syndrome (five genes) and catecholaminergic polymorphic ventricular tachycardia (CPVT) (two genes), while this percentage drops to 20%–25% for Brugada syndrome patients. No data are available for other conditions such as Familial Atrial fibrillation, Progressive AV block and sick sinus syndrome since they have been only recently characterized.

LQT4 and LQT7 variants of LQTS (see below) are considered rare and present peculiar phenotypes. Therefore, systematic analysis in all patients of this gene is not indicated. Finally LQT8 usually arises *de novo* and all the reported

Table 4.1. Genetic loci and genes causing Long QT syndrome

Locus name	Chromosomal locus	Inheritance	Gene symbol	Protein	Phenotype[a]	OMIM ID
LQT1	11p15.5	AD	*KCNQ1*	I_{Ks} potassium channel alpha subunit (KvLQT1)	Long QT	192500
LQT2	7q35–q36	AD	*KCNH2*	I_{Kr} potassium channel alpha subunit (HERG)	Long QT	152427
LQT3	3p21	AD	*SCN5A*	Cardiac sodium channel alpha subunit (Nav 1.5)	Long QT	603830
LQT4	4q25–q27	AD	*ANK2*	Ankyrin B, anchoring protein	Long QT, atrial fibrillation	600919
LQT5	21q22.1–q22.2	AD	*KCNE1*	I_{Ks} potassium channel beta subunit (MinK)	Long QT	176261
LQT6	21q22.1–q22.2	AD	*KCNE2*	I_K potassium channel beta subunit (MiRP)	Long QT	603796
AND/LQT7	17q23.1–q24.2	AD	*KCNJ2*	I_{K1} potassium channel (Kir2.1)	Long QT, potassium-sensitive periodic paralysis, dysmorphic features	170390
LQT8/TS	12p13.3	AD[b]	*CACNA1c*	Voltage-gated calcium channel, CaV1.2	Long QT, syndactyly, septal defect, patent foramen ovale, mental retardation	601005
JLNS1	11p15.5	AR	*KCNQ1*	I_{Ks} potassium channel alpha subunit (KvLQT1)	Long QT, deafness	220400
JLNS2	21q22.1–q22.2	AR	*KCNE1*	I_{Ks} potassium channel beta subunit (MinK)	Long QT, deafness	176261

AD = autosomal dominant; AR = autosomal recessive; RBBB = right bundle branch block; LQT1 to LQT6 also defined as Romano-Ward; JLNS = Jervell and Lange–Nielsen syndrome; TS = Timothy syndrome; [a] syncope and sudden death are additional manifestations possibly occurring in all variants; [b] parental mosaicism was demonstrated.

patients in whom genetic analysis was performed have the same *CACNA1c* gene mutation (see below).

Long QT syndrome

Clinical presentation

The Long QT syndrome (LQTS) is an inherited arrhythmogenic disease in the structurally normal heart characterized by abnormally prolonged QT interval with peculiar morphological abnormalities of the T wave. LQTS manifests with syncope and/or cardiac arrest with a mean age of onset of symptoms (syncope or sudden death) of 12 years. Two major phenotypic variants have been described in the early 1960s: one autosomal dominant (Romano–Ward syndrome)[1] and one rare autosomal recessive (Jervell and Lange–Nielsen syndrome) also presenting with sensorineural deafness[2] (Table 4.1). Another rare LQTS variant presenting with syndactyly and congenital heart defects

has been recently linked to a specific cardiac calcium channel mutation (see below).

Genetic bases and pathophysiology

Seven LQTS genes have been identified as of March 2005 (Table 4.1). Isolated QT interval prolongation with or without syncope/cardiac arrest (Romano–Ward syndrome) may be due to mutations in five different genes while two variants display QT interval prolongation in the context of a multiorgan disease (Andersen syndrome, Timothy syndrome). All but one (LQT4) LQTS genetic subtypes are caused by cardiac ion channels encoding genes.

These share the typical features of the different genetic variants of LQTS by grouping them according to their common pathophysiological substrate.

Defective I_{Ks} (LQT1, LQT5, JLN1 and JLN2)

KCNQ1 (causing LQT1 and JLN1) and *KCNE1* (causing LQT5 and JLN2) encode respectively for the alpha (KvLQT1) and the beta (MinK) subunit of the potassium channel conducting the I_{Ks} current, the slow component of the delayed rectifier current (I_K), the major repolarizing current during phase 3 of the cardiac action potential. In order to form a functional channel, KvLQT1 proteins form homotetramers and co-assemble with (probably two) Mink subunits.

LQT1 is the most prevalent genetic form of LQTS, accounting for approximately 50% of genotyped patients. Hundreds of different mutations have been reported and *in vitro* expression of mutated proteins suggested multiple biophysical consequences but all of them ultimately causing a loss of function through haploinsufficiency or dominant negative effect.[3] Homozygous or compound heterozygous mutations of *KCNQ1* also cause the Jervell and Lange-Nielsen form of LQTS (JLN1).

KCNE1 (LQT5) mutations are rather infrequent accounting approximately for 2%–3% of genotyped LQTS patients and they may cause both Romano–Ward (LQT5) and, if homozygous, Jervell and Lange-Nielsen (JLN2).[4]

Defective I_{Kr} (LQT2 and LQT6)

KCNH2 (LQT2) and *KCNE2* (LQT6) genes encode for the alpha (HERG) and the beta (MiRP) subunit of the potassium channel conducting the I_{Kr} current, the rapid component of the cardiac delayed rectifier. The *KCNH2*-encoded protein, HERG, is a six transmembrane-segment protein that forms homotetramers in the plasmalemma in order to make up functional channels. The physiological role of MiRP protein to recapitulate fully the current has been postulated,[5] although co-assembly of MiRP with other voltage-gated potassium channels such as KvLQT1 has

been also reported.[6] LQT2 is the second most common variant of LQTS, accounting for 35%–40% of mutations. Functional expression studies have demonstrated that *KCNH2* mutations cause a reduction of I_{Kr} current, but, similar to LQT1 mutations, this effect may arise from different biophysical mechanisms.[7] LQT2 is characterized by higher penetrance and severity than LQT1.[8] Mutations in the *KCNE2* gene[9] cause the LQT6 variant of LQTS, which has a very low relative prevalence (<1%) and the associated phenotypes are characterized by incomplete penetrance and very mild manifestations.

Defective I_{Na} (LQT3)

SCN5A encodes for cardiac sodium channel conducting the sodium inward current (I_{Na}). At variance with *KvLQT1* and *HERG* protein mutations, a single SCN5A transcript forms a fully functional channel protein (Nav1.5). Several allelic variants have been reported and functional expression studies showed that, at variance with LQT1 and LQT2-associated mutations, LQT3 defects cause a gain of function with an increased I_{Na} (7). This final effect may originate from altered current kinetic (delayed inactivation) or single channel properties abnormalities (disperse reopenings, bursting). The prevalence of LQT3 among LQTS patient is estimated to be 10%–15%.

Defective Ankyrin B (LQT4)

The phenotype of the LQT4 patients differs from the typical LQTS:[10] QT interval is only mildly prolonged, but they also present with sinus bradycardia, paroxysmal atrial fibrillation (detected in >50% of the patients), and with polyphasic T waves. Recently, a missense mutation in the *ANK2* gene was identified in one family.[11] *ANK2* encodes for an intracellular protein (Ankyrin B) that regulates the proper intracellular localization of plasmalemmal ion channels (calcium channel, sodium channel, sodium/calcium exchanger) and sarcoplasmic reticulum channels (ryanodine receptor, inositol triphosphate receptor). The paucity of LQT4 patients genotyped so far prevents gathering further insights on the phenotypic features of this variant of LQTS.

Defective I_{Ca} (LQT8 – Timothy syndrome)

LQT8, also called Timothy syndrome, is a rare and severe disorder in which severe QT interval prolongation is invariably associated with cutaneous syndactyly (hands and feet) and a plethora of additional phenotypes (some still poorly defined) occurring with variable incidence among the affected subjects. The markedly prolonged and abnormal ventricular repolarization (QT interval duration often exceeds 600 ms) frequently causes the appearance of a 2:1

functional atrioventricular block and macroscopic T wave electrical alternans.

A high proportion of LQT8 patients have congenital heart defects, mental retardation and autism. Furthermore, severe hypoglycemia and immunologic (recurrent infections) disturbances are present in approximately 40% of cases.

The therapeutic approach to LQT8 is unavoidably empiric because of the limited clinical experience. The effectiveness of beta-blockers or other drugs is unknown and primary prevention with ICD may be considered. It appears also important to monitor closely glucose metabolism (intractable fatal hypoglycemia has been reported), and to consider seriously any hyperpyrexia event.

The gene for Timothy syndrome has been recently identified as *CACNA1c* encoding for the cardiac voltage-gated calcium channel (CaV1.2) (Table 4.1).[12] Interestingly, the same mutation G408R was found in all the 13 probands in whom the analysis was performed. In vitro functional characterization showed a net increase of calcium inward current and prolonged duration of action potential duration.[12]

Genotype–phenotype correlation

In the last few years several studies have outlined the distinguishing features of the three most common genetic variants of LQTS (LQT1, LQT2, LQT3), which account for approximately 97% of all genotyped patients.

Locus-specific repolarization morphology and locus-specific triggers for cardiac events have been described.[13] LQT1 patients usually develop symptoms during physical activity; conversely, LQT3 have events at rest. Auditory stimuli and arousal are relatively specific triggers for LQT2 patients while swimming is a predisposing setting for cardiac events in LQT1 patients.[13]

Locus-specific differences of the natural history of LQTS have also been demonstrated and, combined with the QT interval duration, allow genotype-based risk stratification:[8] a QTc >500 ms, and a LQT2 or LQT3 genotype are the strongest predictors of outcome. Gender further modulates the outcome according to the underlying genetic defect: the LQT3 males and LQT2 females are the highest risk subgroups. Preliminary evidence in small patients populations suggests that risk stratification be further refined when the position of a mutation on the predicted protein topology is taken into consideration: LQT2 patients with mutation in the pore-region are at greater risk of cardiac events.[14,15]

Finally, a recent study by Priori *et al.* has demonstrated that the response to beta-blocker therapy is also modulated by the underlying genotype with a satisfactory response among LQT1 but only partial protection afforded by this therapy for LQT2 and LQT3 patients.[16]

Brugada syndrome

Clinical presentation

Brugada syndrome (BrS) is characterized by ST segment elevation in the right precordial leads (V1 to V3), right bundle branch block, and susceptibility to ventricular tachyarrhythmia. The typical age of onset of clinical manifestations (syncope or cardiac arrest) is the third to fourth decade of life, even though malignant forms with earlier onset and even with neonatal manifestations have been reported.[17] Cardiac events typically occur during sleep or at rest.[18] The disease is inherited as an autosomal dominant trait, but there is a striking unbalanced male to female ratio of 8:1 for clinical manifestations. The lack of effective pharmacological treatments makes the risk stratification a primary issue in BrS. Available evidence attributes the highest risk for events to patients with a spontaneously abnormal ECG and a history of syncope. More debated is the usefulness of programmed electrical stimulation (PES).[19]

Genetic basis and pathophysiology

The initial report of *SCN5A* mutations in BrS was published in 1998[20] and, as of today, tens of different mutations have been reported. Unfortunately, *SCN5A* accounts for no more than 20% of clinical cases.[21] Therefore, genetic testing is not conclusive in 80% of BrS patients. Another BrS locus was mapped in a 5 cM region on chromosome 3p22-25 but the corresponding gene has not been identified yet (Table 4.2). Genetic testing, when successful, allows confirmation of the diagnosis in borderline cases, identification of silent carriers, and assessment of reproductive risk. Several electrophysiological abnormalities have been identified all leading to a loss of sodium current:[7] reduced current density, slower recovery of inactivation, shift of voltage dependence of inactivation, enhancement in the intermediate inactivation, altered interaction with the sodium channel β-subunit, and altered trafficking due to loss of ankyrin G binding.[22]

Progressive cardiac conduction defect

Clinical presentation

Progressive cardiac conduction defect (PCCD) is a common disorder in the elderly population. It is characterized by progressive slowing of cardiac conduction through the His-Purkinje system with right or left bundle branch block and widening of QRS complexes. In the majority of cases, it develops as a sporadic trait and is

Table 4.2. Genetic loci and genes involved in Brugada syndrome, Short QT syndrome, atrial fibrillation, conduction block, and sinus node disease

Locus name	Chromosomal locus	Inheritance	Gene symbol	Protein	Phenotype[a]	OMIM ID
BrS1	3p21	AD	SCN5A	Cardiac sodium channel alpha subunit (Nav 1.5)	ST segment elevation, RBBB	601144
BrS2	3p22–25	AD	unknown	unknown	ST segment elevation, RBBB	–
PFHB1	19q13.2–q13.3, 3p21	AD	unknown	unknown	Progressive cardiac conduction defect (PCCD)	113900

AD = autosomal dominant; AR = autosomal recessive; [a] syncope and sudden death are additional manifestations possibly occurring in all variants.

considered degenerative of aging. Familial cases have been reported in some instances, thus suggesting a genetic predisposition.

Genetic defects and pathophysiology
The first identified PCCD locus (also defined as progressive familial heart block, PFHB) locus maps to 19q13.3 with an autosomal dominant inheritance (Table 4.2). The linkage with this region was subsequently confirmed by other authors, but the corresponding gene is yet to be identified. Conversely, by candidate gene screening, after the exclusion of the 19q locus, Schott et al.[23] described two families with a SCN5A co-segregating with conduction defects (Table 4.2). Few other mutations have been reported thereafter and in vitro assays suggest a loss of function effect.[7]

Given the low number of reported mutations/patients, at present it is not possible to estimate the prevalence of SCN5A-PCCD, nor the success rate of genotyping.

Sick sinus syndrome

Clinical presentation
Sick sinus syndrome (SSS) manifests with bradycardia, syncope, dizziness, and fatigue. In some cases, sinus node dysfunction and cardiac conduction defect may co-exist. As for PCCD, the majority of SSS cases occur among elderly subjects and are thought to represent a manifestation of aging. Familial recurrence of SSS has been anecdotally reported, although this is considered an "exceptional finding."

Genetic defects and pathophysiology

In 2003, Benson *et al.*[24] described five affected children from 3 kindreds with congenital SSS, and identified compound heterozygosity (two different mutations, one from paternal and one from maternal origin) for six distinct mutations in the SCN5A gene (Table 4.2). Two of these mutations had previously been associated with Brugada syndrome. Heterozygous carriers were asymptomatic, but showed subclinical cardiac conduction disease, particularly first-degree heart block, suggesting a close relationship between PCCD and SSS. As for PCCD and BrS, in vitro expression of the SSS mutation is consistent with a loss of function.

Familial atrial fibrillation

Clinical presentation

Atrial fibrillation is the most common sustained arrhythmia encountered in clinical practice. It is not life-threatening *per se*, but it is the most frequent cause of embolic stroke. In 3% to 31% of cases no underlying cardiovascular disease can be detected and in some of them a familial inheritance is evident.[25]

Genetic bases and pathophysiology

Brugada *et al.*[26] mapped the first familial atrial fibrillation (FAF) locus to the long arm of chromosome 10 (10q22–q24) in three families (Table 4.2). The gene located in this region has not been discovered yet. Chen *et al.*[27] mapped a large family on the short arm of chromosome 11 (11p15.5), however, and identified a missense mutation of *KCNQ1*, causing a gain-of-function effect on the KvLQT1/MinK channel (see LQT1). The authors speculated that the *KCNQ1*-FAF mutation is likely to initiate and maintain the arrhythmia by reducing duration of the action potential and the effective refractory period in atrial myocytes.

Very recently, another FAF mutation has been reported in the *KCNE2* gene causing an arginine-to-cysteine mutation at position 27 (R27C).[6] This mutation was found in 2/28 probands of families with FAF in whom a systematic screening of cardiac ion channel encoding genes was carried out. Functional study revealed that the mutation had a gain-of-function effect on the *KCNQ1-KCNE2* channel; unlike long QT syndrome-associated *KCNE2* mutations, it did not alter *KCNH2-KCNE2* current.

Unfortunately, despite these anecdotal reports, the genetic determinants of FAF remain poorly characterized. Therefore, at the present time the clinical applicability of genetic testing for FAF is limited to research.

Short QT syndrome

Clinical presentation

The first report of a clinical condition characterized by abnormally short repolarization was from Gussak *et al.* in 2000.[28] They described two siblings and their mother all of whom displayed persistently short QT interval (260–275 ms). Thereafter few additional unrelated cases have been reported. SQTS is also characterized by the absence of structural heart disease, a quite remarkable familial history of sudden cardiac death and a typical, hyperkalemic-like T wave pattern at the resting ECG. No effective treatment for this disease has been identified so far.

Genetic bases and pathophysiology

One *KCNH2* missense mutation was initially identified in two SQTS families.[29] By means of in vitro expression the authors observed a complete loss of the I_{Kr} rectification, resulting in a large increase of current and a gain of function that may explain the abbreviated action potential and therefore the QT interval.

Bellocq *et al.*[30] reported another gain of function mutation that affected the *KCNQ1* gene in a 70-year-old male presenting with idiopathic ventricular fibrillation and short QT intervals (Table 4.2). This mutation causes an increase in transmembrane current and a faster current kinetic, resulting in a reduction of action potential duration.

The third SQTS gene has been recently identified by Priori *et al.*[31] who reported a gain of function mutation in the *KCNJ2* gene, the same as that causing LQT7 (Andersen syndrome) when loss of function is present.

The recent findings on the genetic defects underlying the SQTS phenotype together with the data on LQT3, BrS and FAF, demonstrate that at least five genes encoding cardiac ion channels and involved in the inherited arrhythmogenic diseases (*KCNQ1, KCNH2, SCN5A, KCNE2, KCNJ2*) may carry both gain and loss of function mutations. According to their primary biophysical consequence they originate different, and sometimes opposite, phenotypes. Whereas the electrocardiographic manifestations diverge, the common denominator of these different clinical entities is the electrically unstable substrate that leads to cardiac arrhythmias and sudden death.

Catecholaminergic polymorphic ventricular tachycardia

Clinical presentation

Catecholaminergic polymorphic ventricular tachycardia (CPVT)[32] is characterized by exercise- or acute emotion-induced polymorphic ventricular arrhythmias, often

Table 4.3. Genetic loci and genes causing catecholaminergic polymorphic ventricular tachycardia

Locus name	Chromosomal locus	Inheritance	Gene symbol	Protein	Phenotype	OMIM ID
CPVT1	1q42.1–q43	AD	*RyR2*	Cardiac Ryanondine receptor	Exercise-induced arrhythmias, normal resting ECG, bradycardia, sudden death	604772
CPVT2	1p13.3–p11	AR	*CASQ 2*	Cardiac Calsequestrin	Exercise-induced arrhythmias, normal resting ECG, bradycardia, sudden death	114251

causing syncope, a normal resting electrocardiogram, and the absence of structural cardiac abnormalities. Symptoms usually develop during childhood or adolescence, although anecdotal reports of first symptoms during adulthood have been reported. In approximately 13%, cardiac arrest is the first manifestation of the disease and familial history of sudden deaths is present in 30% of cases.[33] The resting electrocardiogram is unremarkable[33] and the diagnosis relies upon the reproducible pattern of arrhythmias during graded exercise, in which a ventricular tachycardia with an alternating 180° QRS axis on a beat-to-beat basis (the so-called bidirectional VT) is observed. In some patients irregular polymorphic VT is observed but the correlation with exercise remains striking.[33]

Genetic bases and pathophysiology

CPVT1: autosomal dominant
The first locus was identified by Swan *et al.* who mapped the disease to chromosome 1q42–43.[34] In late 2000, Priori *et al.* identified mutations in four families and demonstrated that the CPVT gene on chromosome 1 is the cardiac Ryanodine receptor (*RyR2*).[35] Additional mutations have been reported thereafter (Table 4.3).[36,37]

The Ryanodine receptor is a large protein that tetramerizes across the membrane of sarcoplasmic reticulum (SR) and is a major player in the regulation of the intracellular calcium fluxes and the excitation-contraction coupling. The identification of *RyR2* mutations in CPVT points to the pivotal role of intracellular Ca^{2+} handling in arrhythmogenesis. RyR2 mutant proteins have been expressed in different in vitro models (lipid bilayer, HEK293 cells, HL1-cardiomyocytes) and the results consistently showed that *RYR2* defects cause a Ca^{2+} "leakage" from the SR in conditions of sympathetic (catecholamines) activation,[38,39] while the basal channel activity appears normal.

CPVT2: Autosomal recessive
Lahat *et al.*[40] in 2001 mapped the autosomal recessive variant of CPVT on chromosome 1p23–21 (Table 4.3). Subsequently, the same group identified *CASQ2* as the gene for this locus (Table 4.3).[41] *CASQ2* encodes the cardiac calsequestrin, the Ca^{2+}-binding/buffering protein localized in the terminal cisternae of the SR. Calsequestrin is bound physically and functionally to the Ryanodine receptor and cooperates with control of the excitation contraction coupling.

One experimental study[42] has investigated (in rat myocytes) the *CASQ2* mutation previously identified by Lahat *et al.* This study showed that *CASQ2*-D307H mutation impairs the SR Ca^{2+} storing and release functions, and destabilizes the Ca^{2+}-induced Ca^{2+} release mechanism via reduced Ca^{2+} buffering inside the SR and/or altered responsiveness of the Ca^{2+} release channel complex to luminal Ca^{2+}.

Taken together, the experimental data demonstrated that both genes involved in CPVT pathogenesis affect the amount of Ca^{2+} released from the SR during adrenergic stimulation. Such an effect may create an electrically unstable substrate, probably through triggered activity-mediated arrhythmogenesis.

Conclusions

Many ion channels highly expressed in the heart and controlling the depolarization-repolarization process have been implicated in cardiac arrhythmias and sudden death. Molecular genetics has revealed such a high level of genetic and functional heterogeneity that the classification of diseases based on their clinical phenotype is compellingly challenged. The same protein, resulting from an altered genetic program, may outcrop a variety of apparently unrelated (sometimes opposite) clinical phenotypes, depending

on the specific functional consequences of the single muta-
tions. Despite this apparently impenetrable complexity,
thanks to these studies, our understanding of cardiac phys-
iology and pathophysiology has improved substantially.
Translation into clinical benefits is a laborious and complex
process that is only recently achieving partial success, with
progressively more informative management algorithms
derived from genotype-phenotype correlations. In the
years to come this process will eventually lead to the devel-
opment of individualized approaches for prevention and
therapy of cardiac arrhythmias and sudden death.

Genomics and sudden cardiac death

Introduction

While a great deal of progress has been made identifying
the genetic variants underlying monogenic long and short
QT syndromes, little to no progress had been made with
respect to the common forms of SCD. Indeed, the only reli-
able association reported for a relatively common variant
is with a single nucleotide sequence variant in the SCN5A
Na$^+$ channel gene, found only in African-Americans,
which has a small enhancement of arrhythmia risk.[43] With
one-third of SCD events occurring as a first clinical event,
and fully two-thirds of SCD events occurring in individuals
in clinical circumstances that do not provide sufficiently
accurate prediction to warrant preventive intervention,[44]
the ability to identify genetic susceptibility markers for
SCD is critical.

The limitation of linkage studies

Traditional genomic approaches to identifying genetic sus-
ceptibility loci have relied upon family-based studies and
linkage analyses. These techniques have proven particu-
larly well-suited to monogenic diseases, which are gener-
ally due to rare variants in which carriers are likely to have
disease (high penetrance). In a complex phenotype like
SCD, multiple genes are likely to be involved and the sus-
ceptibility variants are likely to be common ("common
disease, common variant" hypothesis),[45,46] and thus the
penetrance for any individual susceptibility variant is likely
to be low. In addition, the ability to collect DNA from fam-
ilies with SCD is extremely limited, as SCD occurs at later
ages, in which collecting DNA from parents is difficult.
Similarly, collecting samples for alternate family-based
strategies, such as affected sibpair analyses, are difficult,
DNA would need to be collected from a huge number of
individuals in the hope of identifying families that will have

a second SCD event. Given these limitations, researchers
have begun to focus on population-based case-control
association studies, in which unrelated affected individu-
als are compared to appropriate unaffected populations.

Association studies

Association studies: in theory

The association between a specific sequence variant and a
phenotype can arise in two ways. The mutation can occur
multiple times during the course of human history, as in
achondroplasia,[47] each time occurring on a different
genetic background, or haplotype (i.e., it will have different
neighboring polymorphisms each time it occurs). Under
this scenario, whereas the mutation itself will be associated
with disease, neighboring markers will not. More com-
monly, a mutation may occur once or a few times during
evolution, such as with the ΔF508 mutation in cystic fibro-
sis,[48] therefore arising on a distinct haplotype. If this
second model holds true for SCD, we can use a property
known as linkage disequilibrium (LD) to identify a region
harboring the underlying functional variant associated
with the phenotype, even in the absence of knowing the
functional variant itself. LD describes the non-random
association of neighboring polymorphisms with each
other. When a mutation occurs on a specific haplotype, it
will be transmitted to offspring along with its neighboring
polymorphisms, which can then serve as surrogates for
the mutation itself. Nevertheless, meiotic recombination
events occurring between a neighboring polymorphism
and the mutation will decrease the association, or LD,
between that marker and the mutation, and thus markers
closer to the mutation will have stronger associations with
the phenotype.

Association studies: past and present

The model for conducting association studies has been the
"candidate gene" approach, in which a list of genes based
on our current understanding of the biology are mined for
single nucleotide polymorphisms (SNPs) that may be asso-
ciated with SCD. A summary of the studies published to
date is given in Table 4.4. Notably, none of the positive
findings have been replicated in a second study, the gold
standard for validation. In addition, these studies have not
really screened the gene, *per se*, for association with SCD,
but only a specific variant in the gene. There could be add-
itional variants that influence the risk for SCD, but that are
not in LD with the screened SNPs, and thus are missed by
this approach. The revolution in genotyping technologies,
both reducing cost and increasing throughput, has largely
eliminated the single gene/single SNP approach. Indeed,

Table 4.4. Summary of SCD association studies

Gene	Variant	Cases/controls	Association	Reference
Platelet glycoprotein	P1[A1/A2]	98/249	yes	Mikkelsson *et al.* (2000)
α2B-adenoreceptor	in/del	288/412	yes	Snapir *et al.* (2003)
PAI-1	4G/5G	97/113	yes	Anvari *et al.* (2001)
Factor V	Leiden	145/592	no	Reiner *et al.* (2002)
Prothrombin	G20210A	145/592	no	Reiner *et al.*(2002)

there are numerous platforms in which tens of SNPs in hundreds of genes can be screened in a single assay. We can thus start to think about comprehensively screening a gene, using multiple SNPs distributed across the gene. By measuring the LD between our marker SNPs, we can get some measure of our power to identify an unscreened functional variant anywhere in the gene. Although this approach is markedly superior to the single gene/single SNP strategy, and indeed allows for the exploration of genetic pathways (i.e., a series of genes that influence a common outcome), it is still limited by our current understanding of both the biology underlying SCD and of the genome itself.

Association studies: extending the search

Despite the remarkable progress we have made in understanding the human genome, we know the function of fewer than half the identified genes, and have recently discovered non-genic regulatory elements, such as miRNAs. In addition, regulatory elements that are distant from the known structural gene have been identified.[49] Thus, any candidate gene approach has an *a priori* exclusion of more than half of the relevant genome. The remarkable scale-up of genotyping technologies has now reached the point where, with current platforms, we can conduct unbiased whole-genome association studies, screening >500 000 SNPs per sample.[50,51] Thus we can use a high-resolution map of SNPs distributed throughout the genome to identify regions associated with SCD (see Fig. 4.2). Indeed, Ozaki *et al.*[52] have successfully used this approach to identify the lymphotoxin-α gene as a susceptibility locus for myocardial infarction. They screened 92 788 SNPs in 1133 cases and 1006 controls, and identified a functional variant contributing to the observed association.

Assessment of genomic structure

The search for genetic susceptibility loci for complex disease has been limited to looking for a sequence alteration at a particular site. The existence of common copy number polymorphisms, however, in which individuals

have heritable amplifications or deletions of specific genomic regions, have now been reported.[53–55] The role of somatic copy number variation in cancer has long been established, but has not been explored with regards to complex disease. These copy number polymorphisms make intriguing candidates for a complex phenotype like SCD, as they may affect multiple genes and be dosage-dependent across individuals. Until recently, detection of changes has been limited to >1 Mb; however, recent advances have allowed for detection of much smaller changes (> 10 kb), including "genome tiling" BAC arrays, digital karyotyping, optical mapping, and oligonucleotide-arrays.[56–59]

Conclusions

The rapid advancement in genomic technologies has opened new avenues of research for identifying susceptibility loci for SCD. Not only can we perform whole-genome scans for sequence variants, eliminating the bias due to our incomplete knowledge of both the genome and biology underlying SCD, but we can also scan for the role of a new class of variants, copy number polymorphisms. The real limitation now is the availability of well-phenotyped samples and appropriate controls. In recognition of this, several projects are currently underway to generate large cohorts for future study,[60,61] giving significant hope that we will be able to identify genetic risk factors for SCD in the near future.

Proteomics and sudden cardiac death

Overview of proteomics strategies

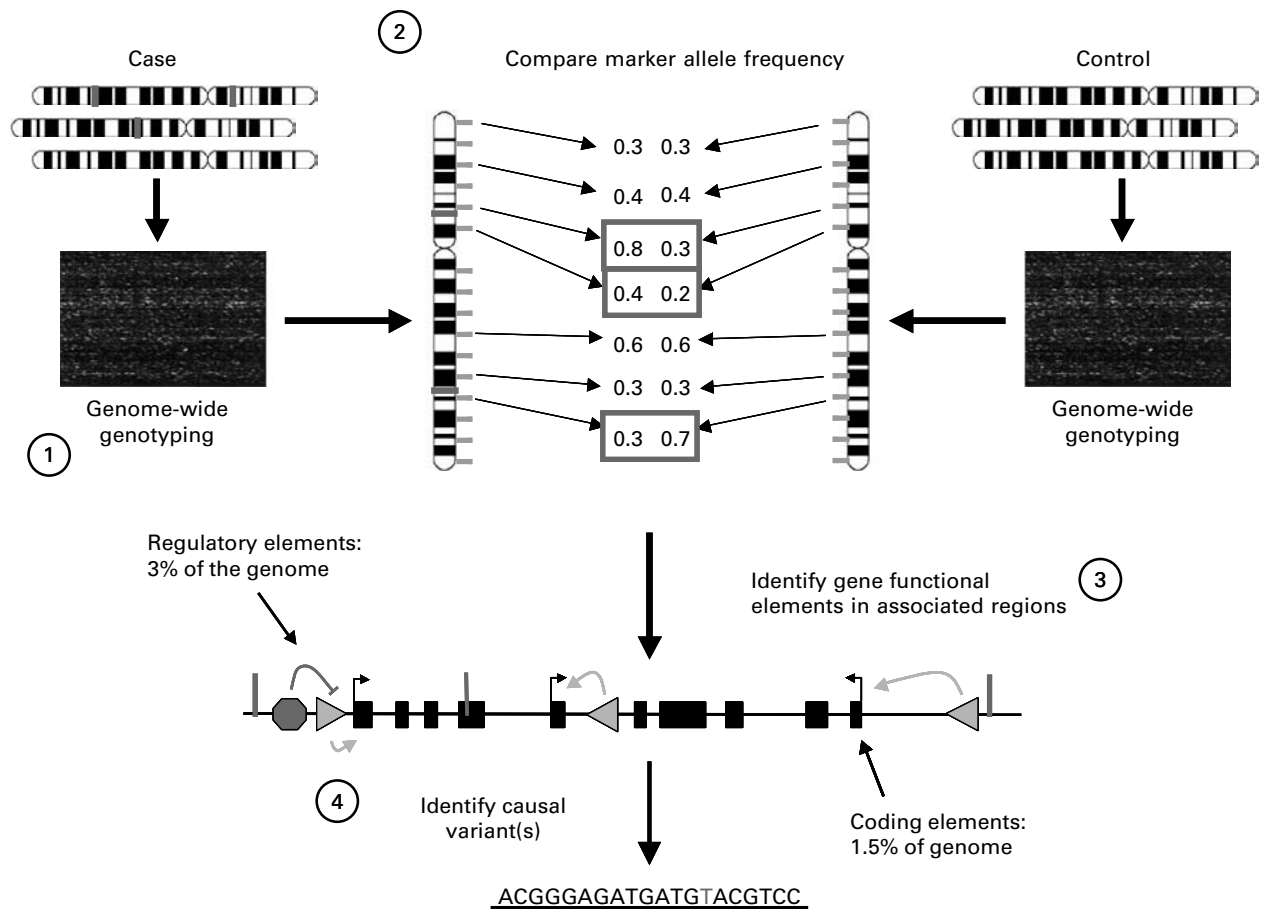
Genetic and genomic strategies as described in this chapter are exceptionally useful for understanding the genotype of diseased individuals. However, although they are powerful, they do not tell the whole story. To understand fully the cellular disease phenotype, it is important to examine not only the genes and mRNA, but also the end


Fig. 4.2. Schematic of genome-wide association study design. (1) Appropriately matched cases and controls are subject to genome-wide SNP genotyping (shown here using Affymetrix chips); (2) SNP allele frequencies are compared to identify regions associated with disease; (3) disease-associated regions are scanned for known functional elements, and cross-species comparisons can be used to identify unknown regulatory elements; (4) direct sequencing of functional elements to identify causal variants.

products – the proteins. Proteomics is the scientific discipline that examines global protein expression (the proteome) in cells. The proteome is dynamic and flexible; proteins are constantly being produced, degraded and modified. Therefore, proteomics strives to quantify proteins as well as to determine the specific isoforms, SNPs and post-translational modifications (PTMs) (eg., phosphorylation, glycosylation, and acetylation) that comprise the proteome. As such, information obtained from proteomic studies is complementary to that obtained from genetics and genomics.

Tissue or serum samples are highly complex mixtures of proteins, and this complexity must be reduced before further analysis. Complexity reduction can be accomplished by attempting to separate all the proteins in the original sample, or by first subfractionating the sample into several less complex mixtures. Often samples are

divided based on subcellular organelles, for instance the mitochondria or myofibrils from cardiac myocardium or extracted on the basis of a shared chemical characteristic, such as hydrophobicity, which can be exploited with various detergents. Once appropriately prepared, the sample can be analyzed by a variety of separation technologies (outlined in Table 4.5). Protein separation is based on using one or more of the intrinsic properties of proteins or peptides: pI (charge), mass (size) or hydrophobicity (water/oil solubility). A greater number of parameters/dimensions used in the separation adds exponential improvements in resolution/separation. The protein separation technologies can be broken down into three main categories: gel electrophoresis; liquid chromatography; and mass spectrometry (MS). In most cases, a combination of these must be used for thorough coverage of the proteome or subproteome.

Table 4.5. Outline of popular proteomic techniques

Technology	Method	Application
Gel electrophoresis		
one-dimensional	− low-moderate separation based on molecular weight	− moderate separation − good for high molecular weight or very hydrophobic proteins
Two-dimensional	− high degree separation based on isoelectric point and molecular weight	− excellent separation and potential for PTM discovery − limited use for very large or very hydrophobic proteins
Two-dimensional-differential gel electrophoresis (DIGE)	− fluorescently tag proteins prior to IEF − tag separate samples with different fluorophores and combine for 2DE	− allows comparison of different samples in the same gel − decreases variability (from gel to gel variation)
Liquid chromatography		
One-dimensional	− affinity columns – based on affinity of proteins to antibodies or other binding ligands − RP-HPLC – based on hydrophobicity − size exclusion columns – based on protein molecular size and shape − ion exchange columns – based on protein charge	− allows moderate separation of proteins or peptides based on a wide variety of properties
Two-dimensional (2DLC)	− IEF-based column followed by RP-HPLC	− combination of two columns for high degree of separation
Mass spectrometry		
MALDI-TOF MS	− protein identification based on peptide mass fingerprint (PMF)	− capable of high through-put analysis of large scale samples − not effective if sample is a mixture of proteins
MS/MS	− protein identification based on peptide fragmentation and amino acid masses	− analysis of more complex mixtures of proteins is possible − requires higher skill level and more time than MALDI-TOF
Immobilized metal affinity column (IMAC)	− chromatographic enrichment for phosphopeptides followed by MS/MS analysis	− enrichment of phosphopeptides allows for greater analysis of this PTM in the MS
Isotope labeling	− Isotope-coded affinity tag (ICAT)-peptides are labeled with heavy and light isotope tags prior to MS stable isotope labeling with amino acids in cell culture (SILAC) – proteins are labeled in cell culture with amino acids containing either heavy or light N or O^{18} labeling – peptides are labeled with either heavy or light oxygen during enzymatic digestion	− all of these procedures allow for accurate relative quantification of peptides between samples − ICAT and O^{18} labeling are good for samples that cannot be obtained from cell culture − SILAC is excellent for quantification since whole protein can be labeled, not just peptides

First described in 1975,[62] two-dimensional gel electrophoresis (2DE) has become one of the most widespread techniques used in proteomics. 2DE separates proteins first by isoelectric point (pI) by a process known as isoelectric focusing (IEF), then in the second dimension by molecular weight. Currently, 2DE has the potential to resolve upwards of 5000 protein spots per gel.[63] Over time, there have been continued improvements in both the first[64,65] and second dimension.[66] With this depth of separation, a significant number of proteins can be analyzed concurrently for changes in both expression level and PTM. Liquid chromatography techniques are similar in that they are used to achieve separation of the proteome on the basis of one or more of the physical properties of proteins.[67,68] The most commonly used is single dimension chromatography, such as reversed phase chromatography. In particular, reversed phase chromatography is often found online with MS, not as a means not to separate proteins, but rather to spread out the resulting peptides to allow for more coverage by the MS, which is especially advantageous when separating peptides from a complex mixture. A movement towards separating proteins by using two- and three-dimensional chromatographic separations is occurring, and often entails combining isochromatographic focusing (pI), ion exchange (charge) or size exclusion (mass) columns with reversed phase HPLC (hydrophobicity).

Once the proteins have been separated into individual or small groups of proteins, MS, which measures extremely accurate masses of proteins (whole mass) or peptides, is used to identify them. MS identification from gels or liquid chromatography techniques involves enzymatic digestion of the protein with the profile of peptide masses compared to a theoretical profile from a known protein database (termed protein mass fingerprinting). A single peptide fragment can be selected in the mass spectrometer and fragmented into its amino acid residues (tandem MS or MS/MS). From these mass spectra, again by homology, the amino acid sequence can be obtained, which allows for unambiguous protein identification. There are many different types of MS analysis each with unique advantages (some of these are listed in Table 4.5). An exhaustive explanation of these technologies is beyond the scope of this chapter, an in-depth review of this material can be found in refs. 69 and 70.

Searching for answers to sudden cardiac death using proteomics

Proteomic analysis of human diseases such as SCD can address a wide variety of biological questions. These technologies can be used to deduce mechanisms of disease through protein alterations or to search for predictive biomarkers of disease. For cardiac diseases there are typically two choices of samples to analyze: either direct analysis of heart tissue or indirect analysis through patient serum or plasma. The advantages and disadvantages as well as appropriate strategies for each are discussed below.

Heart tissue (Fig. 4.3)

The clinical goal of studies on heart tissue is to translate tissue-specific differences into tailored treatment strategies of arrhythmias that target the origin of the malfunction. It is a long process from proteomics and the identification of unique protein changes to identification of a therapeutic target or pathway. It starts with the direct analysis of the protein phenotype of the diseased heart through the analysis of cardiac tissue. This creates a problem when dealing with human heart diseases because of limited tissue availability, although with the appropriate study design it can be possible and compelling.[71] However, owing to tissue limitations, preliminary studies often start with an appropriate and translatable animal model system. Sudden cardiac death presents an even more unique problem since such animal systems are very difficult to develop. Nevertheless, there are fundamental questions about the heart proteome that once answered could lead the way to a greater understanding of cardiac mechanisms and thus SCD. For example, one fundamental question considers the global proteome differences between the conducting tissues of the heart. Although the functions of the ventricles, atria, SA node and AV node are well understood, there are gaps in our knowledge of the similarity or differences of these areas of the heart at the post-translational (protein) level. SCD has primarily been linked to arrhythmic events and as such many of the drugs associated with the prevention of SCD focus on controlling such events. This highlights the extraordinary importance of understanding the conducting regions in the heart. An additional limitation of this kind of study is the purity of the cell preparations. The SA node preparations must not be highly contaminated by the surrounding atrial tissue. Proteomic analysis of SA node as compared to the atrial tissue is underway in our laboratory (JVE) on a rabbit model (Fig. 4.3). It is hoped that this study will reveal differences in expression or PTMs of proteins in these essential tissues. A further advantage of proteomic analysis is the discovery of novel proteins, that were not previously known to be located in these tissues, to exist in mammals, or to exist at all (a hypothetical protein or homology). Often these proteins have no known function. Coupled with the discovery of novel PTMs of proteins, these data represent a wealth of
Fig. 4.3. 2-D gel of atrial tissue (a) from rabbit. Enlargements of gel section from atrial tissue (b) and SA node (c) show potential variation in protein content represented by the different spot patterns.

possibilities toward understanding the protein-based mechanisms of these important cell types.

In contractile tissues, membrane channels that conduct the currents and allow the heart to contract are of key significance, and proteomic technology gives a unique ability to look at the status of multiple channels in these special tissues, although very hydrophobic proteins are still somewhat problematic.[72–74] Development of new detergents (eg., ASB-14[75] and C8φ[76]) coupled with one-dimensional (1D) gel electrophoresis or gel-free separation methods that are amenable to detergents are leading the way in adapting traditional proteomic techniques to membrane proteins. Furthermore, initial enzymatic digestion of membrane-enriched subproteomes enables the analysis of "more soluble" peptides. While proteomics technology is developing quickly, there is not yet a "perfect" proteomic method for these troublesome, but important, proteins that provides all desired information.

After the completion of an in-depth proteomics study, candidate proteins that are associated with the treatment or disease remain. It is then imperative to continue the study with more traditional biochemical or molecular biological techniques to validate the proteomics findings and explain the function of the protein phenotype. Such techniques often include the use of transgenic animals, adenoviral gene transfer, or RNAi of isolated myocytes to overexpress or knockout the protein of interest. Candidate proteins can also be further investigated by analyzing the cellular localization by microscopy techniques. Localization provides key information toward understanding how a protein change may cause or reflect disease phenotypes. Proteomics is very powerful for uncovering the proteins involved in disease processes, but it takes collaboration with other biochemical disciplines to understand fully how protein changes affect phenotype.

Serum

The goals of serum or plasma proteomic studies are most often the identification of biomarkers for a specific disease. Although preferred, these biomarkers do not have directly to be involved in the underlying mechanism of the disease but rather the biomarkers need only reflect or correlate with the disease process. Although analysis of human diseases through blood samples is much more convenient for sample collection, serum has the limitation of being indirect, studying the disease only through the release of proteins from the heart into the blood. Biomarkers of this nature can be used as a predictive index of disease or as a diagnostic marker of the specific disease type or disease progression. For SCD it is possible that heart damage before an event releases proteins or peptides into the blood, producing a predictive proteomic profile and this profile could be used to screen high risk patients for the likelihood of an imminent cardiac event.

Although serum has the advantage of being readily available, it has a major drawback when it comes to proteomic study. The dynamic range of proteins within serum is extremely high, with about 90% of the protein content resulting from only the 10 most abundant proteins.[77] Consequently, the low abundant proteins (often the proteins of interest) are present in such low amounts that it is very difficult to study them. This has led to the development of systems to reproducibly deplete serum of its most abundant proteins.[78,79] An example of this dynamic range problem and potential solution is shown in Fig. 4.4(a) where the same amount of protein is loaded on to a 1-D gel from normal serum (Lane 1) and from IgGs and albumin-depleted serum (Lane 2). Figure 4.4(b) shows a 2-D gel of the fully depleted serum. Clearly, the depleted serum allows visualization of many more low abundant proteins. This depletion technique can be applied to all types of proteomics analysis, in addition to gel-based systems. Figure 4.5 demonstrates the necessity of this depletion applied to 2DLC.

Once the problem of dynamic range has been resolved, the other main problem is developing an appropriate patient cohort for the analysis. One example of a current study (Reynolds Foundation, Johns Hopkins University) cohort is that of patients with implanted ICDs (Implantable Cardioverter Defibrillators). The study involves regularly collecting serum samples and monitoring the arrhythmic incidents recorded by the ICD. Thus, such events can be correlated to the time that serum was taken, and through characterization of the serum, patient's conditions can be correlated with the proteomic phenotype of the serum. A complicating factor is that the proteome is dynamic and there is large biological variation among even control individuals. This variation as well as other factors, such as time course of collection, clotting time, and sex differences must be taken into account in such studies. The overall goal of such large scale serum screens is to allow researchers to predict and potentially prevent SCD.

Findings of such proteomic studies must always be carefully validated against secondary and much larger cohorts. This requires the development of much higher throughput validation technologies that would allow faster validation of potential targets across very large cohorts. This is a quickly developing area of research that has mostly focused on the use of antibody arrays or protein chips. There are several technologies on the market that include A² (Beckman), Luminex (BioRad) and the S+S FastQuant (Millipore). Figure 4.6 illustrates how the A² array is assembled (Fig. 4.6(a)) and the assay methodology (Fig. 4.6(b)).
Fig. 4.4 Serum depletion. Depletion of highly abundant proteins is essential for analysis of serum. It is clear from (a) 1-DE of whole serum and IgG/albumin-depleted serum proteins that many more proteins are visible in the depleted sample (Lane 2) than are in the whole serum sample (Lane 1) when both lanes are loaded with the same overall amount of serum protein. (b) A representative 2-D gel of IgG and albumin-depleted serum proteins.

Future prospects

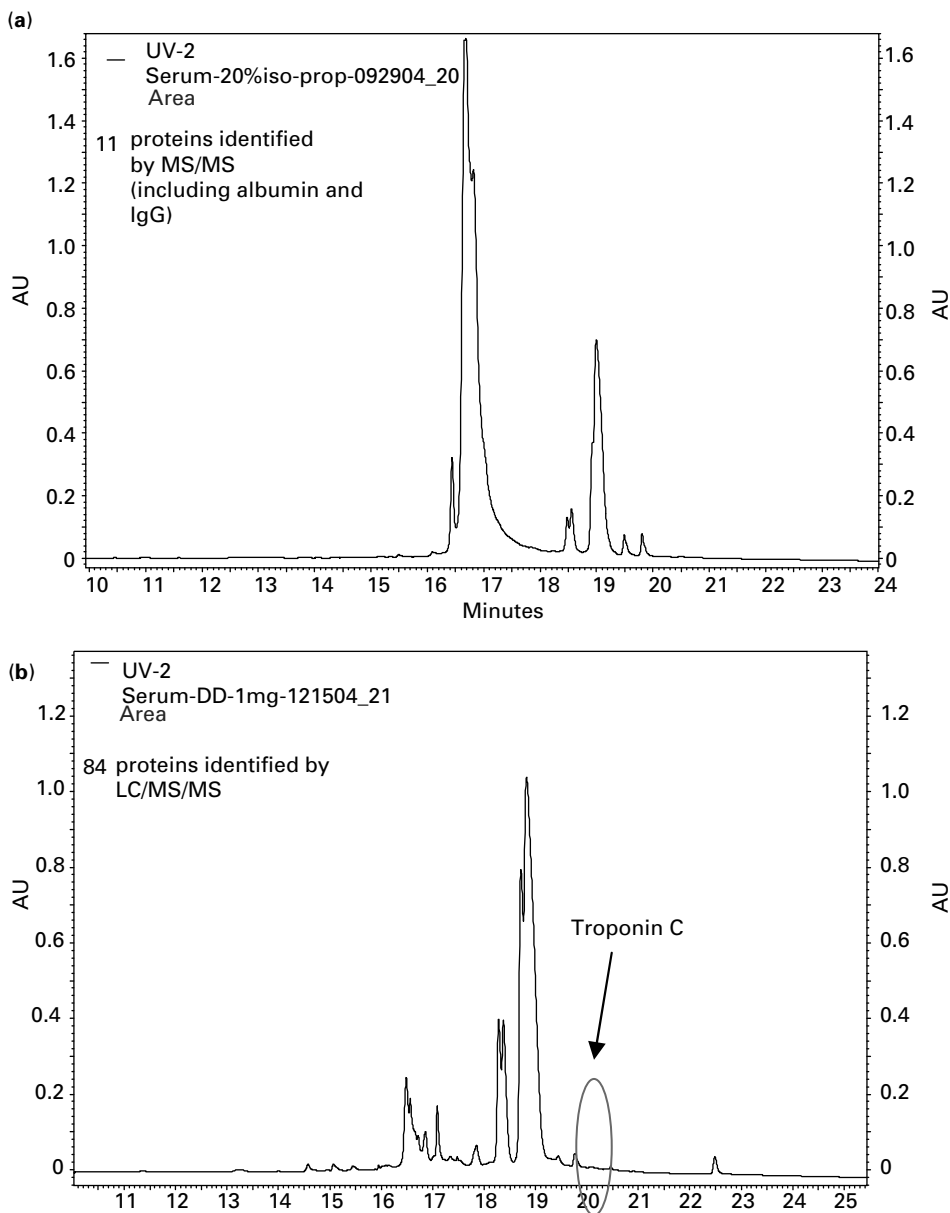
Proteomics is a rapidly evolving field. The technological leaps that have been made since the first two-dimensional gels were described in 1975 are astonishing. Researchers are now capable of separating, identifying, quantifying, and characterizing PTMs of proteins in a much shorter time scale. This ability has almost limitless potential not just for the understanding of disease mechanisms at the cellular level, but equally important, for the discovery of biomarkers to predict and prevent disease progression.


Fig. 4.5. Serum depletion for 2DLC. Depletion of highly abundant proteins from serum is also a requirement for proteomic technologies other than 2DE. Whole serum does not allow for as many proteins to be analyzed as, depleted serum does. (a) 2nd dimension RP-HPLC of whole serum fraction 20 (pH 5.4–5.69) from the 1st dimension (not shown) yields only 11 proteins that were identified by LC MS/MS. (b) 2nd dimension IgG and albumin-depleted serum illustrate that an equivalent 1st dimension fraction (21, pH 5.49–5.56) of depleted serum allows for almost eight times as many identifications (84) from the depleted serum by LC MS/MS.

Conclusions

Advances in our understanding of SCD through the study of inherited arrhythmogenic diseases have been significant. However, there is much left to learn before target therapeutic and diagnostic/prognostic markers are developed. The three scientific strategies discussed in this chapter can work in synchrony to uncover the mysteries behind SCD. Genetics and genomics will continue to provide vital evidence for mutations that predispose patients to arrhythmogenic

Intracellular signaling during myocardial ischemia

Peter H. Sugden

National Heart and Lung Institute Division, Faculty of Medicine, Imperial College London, UK

Introduction

There are several general points to be considered with respect to the perturbations in intracellular signaling that are induced by ischemia and any subsequent reperfusion, and these apply equally to the myocardium and to other tissues. First, what are the changes in the activities of signaling pathways wrought by prolonged periods of ischemia and are these related to any subsequent pathologies? Second, what are the mediators that lead to activation of these signaling pathways and what are the cellular sensors of these mediators? Third, what are the changes that allow short periods of ischemia to be protective against a subsequent period of ischemia that would normally inevitably lead to irreversible myocardial damage (the phenomenon known as ischemic conditioning)? Finally, what are the pharmacological options for intervention so that the damaging effects of ischemia and ischemia–reperfusion can be moderated or the protective effects of conditioning be stimulated? These questions are especially pertinent to the myocardium because the contractile cells (the cardiac myocytes) are terminally differentiated in the adult (i.e., they are incapable of undergoing a complete cycle of cell division), having withdrawn from the cell cycle during the perinatal period. This renders the heart particularly vulnerable to myocyte death such as that occurring during ischemic heart disease because the myocytes that are lost cannot be replaced, and the only palliative alternative is the regional expansion of the preexisting myocyte pool, i.e., cardiac remodeling.[1]

Ischemia and ischemia–reperfusion are associated with gross disturbances in ionic balance and metabolic activity, and increases in the production of reactive oxygen species

(ROS).[2,3] ROS are purposely produced by a number of enzymes (e.g., NAD(P)H oxidases, the xanthine dehydrogenase/oxidase system, various peroxidases) and play important biological roles (e.g., phagocyte-mediated killing of infecting bacteria),[4] but they are also produced as a byproduct of mitochondrial oxidative phosphorylation.[3,5] Even under arobic conditions, incomplete reduction of the end electron acceptor, molecular O_2, gives rise to superoxide anion radicals, hydroxyl radicals, and H_2O_2 (as much as 1%–2% of O_2 is incompletely reduced), and this is exacerbated during ischemia and worsened further during reperfusion.[3,5]

The stress-activated protein kinases (SAPKs)

Classification of SAPKs

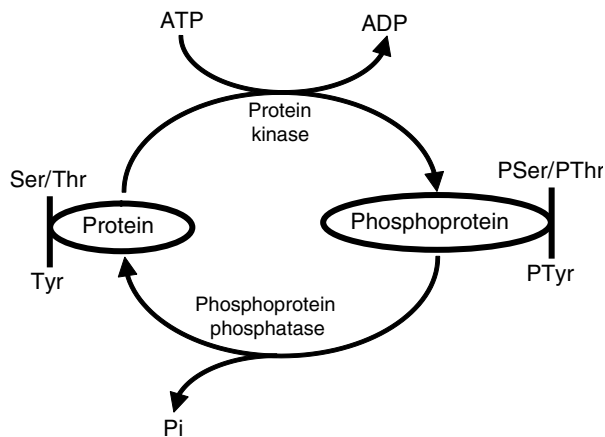
Many signaling events involve reversible protein phosphorylation and dephosphorylation (Fig. 5.1). Signaling in ischemia–reperfusion is no exception. One group of signaling proteins that is strongly activated by ischemia and ischemia–reperfusion is the so-called stress-activated protein kinases (SAPKs).[6–8] These are closely related to the bona fide mitogen-activated protein kinases (MAPKs) that regulate cell growth, cell division, and cell survival (i.e., the extracellular signal-regulated kinases 1 and 2 (ERK1/2), or p44-MAPK and p42-MAPK, respectively[9]). Indeed, in spite of attempts to clarify the terminology to render it more logical,[6] SAPKs are still often considered by many to be MAPKs. The general hierarchy of activation of MAPKs/SAPKs is similar in that a MAPK/SAPK kinase kinase phosphorylates and activates a MAPK/SAPK kinase, which then


Fig. 5.1. Reversible protein phosphorylation and dephosphorylation. Proteins can be phosphorylated on the hydroxyl groups of Ser-/Thr-residues and/or Tyr-residues by protein kinases, with ATP as the phosphate donor. There are up to about 500 protein kinases encoded in the human genome, of which the largest group phosphorylate Ser-/Thr-residues. In some (though probably not all) cases, the phosphorylation(s) will change the biological activity or properties of the protein concerned. Phosphoproteins are dephosphorylated by phosphoprotein phosphatases (about 100 encoded in the human genome) which hydrolyze the phosphoester bond to release inorganic phosphate (Pi). Notably, these cycles are unidirectional (i.e., operate only in the clockwise direction in Fig. 4.1) but are biologically-reversible (though requiring energy from ATP). All possess a level of activity that is altered by biological signaling events to change the proportions of the dephosphoprotein:phosphoprotein. Because of the cyclical nature, alteration of either the protein kinase activity or the phosphoprotein phosphatase activity (or of both in the opposite direction) changes the dephosphoprotein:phosphoprotein balance.

phosphorylates and activates a MAPK/SAPK (Fig. 5.2). Such a "cascade" of protein kinases allows signal amplification and integration. An equally important consideration is how activation is reversed and a variety of classes of phosphoprotein phosphatases is responsible for this. A detailed consideration of such phosphatases, however, is outside the scope of this chapter.

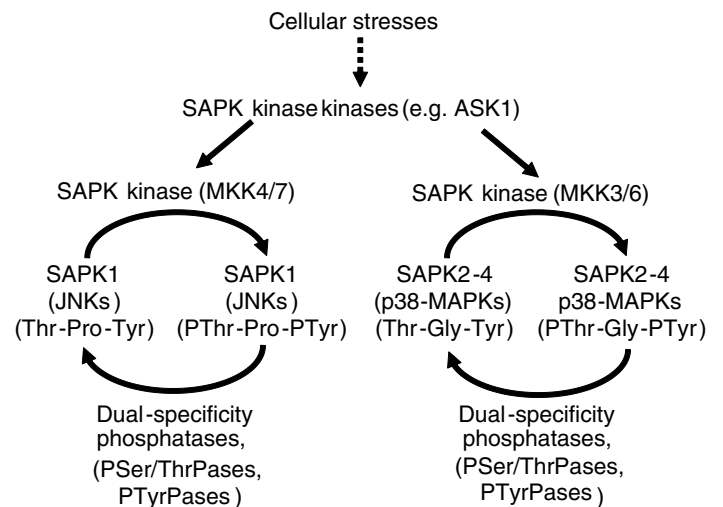
The phosphorylation of MAPKs/SAPKs by MAPK/SAPK kinases is unusual in that a Thr- and a Tyr- residue in a Thr-Xaa-Tyr tripeptide activation loop sequence are phosphorylated, and phosphorylation of both residues is necessary for activation. Furthermore, both phosphorylations are carried out by the dual-function (catalyzing both Ser-/Thr- and Tyr- phosphorylations) MAPK/SAPK kinases. The identity of the variable amino acid (Xaa) in the tripeptide sequence is one criterion used for classification of MAPKs/SAPKs. There is specificity upstream in terms of the protein


Fig. 5.2. The stress-activated protein kinase (SAPK) cascades. Activation of the SAPKs [which include the c-Jun N-terminal kinases (JNKs or SAPK1) and p38-mitogen-activated protein kinases (p38-MAPKs, SAPK2–4)], is the last step of a three-tiered protein kinase cascade. SAPK kinase kinases (which are likely themselves to be phosphorylated and dephosphorylated) phosphorylate and activate SAPK kinases, which then phosphorylate and activate the SAPKs. Activation of these cascades is reversed by dual-specificity phosphoprotein phosphatases which act on all three phosphorylated residues (at the SAPK stage only), protein Tyr-phosphatases (PTyrPases, at the SAPK stage only) and/or protein Ser-/Thr-phosphatases (PSer/PThrPases, at all three stages). For simplicity, the SAPK5 (or ERK5) cascade, which is also activated by cellular stresses, is not shown.

kinase activators of SAPKs. Thus, the SAPK kinases for the SAPK1 group are different from those for the SAPK2 group. The SAPK kinase kinases constitute a fairly diverse group of kinases and it is still not clear whether there is specificity in terms of their SAPK kinase substrates at this level, because the SAPK1 and SAPK2 families are frequently activated in an apparently concerted manner.

SAPK1

The SAPK1 group (Fig. 5.2), or the c-Jun N-terminal kinases (JNKs), were first identified in livers of rats exposed *in vivo* to the stress of administration of the protein synthesis inhibitor, cycloheximide.[10] In SAPK1, Xaa is Pro-. Their best defined substrate is the transcription factor c-Jun which is phosphorylated in its N-terminal transactivation domain (residues Ser-63 and Ser-73) to increase the ability of the protein to activate transcription. A further effect of these phosphorylations is increased stability of the protein towards proteolytic degradation.[11,12] In *Homo sapiens*, there are three *JNK* genes which give rise to multiple alternatively

spliced transcripts.[13] In non-neuronal tissues (including heart), transcripts encoding proteins of approximately 46 kDa and 54 kDa originate from both the *JNK1* and *JNK2* genes. (It is possibly a fairly common misconception that the *JNK1* gene encodes the 46 kDa JNK species and the *JNK2* gene encodes the 54 kDa JNK species: however, as Gupta *et al.*[13] demonstrate, this is not the case.)

SAPK2, SAPK3, and SAPK4

SAPK2, SAPK3, and SAPK4 (Fig. 5.2) are also known as the p38-MAPKs, and the identity of Xaa- is Gly-. The four members of the SAPK2 group (p38-MAPKα and p38MAPKβ) originate from two genes, both of which are alternatively spliced.[14–16] They are inhibited by pyridinylimidazoles such as SB203580 and SB202190,[14] and probably play a role in inflammatory diseases such as rheumatoid arthritis. SAPK3 (p38-MAPKγ, also confusingly termed ERK6) and SAPK4 (p38-MAPKδ) are less well characterized than the SAPK2 group and are not inhibited by SB203580.[14] There is still discussion about the diversity of expression of p38-MAPK isoforms in heart,[17,18] though work in this system has probably concentrated on those which are inhibited by SB203580, i.e., the SAPK2 group.[14] The best-characterized substrates of the SAPK2 group are themselves protein kinases, namely MAPK-activated protein kinases (MAPKAPK) 2 and 3, which phosphorylate the Hsp25/27 small heat shock proteins and their orthologs (e.g., α_B-crystallin).[19,20] Small heat shock proteins are molecular chaperones involved in the control of the stability of the cytoskeleton and possibly apoptosis.[21,22] Whilst the biological role of their phosphorylation is not entirely understood, their phosphorylation state may modulate their ability to regulate cytoskeletal stability.[21] Over-expression of these molecular chaperones protects the heart against ischemia,[23–25] and their phosphorylation during myocardial ischemia or stress has been detected.[26,27] Nevertheless, some doubt remains as to whether the phosphorylation event *per se* is cardioprotective.[28]

SAPK5

The final well-defined member of the SAPK group is SAPK5, also known as extracellular signal-regulated kinase 5 (ERK5) or "big" MAPK 1 (BMK1).[29] The identity of the Xaa- residue is Glu-. Although classified as an ERK on the basis of its Xaa- residue, it appears to be very different from the "classical" ERKs (ERK 1/p44-MAPK and ERK2/p42-MAPK) which, as bona fide MAPKs, regulate cell growth, division, and survival, and which are activated by peptide growth factors and other anabolic mediators. Again, a kinase

distinct from those activating SAPK1–4 is involved in the activation of SAPK5. Regulation of SAPK5 in the heart and cardiac myocytes has not been studied extensively (probably because assessment of its activation is not technically simple), although it is activated by cytotoxic stresses.[30] In other cells, probably the best-defined SAPK5 substrates are the myocyte enhancer factor 2 group of transcription factors,[29] suggesting a role of SAPK5 in regulation of gene expression.

Effects of ischemia and ischemia–reperfusion on SAPK activities

In the isolated heart, global ischemia activates SAPK2 (p38-MAPKα/β) and this probably increases on reperfusion.[31,32] Furthermore, it is possible that the classical SAPK kinase kinase/SAPK kinase cascade is not responsible for this activation, which is instead mediated by SAPK2 autophosphorylation involving an ancillary protein known as TAB1, and the AMP-activated protein kinase.[33,34] In contrast, SAPK1 (JNKs) are not activated by ischemia, but are strongly activated on reperfusion.[31] This is one of the few well-documented examples of differential regulation of SAPK1 and SAPK2 which, as mentioned above, are normally activated *pari passu*. It implies that SAPK1 and SAPK2 are regulated by different upstream activators in this instance. Ischemia and ischemia–reperfusion promote apoptotic and/or necrotic cell death, but it is not clear whether the activation of SAPKs promotes cell death or whether their activation represents a pro-survival response in the face of a cytotoxic insult. The field has been reviewed by both camps recently.[35,36] Resolution of this controversy has not proved simple partly because, although there are relatively selective inhibitors for the SAPK2 cascade (i.e., SB203580 and SB202190), there are no analogous inhibitors of the SAPK1 cascade. Inhibition of SAPK2 with SB203580 does appear to reduce cell death in the myocardium exposed to ischemia–reperfusion[32] an effect that is also seen with "dominant-negative" approaches where activation of SAPK2 is prevented by blocking the SAPK2 cascade with mutated SAPK/SAPK kinase.[37] Furthermore, activation of SAPK1 and SAPK2 is also seen in human hearts in failure following ischemic heart disease.[38]

What are the mediators of ischemia–reperfusion-induced activation of SAPKs?

ROS represent the most likely mediators of ischemia–reperfusion-induced activation of SAPKs. SAPKs are strongly activated by exogenous ROS in the myocardium,[26,39] and the effects of ischemia–reperfusion on

activation of SAPKs can be reduced by antioxidants.[39-41] It is not clear how ROS might activate the SAPKs. As with all cyclical processes, it could be through increased positive signaling (activation of SAPK kinases/SAPK kinase kinases) or decreased negative signaling (inhibition of phospho-protein phosphatases). The SAPK kinase ASK1 (apotosis signal-regulated kinase 1) is activated by ROS in a relatively complex manner, the description of which is beyond the scope of this chapter.[42,43] Equally, the dual-specificity phosphoprotein phosphatases are particularly import-ant in dephosphorylating and inactivating SAPKs (and MAPKs).[43,44] These phosphatases are Cys-dependent and contain a reactive sulphydryl group in their active sites which is susceptible to inactivating and possibly irre-versible oxidation.[45]

How might SAPKs induce myocardial death?

Given that it is not clear how ischemia induces the death of cardiac myocytes, then an obvious corollary is that it is not clear how SAPKs might bring this about. In simple terms, cells die by necrosis (unregulated cell death), apoptosis (regulated cell death), or a combination of these. Necrosis of cardiac myocytes probably involves swelling of the cell itself and of subcellular organelles (because of decreased ATP production and hence disturbances in ionic and metabolic balance), ultimately resulting in cell burst-ing. Necrosis does not require energy in the form of ATP, whereas apoptosis is an energy-requiring process. Apoptosis has been detected in hearts exposed to ischemic and ischemia–reperfusion, and probably occurs in vivo as a consequence of ischemic heart disease.[46–49] There are two pathways of apoptosis, the extrinsic (receptor-mediated) pathway and the intrinsic (mitochondrial) pathway.[50] Ultimately, both lead to the activation of proteolytic effec-tor caspases (e.g., caspase 3) with regulated demolition of cellular contents, nuclear and cellular condensation, and resorption of cellular components into neighboring cells. In the mitochondrial pathway, leakage of mitochondrial proteins such as cytochrome *c* leads to formation of the apoptosome and activation of the initiator caspase, caspase 9.[51] Individuals of a group of proteins (the Bcl2 proteins) either prevent or promote mitochondrial leakage,[51] and these are involved in SAPK1- or SAPK2-mediated apoptosis. An extensive literature in this area now exists (see, for example,[52–58]) though a consensus view has not been reached, probably because different mech-anisms apply to different cell types. For example, activa-tion of the pro-apoptotic Bax or Bad proteins or inhibition of the antiapoptotic activity of Mcl-1 may be essential in SAPK1/SAPK2-activated apoptosis.[52,53,55,59] Further details

are beginning to emerge. Thus, pro-apoptotic Bim is subject to a SAPK1-dependent upregulation at the level of transcription and/or a SAPK1-dependent phosphorylation that may allow it to dissociate from microtubules and either to activate pro-apoptotic Bax/Bak or to inhibit anti-apoptotic Bcl2 in the mitochondrial outer membrane.[54,60] Studies are, as usual, less advanced in cardiac sytems though recent publications suggest that SAPK1 stimulates the mitochondrial pathway of apoptosis,[61] and that migra-tion of Bax (and pro-apoptotic cleaved Bid) to mitochon-dria during simulated ischemia/ischemia–reperfusion may be mediated by an (AMP-activated protein kinase-dependent?) activation of SAPK2.[56,57] A putative scheme of ischemia–reperfusion-induced cell death is shown in Fig. 5.3.

Activation of additional signaling pathways by ischemia–reperfusion

Protein kinase Cδ (PKCδ)

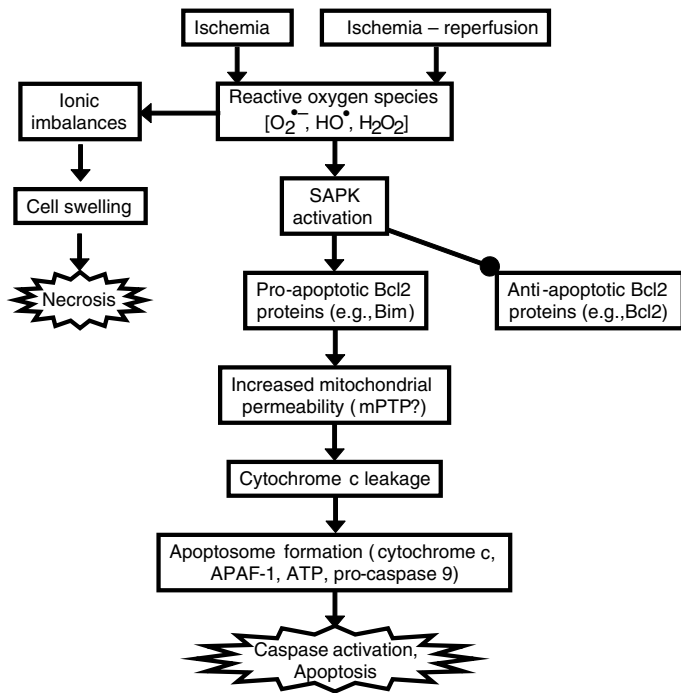
The PKC family are phospholipid-dependent kinases that translate signaling events in the plasma membrane further downstream.[62–64] Although certain members of the PKC family are the cellular receptors for tumor-promoting phorbol esters (and are hence potentially involved in cell division and/or inhibition of apoptosis), PKCδ, even though activated by phorbol esters, appears to promote apoptosis.[65–68] The ROS-mediated pro-apoptotic effects of PKCδ involve its translocation to mitochondria and other subcellular organelles,[65,69] and may additionally involve the non-receptor protein tyro-sine kinase c-Abl (which is activated by ROS), SAPK2 and the pro-apototic Bcl2 proteins, Bax and Bak.[58,70] Alternatively, in neuronal cells, ischemia or ROS causes a caspase-3-dependent cleavage of PKCδ to release its (unregulated and active) catalytic domain.[67,71–73] These two pathways of activation are not necessarily distinct because phosphorylation of a Tyr-residue (Tyr-311) close to the caspase-3-cleavage site in PKCδ appears to enhance the cleavage. Again, analogous studies in myocardial systems are relatively unadvanced, but have still found a focus in PKCδ. Thus, PKCδ has been reported to signal preferentially to the SAPK1 and SAPK2 cascades and to potentiate ischemia-induced damage.[74,75] Furthermore, ROS promote phosphorylation of Tyr-311 (and other Tyr-residues) in PKCδ.[76] These Tyr-phosphory-lations are associated with release of PKCδ into the soluble phase of the cell from the particulate fraction and increased (lipid-independent) catalytic activity.[76] Other


Fig. 5.3. A putative signaling scheme for the death of the cardiac myocyte in ischemia and ischemia–reperfusion. Ischemia and any subsequent reperfusion lead to the formation of reactive oxygen species (ROS, superoxide anion radicals, hydroxyl radicals, H_2O_2) which activate the SAPKs. This leads to phosphorylation of Bcl2 family proteins, increasing the pro-apoptic activity of some and diminishing the anti-apoptotic activity of others. Bcl2 proteins regulate the permeability of the outer mitochondrial membrane, which is increased. The mitochondrial permeability transition pore (mPTP) may also be involved, but this is not regulated through Bcl2 proteins and is in the inner mitochondrial membrane. Cytochrome *c* present in the intermembrane space of the mitochondria leaks out of the mitochondria into the cytoplasm. This leads to the assembly of the apoptosome complex which includes the protein APAF-1, ATP, and inactive initiator pro-caspase 9. Pro-caspase 9 has a low basal activity but, when assembled in the apoptosome, this is sufficient for the transautopeptidase of pro-caspase 9 to occur, cleaving neighboring pro-caspase 9 molecules in the apoptosome. The caspase cascade is triggered, leading ultimately to the activation (by cleavage) of effector caspases such as caspase 3, and cell demolition is initiated. In addition, ROS-induced changes in ionic homeostasis, for which opening of the mPTP may be partly responsible, leads to cell swelling and bursting (necrotic cell death). For a given cell, death can result though apoptosis, necrosis, or a mixture of the two, depending on the signals it receives.

studies have suggested that translocation of PKCδ to the mitochondria following ischemia-reperfusion in the intact heart may induce cell death in the heart by stimulating the mitochondrial pathway of apoptosis.[77]

The endoplasmic reticulum (ER) stress response

The ER stress response (or the unfolded protein response, UPR) embraces a complex series of events that is initially cytoprotective but which, if unrestrained, leads to apoptosis.[50,78] The ER is a complex subcellular organelle that is intimately involved with translation of mRNA species into immature proteins and in their subsequent post-translational processing (polypeptide folding, disulfide bond formation, glycosylation) into mature proteins. The ER is rich in molecular chaperones (proteins that function in these folding processes) such as Grp78. In non-muscle cells, the ER is also the principal intracellular store of Ca^{2+}, although, in cardiac and skeletal muscle myocytes, a specialized form of the ER, the sarcoplasmic reticulum (SR), assumes this role. Disturbances in Ca^{2+} homeostasis (e.g., depletion of ER Ca^{2+} stores) and other stresses (inhibition of glycosylation, oxidative stress, viral infection) trigger the UPR and this involves the release of signaling proteins that are normally tethered to the ER by Grp78 into the cytoplasm. Depletion of SR/ER Ca^{2+} stimulates the UPR in cardiac myocytes.[79] The UPR consists of multiple parallel events, some of which (ASK1, SAPK1/2) have been mentioned earlier. Others include the release of the trans-ER membrane ATF6 transcription factor from its Grp78 tether in the ER, proteolytic cleavage of ATF6 at a juxtamembrane site, and migration of ATF6 to the nucleus where it drives expression of mRNA species encoding proteins (e.g., XBP1, Grp78) which perpetuate the UPR. Induction of the UPR in response to ischemia–reperfusion has not been examined extensively in the heart. Its activation has been detected in ischemic heart disease,[80] however, and conditional activation of a cardiospecifically expressed, cleaved (i.e., activated) ATF6 in transgenic mice protects hearts against ex vivo ischemia-reperfusion injury.[81] Activation of the UPR in a myocardial context will potentially have important implications in cardioprotection.

Ischemic conditioning

In certain settings, controlled myocardial ischemia can confer cardioprotection. Thus, repeated (1–6 times) short periods (5 min) of ischemia interspersed with short periods of reperfusion (5 min) protect the heart against a subse-

quent period of ischemia which would otherwise be lethal.[82–84] This phenomenon is known as ischemic preconditioning and it was recognized in the heart over 20 years ago.[85] The initial period of protection lasts for only 1 or 2 hours but, in vivo, a "second window of protection" occurs over the 24–72-hour period. Recently, it has been recognized that the heart can also be protected if intermittent ischemia–reperfusion is applied after the period of damaging ischemia, a phenomenon known as ischemic postconditioning.[83,84] Ischemic preconditioning may occur either naturally or unintentionally in certain circumstances, for example during "warm-up" angina or during certain surgical procedures (e.g., percutaneous transluminal coronary angioplasty).[82]

Thus, it would potentially be therapeutically useful if ischemic conditioning could be induced pharmacologically and this provides the motivation for the elucidation of its mechanisms. Nonethelesss, a consensus on the mechanisms of ischemic conditioning is still lacking. Multiple initiating stimuli have been identified and include oxidative stress, vasoactive compounds (adenosine, bradykinin, endothelin, NO, and others) and narcotics such as opioids.[82] Intracellular signaling studies have suggested a role for PKC isoforms (especially PKCε)[75,86] and the mitochondrial K^+_{ATP} channel.[87] More recently, a role for "prosurvival" protein kinases such as ERK1/2 and protein kinase B (PKB, also known as Akt) has been proposed.[83] These are described in more detail in the subsequent section. The suggestion is that ERK1/2 and/or PKB/Akt prevent the opening of the mitochondrial permeability transition pore (mPTP) at the time of reperfusion. The mPTP is a non-selective ion pore in the inner mitochondrial membrane and its opening leads to mitochondrial uncoupling, inhibition of mitochondrial ATP regeneration and loss of ion homeostasis, followed ultimately by cell death.[88] Recent evidence from transgenic mouse studies has indicated that inactivation of mPTP opening caused by targetted gene deletion of one of its components (cyclophilin D) protects the heart against ischemia.[89–91] Furthermore, targeting cyclophilin D with cyclosporin A or sanglifehrin A or inhibition of its other components (the adenine nucleotide translocase) has suggested a strategy for protection,[88] though the current agents available are probably unsuited for routine use in vivo because of their wider effects (e.g., cyclosporin A is an established immunosuppressant that also exhibits renal toxicity).

Potential for therapeutic intervention in ischemia–reperfusion injury

With respect to cell signaling, there are two options for strategies of reduction of the damaging effects of ischemia and ischemia–reperfusion, inhibition of cytotoxic pathways or activation of cytoprotective pathways. Allusions have been made earlier in this chapter of how this may be achieved. For example, inhibition of SAPK1 (JNKs) and SAPK2 (p38-MAPKα/β) during ischemia would be predicted to be cytoprotective and ex vivo evidence to this effect has been presented.[32,36,37] In vivo, the SAPK2 inhibitors appear to improve cardiac viability and performance in a hamster model of dilated cardiomyopathy, though a SAPK1 inhibitor (SP600125) was deleterious.[92] (Note, however, that SP600125 is not particularly selective for SAPK1 and it inhibits a number of potentially prosurvival protein kinases in addition to inhibiting SAPK1.[93]) This is clearly an area for future development.

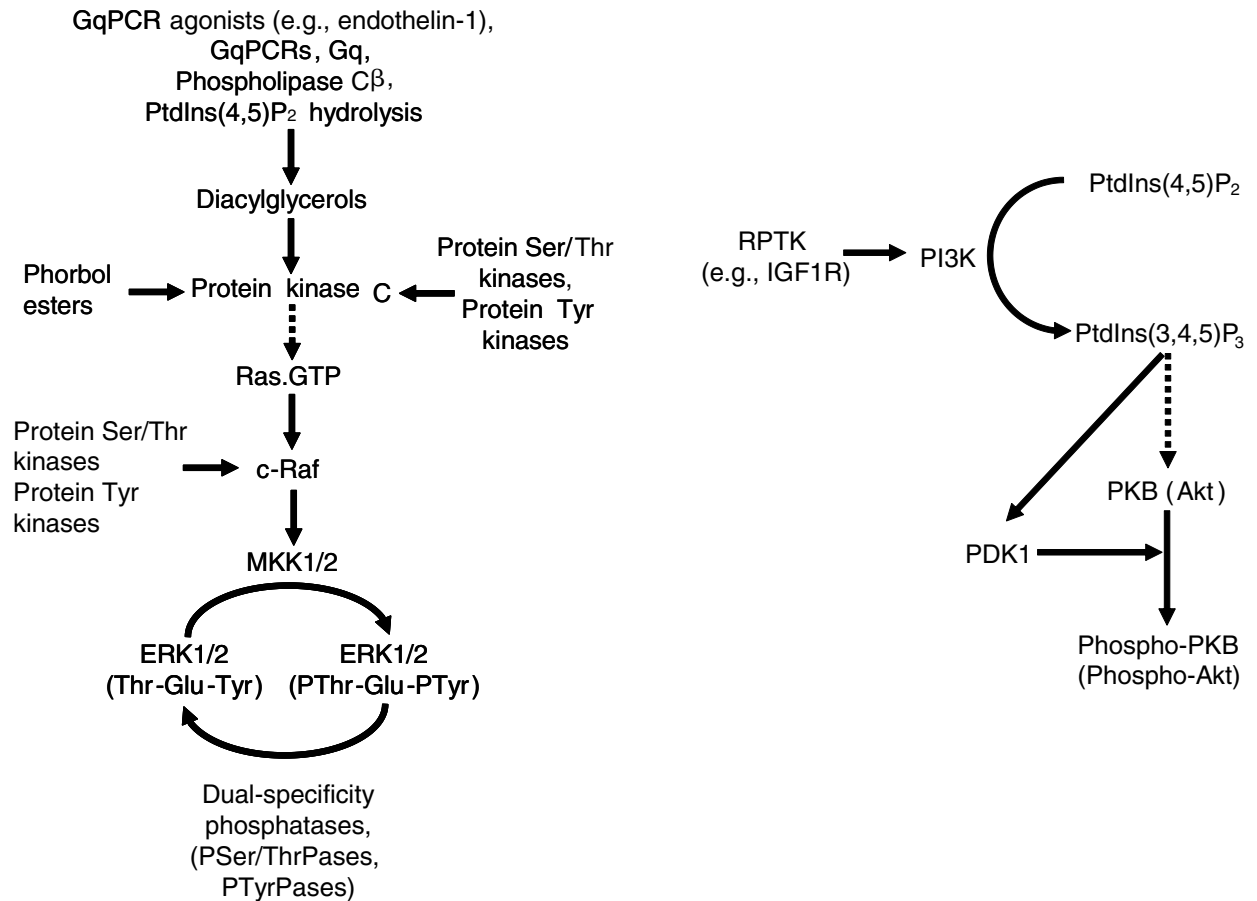
Two cytoprotective pathways have received attention, the PKB/Akt and the ERK1/2 pathways (Fig. 5.4). PKB/Akt is classically activated by peptide growth factors such as insulin-like growth factor 1 and insulin acting at their transmembrane receptor protein tyrosine kinases. A detailed description of the activation of PKB/Akt activation is outside the scope of this article, though an extensive literature exists.[94–96] In the heart, experimental studies have shown that activation of PKB/Akt is cardioprotective.[97] The ERK1/2 cascade is also activated in the cardiac myocyte by a less-extensive range of peptide growth factors (e.g., epidermal growth factor and platelet-derived growth factor, which also act at receptor protein tyrosine kinases) than PKB/Akt. In cardiac myocytes, however, agonists such as endothelin and α_1-adrenergic agonists (which act at a separate class of transmembrane receptors, the Gq/11 protein-coupled receptors) activate ERK1/2.[98,99] This activation probably occurs through a PKC-dependent pathway and hence tumor-promoting phorbol esters are powerful activators of ERK1/2 in cardiac myocytes.[98,99] Again, a detailed description of the ERK1/2 cascade lies outside the scope of this chapter.[9,100] Suffice it to say that the organization of the ERK1/2 cascade is analogous to that of the SAPK cascades. Thus a MAPK kinase kinase (c-Raf, A-Raf or B-Raf) activates MAPK kinases (MKK1/2) which then activate ERK1/2. As with PKB/Akt, there is now extensive evidence that activation of ERK1/2 protects against the damaging effects of myocardial ischemia.[101,102] The mechanisms of cardioprotection are, at least in part, dependent on the abilities of PKB/Akt and ERK1/2 to activate signaling which leads


Fig. 5.4. Pro-survival protein kinases. The extracellular signal-regulated kinase 1/2 (ERK1/2) cascade is the archetypical mitogen-activated protein kinase (MAPK) cascade. Activation of upstream signaling events (not described) leads to activation of the guanine nucleotide binding protein Ras by stimulation of exchange of GTP with Ras-bound GDP increases Ras.GTP loading. The Raf isoforms (c-Raf is shown), which are the MAPK kinase kinases for the ERK1/2 cascade, have a high affinity for Ras.GTP and translocate to the membrane. In the case of c-Raf, phosphorylations and probably dephosphorylations occur at this location, and c-Raf becomes fully activated. c-Raf then phosphorylates two Ser-residues on the MAPK kinases, MKK1 and MKK2, to activate them. MKK1/MKK2 then phosphorylate ERK1 and ERK2 on a Tyr- and a Thr-residue to activate them in turn. Activation of c-Raf is reversed by Ras-mediated hydrolysis of the bound GTP and presumably by changes in its phosphorylation state. MKK1/2 are dephosphorylated by protein Ser-/Thr-phosphatases (PSer/ThrPases). ERK1/2 are dephosphorylated on both Tyr- and Thr-residues by the Cys-dependent dual-specificity protein phosphatases. There are at least 13 dual-specificity phosphatases with differential specificity towards the various MAPKs, and they are either constitutively or inducibly expressed. Alternatively, protein Ser-/Thr-phosphatases or Cys-dependent protein Tyr-phosphatases (PTyrPases) dephosphorylate their respective sites individually. The mechanisms of activation of the ERK1/2 cascade by Gq protein-coupled receptor (GqPCR) agonists such as endothelin-1 are incompletely understood. These agonists (or phorbol esters) activate the diacylglycerol-sensitive protein kinase C isoforms and this probably leads to activation of Ras, though the nature of the connections is unclear (indicated by the dashed arrow). Certain receptor protein Tyr-kinases (e.g., the epidermal growth factor receptor, EGFR) will also activate the ERK1/2 cascade in the heart and are thus potentially prosurvival, but these have been omitted for the sake of simplicity.

In the protein kinase B/Akt (PKB/Akt) signaling pathway, activation of receptor protein tyrosine kinases (RPTKs, e.g., the insulin-like growth factor 1 receptor, IGF1R or the IGFR) by their individual extracellular ligands (e.g., IGF1, EGF) leads to their autophosphorylation on specific Tyr-residues. This increased Tyr-phosphorylation promotes binding of phosphoinositide 3-kinase (PI3K) to these phospho-Tyr- (*P*Tyr-) residues. This event places the PI3K catalytic subunit in the plane of the membrane where it phosphorylates phosphatidylinositol 4,5-bisphosphate [PtdIns(4,5)P$_2$] to PtdIns(3,4,5)P$_3$. In the unstimulated state, a proportion of the Ser-/Thr-protein kinase 3-phosphoinositide-dependent kinase 1 (PDK1) is bound to the membrane through its phospholipid-binding domain by the basal levels of PtdIns(3,4,5)P$_3$ present. When PI3K is activated, PtdIns(3,4,5)P$_3$ levels in the plane of the membrane increase and protein kinase B (PKB) translocates to this locale by binding to PtdIns(3,4,5)P$_3$. The juxtapositioning of PDK1 and PKB allows PDK1 to phosphorylate and activate PKB/Akt.

to a reduction in apoptosis. This is mediated in a number of ways–phosphorylation and inhibition of pro-apoptotic Bcl2 proteins and repression of genes encoding proapoptotic protein mediators representing two of them.[103,104] Why then is there not more emphasis on promoting the activation of PKB/Akt and ERK1/2 in the treatment of myocardial ischemia? The problem is that unregulated activation of these pathways in cells capable of division would potentially induce malignancy, and so systemic delivery of such agents would be potentially harmful. Indeed, mutants of a number of the components of the cell survival pathways (c-Raf, B-Raf, PKB/Akt) are established oncogenes.

Conclusions

Understanding of the signaling processes involved in ischemia–reperfusion injury and myocardial cell death has increased dramatically recently and this understanding has led to the formulation of protective strategies. Nevertheless, complicating factors (the problems of toxicity of known inhibitors of cytotoxic signaling pathways, the possibility of malignant transformation in the case of activation of cytoprotective pathways) have so far precluded informed clinical application. It is likely that future refinements (e.g., localized targeting of therapeutic interventions) will eventually bring benefits.

Electrophysiology of ventricular fibrillation and defibrillation

Wei Xiong and Gordon F. Tomaselli

Department of Medicine, Division of Cardiology, Donald W. Reynolds Cardiovascular Clinical Research Center,
Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

Sudden cardiac death remains a major public health problem in the United States. Despite extensive study and effective treatments for malignant ventricular arrhythmias more than a quarter of a million people die suddenly each year in this country.[1] Sudden death accounts for more than half of all deaths related to cardiovascular disease, coronary artery disease is the most common pathological condition found in patients who die suddenly, and ventricular fibrillation is the most common immediate cause of death.[2]

In the last decade a decline in the incidence of out-of-hospital ventricular fibrillation and a measurable improvement in the long-term survival of patients who have been resuscitated have been documented in the most well-studied communities.[3,4] Despite these gains and perhaps because of the changing etiology of cardiac arrest, the overall survival of cardiac arrest victims has not changed in the past two decades.[3] In communities with the most sophisticated emergency medical services, the maximal survival rate for out-of-hospital ventricular fibrillation is about 30%.[3,5] Understanding the mechanism of ventricular fibrillation is critical to making a meaningful impact on the incidence of this arrhythmia and improving the survival of sudden death victims.

Ventricular fibrillation was described by Ludwig and Hoffa in 1849 as an incoordinate heart action that produced a high metabolic rate of the myocardium but no useful contractions.[6] The hemodynamic consequences of the disordered cardiac contraction and the fundamental electrophysiologic basis of ventricular fibrillation were understood by the turn of the century. Porter, in 1898, stated that the essential nature of fibrillatory contractions is the result of abnormalities in impulse conduction.[7] Observations by several investigators supported the concept that a critical mass of tissue was required to maintain ventricular fibrillation, spontaneous recovery being common in the fibrillating hearts of small animals such as cats, rabbits, mice, and fowl, while spontaneous recovery in canine, bovine, and human hearts is rare.[8]

By the 1930s a contemporary understanding of ventricular fibrillation was established with only rudimentary electrocardiographic and hemodynamic measurements. This included the concepts that the electrophysiological mechanism is re-entry,[8] anoxia develops with cessation of coronary blood flow, and the progressive decline in the strength of contractions is due to substrate deprivation and accumulation of metabolic byproducts.[9] The last 70 years have seen considerable refinement of our understanding of the electrophysiology, hemodynamics, and metabolic consequences of ventricular fibrillation. Despite intensive study, however, our understanding of the pathophysiology of this lethal ventricular arrhythmia is far from complete.[10,11]

In this chapter we will review the electrophysiological mechanisms of ventricular fibrillation, the resultant mechanical and metabolic derangements associated with this arrhythmia, and the clinical circumstances under which ventricular fibrillation occurs with particular emphasis on the most common precipitant, myocardial ischemia. Finally, a brief perspective on the prevention and treatment of ventricular fibrillation will be presented.

Basic science

Electrophysiology of ventricular fibrillation

Ventricular fibrillation is a dynamic arrhythmia changing electrically, mechanically, and mechanistically over time. The changing nature of fibrillating myocardium was first summarized by Wiggers who described four phases of ventricular fibrillation.[6] The first or undulatory stage of ventricular fibrillation is characterized by comparatively large wavefronts of excitation when induced by a premature stimulus in the vulnerable period. The undulatory stage is short-lived, lasting 1 to 2 seconds. The second or convulsive stage lasts from 10 to 30 seconds and the hallmark of this phase is the division of the initial wavefronts of activation into smaller segments that activate the ventricle more rapidly. The third stage could last minutes and was termed the tremulous stage, the heart having this appearance as the result of a large number of segments of reentry. In the final stage contractions become progressively weaker as a result of anoxia.[6]

More recent studies that utilize high density mapping of the myocardium have focused on the mechanisms of initiation of ventricular fibrillation (stages 1 and 2) and maintenance (stage 3) of this arrhythmia. The mechanisms of initiation of ventricular fibrillation may differ from the electrophysiologic mechanisms that maintain this tachycardia. Moreover, no single mechanism suffices to explain the initiation of all clinical and experimental ventricular fibrillation, which is critically dependent on the myocardial substrate. Independent of the mechanism initiating fibrillation, the maintenance of this arrhythmia requires a critical mass of fibrillating myocardium, and the appropriate relationship between conduction velocity and refractoriness of the ventricle.[2]

On the surface ECG, ventricular fibrillation appears as an extremely irregular, almost random process of electrical activation. This apparent turbulent pattern of cardiac activity has led to a traditional belief that ventricular fibrillation is the consequence of total disorganized activity; however, on closer examination there is organization in ventricular fibrillation. The multiple wavelet hypothesis,[12,13] initially developed for atrial fibrillation, was proposed by Moe in 1962. Two years later, the first computer model of cardiac fibrillation demonstrated that heterogeneity of refractory periods accounted for the degeneration of periodic re-entrant activity to fibrillation.[14] It was not until 20 years later, however, that firm experimental support for the multiple wavelet hypothesis was provided by Allessie and colleagues.[15] Using high-resolution mapping technology, they demonstrated that multiple propagating wavelets caused fibrillatory activity in the canine atrium.[15]

A related but alternative theory explaining fibrillation in the heart is spiral wave re-entry. This theory posits that fibrillation is the result of activation of the heart by meandering spiral waves (2D) or scroll waves or rotors (3D). Like leading circle re-entry, spiral wave re-entry does not require the presence of an inexcitable anatomical obstacle. The nature of spiral waves produces the conditions necessary for re-entry. The curvature of an activation wavefront creates a spiral of activation with the core of the spiral conducting slowly due to current source-sink mismatch and the distal activation wavefront conducting more rapidly. Although the core of the spiral is excitable, it remains unexcited by the extreme curvature of the wavefront; thus, the location of the core is free to move or drift. Fibrillation produced by scroll waves may be the result of movement or meandering of one or a small number of rotors or the propagation of smaller meandering rotors from a stable mother rotor. In optical mapping studies in isolated perfused canine hearts, transiently erupting rotors, frequent wavefront collisions, and wavebreak generation were easily detected in the fibrillating ventricle.[16] Ventricular fibrillation arises from breakup of a single spiral wave or a pair of counter-rotating spiral waves into multiple smaller wavelets.

In contrast to the multiple wavelet hypothesis, in which constant formation of new wavelets via disintegration of a spiral wave leads to multiple wavelet fibrillation, the mother rotor hypothesis proposes that a single stable high-frequency firing rotor is the driving force of ventricular fibrillation.[17] The multiple wavelets result from the failure of 1:1 conduction originating from the rapid mother rotor to the surrounding myocardium and are merely epiphenomena. In a normal Langendorff-perfused rabbit heart, a single drifting spiral wave was associated with rapid polymorphic ventricular tachycardia that was indistinguishable from ventricular fibrillation.[18] Jalife and colleagues have proposed that the rapid firing rotor with its dominant frequency is the fundamental source that maintains the overall activity. The fast moving wave front originating from a stable focal source propagates across neighboring myocardial tissue and collides with the obstacles along the wavefront, produced by both functional and anatomical heterogeneities, resulting in breakup of the spiral wave and formation of multiple wavelets. The anatomical heterogeneities include the normal atrial and ventricular structures, such as coronary arteries, papillary muscles, atrioventricular rings, orifices of aortic and pulmonary vessels, and changes in orientation of transmural muscle fibers. These unstable wavelets produce the fibrillatory pattern of the ECG.

Heterogeneities of repolarization and conduction in the heart are important contributors to the genesis of ventricular fibrillation. Restitution is a property of cardiac myocytes that explains the changes in action potential duration (APD) with changes in the timing or coupling of activation during a rhythm at steady state. Thus the APD of an extrasystolic beat is determined by the coupling interval of that beat and the APD of the preceding beats. The restitution hypothesis suggests that large oscillations of the APD of the wavefront lead to breakup of spiral waves into multiple wavelets. This process requires that the slope of the action potential restitution curve, the ratio of APD to the preceding diastolic interval, is ≥ 1, indicating that small changes in diastolic intervals lead to dramatic changes in APD. Indeed, the slope of the APD restitution curve is a target for antifibrillatory therapy. Investigators have demonstrated through experiments and simulations that flattening of the restitution curve is antifibrillatory.[19] The dynamic changes in repolarization may further exaggerate existing temporal and spatial heterogeneities in repolarization that constitute an important component of the substrate for ventricular fibrillation (Fig. 6.1). Restitution is a property of conduction as well and recent reports similarly suggest that steep restitution of conduction may be profibrillatory.[20] Importantly, restitution curves for both repolarization and conduction are multiphasic so that simply changing the shape of a portion of the curve may not produce the anticipated effects on predisposition to fibrillation.

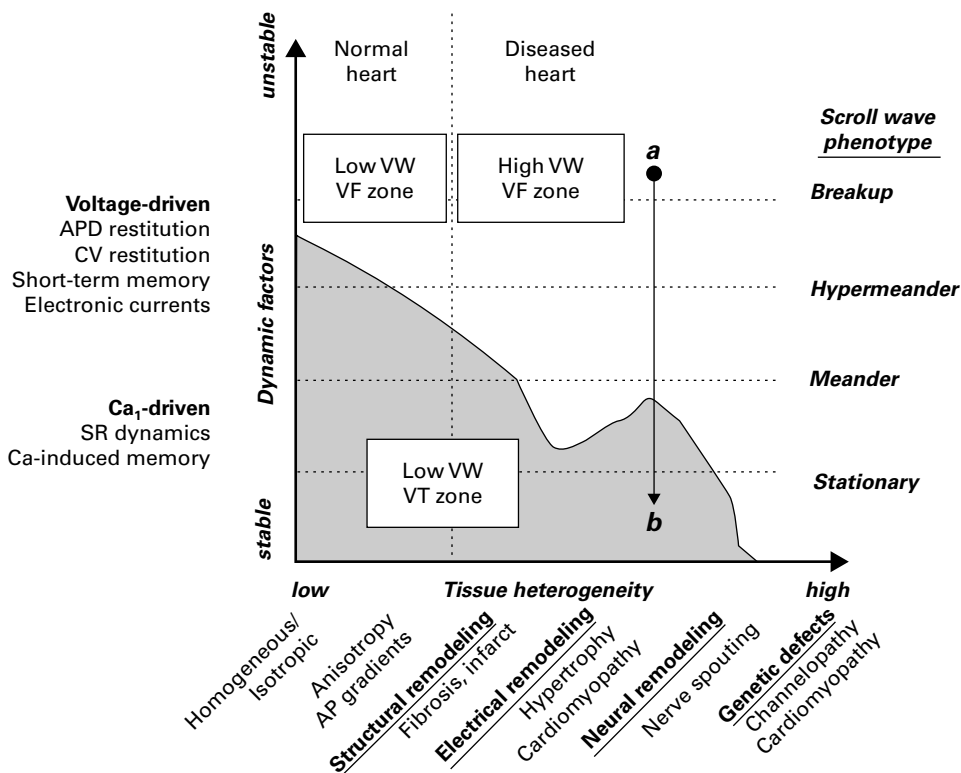
The ion channels that participate in the perpetuation of ventricular fibrillation have been debated. Depolarization of the membrane potential during fibrillation would imply that the action potential generated in myocardial cells during this rhythm should be so-called "slow" action potentials, whose upstrokes are mediated by Ca^{2+} channels. There is general agreement that in the later stages after several minutes of fibrillation, Na^+ channels that underlie the upstroke of the "fast" action potential are inactive.[21–23] The role of the Na^+ channel in early ventricular fibrillation is less clear. Recent evidence in a non-ischemic model of VF in an intact canine heart has demonstrated the participation of both Na^+ channels and Ca^{2+} channels in the electrical activation of the fibrillating heart.[21] The rate of the rapid upstroke of the action potential and the inability of either verapamil or the Na^+ channel-specific toxin tetrodotoxin (TTX) to prevent ventricular fibrillation supports a role for


Fig. 6.1. A plot illustrating the theoretical interaction between dynamic factors and tissue heterogeneity responsible for producing ventricular fibrillation. The therapeutic objective is to move the patient from the vulnerable window (white) to the zone of reduced tissue heterogeneity or more stable dynamic factors (gray). Reprinted with permission.[262]
Fig. 6.2. Long-term recordings from a patient who developed ventricular fibrillation. At the onset the surface ECG morphology is consistent with type I ventricular fibrillation. After some time the activation slows and the surface ECG is consistent with type II ventricular fibrillation which ultimately terminates with asystole. Reprinted with permission.[263]

both of these channels in the early stages of the arrhythmia. Identifying the molecular participants in fibrillation during its early stages may provide insights into the mechanism of maintenance of ventricular fibrillation and the mechanism of defibrillation. The latter is particularly relevant to ventricular fibrillation that is treated immediately by implanted defibrillators.

Recent studies have suggested an important role of the inward rectifier potassium current (I_{K1}) in rotor stabilization during ventricular fibrillation.[24,25] In isolated perfused guinea pig hearts, a stable high frequency rotor is always found in the anterior left ventricle maintaining ventricular fibrillation. Cellular experiments with voltage clamp recording have demonstrated that the current density of the outward component of I_{K1} was larger in myocytes isolated from left ventricles than that from right ventricles. Computer simulations further suggested that larger I_{K1} is associated with shorter APD, faster activation, and more stable rotors. On the other hand, a different study of ventricular fibrillation in guinea pig hearts did not find the fastest activation rate or sustained rotors in the anterior left ventricular epicardium.[26] Instead, they observed that the maintained ventricular fibrillation was characterized by the presence of multiple wavelets. The faster activation

rates were located in the apex and slower activation rates were found at the base of the heart, which might be related to the spatial gradient of the rapid component of the delayed rectifier current (I_{Kr}). An alternative explanation for the two competing hypotheses of ventricular maintenance is provided by different types of ventricular fibrillation (type I and type II, Fig. 6.2). In large mammalian hearts, however, mother rotors have not been convincingly demonstrated.[27,28] Thus, it appears that at least at the initial stages of ventricular fibrillation in large mammalian hearts, dynamic wavebreak is a prominent mechanism.

Structural heart disease and sudden death

The mechanism(s) of sudden cardiac death, and ventricular fibrillation in particular, have been described in terms of a biological model by Myerburg and colleagues, where functional alterations initiate a common electrogenic pathway that permits otherwise benign electrical events to initiate lethal arrhythmias in the setting of structural heart disease.[29] There are numerous specific pathological conditions that can provide the appropriate substrate for ventricular fibrillation, which can be divided into four general classes: myocardial infarction, hypertrophy,

cardiomyopathy, and structural electrical abnormalities.[29] The overwhelming majority of structural abnormalities are the result of coronary artery disease, with ischemia and reperfusion providing a major adverse modulatory influence that may predispose to VF.

Pathological examination of the hearts of patients who die suddenly reveals prior myocardial infarction in up to 75% of cases,[30,31] although acute myocardial infarction occurs in the minority of cases.[32] The presence of mural thrombus in the coronary arteries is common in pathological examination of hearts of sudden cardiac death victims and may be responsible for transient ischemia or reperfusion of the myocardium that triggers ventricular tachycardia or fibrillation.[33] Such transient functional changes in the setting of any structural disease are likely to have adverse electrophysiological consequences that can be associated with sudden death.[29] Other such modulatory functional influences include metabolic and hemodynamic changes, neurohumoral influences, and the presence of toxins and drugs such as antiarrhythmics.

There is a strong epidemiological association between ventricular hypertrophy and sudden cardiac death that holds true for both primary[34] and secondary[35–37] causes of ventricular hypertrophy. The clinical data available suggest that the majority of sudden deaths in patients with left ventricular hypertrophy are related to malignant ventricular arrhythmias, although adverse hemodynamic consequences of SVT or severe bradyarrhythmias are likely to play a role in some high-risk patients.[38,39] Because of the heterogeneity of this group the appropriate diagnostic and therapeutic strategies for sudden death prevention, short of prevention of ventricular hypertrophy, are controversial and should be tailored for each patient.

Patients with dilated cardiomyopathy of any cause are at high risk of sudden death. The mechanism(s) of death may vary depending on the subgroup of patients selected,[40] but all subgroups are likely to include a significant proportion who die as a result of malignant ventricular arrhythmias. The anatomic and electrophysiogical heterogenity that characterizes the myopathic ventricle provides a suitable substrate for ventricular arrhythmias, which is the probable mechanism of sudden death in the majority of these patients. Unfortunately, identification of those at highest risk and the optimal therapeutic approaches remain elusive.[41]

Other structural and electrical cardiac abnormalities may predispose to ventricular fibrillation in the absence of fibrosis or scar. These include accessory pathways with rapid anterograde conduction[42] and abnormalities of repolarization such as that associated with the long QT syndrome.[43,44] Both substrates are subject to functional modulation by endogenous (e.g., neurohumoral) and

Table 6.1. Factors enhancing the vulnerability of the myocardium to fibrillate

Intrinsic	Extrinsic
Hypertrophy	Increased sympathetic nervous system activity
Ischemia	Vagal stimulation
Myocardial failure	Metabolic abnormalities
Enhanced AV conduction	hypokalemia
bypass tracts	hypomagnesemia
"fast" AV node	Antiarrhythmics and other drugs
Abnormal repolarization	psychotropics
(congenital or acquired)	digitalis
Bradycardia	sympathomimetics
	terfenidate, hisminal
	Environmental (electrocution)

exogenous (e.g., antiarrhythmic drugs) factors that could alter the electrophysiological state of the heart and predispose to ventricular tachycardia and/or fibrillation.

Modulation of a myocardial substrate may lower the ventricular fibrillation threshold, dramatically enhancing the tendency of the heart to fibrillate. The major endogenous factors include myocardial ischemia, autonomic nervous system tone, and metabolic and electrolyte disturbances (Table 6.1). The state of the autonomic nervous system is particularly relevant to sudden cardiac death due to ventricular arrhythmias in patients with myocardial infarction and patients with congenital or acquired QT prolongation. Regeneration of cardiac sympathetic nerves (nerve sprouting) can produce heterogeneous sympathetic innervation and a predisposition to ventricular fibrillation and sudden cardiac death.[45–47] After myocardial infarction there is a region of viable but denervated myocardium that may exhibit arrhythmogenic hypersensitivity to catecholamines.[48] This may contribute to the increased risk of sudden death in patients with heightened sympathetic tone after MI, as assessed by studies of heart rate variability[49] and the efficacy of beta-blocking drugs in reducing mortality after infarction.[50,51] Other possible salutary effects of beta-blockers include: prevention of myocardial ischemia, prevention of catecholamine-induced hypokalemia, and antagonizing catecholamine effects on platelet aggregation.[52] Interestingly, intravenous magnesium chloride, which has many cellular effects, also blocks catecholamine release[53] and may reduce mortality in myocardial infarction.[54]

Metabolic and electrolyte disturbances also modulate potentially arrhythmogenic substrates, increasing the likelihood of ventricular fibrillation. Diuretic usage with its

associated hypokalemia and hypomagnesemia has been associated with ventricular fibrillation and sudden cardiac death in patients with acute MI,[55,56] hypertensive heart disease,[57] and heart failure.[58] Changes in serum K^+ may influence the electrophysiological substrate in a number of ways, including altering automaticity, changing excitability, and altering the function of repolarizing currents.

Antiarrhythmic drugs have received much attention recently, not for their efficacy but for their potential for arrhythmia aggravation.[59,60] The propensity of drugs that prolong the QT to produce polymorphic VT and ventricular fibrillation is well known.[61–65] Agents without substantial effects on repolarization may also cause arrhythmia aggravation and increase mortality in patients with structural heart disease.[59,60] In addition to the possibility of arrhythmia aggravation, these agents may interfere with definitive therapy for ventricular fibrillation by increasing the threshold for defibrillation (see below).

The problem of ventricular fibrillation in patients without structural heart disease is a vexing but fortunately uncommon problem.[66] A recent review of 19 studies with a total of 54 patients defined the demographics of patients with apparently normal hearts and ventricular fibrillation. The patients are predominantly middle-aged males, only a quarter have a prior history of syncope, and non-invasive electrocardiographic studies are generally unrewarding. Spontaneous reversion of ventricular fibrillation in this group was uncommon (less than 10%) consistent with the findings of ventricular fibrillation in the presence of structural heart disease.[67] In the absence of an exogenous agent that alters the electrophysiology of the myocardium, the mechanism of ventricular fibrillation and sudden death is poorly defined since there are no strategies to identify these patients prospectively. It is possible that transient functional disturbances that interact with abnormal myocardium, as described previously, may under extreme circumstances produce electrophysiological changes of sufficient magnitude to initiate ventricular arrhythmias in normal hearts. The role of abnormalities of repolarization and, specifically, dispersion and inhomogeneity of repolarization has recently received attention as a mechanism of arrhythmias in normal hearts.

Increasing evidence suggests that genetic factors contribute to the risk of sudden death independent of the risk for coronary artery or other structural heart disease. Two population-based studies suggest that there is a significant genetic influence in the risk of SCD by virtue of the familial clustering of events.[68,69] In a population-based case-control study from Seattle, the rate of cardiac arrest in first-degree relatives of arrest victims was 50% greater than the rate in control subjects, independent of other risk factors for SCD.[68]

In the Paris Prospective study of male municipal employees, a history of SCD in one parent increased risk by 80%; a history of SCD in both parents led to an extraordinary 880% increase in the risk of SCD for the offspring. Again this was independent of other known risk factors for coronary or other structural heart disease.[69] Thus, independent of the presence or risk of myocardial disease, a significant component of the risk for cardiac arrest often resulting from ventricular fibrillation, is genetically determined.

Myocardial substrates for ventricular fibrillation

The development of ventricular fibrillation requires an initiating stimulus and a susceptible myocardium that interact in a complex, incompletely understood fashion. There are many factors that can enhance the vulnerability of the myocardium to fibrillate and thus lower the ventricular fibrillation threshold (Table 6.1). Some are intrinsic to the heart, such as myocardial mass and the existence of bypass tracts, others are the result of cardiac pathology producing local depolarization and abnormal automaticity, and still others can result from altered neurohumoral input to the heart generating increased non-uniformity of refractoriness or altered automaticity.[2,70,71] We will focus on recent findings concerning the induction of fibrillation, with emphasis on the mechanisms that may be operative in patients with common forms of structural heart disease. For a comprehensive discussion of some of the previous literature the reader is referred to several excellent reviews.[2,70,72,73]

Ventricular fibrillation in myocardial ischemia

Ischemic myocardium is one of the most studied and complex models of ventricular fibrillation, providing an appropriate substrate for re-entry, abnormal automaticity, or triggered arrhythmias. For a comprehensive treatment of the mechanisms of arrhythmogenesis in acute and chronic coronary artery disease, the reader is referred to a review by Janse and Wit.[74]

In ischemic tissue, ventricular tachycardia often precedes, and subsequently degenerates into fibrillation.[75] It is clear that arrhythmogenic conditions in ischemic myocardium are dynamic and predispose to the slowed conduction and unidirectional conduction block required to support re-entry. Ischemia also enhances automaticity of Purkinje fibers, promotes abnormal automaticity of muscle fibers, and is associated with alterations in Ca^{2+} homeostasis and enhanced endogenous catecholamine release associated with non-re-entrant arrhythmias.

Ventricular arrhythmias appear in two distinct phases in the first 30 minutes after complete occlusion of a coronary

Table 6.2. Ventricular arrhythmias associated with experimental ischemia

	Phase Ia	Phase Ib
Onset	2–10 minutes	15–20 minutes
Abnormal electrograms	+ + + +	+
Prevention by sympathetic nervous system block	No	Yes
Mechanism	Re-entry	? Automaticity, triggered

artery in an experimental animal (Table 6.2). The first phase occurs immediately after occlusion of the vessel (2–10 minutes) and is called phase Ia; the second or phase Ib occurs 15–20 minutes after coronary occlusion. Experimental evidence suggests that the mechanisms of phase Ia and Ib arrhythmias are different. Phase Ia arrhythmias occur in the setting of marked conduction slowing and delayed activation of the subepicardial muscle.[76] Ventricular electrograms recorded from the epicardial surface of the heart at this time are fractionated and reduced in amplitude, consistent with depolarization of the membrane and slowed conduction.[77] High density mapping has confirmed that during this phase ischemic ventricular arrhythmias are primarily re-entrant. Phase Ib arrhythmias are characterized by less abnormal electrocardiograms[76] and these arrhythmias can be effectively prevented by beta-blockers or prior catecholamine depletion of the myocardium.[78] It seems most likely that phase Ib ventricular arrhythmias are related to the release of endogenous catecholamines that increase the likelihood of non-re-entrant mechanisms such as abnormal automaticity and/or triggered activity.

Reperfusion of ischemic myocardium may also be arrhythmogenic.[79] Indeed, in some species VF occurs more frequently with reperfusion than after ligation of a coronary artery.[80] In humans, reperfusion-associated arrhythmias are frequent, the most common being accelerated idioventricular rhythms, but ventricular fibrillation is decidedly rare.[81] Experimental evidence suggests that macrore-entry is not a common mechanism of ventricular arrhythmias during reperfusion.[82,83] High density mapping of reperfused ischemic myocardium fails to reveal diastolic electrical activity during ventricular tachycardia, and tachycardia is initiated from discrete sites in the subendocardial border zone that lack conduction delay or inexcitable segments.[82–84] Reperfusion-induced ventricular arrhythmias may be due to delayed afterdepolarization-mediated triggered activity.[85] Indirect evidence for this assertion is suppression of these arrhythmias by Ca^{2+} channel block-

ers[85] and α-adrenergic blocking agents,[86] both of which would suppress the rise in intracellular Ca^{2+} during reperfusion and suppress delayed afterdepolarizations (DADs).

The incidence of experimentally induced reperfusion arrhythmias is dependent on the duration of preceding ischemia. In the canine model, at least 3 minutes and less than 30–60 minutes of coronary occlusion are associated with reperfusion-induced ventricular fibrillation.[87] The rate of restoration of coronary flow also influences the arrhythmogenicity of reperfusion. Upon reperfusion of ischemic myocardium, differential recovery of refractoriness, tissue resistance, and conduction establish exaggerated heterogeneity of electrophysiological properties of the myocardium and create a highly arrhythmogenic substate that is particularly pronounced in the border zone, where action potentials are normal.[74] Longer periods of ischemia, similar to that occurring in patients with acute myocardial infarction who receive thrombolytic therapy, are associated with irreversible cell damage and are generally not associated with the malignant ventricular rhythms seen after shorter periods of ischemia (Figs. 6.2, 6.3).

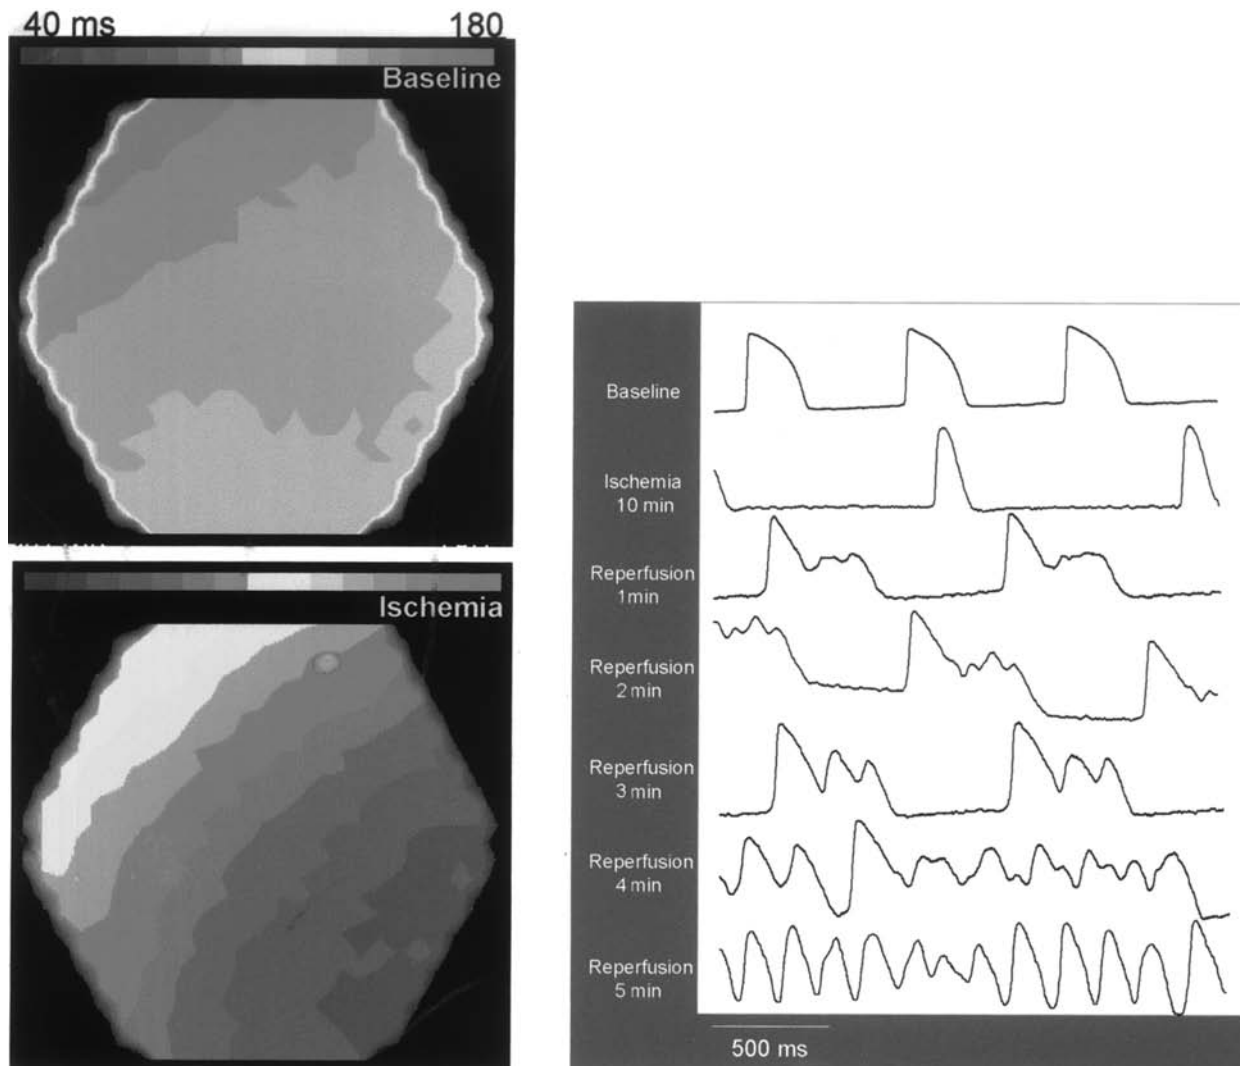
The cellular and molecular mechanisms of arrhythmias associated with myocardial ischemia are incompletely understood. Accumulation of extracellular K^+ occurs in early ischemia and is related to a net K^+ efflux from myocytes resulting in potentially arrhythmogenic changes in excitability.[88,89] Several mechanisms have been proposed to explain the accumulation of extracellular K^+, including inhibition of Na^+–K^+ ATPase, increased K^+ efflux coupled to the efflux of anions generated during ischemia, or modulation of sarcolemmal K^+ channels. Among the K^+ channels most likely to participate in K^+ efflux from ischemic myocytes is the ATP-sensitive K^+ channel, $I_{K(ATP)}$. This current is a time-independent, K^+-selective current that is blocked by ATP and sulfonylureas (e.g., glibenclamide). The conductance and activity of the channel are regulated in a complex fashion by a variety of factors, including internal Mg^{2+},[90,91] ADP,[92] GDP,[93] stimulation of adenosine A1 receptors,[94] and lactate.[95] Modulation of the sensitivity of $I_{K(ATP)}$ to ATP by other byproducts of ischemia has been proposed to account for the apparent increase in channel activity despite very modest reductions in intracellular ATP in early ischemia. Excised patches of membrane from cardiac cells containing $I_{K(ATP)}$ are inhibited with high affinity by sulfonylurea drugs. In intact myocardium, ischemia-induced shortening of the action potential and extracellular K^+ accumulation are only incompletely blocked by higher doses of sulfonylureas. Similarly, if $I_{K(ATP)}$ is activated in isolated heart cells by metabolic inhibition, these agents are not as effective channel blockers as in excised membrane patches.[93,96,97] Modulation of the affinity of these


Fig. 6.3. Optical map of conduction in a guinea pig heart subject to global ischemia. The crowding of conduction isochrones indicates substantial slowing of conduction with ischemia and during early reperfusion. Optical APs during ischemia and reperfusion reveals AP shortening with ischemia and relengthening with reperfusion that is spatially and temporally heterogeneous and is associated with afterdepolarization-mediated triggered activity. (See Plate 6.3.)

blockers by other substances produced during myocardial ischemia has been suggested as the cause of this discrepancy.[93,97] Although $I_{K(ATP)}$ is likely to mediate extracellular K^+ accumulation during ischemia, activation of other K^+ conductances such as Na^+-activated[98] or arachidonic acid-activated K^+ channels[99] cannot be excluded. Current experimental evidence supports the hypothesis that anion countertransporters and $I_{K(ATP)}$ play a major role in ischemia-induced K^+ accumulation, and modulation of these currents may have therapeutic importance in prevention of ischemia-associated arrhythmias and preservation of ischemic myocardium.

Other electrophysiologic and metabolic consequences of ischemia may conspire to produce arrhythmias. Ischemic cells are depolarized at rest and have a different action potential contour from normally polarized cells. These voltage differences support an injury current that has been implicated as an arrhythmogenic substrate in ischemic tissue.[100] Computer modeling of the ischemic border zone has suggested that injury current flowing through an inexcitable gap may be responsible for increased spontaneous diastolic depolarization of latent pacemakers, producing automatic arrhythmias or generating a trigger for a re-entrant tachycardia.[101] Instability

and collapse of the mitochondrial membrane potential mediated by inner mitochondrial anion channels (IMAC), leads to release of reactive oxygen species and arrhythmogenic oscillations of the cell membrane potential. Inhibition of the collapse of the mitochondrial membrane potential with blockers of the mitochondrial benzodiazepine receptors (e.g., 4-chlorodiazepam) that regulate IMAC reduce the incidence of VF in experimental ischemia and reperfusion.[102]

Analysis of spiral wave breakup during ventricular fibrillation in a regionally ischemic heart has shown that ischemia causes an increase of wavebreaks in the ischemic border zone and a decrease of wavebreaks in the ischemic zone.[103] Ischemia-induced alterations in APD dynamics may also predispose to the development of ventricular fibrillation; flattened APD restitution slope and reduced conduction velocity in ischemic myocardium sets the stage for type II ventricular fibrillation.[104] In contrast, steepened APD restitution and only modestly changed excitability in the non-ischemic zone facilitates the development of type I ventricular fibrillation.[104] Whether the non-ischemic zone plays a role in ventricular fibrillation, however, remains uncertain.[103,105] Furthermore, the ischemic border zone could be important in initiating ventricular fibrillation, but it may not necessarily be critical in the maintenance of ventricular fibrillation.[106]

The Purkinje network may participate in the initiation of arrhythmias in ischemic myocardium. The differential effect of coronary occlusion on more superficial and deeper endocardial Purkinje fibers may set up the conditions for microre-entry or reflection.[107] Additionally, afterdepolarizations have been observed in Purkinje fibers exposed to potentially toxic byproducts of ischemia such as lysophosphoglycerides.[108] It is conceivable that injury currents or currents induced by myocardial stretch could induce afterdepolarizations and triggered arrhythmias that originate in the Purkinje fibers. These fibers may also be subject to enhanced automaticity, which is a proposed mechanism of delayed arrhythmias in ischemic myocardium.[109,110]

The Purkinje network may also be important in maintaining malignant ventricular arrhythmias associated with ischemia. Intracavitary application of phenol in a canine model of ischemia prevented the production of ventricular fibrillation, but did not eliminate premature ventricular contractions or slower re-entrant ventricular arrhythmias in the ischemic zone. These data suggest that ectopic activity need not originate in the subendocardial Purkinje system, and that the absence of VF in this model may be related to the failure of re-entrant waves in the ischemic territory to be transmitted throughout the ventricles via the Purkinje network.[111]

Sympathetic nervous system activation plays an important role in the genesis of arrhythmias during myocardial ischemia. Much of the evidence for this assertion is indirect but compelling and includes increased catecholamine levels during ischemia at times when ventricular arrhythmias are most likely,[112] reduction in the frequency and severity of arrhythmias in the presence of denervation or beta-blockade,[50,51] and the arrhythmogenic effects of enhanced sympathetic activity during ischemia[113] The mechanism by which activation of the sympathetic nervous system exerts its effects has not been defined, although many possibilities exist. Catecholamines can restore the resting membrane potential in depolarized ischemic myocardium through K^+ channel-mediated effects[114,115] and enhanced activity of the Na^+–K^+ ATPase.[116] The change in resting membrane potential in the presence of catecholamines will affect other electrophysiological properties such as action potential upstroke and duration. Other potential arrhythmogenic mechanisms are catecholamine-induced increases in the rate of rise of phase 4 diastolic depolarization and similarly induced increases in the amplitude of DADs, important prerequisites for the production of automatic and triggered arrhythmias, respectively.

Chronic arrhythmias that persist for years after myocardial infarction may cause ventricular tachycardia, fibrillation, and sudden cardiac death. Ventricular mapping and the induction and termination of ventricular tachycardia by programmed stimulation suggests that these arrhythmias are re-entrant. The substrate and mechanisms of ventricular tachycardia and ventricular fibrillation in chronic coronary artery disease are fundamentally different from those in acute ischemia, where depressed membrane potentials are a prominent cause of conduction slowing and block. In chronic arrhythmias the substrate consists of viable myocardial cells intermixed with fibrosis, with tissue anisotropy being a major cause of conduction slowing.[74]

The pathogenesis of ventricular fibrillation in chronically ischemic myocardium has been limited by the absence of an animal model with sufficiently high rates of ventricular fibrillation. Recently, Canty and coworkers have demonstrated the importance of hibernating but not infarcted myocardium in the development of VF and SCD in a swine model of coronary artery occlusion. SCD in these animals occurred independently of the severity of LAD stenosis, the presence of myocardial necrosis, or scar.[117] Studies of tissue and cellular electrophysiology demonstrate features that may contribute to SCD, including myocyte hypertrophy,[118] defective SR calcium uptake,[119] interstitial fibrosis, and heterogeneous SNS innervation. Importantly, the diurnal variation of SCD is similar to that observed in humans and seems to be modulated by sympathetic tone. This link may

result from inhomogeneity in myocardial repolarization during sympathetic activation, because regional reductions in presynaptic norepinephrine uptake are found in hibernating myocardium.[120] These changes may be germane to human studies, which have demonstrated that revascularization has a positive effect on mortality in patients with chronic ischemia.

Studies in humans have provided insight into the pathogenesis of conduction slowing in hibernating myocardium. In biopsy samples taken from chronically ischemic, functionally downregulated ventricular myocardium, as assessed by thallium scanning and MR imaging, biopsy samples from hibernating, reversibly ischemic, and normal myocardium exhibited significant differences in the density of Cx43, a major intercellular ion channel in the ventricle and an important mediator of cell-to-cell conduction. In addition to decrease in density, the morphology of GJ plaques on immunohistochemical staining changes with a reduction in the plaque size.[121]

Ventricular fibrillation in cardiomyopathy

The mechanism of sudden death and ventricular arrhythmias is less certain in non-ischemic cardiomyopathy, but recent evidence suggests abnormal repolarization of the ventricle may be important. Myocardial cells possess a characteristically long action potential (Fig. 6.4): after an initial rapid upstroke, there is a plateau of maintained
Fig. 6.4. Action potential and underlying currents with changes in heart failure. Representative action potentials from the epicardial surface of a normal (thick line) and failing (dotted line) ventricle. The surface QRST complex is shown overlying the action potentials. The left hand column shows the currents that underlie the ventricular action potential. The right hand columns are the message and gene names for the major subunits that encode the currents. Schematics of the trajectories of the currents during the action potential are shown in the center of the slide, the thick lines represent the normal currents and the dotted lines the currents in failing hearts.

depolarization before repolarization. In cells from failing hearts, animal and human studies consistently reveal a significant prolongation of action potentials compared to those in normal hearts, independent of the mechanism of heart failure.[122–125] The plateau of the action potential is known to be quite labile; this is a time of high membrane resistance, during which small changes in current can easily tip the balance either towards repolarization or towards maintained depolarization. As a rule, the longer the action potential, the more labile is the repolarization process. Maintained or secondary depolarizations that occur before termination of the action potential called early after depolarizations (EADs) can initiate arrhythmias including torsades des pointes ventricular tachycardia and ventricular fibrillation (Fig. 6.5). A variety of conditions common in patients with heart failure can affect either outward (repolarizing) or inward (depolarizing) currents resulting in EADs. Such factors include hypokalemia, hypocalcemia, hypomagnesemia, acidosis, or antiarrhythmic drugs. Increasing inward current will also favor the production of EAD-mediated triggered activity, as might occur with β-adrenergic stimulation or after endogenous release of lipid metabolites that interfere with Na^+ channel inactivation.[126] Stretch-responsive channels have been described in ventricular myocardium[127,128] and proposed to contribute to EADs and enhanced susceptibility to arrhythmia in heart failure.[129]

The ability to isolate viable human ventricular myocytes has enabled the dissection of the changes in membrane current that occur in myocardial failure. The inward Na^+ and Ca^{2+} currents do not appear to be altered, at least under basal conditions. Sakaibara et al.[130] found no disease-related changes in gating or permeation of Na^+ currents in human ventricular cells. Measurement of both dihydropyridine binding sites[131] and inward Ca^{2+} current in ventricular myocytes from failing hearts also reveal no differences compared to non-failing control cells.[124,132] Nevertheless, there are reports of changes in Ca^{2+} channel gating in failing ventricular myocytes,[133] perhaps mediated by changes in auxiliary subunit expression.[134] Human ventricular myocytes contain at least two distinct classes of voltage-dependent K^+ channels. The inward rectifier K^+ current, I_{K1}, sets the resting membrane potential and contributes to the terminal phase of repolarization. The density of I_{K1} is reduced by nearly 40% in cells from myopathic ventricles compared with controls.[125] Another important K^+ current is the transient outward current, I_{to}. Unlike the inward rectifier, I_{to} is expressed in heart cells in a species- and cell type-specific fashion. This current plays a crucial role in the early phases of repolarization and in setting the potential of the plateau of the action potential, which in turn influences all currents

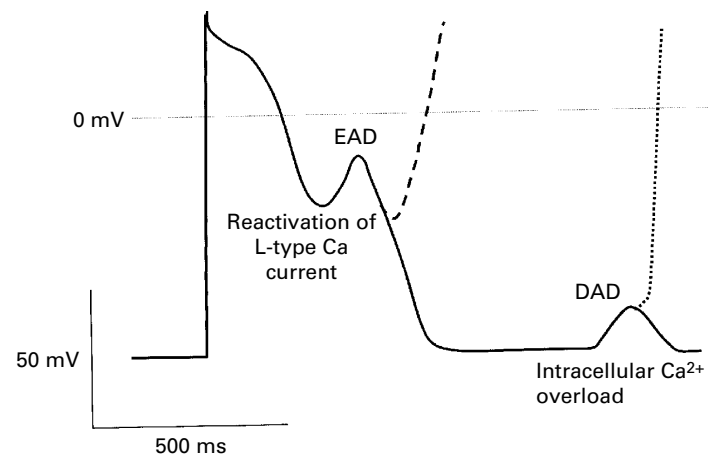
that are active during the remainder of the action potential. Ventricular myocytes from the mid-portion of the ventricular wall have a substantial I_{to} that is blocked by 4-aminopyridine (4-AP). This 4-AP-sensitive current is also significantly reduced (35%–40%) in cells from failing ventricles.[125] Similar changes in I_{to} have been noted in diseased human atria,[135] chronically infarcted canine ventricle,[136] and hypertrophied rat ventricle,[137] all of which are arrhythmogenic substrates. Prolongation of the action potential alone would not necessarily suffice to produce ventricular arrhythmias, particularly if the prolongation were homogeneous. Variations in APD in the failing heart, however, create increases in the dispersion of repolarization and refractoriness that are arrhythmogenic.[138,139] Regional differences in the density of K^+ currents, particularly I_{to}, have been described in several experimental animal models.[140] Spatial inhomogeneity of repolarization in heart failure may be explained by exaggerated regional variability in K^+ currents; however, the role that functional downregulation of K^+ currents plays in potentiating the spatial dispersion of repolarization in heart failure is controversial. For example, in rapid-pacing canine heart failure, induced by rapid pacing, transmural K^+ currents such as I_{K1}, I_{to1}, and the slow component of the delayed rectifier K^+ current (I_{Ks}) were


Fig. 6.5. Interruptions of repolarization called afterdepolarizations may mediate the initiation of polymorphic ventricular tachycardia and ventricular fibrillation. Early afterdepolarizations (EADs) occur before the completion of repolarization and result from reactivation of L-type calcium current during phase 3 of the action potential. Delayed afterdepolarizations (DADs) occur after completion of repolarization and result from oscillatory release of calcium from the sarcoplasmic reticulum with activation of depolarizing currents. If either EADs or DADs are of sufficient amplitude a subsequent action potential may ensue ("triggered" action potential).
Fig. 6.6. Decreased expression and redistribution of Cx43 protein in the failing heart. (a) Western blot shows a reduction in Cx43 protein in the failing heart (HF) in both the endocardial and epicardial regions of the left ventricle compared with normal heart (NL). (b) Immunohistochemical staining demonstrates redistribution of Cx43 from the cell ends to the lateral margins of the cell. Cx43 co-localizes with the intercalated disc protein N-cadherin in the normal but not the failing ventricle. Modified from Akar *et al.*[151] reproduced with permission. (See Plate 6.6.)

homogeneously decreased across the left ventricular wall.[141] Other ionic currents contribute to repolarization in the heart; alterations in Ca^{2+} handling have electrogenic consequences that may contribute to temporally and spatially labile repolarization. In the same heart failure model, transmural NCX currents were most prominently increased in endocardial myocytes but were not changed in the epicardial cells,[142] disrupting the transmural heterogeneity of NCX and potentially leading to enhanced vulnerability to cardiac arrhythmias. Another plausible contributor involves the influence of the autonomic nervous system, which has a prominent role in heart failure. Additionally, heterogeneity of sympathetic nervous system innervation is well-described in cardiomyopathy patients[143] and has been correlated with heterogeneity of recovery of excitability.[144]

Abnormalities of APD and afterdepolarizations may produce arrhythmias by triggered mechanisms or may predispose the myocardium to re-entry by inhomogeneous changes in APD and dispersion of refractoriness.[145] Spontaneous ventricular tachycardia in a rabbit model of non-re-entrant heart failure was attributed to repetitive non-re-entrant activation at subendocardial sites.[146] Furthermore, in patients with end-stage idiopathic cardiomyopathy, spontaneous and induced ventricular arrhythmias occur primarily in the subendocardium by a focal non-re-entrant mechanism, which may result from EADs or DADs.[147]

Significant changes in the network properties of the heart characterize heart failure. In particular, conduction velocity slowing is a prominent feature of the failing ventricle and restitution of conduction is altered (Fig. 6.6). In some models of HF, reductions in Na current density contribute to conduction slowing.[148] Fibrosis is characteristic of human and a number of animal models of heart failure contributing to conduction slowing and block.[149,150] Intercellular ion channels are also remodeled in the failing heart. This remodeling includes a downregulation of Cx43 and aberrations in the subcellular location of the channel, with increased expression on the lateral cell borders (Fig. 6.6). Morphological changes in gap junctions have been described. All of these changes are associated with profound regional changes in conduction in the failing compared with the normal heart. (Fig. 6.7)[151]

Experimental evidence supporting re-entry for initiation of arrhythmias in non-ischemic cardiomyopathy is scarce, even in settings where inhomogeneities of APD or refractoriness have been defined.[152,153] The failure of programmed stimulation of the ventricle in either animal models or humans also argues against an excitable-gap re-entry mechanism for ventricular arrhythmia production in non-ischemic cardiomyopathy. This does not preclude the possibility that VF due to multiple wavelet re-entry is induced by other mechanisms in cardiomyopathy.
Fig. 6.7. Slowed conduction in the failing heart. Optical maps from wedges of left ventricular myocardium stained with a voltage-sensitive dye. Isochronal maps reveal crowding of isochronal lines in the failing tissue preparation. Below the maps are the upstrokes of the action potentials from several regions in the imaging window; the separation of the upstrokes confirms the conduction slowing in the failing heart. (See Plate 6.7.)

Ventricular fibrillation is less well studied in hypertrophic cardiomyopathy (HCM) but clinical data support a strong association between left ventricular hypertrophy and ventricular arrhythmias and sudden death. As has just been outlined for dilated cardiomyopathy, abnormalities in refractoriness and repolarization are important in arrhythmogenesis in this form of heart disease. Experimental animal models of hypertrophic heart disease have demonstrated an increase in duration of action potentials and, more important, an increase in spatial dispersion of repolarization, without significant changes in impulse conduction.[153] In the dog model with chronic complete atrioventricular block (AVB), there is biventricular hypertrophy.[154] Although systolic function is maintained during 9 weeks of AVB, the APD of the left, but not the right, ventricle is significantly prolonged in chronic AVB compared to that of the control, thereby leading to increased interventricular dispersion of repolarization that is particularly prominent at slow pacing rates. This model is more susceptible to torsades de pointes (TdP), which are associated with increased dispersion of repolarization, afterdepolarizations, and

triggered arrhythmias.[154,155] In the heart with biventricular hypertrophy, the slow component of delayed rectifier K$^+$ current, I$_{Ks}$, is downregulated[156] and NCX is upregulated.[157] The changes in dispersion of repolarization have been associated with lower ventricular fibrillation thresholds, and both the dispersion of repolarization and reduction in ventricular fibrillation threshold were reversed with K$^+$ channel antagonists.[153] Patients with primary hypertrophic cardiomyopathy have also been reported to have dispersion and inhomogeneity of conduction, which has been attributed to the histologic disarray of myofibrils in this disease.[158] Inhomogeneities of both repolarization and conduction would be expected to increase the risk of potential lethal arrhythmias in patients with HCM.

Ventricular fibrillation in normal hearts

Re-entry may be initiated by electrical stimulation of normal myocardium, producing fibrillation. In many pathophysiological circumstances, heterogeneous recovery of excitability occurs and may enhance ventricular vulnerability, particularly in the earlier phases of recovery.

It has been demonstrated recently, however, that inhomogeneous dispersion of refractoriness or recovery is not a necessary precondition for electrical induction of VF in normal myocardium.[159,160] In a normal canine heart an appropriately timed suprathreshold stimulus can generate re-entry around a critical point where the field of the stimulus intersects myocardium in the terminal phases of recovery.[160] High density mapping in the region of the stimulus confirmed the presence of a re-entry circuit in the shape of a figure-of-eight prior to the development of VF. These data suggest that regions of the myocardium that are adjacent to the area directly depolarized by the suprathreshold stimulus are not activated, but undergo a graded prolongation of their refractory period.[161] This establishes functional unidirectional conduction block in normal tissue with homogeneous dispersion of refractoriness, a mechanism that may be operative in ventricular fibrillation that is the result of electrical injury.[159]

Inhomogeneities in recovery may exist in normal myocardium, particularly at the junction of ventricular muscle and the specialized conducting system, tissues that have well documented differences in APD that are exaggerated by premature stimulation.[162] Mapping during suprathreshold extrastimulation failed to reveal any participation of the Purkinje fiber network in this model of initiation of ventricular fibrillation, although participation of the specialized conducting system in the maintenance of ventricular fibrillation or its initiation in other models certainly cannot be excluded.[159]

These studies have important implications for the mechanism of initiation of fibrillation, but similarly they also suggest explanations for the concept of the upper limit of vulnerability,[163] and postshock reinitiation of fibrillation as a cause of failed defibrillation.[164] A shock strength above the upper limit of vulnerability will not induce ventricular fibrillation regardless of when it is delivered in the cardiac cycle. The upper limit of vulnerability tends to move in parallel with the defibrillation threshold. Although many electrophysiological mechanisms exist to explain the initiation and maintenance of ventricular fibrillation, the exact mechanism(s) in a given clinical situation are generally unknown. It is most likely that several of the potential offending conditions conspire to produce fibrillation in humans. Using high-resolution optical mapping and computer simulations, Jalife and colleagues[17,18,165,166] have suggested that, in the structurally normal heart, monomorphic ventricular tachycardia results from stationary rotors, but polymorphic ventricular tachycardia and ventricular fibrillation are caused by a single or paired ("figure-of-eight") non-stationary rotors.

Primary electrical diseases of the heart

Fortunately, sustained ventricular tachycardia and ventricular fibrillation rarely occur in structurally normal human hearts; however, primary electrical diseases of the heart such as long[167] and short QT syndromes,[168] catecholaminergic polymorphic VT(CPVT),[169] and Brugada syndrome[170,171] are associated with life-threatening ventricular arrhythmias. (See Chapter 52 for additional discussion of primary electrical diseases of the heart.)

The long QT syndrome is characterized by the prolonged QT interval on the surface ECG, frequent episodes of syncope, and a high incidence of sudden death resulting from ventricular tachycardias especially TDP. There are two clinical forms of congenital long QT syndrome: the Romano–Ward syndrome[172,173] is transmitted as an autosomal dominant trait, and the Jervell and Lange–Nielsen syndrome[174] as an autosomal recessive trait, associated with sensoneurinal deafness. Romano-Ward syndrome is associated with gene mutations of different channels: LQT1($KCNQ1$ encoding KvLQT1), LQT2 ($KCNH2$ encoding HERG), LQT3 ($SCN5A$), LQT5 (KCNE1), and LQT6 ($KCNE2$) generates mutants I_{Ks}, I_{Kr}, I_{Na}, mink (combined with KvLQT1 generates I_{Ks}), and MiRP1 (combined with HERG generates I_{Kr}), respectively.[167,175–180] The Jervell and Lange-Nielsen syndrome is very rare and almost exclusively linked to I_{Ks}. The delayed activation or incomplete inactivation of the Na^+ channel or reduction in function of K^+ channels is responsible for the prolonged QT interval. Acquired forms of LQTS are far more common than congenital forms. Acquired LQTS may occur in subjects with subclinical inherited mutations in cardiac ion channels often made clinically manifest by extrinsic factors such as exposure to drugs, structural heart disesase, or electrolyte abnormalities. Certain drugs, such as Class IA and III antiarrhythmics, antihistamines, antimicrobials, and antifungals can alter cardiac ion channel function and/or interfere with the metabolism of other drugs that impair repolarization, resulting in prolongation of the QT intervals and increased risk of sudden death. The short QT syndrome (SQTS) is a more recently described clinical entity characterized by the presence of a short QT interval (QTc < 320 ms) associated with cardiac tachyarrhythmias, syncope, and sudden death. It has been linked to mutations in I_{Kr}, I_{Ks}, and I_{K1} (encoded by $KCNJ2$).[168,181–183] It has been speculated that the arrhythmogenic mechanism is related to heterogeneous abbreviation of the APD and significant transmural dispersion of repolarization setting the stage for ventricular fibrillation.

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an early-onset, inherited and malignant

arrhythmogenic disorder characterized by exercise- or stress-induced ventricular arrhythmias in the absence of structural alterations of the heart. This disorder has been linked to mutations of the *RyR2* (cardiac ryanodine receptor gene)[184,185] and *CASQ2* (calsequestrin gene)[186,187] with autosomal dominant and recessive transmission, respectively. The precise molecular pathogenesis of CPVT is not entirely clear, but it is associated with a leaky RyR2 channel due to a defect in binding to its associated protein FKBP12.6 (calstabin 2) or impaired sarcoplasmic reticulum Ca^{2+} storage.

Brugada syndrome is an autosomal dominant form of idiopathic ventricular fibrillation characterized by ST-segment elevation in right precordial leads V1 to V3 and often with apparent right bundle-branch block.[170,171] The distribution of Brugada syndrome is worldwide, but it is particularly prominent in southeast Asia where it accounts for a significant minority of sudden deaths in the young. Causative mutations have been discovered in the alpha subunit of the cardiac sodium channel gene *SCN5A*.[188] Since the original description, numerous other *SCN5A* mutations have been described. There are other cohorts that are not linked to SCN5A, consistent with genetic heterogeneity of the syndrome.[189] The disease-causing mutations generally result in a loss of function or reduced sodium current due to accelerated inactivation of the sodium channel.

Therapy of ventricular fibrillation

Therapeutic interventions in the management of ventricular fibrillation can be divided into those designed to prevent the arrhythmia or those designed to treat established fibrillation. Strategies to prevent ventricular fibrillation include preventing triggers for induction of fibrillation and reducing the tendency of the myocardium to fibrillate, thus raising the ventricular fibrillation threshold. Treatment of established ventricular fibrillation is prompt defibrillation, most often requiring the delivery of a transthoracic or transmyocardial shock of sufficient strength to terminate the fibrillation.

In communities with the best emergency medical services, survival rates for patients with out-of-hospital ventricular fibrillation is only 25%–33%,[3] emphasizing the importance of identifying patients at risk and implementing strategies to prevent this problem. The only definitive treatment of ventricular fibrillation is expeditious defibrillation. Failing this, efforts should be made to protect the fibrillating myocardium by limiting the adverse metabolic consequences of ongoing fibrillation.

Prevention of ventricular fibrillation

One of the most common circumstances in which ventricular fibrillation is encountered and effectively treated is acute myocardial infarction. Since the inception of the coronary care unit, a major emphasis of the management of the acute myocardial infarction patient has been prevention or prompt treatment of lethal ventricular arrhythmias. The early observation of frequent ventricular arrhythmias complicating acute myocardial infarction[190] and the effectiveness of intravenous lidocaine in prevention of these arrhythmias led to the widespread use of prophylactic lidocaine in this and many other clinical settings. More recent data call into question this approach. Meta-analyses of the use of prophylactic lidocaine in acute MI do support a reduction in the incidence of ventricular tachyarrhythmias, but patients treated with lidocaine experienced a slightly increased overall mortality.[191,192] Another meta-analysis of the incidence of primary ventricular fibrillation complicating acute MI revealed a steep decline in the incidence of fibrillation over the past three decades; indeed, the incidence of primary ventricular fibrillation in 1990 was so low that it was estimated that 400 patients would have to be treated with lidocaine to prevent a single episode.[193] The reason for the decline in ventricular fibrillation is not clear and may be related to several factors, including the more widespread use of beta-blocking drugs, aggressive correction of electrolyte abnormalities, the use of thrombolytic agents, early percutaneous coronary interventions for revascularization, more liberal use of analgesics, and less restrictive criteria for entry into a coronary care unit. Regardless of the etiology of the reduced incidence of ventricular fibrillation, these data make the routine use of lidocaine in acute myocardial infarction an unsupportable strategy.[191–193] The only agents thus far shown both to reduce the incidence of ventricular fibrillation and mortality in acute myocardial infarction are the beta-adrenergic blocking drugs.[50,194]

The problem of prevention of ventricular fibrillation and sudden death in the absence of an acute myocardial infarction has proven to be intractable. Among the many reasons for our inability to prevent sudden death in patients with heart disease, are an incomplete understanding of the mechanism of sudden death, inability to risk-stratify patients accurately, and the limited efficacy of pharmacotherapy for prevention of ventricular tachyarrhythmias. A review of the all the clinical and diagnostic tools available to risk-stratify patients is beyond the scope of this chapter. The evaluation of patients with cardiovascular disease who are at risk must be individualized, and

implicit in this statement is a thorough understanding of the nature and extent of heart disease in a given patient. In patients with coronary artery disease the most consistent indicator of risk of mortality is left ventricular dysfunction.[195,196] The role of other diagnostic procedures remains controversial in patients who have not experienced an arrhythmic event but are considered to be at risk. The signal averaged electrocardiogram (SAECG) is a method of identifying low amplitude signals at the body surface by averaging many time-aligned ECG complexes. The SAECG can identify regions of slowed conduction that are manifest as "late potentials" or a prolonged signal-averaged QRS duration. These abnormalities of conduction are indicative of the presence of the substrate for ventricular tachyarrhythmias, but have a low positive predictive value.[197–199] The role of electrophysiological testing is also unclear; inducible ventricular tachycardia in patients with non-sustained ventricular tachycardia and reduced left ventricular function identifies a group of patients at high risk for sudden death, but even in this group the positive predictive value of electrophysiologic testing is low (20%–30%).[200,201] Risk stratification is more problematic in the absence of coronary artery disease, although recent reports of the utility of the SAECG have identified patients at risk in one series, although the predictive value of a positive test is low.[202] Even if risk stratification were optimized, there are very few clincal situations where ventricular fibrillation can be effectively prevented. In the case of ventricular fibrillation associated with coronary artery disease, attempts at prevention of sudden death by using antiarrhythmic drugs have been a dismal failure thus far. The hypothesis tested by the Cardiac Arrhythmia Suppression Trial,[59,60] that is, prevention of premature ventricular contractions will prevent ventricular tachycardia and fibrillation and thus reduce sudden death in patients with a prior myocardial infarction, was not only unproven, but patients treated with the agents used in this trial had an increased mortality. Either the hypothesis is faulty or the agents used in this study were not well chosen in that they reduced the frequency of less malignant ventricular arrhythmias but increased the $$ prevalence of more serious or compromising arrhythmias. The only drugs at present that have been shown to reduce the mortality after myocardial infarction are beta-blockers.[50,51] The mechanism by which these drugs reduce mortality is unknown, but at the concentrations used in the postmyocardial infarction trials they do not have substantial local anesthetic antiarrhythmic effects. The actions of beta-blockers that are relevant to prevention of sudden death and ventricular fibrillation include prevention of ischemia, antagonism of serum catecholamine effects on the heart, prevention of catecholamine-induced platelet aggregation, hemodynamic improvement, and restoration of inhibitory GTP-binding protein levels in heart failure patients.[52] Studies examining the effect of antiarrhythmics such as amiodarone on mortality in the postinfarction period have revealed mixed results; a meta-analysis of the major trials of amiodarone suggests an overall reduction in mortality by the drug in post-MI and HF patients,[203] which contrasts with most other antiarrhythmic drugs that have at best a neutral effect on overall mortality in this setting.

Other clinical circumstances where effective preventive strategies exist in the management of ventricular fibrillation include the use of calcium channel antagonists in coronary vasospasm,[204] left stellate ganglion resection or beta-blockers and pacing in the long QT syndrome,[43,44] and catheter or surgical ablation of rapidly conducting manifest accessory pathways in the Wolff-Parkinson-White syndrome.[42] In the absence of effective prevention of ventricular fibrillation, implantable defibrillators are the best therapeutic option in the high-risk patient.

Patients resuscitated from ventricular fibrillation in the absence of an acute transmural myocardial infarction[205] are at high risk for recurrence of this arrhythmia and sudden death.[206–208] The evaluation of these patients should be directed at determining the etiology of sudden death and the nature and extent of any underlying heart disease. In the majority of cases a standard cardiac evaluation is supplemented by cardiac catheterization with coronary angiography and left ventriculography and electrophysiologic study. Therapy is individualized based on the evaluation; for example, patients with ischemia, no inducible ventricular arrhythmias, and retained left ventricular function may be treated with surgical myocardial revascularization alone.[209–211] Patients who have an inducible tachycardia may require therapy directed at the arrhythmic substrate such as surgical ablation, antiarrhythmic drugs, or implantation of a cardioverter-defibrillator.[212]

Recently the identification and ablation of triggers for VF has proven to be an effective strategy in selected patients.[213–218] In patients with structurally normal hearts, ventricular fibrillation and monomorphic ventricular premature beats with fixed coupling intervals, localization by endocardial mapping, and ablation eliminated the premature beats and ventricular fibrillation.[213] Similar reports in patients with LQTS and Brugada syndrome[215] and recurrent ventricular fibrillation postmyocardial infarction[217] have appeared.

Defibrillation

Definitive treatment of ventricular fibrillation requires timely correction of the arrhythmia by delivery of an electrical shock to the heart. Defibrillation has been utilized clinically for decades, but its mechanism remains obscure. Recent advances, in particular the refinement of voltage mapping with optical dyes, has allowed the study of electrical events immediately after a shock to the heart. Several hypotheses on the mechanism of defibrillation have been elaborated. The critical mass hypothesis states that defibrillation is achieved when a critical mass of myocardium is depolarized by the shock, and activation waves are extinguished. In such circumstances, the critical mass is considered to be about 75% of the ventricular myocardium[219] and unsuccessful defibrillation results from a failure to depolarize a sufficient amount of the fibrillating myocardium. Alternatively, the observation of an isoelectric window or period of electrical silence, and a different pattern of ventricular activation in the postshock period has suggested that failed defibrillation may be the result of reinitiation of fibrillation by the defibrillating shock.[164] This theory of defibrillation states that in order to defibrillate the myocardium reliably, the shock strength must exceed the upper limit of vulnerability throughout the myocardium. The upper limit of vulnerability is that shock strength above which fibrillation cannot be induced regardless of when it is delivered during the cardiac cycle. The correlation between the defibrillation threshold and the upper limit of vulnerability in animal models,[220] and the similar pattern of ventricular activation after failed defibrillation or when shocks below the upper limit of vulnerability are delivered during sinus rhythm, are in direct support of this hypothesis.[164] In either case, delivery of an insufficient amount of energy will result in failure to terminate or reinitiation of ventricular fibrillation. This is to be distinguished from the ventricular fibrillation threshold, which is irrelevant in ongoing fibrillation, and is the energy necessary to induce the arrhythmia in the non-fibrillating myocardium. Another hypothesis of the mechanism of defibrillation that has recently gained traction is the virtual electrode polarization hypothesis (VEP).[221,222] The VEP hypothesis states that monophasic shocks to the myocardium result in depolarization and repolarization of adjacent regions of the heart. If the voltage gradient between these regions is optimal, activation wavefronts from the depolarized regions may activate the hyperpolarized regions leading to re-entry and re-initiation of ventricular fibrillation.[221] Adjacent areas of differentially polarized myocardium create phase singularities, a tissue substrate for the initiation of functional re-entry.[222] The

unifying requirements for successful defibrillation according to any of these hypotheses are that the shock must be of sufficient strength to extinguish fibrillation and must not generate a new arrhythmia.

The energy required to defibrillate the heart reliably depends on many factors, including the nature of the shocking waveform, the configuration of the defibrillating electrodes, the duration of ventricular fibrillation, and the presence and extent of underlying heart disease. Many other variables that have not been well-characterized may also influence the energy requirement for defibrillation. Motivated by the development of automatic internal defibrillators, the duration of fibrillation and the effect of subthreshold shocks on the ability to defibrillate the heart have been closely examined. Data in humans are scarce, particularly for patients who experience out-of-hospital ventricular fibrillation. Studies that have attempted to evaluate the effect of the duration of ventricular fibrillation on resuscitation have generally shown that survival is worse if fibrillation is of longer duration[223] and if the electrocardiographic appearance of fibrillation is "finer" on the ECG.[224] The success of transthoracic defibrillation in patients experiencing in-hospital cardiac arrest was improved with shorter delays to defibrillation and in the absence of hypoxia and acidosis.[225] More recently such studies have been extended to defibrillation by internal defibrillating systems.

Several notable advances in clinical defibrillation have been made in recent decades. Biphasic waveforms have been shown to be superior to monophasic waveforms in reducing the energy requirement for defibrillation.[226–230] Biphasic waveforms with lower energies provide the additional benefit of reducing postshock myocardial dysfunction and improving cerebral perfusion.[231–233] Public access defibrillation programs improve the outcomes of patients with out-of-hospital cardiac arrest.[234,235] The automated external defibrillator (AED), which can automatically analyze cardiac rhythms, has been an important component of public access defibrillation initiatives.[236,237]

The development and clinical utilization of the internal cardioverter defibrillator (ICD) has dramatically altered the management of patients who survive episodes of sudden death secondary to ventricular tachyarrhythmias.[238] The ICD provides a mechanism for correction of potentially lethal ventricular arrhythmias, regardless of the underlying cause. In view of the limitations in our ability to prevent ventricular tachycardia and fibrillation and sudden death recurrences in patients with structural heart disease, the importance of this therapeutic modality is difficult to overstate. Since their development, ICDs have

become more versatile with the ability to pace, cardiovert, defibrillate, and resynchronize cardiac contraction. The increase in versatility has made these devices more complex and has increased the possibility that definitive therapy for ventricular fibrillation could be delayed by attempts at antitachycardia pacing and low energy cardioversion. In general, the longer the duration of ventricular fibrillation, the greater the energy required for defibrillation, both in experimental animals[239] and humans.[240–242] This effect of the delay to defibrillation shock delivery is less important with shock energies near the maximal output of implanted defibrillators (30–35 J) and with times to shock delivery that are within 30 seconds of the onset of ventricular fibrillation.[240,242]

A major confounding influence on the efficacy of defibrillation is the use of antiarrhythmic drugs. The effects of these agents have been studied in both animal models and humans with implanted defibrillators. There is not a consistent correlation between the animal and human data and conflicting results with use of the same preparation and different experimental conditions complicate the interpretation of these results. The assumption that any antiarrhythmic agent can adversely affect the defibrillation threshold is prudent. Despite the variance in the data, several consistent effects of certain antiarrhythmic agents on defibrillation energy have been observed. Sodium-channel-blocking drugs, particularly those with slower unblocking kinetics (i.e., class IC effects) such as flecainide and propafenone will raise both defibrillation and pacing threshold energy requirements,[243–245] and chronically administered amiodarone has similar effects.[246–248] Studies in an anesthetized canine model suggest that agents that block Na^+ channels without a substantial effect on the action potential duration (e.g., lidocaine, mexiletine, tocainide) tend to increase the energy requirements for defibrillation; conversely, agents that prolong the APD tend to decrease this energy.[249] There are no systematic studies in humans to support this hypothesis, but anecdotal reports of increases in defibrillation requirements by Na^+ channel-blocking drugs do not contradict this paradigm.[247,248,250,251]

In addition to successful defibrillation, successful resuscitation is determined by the recovery of spontaneous circulation. Until defibrillation is possible, artificial support of the circulation is the essential goal of CPR. Several clinical studies have shown that the likelihood of successful termination of ventricular fibrillation and survival is inversely related to the duration of cardiac arrest.[252–254] The importance of CPR in improving the aortic-right atrial pressure gradient and therefore coronary perfusion has been demonstrated in several animal models of cardiac arrest.[255–257]

The improvement of coronary blood flow in these studies has been associated with improved efficacy of resuscitation.[255–257] The issue of what is "optimal" CPR, the role of chest compressions prior to defibrillation during prolonged arrests, and advanced life support is discussed elsewhere in this volume.

The typical clinical situation of out-of-hospital cardiac arrest does afford the possibility of prompt defibrillation; in most cases patients have had no circulatory support during prolonged ventricular fibrillation. Immediate defibrillation in this circumstance terminates ventricular fibrillation, but often asystole or electromechanical dissociation follows the shock and is associated with a very high mortality.[258–260] More recent data suggest that after prolonged unsupported ventricular fibrillation, administration of epinephrine and CPR may improve the chances of defibrillation to a life-sustaining rhythm.[261]

Conclusions and future directions

Ventricular fibrillation is the most common cause of sudden cardiac death. If untreated, this arrhythmia is rapidly and uniformly fatal. There are many factors that predispose to VF in patients with structural heart disease, but our ability to identify patients who will experience VF is limited. In the absence of effective pharmacotherapy to prevent VF the only reliable treatment strategy is prompt defibrillation. In the patients at highest risk this is performed automatically by the internal cardioverter defibrillator. It is likely that in the near term these devices will be used more frequently in patients at high-risk, particularly with the recent introduction of non-thoracotomy defibrillating lead systems and the development of smaller, pectorally implanted pulse generators. Further refinements including the development of "leadless" defibrillators may further reduce the risk of implantation, but at the cost of some limitations in the therapeutic flexibility of these devices. The ICD is likely to be the mainstay of therapy of ventricular fibrillation until our strategies for defining who is at greatest risk of developing it are more complete.

Our understanding of the mechanism of the initiation and perpetuation of ventricular fibrillation has been advanced by elegant mapping studies and more recently, investigation of the molecular participants in this arrhythmia has complemented the mapping data. Despite this, our understanding of ventricular fibrillation is quite rudimentary and more complete elucidation of the basic mechanisms of ventricular fibrillation has the potential benefit of the development of preventive and treatment strategies, as well as more effective protection of the heart in fibrillation.

The neuroendocrine response to global ischemia and reperfusion*

Martin W. Dünser, Stefan Jochberger, Karl-Heinz Stadlbauer, and Volker Wenzel

Department of Anesthesiology and Critical Care Medicine, Innsbruck Medical University, Innsbruck, Austria

The neuroendocrine system

Early during evolution, the *neuroendocrinium* developed as its own organ system. With its numerous intercellular and inter-organ mediators, the hormones, it fulfills important functions to synchronize and connect organs and tissues. Likewise, during stress, the neuroendocrine system, as a complex orchestra with not yet fully understood interactive mechanisms, plays one of the most important roles in the body's adaptation to harmful events, such as injury or disease.

Operational definitions (by Jacobo Wortsman, M.D.)

In general terms the endocrine system comprises hormone-producing organs (glands) that regulate the function of other organs. On functional activation, endocrine organs release their secretory products into the blood. Thus, activation can be assumed to occur when there is evidence of increased hormone concentrations in plasma.

Stress may be defined as any changes in the external or internal environment that elicit a highly organized and synchronized neuroendocrine response. Whereas changes in the internal environment can be quantified according to the degree of interference with homeostasis, changes in the external environment (psychologic stress) cannot be quantified in this manner. Thus, the description of stress must include both the nature of the stressful stimulus and the subsequent functional changes. Nevertheless, because of the universal and severe organ involvement during

cardiac arrest, it can be safely assumed that this condition *per se* represents a stress of maximal degree, without consideration of hormone levels.

The term neuroendocrine response, as used in the description of endocrine reactions to stress, emphasizes the regulatory control placed by the hypothalamus over the entire endocrine system. This control is exerted through the production of specific peptides that are translocated to the anterior lobe of the pituitary gland *via* a venous portal system. The hypothalamus has direct nerve connections with the posterior lobe of the pituitary gland, which stores and releases hormonal products. The peripheral endocrine glands (adrenal cortex, thyroid, and gonads), however, receive pituitary trophic stimulation *via* the general circulation. An important exception to this organizational pattern is the direct regulatory control of the adrenal medullae by the central nervous system.

Methodologic issues in studies of the neuroendocrine response to cardiac arrest (by Jacobo Wortsman, M.D.)

Studies on cardiac arrest in human subjects are fraught with interpretive errors because of the rapidity and intensity of physiologic changes, the use of strong therapeutic agents, and the unpredictability of outcome. For example, uncertainties about the exact time of the cardiac arrest and attendant variability in the interval between arrest and initiation of resuscitation procedures (downtime) make determination of the actual sequence of response events difficult. In general, when cardiac arrest occurs in an intensive care unit,

---

downtime is usually extremely short (seconds), whereas it is much longer (minutes) in out-of-hospital events. The interfering effect of drug therapy must also be considered since patients at risk for cardiac arrest are often receiving multiple drugs. Furthermore, cell death due to cardiac arrest could produce postmortem release of hormones unrelated to the stress reaction. Thus, if possible, biochemical analyses should be performed to identify hormonal products rigorously since substances appearing during global ischemia could differ from the normal circulating products. Of particular concern for studies in endocrine physiology is the abnormally low and irregular blood flow inherent to cardiac arrest and resuscitation maneuvers.[1, 2] The resulting altered hemodynamics could produce plasma compartmentalization; and, in such cases, samples of peripheral blood obtained during cardiopulmonary resuscitation (CPR) might not reflect the rates of hormone secretion and removal that prevail in the intact circulation.

Animal models provide extremely important tools for the study of cardiac arrest and resuscitation. Notably, however, the experimental approach carries the limitations imposed by the evolutionary gap when applied to the stress response of humans. It is reasonable to assume that the crucial role and involvement of higher centers in the central nervous system (as initiators or targets of the stress reaction) can only be determined in humans.

Neuroendocrine response in the immediate cardiac arrest period

Pathophysiologically, the period of acute cardiac arrest with cessation of systemic blood flow is inevitably associated with global ischemia. Depending on the type and function of the cells, cellular and organ dysfunction occurs, that is followed sooner or later by cell destruction, organ failure, and death. Clinically, the period of cardiac arrest represents a period of global ischemia including the downtime and later the period of cardiopulmonary resuscitation with mechanical, electrical, and pharmacological interventions. The immediate cardiac arrest period ends either when spontaneous circulation returns and reperfusion starts, or when resuscitative efforts are withdrawn.

Pituitary gland

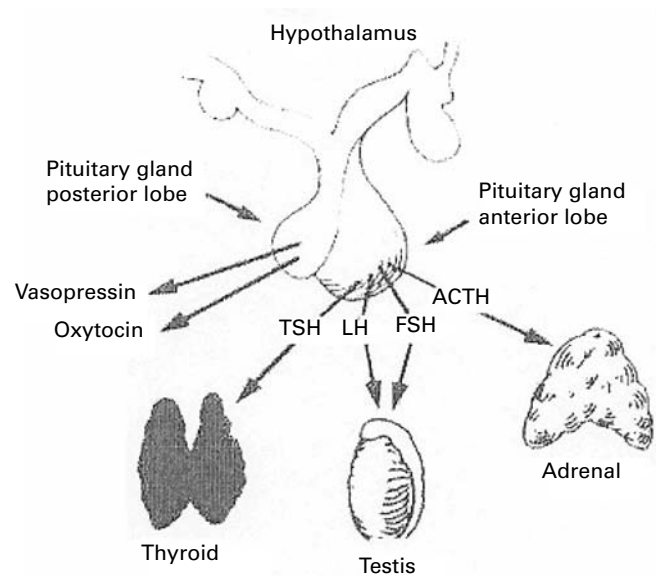
The anterior lobe of the pituitary gland produces and releases peptides that control the function of the adrenal cortex (adrenocorticotropin), the thyroid gland (thyrotropin), and the gonads (gonadotropins). In addition, the anterior pituitary synthesizes other peptides such as growth


Fig. 7.1. The pituitary gland. Endocrine organs controlled by the anterior lobe of the pituitary gland. Not represented in the figure are pituitary hormones acting on non-endocrine targets, such as prolactin, growth hormone, and β-endorphin.

hormone (GH), prolactin, β-endorphin, and β-lipotropin which act on different neuroendocrine targets. Secretion of anterior pituitary hormones is regulated by specific hypothalamic releasing factors that are transported through the portal hypophyseal vascular system (Fig. 7.1).[3]

Anterior lobe

Pro-opiomelanocortin complex

The main product of the corticotrophic cells of the adenohypophysis is the pro-opiomelanocortin (POMC) complex which is a 266-amino acid molecule. During post-translational processing, prohormone convertase enzymes can cleave the POMC complex into different hormones. This generates adrenocorticotropin (ACTH) and β-lipoprotein (β-LPH). ACTH can be further processed to generate 7- or α-melanocyte stimulating hormone (7- or α-MSH), and corticotropin-like intermediate lobe peptide (CLIP), whereas β-LPH can be processed to generate β-LPH and β-endorphin.[4] Under physiologic conditions, POMC is mainly processed to the N-terminal glycopeptide, ACTH, and β-LPH; smaller amounts of the other peptides are also present.[5] Additional posttranslational modifications of the POMC complex have been described,[6, 7] but their biologic activities remain to be determined.

From those hormones that can be processed in the POMC complex, ACTH, 7- or α-MSH, and β-endorphin have been evaluated in the acute setting of cardiac arrest.

Table 7.1. Plasma hormone concentrations during cardiopulmonary resuscitation in resuscitated and non-resuscitated patients[20]

Hormone	Resuscitated patients (n=20)	Non-resuscitated patients (n=14)	p
Adrenocorticotropin (pg/ml) (25–50)	237 (29–572)	45 (1–794)	0.018
Cortisol (μg/dl) (5.0–25.0)	32.6 (5.9–74.7)	18.4 (9.6–70.1)	0.481
Arginine vasopressin (pg/ml) (1–3)	122 (20–469)	88 (5–156)	0.049
Renin (ng/l) (10–30)	46.5 (22–88)	11 (9–40)	0.017

Data are shown as median and range. The normal range of values is displayed after the name of the hormone in the left column.

ACTH

ACTH is the principal regulator of cortisol production in the *zona fasciculata* of the adrenal cortex, whereas it is of secondary significance in aldosterone and adrenal androgen production. The peripheral effects of ACTH are mediated *via* cyclic adenosine $3', 5'$-phosphate (cAMP)-coupled receptors on adrenal cell membranes. ACTH stimulates cortisol synthesis and secretion by affecting several steps in the steroidogenesis pathway. Although cortisol is not stored in the adrenal cortex, but is synthesized within minutes, the effects of ACTH on adrenal cortisol production can be readily measured after secretion of the hormone.

The synthesis of POMC and hence the secretion of ACTH is under the control of the corticotropin-releasing hormone (CRH) and to a lesser degree of arginine vasopressin. Both hormones are synthesized in the parvocellular cells of the paraventricular hypothalamic nucleus, and are under the negative control of circulating glucocorticoids. Vasopressin stimulates ACTH release only weakly by itself, but is strongly synergstic with the effects of CRH.[8] Other endocrinologic and non-endocrinologic factors have been shown to modulate ACTH release. While the vasoactive intestinal peptide (VIP),[9] catecholamines,[10] ghrelin,[11,12] as well as pro-inflammatory cytokines[13] stimulate ACTH release by indirect modulation of CRH secretion, angiotensin II was reported to stimulate ACTH release directly from pituitary cells.[14] Opiates and opioid peptides,[15] and probably also the atrial natriuretic peptide (ANP),[16, 17] decrease ACTH production.

During cardiac arrest and CPR in patients on the intensive care unit, ACTH levels were significantly higher when compared to those in other critically ill patients. This elevation was detectable within the first 10 minutes after cardiac arrest, when the plasma concentrations reached a mean value of 166 pg/ml (normal range <130 pg/ml), and remained elevated throughout the first hour.[18] In a study of a large population of patients with out-of-hospital cardiac arrest (n=205), it was found that the mean ACTH level (160 pg/ml) was similar to that observed in intensive care

unit cardiac arrest.[19] Further evaluation of patients with out-of-hospital cardiac arrest showed that initial plasma ACTH levels were lower in individuals in whom spontaneous circulation did not return (133 ± 227 pg/ml; $n=161$) than in those who had return of spontaneous circulation (229 ± 260 pg/ml, $n=44$, $p<0.05$).[19] Similar results were observed in two other studies, including 34 and 60 patients with out-of-hospital cardiac arrest (Table 7.1). In both studies, ACTH concentrations were higher in patients who had a return of spontaneous circulation compared to concentrations in the patients who could not be resuscitated.[20, 21] In 10 patients who underwent testing of "implanted cardioverter defibrillator" devices, a short period of cardiac arrest under light sedation slightly increased ACTH concentrations, but did not appear to stimulate catecholamine secretion.[22] In an animal experiment, serum ACTH concentrations were observed to be significantly higher in pigs resuscitated with vasopressin (0.4 IU/kg, $n=7$) when compared to pigs receiving epinephrine (0.045 mg/kg, $n=7$) (ACTH, $p=0.001$; cortisol, $p=0.005$).[23]

β-Endorphins

Endorphins play an important role as possible neuroregulators in pain transmission, analgesia, tolerance and dependence, as well as in behavior and endocrine pathways, mainly those related to the hypothalamo-pituitary axes.[24] β-Endorpin is known to be released during pain stimulation in the rat and during thermal injury or surgical procedures in humans.[4, 25, 26] β-Endorphin binds to opioid receptors and is thought to be an endogenous mediator for stress-induced analgesia.[5] Moreover, recent data suggest that endorphins act not only as neuroregulators, but also have direct effects on calcium channels of the cerebral vasculature.[6]

Only few studies so far have examined β-Endorphins during cardiac arrest. During cardiopulmonary resuscitation, β-Endorphins were found to be significantly elevated when compared to intensive care unit patients without cardiac arrest.[18] Such an increase in β-Endorphin levels

was most pronounced in hypoxic cardiac arrest.[27] β-Endorphin concentrations remained high at least for 10 to 20 minutes after cardiac arrest.[18] The sudden increment of β-Endorphin in brain tissue and body fluids of dogs who were conscious at the moment of cardiac arrest led to the hypothesis that β-Endorphins could participate in the sensations narrated by subjects in the so-called near-death experience.[28]

Melanocyte stimulating hormones (MSH)

The general designation – γ-MSH refers to peptide fragments that are derived from the aminoterminal region of the POMC and have partial structural homology to the melanotropins.[29,30] Among the several amino acid sequences that have been postulated for – γ-MSH peptides, 73-MSH is the most extensively investigated.[31] Although γ_3-MSH exerts only weak melanotropic activity, it can enhance the adrenal-stimulating effect of ACTH.[32, 33]

α-MSH is a tridecapeptide melanocortin structurally related to ACTH. It is found principally in the brain and the pituitary, although keratinocytes and blood monocytes can also release α-MSH. Moreover, α-MSH has potent anti-inflammatory actions in both the brain and in peripheral tissues.

Only one clinical study has investigated MSH levels in patients during cardiac arrest. In this analysis, γ_3-MSH immunoreactivity was found to be consistently elevated in patients with cardiac arrest when compared to intensive care unit controls (162 ± 20 vs. 35 ± 6 pg/ml; $p < 0.001$). γ_3-MSH seems to be an important component of the massive release of pituitary and adrenal glandular hormones during cardiac arrest.[18]

An interesting study in rats with prolonged global ischemia due to respiratory arrest demonstrated that if an intravenous injection of α-MSH was given at the start of mechanical ventilation there was an immediate (<1 minute) increase in cardiac output, heart rate, mean arterial pressure, and pulse pressure, with full recovery of electroencephalographic patterns and blood gas parameters after 30 to 45 minutes. All animals eventually recovered completely.[34] These results suggest that melanocortin peptides not only affect resuscitation during pre-terminal ischemia, but may also have potential therapeutic values in global and local ischemia.

Prolactin

Prolactin is a mammotrophic peptide that is unique among the pituitary hormones for being only under tonic inhibitory control by the hypothalamus. The hypothalamic factor that suppresses prolactin secretion is thought to be dopamine.[3] In addition to promoting mammary gland development and milk production, prolactin plays a pivotal role in the immune system. Physiologic studies have demonstrated the presence of prolactin receptors on human T- and B-lymphocytes,[35] and showed that T-lymphocytes depend on prolactin for maintaining immune competence.[36]

Cardiac arrest is associated with a marked elevation in serum prolactin concentrations (44 ± 10.2 ng/ml; frequency of abnormally high values 60%; $n = 15$). Prolactin levels increase within the first 10 minutes of cardiopulmonary resuscitation and remain elevated throughout resuscitation.[18] Another study of prolactin serum levels in patients with out-of-hospital cardiac arrest found that prolactin levels were significantly higher in patients who could be successfully resuscitated when compared to patients in whom cardiopulmonary resuscitative efforts remained ineffective (95.9 ± 13.6 vs. 23.9 ± 5.6 ng/ml; $p = 0.0001$). Decreased prolactin concentrations in non-resuscitated patients may have been a result of exhaustion of the neuroendocrine system, or due to differences in bioavailability at the site of blood sampling, on the basis of differences in hemodynamics.[37]

Prolactin release during cardiac arrest was speculated to be mediated by β-endorphin,[38] but the correlation between prolactin and β-endorphin concentrations was found to be small and non-significant ($r = -0.1$; $p > 0.1$; $n = 117$).[18] The correlation of prolactin with another marker of stress intensity, serum cortisol, was highly significant ($r = 0.44$; $p < 0.01$).[18]

Growth hormone (GH)

GH, or somatotropin, is released in a pulsatile fashion from somatotrophs of the pituitary gland. Two hypothalamic hormones control GH secretion: GH-releasing hormone, which stimulates the production and induces the release of GH; and somatostatin, which acts as an inhibitor.[3] GH affects body growth and metabolism directly and indirectly through stimulation of the liver to produce insulin-like growth factor-1 (IGF-1, also known as somatomedin C). Apart from its general effects causing growth, GH has multiple specific metabolic effects, including enhancement of total body protein, mobilization of fat stores, and conservation of carbohydrates.

Since the 1980s, a series of synthetic GH-releasing peptides and non-peptide analogs, together labeled GH secretagogues, have been developed with potent GH-releasing capacities acting through a specific G-protein-coupled receptor located in the hypothalamus and the pituitary.[39, 40] The endogenous ligand for the GH receptor is known as ghrelin, a highly conserved 28-amino-acid peptide[41] originating in the stomach as well as in the hypothalamic

arcuate nucleus, that has recently emerged as a key factor together with GH-releasing hormone and somatostatin, involved in the complex control of GH secretion. These regulatory factors act in concert to achieve a pulsatile secretion of GH.

To date, there are no studies on the GH response during global ischemia or cardiac arrest, although a significant release would be expected to maintain at least cerebral glucose supply.

Neurohypophysis (posterior lobe)

Vasopressin

Vasopressin is an endogenous nonapeptide hormone with antidiuretic, vasomotoric, hemostatic, and central nervous effects. The hormone is produced in the magnocellular nuclei of the hypothalamus and stored in neurosecretory vesicles of the neurohypophysis. It is secreted upon osmotic, hemodynamic, and endocrinologic stimuli. Most newly synthesized vasopressin is stored intracellularly; only 10%–20% of the total hormonal pool within the posterior pituitary can be readily released.

Important hemodynamic signals for secretion are reduced atrial filling, as well as decreased arterial blood pressure. Any reduction in blood volume or venous return stimulates vasopressin secretion via activation of stretch receptors located in the left atrium and pulmonary arteries (Gauer–Henry reflex). Activation of baroreceptors in the aortic and carotid sinus further augments vasopressin secretion via the glossopharyngeus and vagal nerves.[42] Baroreceptor-mediated vasopressin secretion, however, is the primary stimulation release in hypotensive states.[43]

In addition to osmolar and hemodynamic stimuli, endotoxin as well as pro-inflammatory cytokines can stimulate secretion of vasopressin independently of plasma osmolarity, blood pressure, or intravascular volume status.[44–46] Endocrinologically, angiotensin II and III, as well as endothelins (ET), norepinephrine, and epinephrine are physiologic secretagogues of vasopressin,[42, 47, 48] whereas ANP suppresses vasopressin secretion.[49, 50]

In plasma, vasopressin is bound to proteins; 10% at basal plasma concentrations and up to 40% at higher concentrations. Serum half-life varies between 8 and 15 minutes. Splanchnic and renal enzymatic degradation are primary pathways of inactivation. Renal clearance of vasopressin results from glomerular filtration, degradation, or reabsorption in the proximal nephron, and additional secretion into the distal nephron. Ten percent of vasopressin is excreted as active hormone. Renal clearance remains unaffected by changes in serum concentration over a broad range.[51] Splanchnic clearance of vasopressin is accomplished almost equally by the intestine and the liver.[52] Because the sum of splanchnic and renal elimination of vasopressin is less than estimates of its metabolic rate, there seems to be a pharmacologically significant clearance of vasopressin by other organs.[51]

Peripheral effects of vasopressin are mediated by three different G protein-coupled receptors. V1a-receptors have been found on vascular smooth muscle cells and induce vasoconstriction by an increase in cytoplasmic ionized calcium via the phosphatidyl-inositol-bisphosphonate cascade.[53] In contrast to catecholamine-mediated vasoconstriction, effects of vasopressin are also preserved during hypoxia and severe acidosis.[54] Vasopressin-mediated vascular effects differ substantially within particular vascular beds, however. Physiologically, most arterial beds exhibit vasoconstriction in response to vasopressin,[55, 56] with vasopressor effects being strongest in the splanchnic, muscular, and cutaneous vasculature.[57]

Paradoxical vasodilatation to vasopressin has been described in the pulmonary, coronary, vertebrobasilar, and gastrointestinal circulation.[58–60] The underlying mechanisms seem to be nitric oxide dependent.[58] Recently, there is increasing evidence of hemodynamically relevant V1a-receptors on cardiomyocytes. *In vitro* and animal experiments have demonstrated an increase in intracellular calcium concentration and inotropy after stimulation of myocardial V1a-receptors.[61,62] V1a-receptors are further expressed on thrombocytes. Upon stimulation, they induce an increase in intracellular calcium, thereby facilitating thrombocyte aggregation.[63] Vasopressin also increases expulsion of thrombocytes from the bone marrow.[64] Other hemostatic effects are mediated by V2-receptors. Prostacyclin generation is stimulated; tissue-type plasminogen activator activity, factor VIII-related antigen activity, factor VIII coagulant activity, and von Willebrand factor multimeres all increase upon V2-receptor stimulation.[65] Stimulation of V1a-receptors on hepatocytes increases glycolysis and glycogenolysis, gluconeogenesis, and esterification and oxidation of free fatty acids, as well as production of ketone bodies.[66]

V1b-receptors are found on the anterior hypophysis. Stimulation induces liberation of ACTH and consequently enhanced cortisol secretion from the adrenal glands.[67] Accordingly, Kornberger *et al.*[23] reported significantly higher serum ACTH and cortisol concentrations in animals resuscitated from cardiac arrest with vasopressin when compared to epinephrine. V1b-receptors are further expressed on pancreatic isle cells where they induce insulin secretion.[68] Nevertheless, stimulation of insulin secretion by vasopressin only seems to be relevant during moderate to severe hyperglycemia.[69]

In the kidney, V2-receptors are located on distal tubules and collecting ducts. Upon stimulation, they facilitate integration of aquaporines into the luminal cell membrane, leading to increased resorption of free water *via* an adenylate cyclase-dependent mechanism.[42] Despite this antidiuretic effect, a paradoxical increase of urine output has been reported during continuous vasopressin infusion in vasodilatory shock.[70–72] One explanation for this observation is the selective V1a-receptor-mediated vasodilatation of the afferent and vasoconstriction of efferent glomerular arterioles which results in a significantly increased glomerular filtration pressure.[70] V2-receptor-associated natriuretic and diuretic effects as well as release of the atrial natriuretic factor may also be involved.[72] Additional physiological effects of vasopressin on specific brain functions, temperature regulation, and myometrical contractions have been reported.[42, 73]

During cardiac arrest, serum vasopressin levels were found to increase significantly. A canine study of 10 minutes of fibrillatory cardiac arrest showed that AVP levels increased from 1.7 ± 1 pg/ml during spontaneous circulation to 29.9 ± 33.3 pg/ml during cardiac arrest and cardiopulmonary resuscitation ($p = 0.01$). In this model, there was a moderate positive correlation between aortic pressure and circulating endogenous vasopressin levels after the first dose of epinephrine ($r = 0.5$). Additionally, animals with return of spontaneous circulation showed a trend towards higher concentrations of vasopressin in serum ($p = 0.12$).[9] In a study including 34 patients with out-of-hospital cardiac arrest, vasopressin concentrations were significantly increased. Resuscitated patients had significantly higher vasopressin concentrations than did non-resuscitated patients (122 pg/ml vs. 88 pg/ml; $p = 0.049$).[20] In another study of 60 patients with out-of-hospital cardiac arrest, vasopressin serum levels before and after the first epinephrine dosage were significantly higher in patients with return of spontaneous circulation when compared with those in patients who could not be resuscitated (193 ± 28 vs. 70 ± 9 pg/ml, $p < 0.001$; 177 ± 27 vs. 58 ± 9 pg/ml, $p < 0.001$).[21] According to these data, it can be assumed that endogenous vasopressin release may have an important effect on patient outcome from cardiac arrest.

Thyroid gland

Thyroid hormones

The thyroid gland is composed of follicles filled with colloid. Colloid consists of the protein thyroglobulin, which serves as the matrix for synthesis of the thyroid hormones. On glandular stimulation by pituitary thyrotropin (TSH),

thyroid hormones are released into the circulation, accompanied by small amounts of thyroglobulin.[16] The thyroid hormones triiod-thyronine with three iodine atoms *per* molecule (T3) and thyroxine with four iodine atoms (T4) have important effects on calorigenesis, somatic growth, and cardiovascular function.[16] T3 and T4 differ significantly in their metabolism.[16] Whereas T4 is synthesized exclusively in the thyroid, T3 is mainly produced in peripheral tissues by deiodination of T4. Reverse T3 is an alternate product of T4 deiodination that is biologically inactive.[16, 74]

Studies performed in 24 cardiac arrest patients in the intensive care unit showed low concentrations of total T4 (3.8 ± 0.6 μg/dl; normal range: 1.2–4.2 μg/dl) and T3 (48 ± 6 ng/dl; normal range: 80–200 ng/dl).[14] On the other hand, reverse T3 was increased to 53.5 ± 9.7 ng/dl (normal range: 8–26 ng/dl) and dialyzable T4 to $0.029 \pm 0.0003\%$ (normal range: 0.016–0.028%).[14] Although TSH was slightly higher in cardiac arrest than in non-cardiac arrest patients in intensive care units (6.2 ± 2 μg/ml vs. 3.6 ± 3.3 μg/ml), the difference was not statistically significant.[14] Serum thyroglobulin levels remained unchanged throughout resuscitation.[14] A similar hormonal profile of decreased T4, free T4, T3, and free T3, as well as increased reverse T3 was noted in dogs after cardiac arrest periods of 30 seconds to 9 minutes.[75] Analysis of 473 patients with out-of-hospital cardiac arrest found that patients exhibiting total T4, T3, and reverse T3 closer to the normal range and TSH levels that were higher, were significantly more likely to survive than were patients with low thyroid hormone levels.[76]

It appears that the thyroid profile of cardiac arrest is most compatible with peripheral hypothyroidism, and the relatively higher TSH concentrations in these patients suggest an appropriate response to a state of hypothyroidism. Taken together, the current data provide strong evidence against active participation of thyroid hormones in cardiac arrest.

Calcitonin

Calcitonin is a peptide hormone that is synthesized in and secreted from the parafollicular cells, also known as C cells, of the thyroid gland. The primary stimulus for calcitonin secretion is increased plasma calcium concentration. Whereas in young subjects calcitonin rapidly decreases blood calcium by reducing the function and formation of osteoclasts, calcitonin has only weak effects on plasma calcium levels in adults.[77]

Although there are no clinical or experimental studies that examine the course of calcitonin concentrations during cardiac arrest, calcitonin was measured in acutely traumatized patients ($n = 11$). Ninety-one percent of these patients had increased serum calcitonin concentrations

on admission to the emergency department. Median calcitonin concentrations in acutely traumatized patients were higher throughout the study period than in elective surgery patients ($P < 0.05$). Interestingly, despite these increased calcitonin concentrations and hypocalcemia in most patients, loss of urinary calcium was within the normal range.[78]

Parathyroid glands

The parathyroid consists of four small glands that are variably located behind the four poles of the thyroid gland. The parathyroid glands are the body's main location of parathyroid hormone production. The parathyroid hormone is a classical peptide hormone whose secretion is almost completely dependent on plasma calcium concentrations. Once released into the circulation, parathyroid hormone increases plasma calcium and reduces phosphate concentrations. While the parathyroid hormone-induced fall in phosphate concentration occurs rapidly, the rise in calcium can be divided into a rapid and a slow phase. The rapid effect is mostly due to parathyroid hormone-induced inhibition of renal calcium excretion. Calcium and phosphate absorption from the bone by stimulation of osteoclasts is responsible for the slow effects of parathyroid hormone on plasma calcium concentrations.[77]

No data currently exist on parathryoid hormone concentrations in patients with cardiac arrest. One clinical study, however, analyzed parathyroid hormone levels during global ischemia in acutely ill patients admitted to the emergency department. Elevated parathyroid hormone concentrations (>55 pg/ml) were observed in 16% of patients, most frequently in patients with myocardial infarction (28%) and congestive heart failure (42%). Parathyroid hormone levels significantly correlated with the APACHE II score ($P < 0.0001$) and also with the length of hospital stay ($P < 0.002$). Moreover, in that study, parathyroid hormone concentrations were identified as a strong predictor of patient outcome, with significantly higher serum concentrations observed in patients who subsequently died than in patients who eventually survived ($P < 0.03$).[79]

Adrenal glands

The adrenal glands comprise two embryologically different tissues, the adrenal cortex and medulla. Although anatomically and histologically distinct, there is no strict separation in localization of the two tissues. Recent studies have proven that chromaffin cells, once thought to be located exclusively in the medulla, can also be found in all cortical zones, and that cortical cells are found in the adrenal medulla as well.[79, 80] This close co-localization is assumed to be a prerequisite for paracrine interactions.[81]

The adrenal medulla takes a special position within the endocrinologic system since it is not integrated into specific endocrinologic axes, but is directly innervated by terminal nerves of the sympathic trunk. Although the adrenal cortex is largely under the control of the hypothalamus and the adenohypophysis, a direct influence of autonomic nerve terminals on adrenocortical cells has been suggested.[82] The detection of chemo- and baroreceptors in the adrenal cortex further suggests efferent innervation as well.[83,84]

Adrenal medulla

In addition to the terminal sympathetic nerve endings, the adrenal medulla is the main source of plasma norepinephrine. For epinephrine, the adrenal glands are the only plasma source. Thus, plasma concentrations of epinephrine do not only represent activation of the adrenal medulla, but are also considered the most sensitive marker for activation of the neuroendocrine response to stress.[85]

Catecholamines
Epinephrine levels in cardiac arrest are markedly elevated to the highest concentrations ever reported.[86] Whereas the normal resting values of epinephrine are 0.034 ± 0.002 ng/ml, peak levels may reach 10.3 ± 2.9 ng/ml during cardiac arrest ($p < 0.01$)[86] and the highest recorded spontaneous plasma epinephrine concentration during cardiac arrest was 35.6 ng/ml.[86] Extraordinarily elevated epinephrine levels have also been observed in porcine and canine models of cardiac arrest.[87, 88] Activation of the adrenal medulla is probably initiated by the cessation of blood flow, which produces maximal stimulation of vascular receptors in the cardiocirculatory system and results in massive discharge of epinephrine.[89, 90] Extensive manipulations associated with cardiopulmonary resuscitation do not appear to contribute to this elevation in epinephrine plasma levels, because peak concentrations are similar in dogs during cardiopulmonary resuscitation, or assisted with cardiopulmonary bypass (Fig. 7.2).[91]

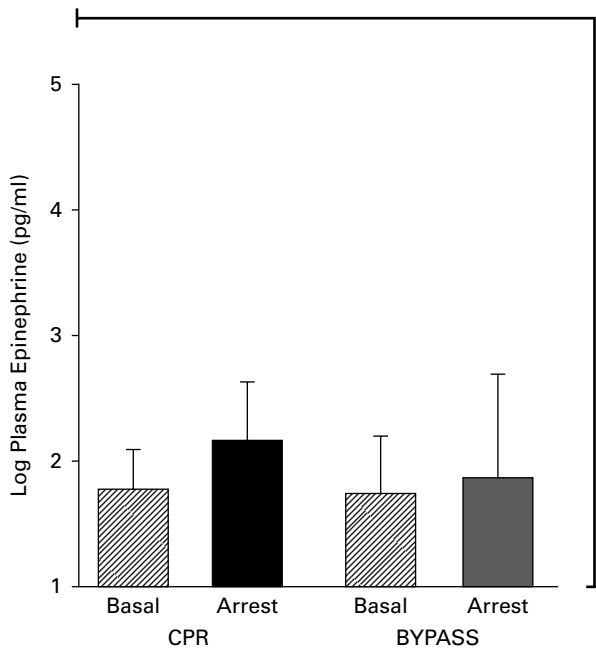
Plasma norepinephrine levels also markedly increased during resuscitation, from normal resting levels of 0.52 ± 0.06 ng/ml up to 7.37 ± 1.8 ng/ml.[85] In addition, the correlation between simultaneous increases in plasma concentrations of epinephrine and norepinephrine during cardiac arrest is highly significant.[86, 92] Since experimental adrenalectomy before cardiac arrest produces almost total (about 80%) suppression of the rise in plasma epinephrine and norepinephrine,[88, 93] it appears that the two plasma


Fig. 7.2. Plasma epinephrine levels during experimental cardiac arrest in dogs.[91] Left, animals resuscitated with standard CPR; right, animals resuscitated with cardiopulmonary bypass. There are no differences in basal or peak epinephrine levels between the two groups.

catecholamines share a common adrenomedullary source in cardiac arrest. Recent evidence suggests, however, that the release of epinephrine precedes that of norepinephrine. The marked rise in plasma epinephrine precipitated by the administration of epinephrine at therapeutic dosages in cardiac arrest is followed by proportional increases in plasma norepinephrine levels.[94] Therefore, stimulation by epinephrine is likely to be the mechanism for the previously unexplained observation of higher plasma norepinephrine levels among cardiac arrest patients treated with epinephrine.[86] Taken together, the data suggest that plasma epinephrine itself may be the primary and perhaps most important stimulus driving the rise of plasma norepinephrine during cardiac arrest. Whether norepinephrine released during cardiac arrest is primarily derived from adrenal or extra-adrenal compartments (neurogenic or non-neurogenic) is not yet clear.

The effects of epinephrine administration in cardiac arrest have been the subject of numerous studies performed in the clinical or experimental setting. It has been concluded that administration of epinephrine may improve the outcome of cardiac arrest.[95–99] Thus epinephrine has become an important component in the therapy of cardiac arrest.

Adrenal cortex

The adrenal cortex is the main steroid hormone-producing organ of the body. More than 30 steroid hormones have been isolated from the adrenal cortex, but only two are of exceptional importance to the normal endocrine function: aldosterone and cortisol. According to functional and histological grading, the adrenal cortex can be divided into three different zones.

- The outer *zona glomerulosa* represents the site of mineralocorticoid production with its physiologically most important representative, aldosterone. The function of the *zona glomerulosa* is mainly modulated by the extracellular fluid content of angiotensin II, potassium, but also to a lesser degree by ACTH.
- The central *zona fasciculata* constitutes about 75% of the adrenal cortex and is the main site for synthesis of glucocorticoids. Apart from ACTH, numerous cytokines and other intercellular mediators influence the biosynthesis of glucocorticoids, of which cortisol is the most important and 95% of the glucocorticoid activity of the *zona fasciculata* is provided by cortisol.
- The inner *zona reticularis* is the site of adrenal androgen production. The *zona reticularis* does not only synthesize dehydroepiandrostenedione and androstenedione, however, but also synthesizes small amounts of estrogen and some glucocorticoids. ACTH regulates secretion of these hormones, although other factors such as cortical androgen-stimulating hormone, released from the pituitary, may be involved as well.

Cortisol

Cortisol is the predominant corticosteroid produced in the human body. In a healthy, unstressed person, cortisol is secreted according to a diurnal pattern. Circulating cortisol is bound to corticosteroid-binding globulin (CBG), with less than 10% in the free, bioavailable form. Its effects are mainly mediated by stimulation of nuclear receptors and modulation of genetic transcription. During recent years, however, studies show that there may be increasing numbers of cortisol effects that are not mediated by nuclear, but by cytosolic or membrane receptors.

As one of the most important physiologic stress hormones, cortisol has catabolic, anti-inflammatory, and vasoactive properties on the peripheral vasculature. Thus, cortisol also contributes to the peripheral vascular tone by facilitating adrenergic vasoconstriction and exerting permissive effects on the synthesis of catecholamines and other vasoactive peptides.[100, 101] Furthermore, cortisol has inotropic effects and can modulate free water distribution within the vascular compartment.[102] Another effect that may be of relevance during and after cardiac arrest, is the

possible involvement of cortisol in the modulation of neuronal death during ischemia. An animal study shows that adrenalectomy and administration of a glucocorticoid receptor blocker reduced neuronal cell death after transient global ischemia, suggesting adverse effects of cortisol on neuronal cell survival from ischemia.[103]

Cardiac arrest in intensive care unit patients was associated with a significant elevation of serum cortisol concentrations (48.3 ± 7.6 μg/dl).[18] Overall, high serum cortisol concentrations were found in 86% of intensive care patients during cardiac arrest. Levels of CBG, on the other hand, were significantly decreased when compared with non-cardiac arrest patients in the intensive care unit.[18] Such a decrease in CBG results in a significant increase of its free serum portion and bioavailability during cardiac arrest. In 10 patients undergoing testing of implanted cardioverter defibrillator devices, serum cortisol concentrations increased significantly from 367 ± 62 to 539 ± 64 nmol/l ($p < 0.001$) during induced ventricular fibrillation.[22]

A study of serum cortisol profiles in patients with out-of-hospital cardiac arrest[19] presented results similar to those observed in patients with cardiac arrest in the intensive care unit. Initial serum cortisol levels in these patients were increased to 32 ± 33.1 μg/dl ($n = 205$) with the free fraction being equally elevated to 25% of the total cortisol level. Another trial including 60 patients with out-of-hospital cardiac arrest observed lower, but still supranormal cortisol levels (18 ± 3 and 15 ± 2 μg/dl in survivors and non-survivors, respectively).[21]

Initial serum cortisol concentrations at the time of cardiac arrest may therefore be an ancillary predictor of survival. Indeed, subjects with serum cortisol levels below 30 μg/dl at the time of cardiac arrest had a 96% mortality at 6 hours and a 100% mortality at 24 hours.[19,104] A recent trial found a significant difference in serum cortisol concentrations shortly after cardiac arrest between survivors (34.1 ± 11.2 μg/ml) and non-survivors (19 ± 2.8 μg/ml; $p = 0.0034$). Interestingly, there was no correlation between serum ACTH concentrations and patient outcome.[105] The possible biological significance of cortisol release during cardiac arrest is difficult to interpret and has not yet been studied. Therefore, it remains to be established whether cortisol plays a direct role in the maintenance of cellular functions during global ischemia or is simply a prognostic marker.

Renin–angiotensin–aldosterone system
Angiotensin II is one of the most potent endogenous vasoconstrictive peptides. It is cleaved from angiotensin I by the angiotensin-converting-enzyme whose major site of production is the lung epithelium.[106] Strong vasoconstrictive effects can partly be explained by angiotensin II-induced release of ET[33] and central activation of the sympathetic nervous system.[8] Another major effect of angiotensin II is the stimulation of aldosterone production and release from the adrenal glands.

In addition to the adrenal cortex, aldosterone is also locally produced in the heart and the vessel wall.[107–110] Since neither the aldosterone synthase nor 11-beta-hydroxylase has so far been detected in the myocardium or the vascular smooth muscle cells, it is hypothesized that aldosterone is extracted from the circulation by yet unknown mechanisms. Secretion of aldosterone from the adrenal cortex, the heart, and the vessels is mainly stimulated by angiotensin II and III. ET and serotonin are less potent stimulators, while potassium, the natriuretic peptides, and dopamine inhibit aldosterone secretion.[110]

Once released into the circulation, aldosterone exerts its effects by stimulation of cytoplasmic and transmembrane mineralocorticoid receptors, inducing both genomic and non-genomic effects. Such aldosterone receptors have been observed on endothelial cells, vascular smooth muscle cells, renal tubules, the colon, salivary glands, heart, and brain. Aldosterone plays a key role in the maintenance of sodium and water balance by regulation of epithelial tubular sodium absorption and transcription of sodium-potassium ATPase. By activation of central sympathetic neural pathways, aldosterone can also increase blood pressure. Non-epithelial effects of aldosterone are mediated through a second messenger system that involves activation of the sodium/hydrogen antiporter.[111]

Whereas aldosterone levels have not yet been examined in cardiac arrest, there are data on its precursors, renin and the angiotensins. Patients with out-of-hospital cardiac arrest presented with significantly increased renin concentrations when compared with a normal population (4.6 ng/dl; normal range: 1–3 ng/dl).[20] Elevation of plasma renin activity, however, appeared to be restricted to those who subsequently achieved return of spontaneous circulation, whereas renin elevation was not observed in non-resuscitated patients (1.1 ng/dl; $p < 0.2$ vs. resuscitated patients).[20] Also angiotensin II levels were found to be significantly elevated in canine cardiac arrest, where angiotensin II concentrations increased from 14.7 ± 12.9 pg/ml during spontaneous circulation to 151 ± 105 pg/ml during cardiac arrest and cardiopulmonary resuscitation ($p < 0.05$).[9]

Because of its potent vasoconstrictive effects, administration of angiotensin II has also been studied as a resuscitation drug during cardiac arrest. Infusion of 0.05 mg/kg of angiotensin II resulted in a significant improvement of both myocardial blood flow and short-term survival in a pig model of cardiac arrest.[112] Similar effects of angiotensin

II injection on diastolic aortic pressure as well as myocardial and cerebral blood flow were observed in another animal model of cardiac arrest.[113,114] The hemodynamic effects of angiotensin II during cardiac arrest apparently are not caused exclusively by direct arteriolar vasoconstriction *via* angiotensin II receptors, but are also mediated by a massive catecholamine release with adrenergic peripheral vasoconstriction.[115]

Unconventional endocrine organs

Endothelium

Endothelin (ET) was first isolated by Yanagisawa *et al.* in 1998. They identified the endothelium-derived contracting factor as a 21-amino acid peptide from porcine aortic endothelium cells. The peptide possessed strong vasoconstrictive properties and was at least ten times as potent as those of angiotensin II. This peptide was named ET-1 and together with ET-2 and ET-3 belongs to the ET isopeptide family.[116] ET-1 synthesis is not limited to the endothelium, but it is also produced in a broad variety of other cells, including vascular smooth muscle cells,[117] mucosal epithelium,[118] macrophages,[119] mast cells,[120] cardiomyocytes,[121] neurons,[122] tracheal epithelium,[123] renal medulla,[123] hepatic sinusoids, and Kupffer cells.[124]

Factors known to stimulate the endothelium to release ET-1 include low vascular shear stress,[125] hypoxia,[126] endotoxin,[127] transforming growth factor β,[128] adrenalin,[129] thrombin and angiotensin II.[130] Inhibition of ET-1 release occurs in response to prostacyclin,[131] nitric oxide,[132] ANP,[133] and heparin.[133]

Under physiologic conditions, ET-1 is considered to act as a paracrine mediator, and effects are mediated by at least two types of G-protein-coupled receptors, the ET_A and the ET_B receptors.[134, 135] In addition to its highly potent vasoconstrictive effects, *in vitro* and animal studies have shown that ET is a particularly strong constrictor of renal mesangial and coronary vessels. ET receptor stimulation has further been associated with bronchoconstriction, endocrine regulation, and stimulation of monocytes to produce interleukins (interleukin-1, 6, 8), prostaglandin E_2, and substances that trigger formation of superoxide radicals.

During cardiac arrest, ET serum concentrations were found to be slightly increased over those under normal conditions. There was no significant difference in serum ET levels during cardiac arrest between patients who were successfully resuscitated and who were not (4.3 ± 0.9 vs. 5.5 ± 0.4 pg/ml).[21]

Because of its strong vasoconstrictive effects, ET-1 injection (50–300 μg) was studied during cardiac arrest soon after its physiologic identification. First studies underlined the potent vasopressor activities of ET-1 and reported significantly increased cerebral perfusion pressures, diastolic aortic pressure, as well as vital organ blood flow after ET-1 injection.[136–139] Nonetheless, ET-1 administration did not elevate myocardial blood flow because of sustained coronary vasoconstriction.[137] During cardiopulmonary resuscitation, ET-1 administration resulted in a lower end-tidal carbon dioxide partial pressure presumably due to decreased cardiac output. After return of spontaneous circulation, the continued ET-1-mediated intense vasoconstriction led to higher aortic diastolic pressure and very narrow pulse pressure. Of greater importance, postresuscitation mortality was significantly higher in the ET-1 group (6 of 8 vs. 0 of 8 with epinephrine-treated animals, $p < 0.01$).[140, 141]

Heart

The myocardium is known to produce and secrete natriuretic peptides which lower blood pressure by vascular relaxation and stimulate renal sodium excretion. Currently, the ANP and the brain natriuretic peptide (BNP) have been extensively examined. Both hormones are released into the blood in response to atrial distension.[142–145] They play a complex role in promoting natriuresis and diuresis, inhibiting the renin-angiotensin-aldosterone axis, and acting as a direct vasodilator.[146,147] Natriuretic peptides have been shown to reduce myocardial pre- and afterload, improve left ventricular function, dilate coronary arteries, and ameliorate exercise-induced myocardial ischemia.[148–151] BNP has a half-life of about 3 minutes as it is removed from circulation by binding to natriuretic peptide clearance receptors (c-type receptors), which are located on endothelial cells, and it is inactivated through cleavage by neutral endopeptidases.[152]

In dogs, the ANP response to cardiopulmonary resuscitation consists of an elevation from baseline values of 55 ± 46 pg/ml during spontaneous circulation to 293 ± 73 pg/ml during cardiac arrest.[9] ANP was measured in plasma of patients with out-of-hospital cardiac arrest ($n = 14$) by an assay with a detectability limit of 50 pg/ml.[153] The peptide was detectable in 3 of 29 healthy controls and in 8 of 14 cardiac arrest patients, where ANP serum levels were also significantly higher ($p < 0.01$ vs. controls).[152] Furthermore, the distribution of ANP levels in cardiac arrest correlated significantly with the presence of a pressor response to adrenalin.[153] Thus, a significant pressor response (>3 mmHg) was observed among cardiac arrest patients who had low (undetectable) rather than measurable ANP levels.[153] As a result, the actual concentration of ANP had a strong predictive power for development of an adrenalin pressure response during cardiopulmonary resuscitation.[153]

Kidney

In addition to its important physiologic functions in controlling water, electrolyte, and acid base homeostasis, the kidney is also an endocrinologic organ. While the kidneys control the production of calcitriol, a hormone essential to regulation of calcium homeostasis, renin and erythropoietin are the most important hormones in the body's response to global ischemia and reperfusion.

Renin

The juxtaglomerular complex consists of macula densa cells in the initial portion of the distal tubule and juxtaglomerular cells in the walls of the afferent and efferent arterioles. Experimental studies suggest that volume depletion and low blood pressure decrease glomerular filtration and may thus slow the flow rate in the loop of Henle. This increases reabsorption of sodium and chloride cells in the ascending tubule and reduces the concentration of sodium chloride in the macula densa cells. Such a decrease in sodium chloride concentration, in turn, initiates a signal by the macula densa to stimulate renin secretion from the juxtaglomerular cells of the afferent and efferent arterioles, which are the major storage sites for renin. Plasma renin functions as an enzyme to increase the formation of angiotensin I, which is converted to angiotensin II. Finally, angiotensin II constricts the efferent arterioles, thereby increasing glomerular hydrostatic pressure and contributing to normalization of the glomerular filtration rate.[154]

Patients with out-of-hospital cardiac arrest presented with significantly increased renin concentrations when compared with a normal population (4.6 ng/dl; normal range: 1–3 ng/dl) (17 am), but elevation of plasma renin activity appeared to be restricted to those who subsequently achieved return of spontaneous circulation. In contrast, renin elevation was not observed in non-resuscitated patients (1.1 ng/dl; $p < 0.2$ vs. resuscitated patients).[20]

Erythropoietin

Erythropoietin is a glycoprotein hormone that is secreted from the kidney. Currently, it is not known exactly where erythropoietin is formed in the kidney, but production in the renal tubular epithelial cells seems to be likely. Whereas the kidneys produce approximately 90% of the circulating erythropoietin, the remaining portion of the hormone is synthesized in the liver. Anemia, global ischemia, and hypoxia are the major stimuli for production and secretion of erythropoietin. Interestingly also, local hypoxia in other parts of the body, but not in the kidneys, also stimulates secretion of renal erythropoietin, which suggests that there might be some non-renal sensor sending additional signals to the kidneys. Moreover, norepinephrine, epinephrine, and several prostaglandins can stimulate release of erythropoietin. Erythropoietin not only stimulates production of proerythroblasts from the hemopoietic stem cells in the bone marrow, but also increases the rate at which these cells pass through the different erythroblastic stages.[155]

Although no clinical or experimental data yet exist on erythropoietin in the immediate cardiac arrest period, it can be assumed that global ischemia induces a significant increase of erythropoietin secretion. In healthy individuals, increased plasma erythropoietin concentrations are observed within 2 hours of exposure to acute hypoxic or anemic conditions.[156, 157]

Gastrointestinal tract

Insulin

Insulin is synthesized as a prehormone in the β-cells of the islets of Langerhans in the pancreas. After posttranslational processing, insulin secretion is mainly regulated by plasma glucose levels. Elevated serum glucose concentrations cause increased glucose uptake in the pancreatic islet cells and led to an increase in cellular metabolism, causing an elevation of the ATP/ADP ratio. This leads to inhibition of the ATP-sensitive potassium channels, that again results in depolarization of the cell, leading to calcium influx and insulin secretion. Once released into the circulation, first into the hepatic circulation, insulin exerts its profound metabolic effects principally by stimulation of membranous insulin receptors. While in the liver, insulin increases the storage of glucose together with a decrease in hepatic glucose release, and in most non-hepatic tissues, insulin increases the glucose uptake by increasing the number of different plasma membrane glucose transporters (GLUT 1–4).

In addition to its central role in regulating glucose metabolism, insulin stimulates lipogenesis, diminishes lipolysis, and increases amino acid transport into cells. Moreover, insulin is known to alter the cellular content of numerous messenger RNAs and thus may control protein synthesis.

Despite marked hyperglycemia, plasma insulin levels progressively decrease during cardiac arrest.[158, 159] Although the hypoinsulinemia of cardiac arrest can be explained by decreased pancreatic blood flow, the absence of a decrease in pancreatic polypeptide (PP) levels does not support such an interpretation.[160] Moreover, hypoinsulinemia and hyperglycemia persist long after the return of spontaneous circulation.[158, 159] It is possible that the low splanchnic blood flow associated with CPR[1] masks systemic PP and/or insulin release. Washout increases failed to develop after return of spontaneous circulation, however.[61] These experimental results suggest that the endocrine digestive system

products are not actively released by the neuroendocrine response to the stress of cardiac arrest.

Intestinal hormones
A number of substances found in abundance in the enteric and pancreatic nervous system affect gastrointestinal motility and the composition of digestive secretions.[162] Among the factors with functional activity are the peptides pancreatic polypeptide (PP), neurotensin, substance P, and VIP. These peptides are also produced in the central nervous system and are secreted in response to both food and neural stimulation.[161] Immunohistochemical studies of nervous tissue have shown that these generically called gastrointestinal neuropeptides are localized to specific nerve endings. Thus, they are thought to have important roles as neurotransmitters.[161] However, synthesis of neuropeptides occurs not only in enteric nerves and central nerves, but also in immune cells of lymphoid tissues in the gut. Lymphocytes express receptors for most of these neuropeptides, but other immune cells, such as macrophages and mast cells, are capable of responding to the intestinal hormones. The neuropeptides differ in their ability to generate lymphoproliferative responses, cytokine production, and immunoglobulin synthesis. Some neuropeptides, particularly cholecystokinin, gastrin-releasing peptide, and neurotensin, appear to play an important role in maintaining mucosal immunity in patients who cannot receive enteral feeding during critical illness or after intestinal resection.[162]

The blood levels of gastrointestinal neuropeptides have been determined in experimental cardiac arrest to evaluate a possible involvement of the gastrointestinal tract in the neuroendocrine response to stress.[160] This protocol examined the effects of ventricular fibrillation and return of spontaneous circulation in sham-operated and adrenalectomized dogs.[160] Measurement of PP, VIP, neurotensin, and substance P showed that only VIP was affected by experimental manipulations. VIP increased significantly after cardiac arrest, but only in the sham-operated group.[160] Of note, adrenalectomy *per se* appeared to affect some of the peptides, since both plasma PP and VIP levels were higher in adrenalectomized than in sham-operated animals.[160]

Neuroendocrine response in the postcardiac arrest period

Pathophysiologically, reperfusion after cardiac arrest begins with return of spontaneous circulation and renewed supply of oxygen to the cells. Clinically, the reperfusion phase reflects the postcardiac arrest period of critical illness in the

emergency department and/or the intensive care unit. Although global ischemia is terminated in the reperfusion phase, formation of free oxygen radicals and systemic activation of the immune, coagulation, and neuroendocrine system contribute to ongoing cell dysfunction and death. Overwhelming systemic inflammation and multiple organ dysfunction are frequent complications during the reperfusion period after cardiac arrest, and have recently been summarized by the term "post-resuscitation disease."

Postresuscitation disease is associated with hemodynamic instability and multiple organ dysfunction that can contribute to adverse neurologic outcome.[163] The hemodynamic status of postresuscitation disease shares common features with septic shock and is typically associated with reversible myocardial dysfunction and vasodilation with low filling pressures requiring volume expansion, as well as inotropic and vasoactive drugs.[164] Moreover, the immunoinflammatory and coagulatory profile observed in patients after return of spontaneous circulation typically resembles that of patients with systemic inflammatory response syndrome or sepsis, thus characterizing a sepsis-like syndrome.[165, 166]

The distinct neuroendocrine response patterns in acute and prolonged critical illness

It was previously assumed that the stress response during the acute life-threatening event persisted throughout the course of critical illness, but this assumption has been disproved. During the initial response to an acute stress event, such as global ischemia and reperfusion, severe trauma, sepsis, or major surgery, the anterior pituitary actively releases its hormones into the circulation, while in the periphery, anabolic target organ hormones are inactivated. This response is thought to be beneficial and adaptive in order to overcome the acute disease. When critical illness becomes prolonged, however, pulsatile secretion of hormones becomes uniformly reduced and high stress hormone levels begin progressively to decrease to physiological or even subnormal values. In the pituitary gland, however, this is most probably due to several complex mechanisms, such as decreased (hypothalamic) stimulation, depletion of hormone stores, reduced activity of target tissues, and impaired anabolism.[167, 168]

Pituitary gland (anterior lobe)

ACTH
After the return of spontaneous circulation, plasma ACTH concentrations remain persistently elevated for at least 6

hours.[19] Indeed, in one study, ACTH did not decrease to a mean level of 65 pg/ml until 24 hours after cardiac arrest.[19]

Although high levels of ACTH and cortisol coexist in cardiac arrest,[18] a causative relationship between ACTH and cortisol has not yet been detected. Thus, comparison with healthy subjects showed that only 23% of postcardiac arrest intensive care unit samples had ACTH concentrations above the normal range, whereas serum cortisol was elevated in 86% of these samples.[18] Moreover, the overall correlation between cortisol and ACTH was low and did not even reach statistical significance ($r = 0.26$; $p > 0.2$).[18] The most important evidence against an ACTH-mediated stimulation of cortisol release is the response to a challenge with exogenous ACTH in out-of-hospital cardiac arrest. Testing of this population showed no serum cortisol response at either 6 or 24 hours after resuscitation, indicating that the adrenal was refractory to ACTH.[19] Therefore, it appears that adrenocortical ACTH release during and after cardiac arrest may be driven through a pathway other than ACTH, possibly including ET.[169] The reason for the low levels of ACTH during this phase of severe stress is unclear, although a role of ANP or substance P has been suggested.[169] It is interesting that additional evidence of perturbed ACTH secretion has been uncovered in critical illness, where ACTH levels are both not suppressed after administration of dexamethasone and also show an exaggerated response to its releasing factor (CRH).[170]

Therefore, global ischemia and in particular reperfusion is associated with dysregulated ACTH secretion and obvious loss of adrenal responsiveness to ACTH. The latter could represent specific adrenal dysfunction or just irregular adrenal perfusion. Regardless of the mechanism of the adrenal defect, the data indicate that plasma ACTH is biologically ineffective during cardiac arrest and the immediate postresuscitation phase. High levels of ACTH in the postresuscitation period can therefore only be taken as an indicator of the intensity of the neuroendocrine stress response.

β-*Endorphins*

No study so far has specifically evaluated β-endorphin concentrations in the post-resuscitation phase after cardiac arrest. Only Wortsman et al. have reported on elevated β-endorphin levels during the resuscitation phase after cardiac arrest.[18] Nonetheless, there are some reports on changes in β-endorphin concentrations during chronic and acute stress, such as shock or critical illness.[171] In an animal model of shock, β-endorphin was substantially increased during hemorrhage[172] and sepsis.[173] Similarly, Schmidt *et al.* observed significantly elevated β-endorphin levels that paralleled epinephrine and norepinephrine plasma concentrations during acute and chronic stress in

critically ill patients.[174] High levels of β-endorphin are assumed to modulate hemodynamic stability, neuroendocrine, and cytokine responses during stress, such as hemorrhagic shock.[175]

Of great interest with respect to cardiac arrest is an inhibitory effect of β-endorphin on plasma membrane calcium currents.[6] Recent studies have attributed such a possible neuroprotective effect of endogenous opioid peptides to the μ-receptor coupled to G(o)-type GTP-binding protein.[176, 177] β-Endorphin also acts as a direct vasodilator on the cerebral circulation and may thus have additional neuroprotective effects.[6] Nonetheless, administration of naloxone to dogs with cardiac arrest failed to have a beneficial effect on outcome.[7]

Melanocyte stimulating hormones

MSH concentrations have so far not been investigated in the postcardiac arrest period, although, several studies have reported a potential role of melanotropins in the treatment of global and local ischemia as well as reperfusion.

α-MSH and other ACTH fragments were reported to improve significantly blood pressure, pulse amplitude, and survival in otherwise fatal hemorrhagic shock in rats.[178] Similar effects of melanocortin peptides were observed in myocardial ischemia and reperfusion injury when MSH administration prevented free radical discharge, the development of severe ventricular arrhythmias, and an abrupt fall in systemic arterial resistance, with a consequent increase in survival.[179–181] The protective effects of melanocortins may be due to MC_3 receptor-mediated inhibition of oxygen free radical discharge and a reduced inflammatory response. Anti-inflammatory effects of MSH can be linked to stimulation of central melanocortin receptors,[182, 183] and to the inhibition of NF-κB activation.[184]

Based on the immune modulating effects of α-MSH, Delgado-Hernandez et al. have demonstrated that intrathecal injections of α-MSH can abrogate the inflammatory response in the peritoneum and lung after intraperitoneal administration of lipopolysaccharide, whereas intraperitoneal injections of similar dosages of α-MSH did not reduce this inflammatory response.[185]

Prolactin

Following the rapid increase in serum prolactin concentrations shortly after cardiac arrest, prolactin levels remain elevated throughout the postresuscitation period.[18] In one study, 5, 15, 30, and 60 minutes after restoration of spontaneous circulation, prolactin serum concentrations were significantly elevated (Fig. 7.3).[37] Cytokines again may play an important role. Although prolactin appears to have immunostimulatory properties in animal models as well

as in humans,[186–188] it remains unclear whether relative hyperprolactinemia during the initial phase of critical illness contributes to the activation of the inflammatory cascade.

In prolonged critical illness, serum prolactin levels are no longer elevated, and its secretory pattern is characterized by a reduction in the pulsatile fraction.[189, 190] It is not known whether the blunted prolactin secretion plays a role in the anergic immune dysfunction or the increased susceptibility of long-term critically ill patients to infections.[191, 192] In addition to endogenous suppressing factors, therapeutic interventions, such as dopamine infusion, may also reduce prolactin production and release. Thus, dopamine was shown to aggravate both T-lymphocyte dysfunction and impaired neutrophil chemotaxis.[188, 193, 194]

Growth hormone

Secretion of GH and its biologic activity have recently been studied in critically ill patients. In these subjects, circulating levels of GH were observed to be persistently elevated, whereas GH-binding activity in plasma was decreased.[8,195,196] These alterations of physiologic GH homeostasis have been interpreted as acquired peripheral resistance to GH.[195, 196]

During the initial phase of reperfusion and acute illness, serum levels of GH increase, and both peak and interpulse GH levels are elevated.[195, 197, 198] Although the physiologic mechanisms involved in the GH release in response to stress are yet to be elucidated, they may be similar to those observed in starvation, when an enhancement of circulating GH levels occurs in response to elevated levels of GH releasing hormone and absence of somatostatin.[199]

In the acute phase of critical illness, however, there is a reduction in circulating IGF-1 levels, despite elevated GH concentrations. Serum levels of IGF-binding proteins are concomitantly decreased.[196, 200] It has been hypothesized that these alterations in GH homeostasis during the initial phase of critical illness are mediated by inflammatory cytokines such as tumor necrosis factor α, and interleukin-1 and –6.[201] High concentrations of IGF-binding protein-1 in serum have been observed to correlate specifically with intensive care unit mortality in the chronic phase of critical illness, weeks before death.[202] The predictive value of a high serum IGF-binding protein-1 concentration was comparable to that of a high APACHE-II score.[203]

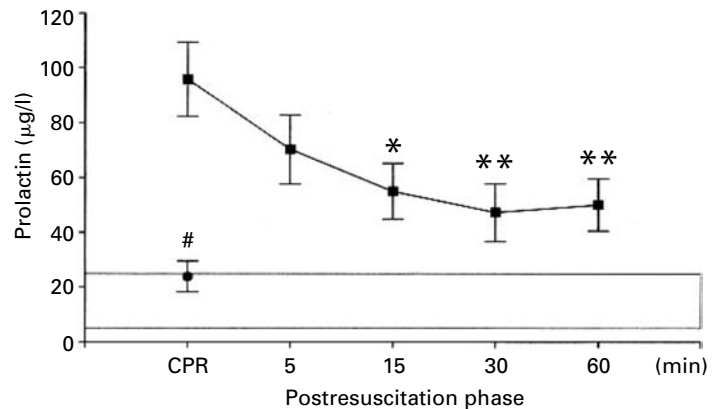
Although during prolonged critical illness, GH continues to be released in a high frequency pulsatile fashion, the amount of GH released with each pulse is significantly reduced.[189, 201, 204] Hence, mean GH serum levels during prolonged critical illness can reach values observed during health, but are substantially lower than are those during acute stress.[197] This relative deficiency of GH,


Fig. 7.3. Plasma prolactin concentrations during cardiopulmonary resuscitation (CPR) and within the first hour after restoration of spontaneous circulation.[37] Solid squares, values for resuscitated patients; solid circle, values for non-resuscitated patients; shaded rectangle, the normal range of prolactin. *P < 0.01 vs. CPR; **P < 0.001 vs. CPR; P < 0.0001 vs. values of resuscitated patients. Values are expressed as mean + / −SEM.

which is often observed in the chronic phase of critical illness, may help to explain the catabolic "wasting syndrome" which frequently occurs in long-term critically ill patients. Interestingly, a greater loss of pulsatility and regularity within the GH secretory pattern and lower IGF-1 serum concentrations have been observed in male compared with female patients.[168] Although the underlying disease process contributing to these alterations in the GH axis during prolonged critical illness are not completely understood, some authors suggested that a dysfunctional pituitary gland may fail to produce GH and thus contribute to low GH levels. Alternatively, reduced stimulation of somatotrophic cells by endogenous releasing factors, such as GH releasing hormone or ghrelin, as well as increased bioavailability of somatostatin, or endogenous or exogenous dopamine may decrease GH secretion.[201]

Clinical studies have shown that administration of GH improved negative nitrogen balance in patients with severe burns,[205] postsurgical patients,[206] patients in the early phase of sepsis,[207] and other critically ill patients.[208] Some small studies have even indicated that this improvement in nitrogen balance resulted in a shorter duration of mechanical ventilation, and a shorter stay in the intensive care unit or the hospital.[209–213] In an animal study of hemorrhagic shock after trauma and sepsis, however, administration of GH and IGF-1 resulted in more severe metabolic acidosis and impaired compensation of hemorrhage.[214] Similarly, a large multicenter study found that in patients with prolonged critical illness, high doses of GH

were associated with increased morbidity and mortality ($p<0.001$; relative risk of death for patients receiving GH was 2.4). Among survivors, both the intensive care and hospital length of stay were prolonged in the GH group,[215] Exact reasons for increased morbidity and mortality associated with high GH levels in critically ill patients remain unclear, but direct and indirect modulation of immune function appears to play an important role.[215]

Gonadotropins

The pituitary gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), act on the gonads (ovaries or testes) to determine sexual development and the reproductive potential. Secretion of gonadotropin is controlled by the hypothalamus and by a negative feedback mechanism triggered by testicular testosterone and ovarian estrogens.[3]

Although the gonadotropin hormonal response to cardiac arrest has not yet been studied, a significant amount of data has been collected on FSH and LH levels during critical illness. Patients in medical or surgical intensive care units usually present with a reversible impairment of gonadotropin secretion,[216] this effect is related to both the severity and duration of the underlying illness.[217] Studies in critically ill postmenopausal women, who normally have high FSH and LH levels, have shown suppressed gonadotropin concentrations.[218] In one study, levels somewhat below the expected concentrations of 30 IU/ml were found in 69% of patients, with concentrations frankly depressed (<5 IU/ml) in an additional 25%.[216] Since these patients did not respond to the hypothalamic peptide gonadotropin-releasing hormone, it was concluded that the gonadotropin secretory defect may involve predominantly the pituitary gland.[216] Studies in men with critical illness have shown comparable decreases in serum LH and FSH.[216, 219]

Endogenous dopamine or opiates may be involved in the pathogenesis of hypogonadotropic hypogonadism, while iatrogenic factors such as exogenous dopamine and opioids may further diminish blunted LH secretion.[219, 220] Animal data suggest that prolonged exposure of the brain to interleukin-1 may also contribute by suppressing synthesis of LH releasing hormone.[221]

Nevertheless, these abnormalities are reversible, and patients tested after recovery had normal gonadotropin concentrations.[217] In some types of less severe acute stress, such as minor surgical procedures or short-term fasting, gonadotropin levels were not found to be decreased.[222, 223] Therefore, it may be concluded that reproductive hormones are generally suppressed during chronic stress of high intensity, but not acute stress of minimal intensity.

The extent of the impairment of gonadotropin secretion has been reported to correlate with patient outcome. Patients presenting with hypogonadotropism during critical illness were more severely ill, had a longer duration of treatment in intensive care units and hospitalization as well as a higher incidence of parenteral hyperalimentation, lower serum albumin levels, and a higher mortality when compared with patients presenting with gonadotropin levels within the expected serum range (>30 IU/L).[216]

Neurohypophysis (posterior lobe)

Vasopressin

Thus far, vasopressin serum levels have not yet been examined during critical illness after cardiac arrest. However, several recent studies have focused on the evaluation of the role of endogenous vasopressin levels during septic shock.

As animal and human studies both showed, plasma vasopressin levels demonstrate a biphasic pattern during septic shock. In early septic shock, vasopressin concentrations significantly increase, while they begin to decline as early as 6 hours after the onset of septic shock. At 36 hours, vasopressin concentrations were found to be inappropriately low for the degree of hypotension in one-third of patients, and may thus represent a relative deficiency of vasopressin.[224] Similarly, Landry and coworkers have repeatedly observed inadequately low vasopressin concentrations in the course of septic shock,[225] vasodilatory shock after cardiac surgery[226] and cardiac transplantation,[227] late hemorrhagic shock,[228] as well as in hemodynamically unstable organ donors.[229]

Low vasopressin levels are most likely due to impaired vasopressin secretion, rather than increased metabolism as vasopressinase levels remain undetectable during established septic shock.[230, 231] A single study of three patients reported undetectable levels of vasopressinase in plasma, which were attributed to renal and hepatic dysfunction commonly seen in septic patients.[231] Hence, proposed mechanisms for decreased serum vasopressin levels in late septic shock include exhaustion of pituitary stores caused in response to baroreceptor-mediated release, autonomic dysfunction, inhibitory effects of increased concentrations of norepinephrine in serum, and increased release of nitric oxide in the posterior pituitary.[225, 230, 232] It is known that neurohypophyseal stores of vasopressin may easily be depleted after profound osmotic stimulation,[229, 233] and probably also after profound baroreflex stimulation. In support of this hypothesis, immunohistochemical analysis of the neurohypophysis in dogs revealed that vasopressin all but disappeared after 1 hour of severe hemorrhagic hypotension (Fig. 7.4).[230] Moreover, sepsis and a massive
Fig. 7.4. Vasopressin immunoreactivity in the neurohypophysis in dogs. [230] (a) section of the neurohypophysis from a normal dog. There is staining of the macrovesicles with antivasopressin serum, a reaction indicative of replete stores of vasopressin. (b) section of the neurohypophysis from a dog after severe hemorrhagic hypotension (mean arterial pressure, ≤ 40 mm Hg) for 1 hour. There is minimal staining with antivasopressin serum. For both panels, paraformaldehyde-fixed pituitary glands were sequentially incubated with a vasopressin monoclonal mouse antibody, a horse antimouse IgG conjugated to biotin, and avidin-conjugated horseradish peroxidase and stained with 3,3-diaminobenzidine in the presence of hydrogen peroxide (x 320).

surge of proinflammatory cytokines, as also occurs during postresuscitation disease, may lead to hypothalamic dysfunction and nitric oxide-mediated impairment of vasopressin synthesis, transport, storage, and release.[234]

Serum vasopressin concentrations 24 hours after admission to the intensive care unit were significantly higher in 239 mixed critically ill patients when compared with healthy controls $(11.9 \pm 20.6$ vs. 0.92 ± 0.38 pg/ml, $p < 0.001$).[235] There was no detectable relationship between endogenous vasopressin levels and any specific hemodynamic index, indicating that endogenous AVP concentrations contribute only little to the maintenance of arterial blood pressure in critical illness. Whereas patients with hemodynamic dysfunction still had a detectable correlation between AVP serum concentration and the incidence of cardiovascular function $(p = 0.042)$, however, patients in shock completely lost such a relationship $(p = 0.334)$. This suggests that the physiologic association between hemodynamic parameters and AVP serum concentrations is substantially altered in critically ill patients with hemodynamic dysfunction, and completely lost in patients with shock. Additionally, during this early phase of critical illness, only 32/239 patients (13.4%) fulfilled the criteria for relative vasopressin deficiency. Absolute vasopressin deficiency, defined as serum vasopressin concentrations <0.83 pg/ml, was detected in only four study patients (1.7%) and was not associated with diabetes insipidus, but with a low degree of organ dysfunction and beneficial patient outcome.

Leptin

Adipocytes are the body's main site of leptin production and secretion. Circulating leptin is known to correlate positively with fat mass and body weight in healthy volunteers, as well as in subjects with obesity and with conditions of chronic undernutrition.[236, 237] Adipocytes have been shown to release leptin in a pulsatile fashion, following a marked circadian rhythmicity with elevated nocturnal values.[238, 239] Factors known to influence leptin release from adipocytes in man are insulin, GH, IGF-1, thyroid hormones, glucocorticoids, cytokines, and β-adrenoreceptor agonists.[240–243]

Leptin is not only a central hormone in appetite control and regulation of energy expenditure,[244] but has recently emerged as an important regulator of T-cell-dependent immunity.[245, 246] Furthermore, as a cytokine, leptin affects thymic homeostasis and, similar to other pro-inflammatory mediators, it promotes cytokine production.[247] Leptin exerts its effects by stimulation of its receptors in hypothalamic neurons. Its peripheral effects are mainly mediated by melanocortins.[248]

Recent animal and human studies have suggested that leptin secretion is closely related to the function of the hypothalamic–pituitary–adrenal axis and the immune system, both of which crucially influence the course and outcome of critical illness. Mean leptin plasma concentrations were threefold higher $(18.9 \pm 4.5$ ng/ml) in critically ill patients when compared to those in healthy controls $(3.8 \pm 1$ ng/ml; $p < 0.05$). Patients surviving septic shock had significantly higher leptin plasma concentrations than did non-survivors $(25.5 \pm 6.2$ vs. 8 ± 3.7 ng/ml; $p < 0.01$).[249] Another study demonstrated that leptin serum concentrations in critically ill patients with sepsis lost their correlation with body mass index, but correlated significantly with serum IGF-1 concentrations.[250] Similarly, Carlson

et al. found no correlation between serum leptin concentrations and resting energy expenditure or insulin sensitivity in human sepsis.[251]

Thyroid gland

Thyroid hormones
Similar to the acute cardiac arrest period, thyroid hormone levels have been found to be low during reperfusion, indicative of a continuing hypothyroid state in the immediate post-cardiac arrest period. Twelve hours after a 9-minute cardiac arrest period in dogs, total and free T4 as well as T3 serum concentrations were found to be significantly decreased when compared to pre-arrest levels. Reverse T3 concentrations were elevated, indicating a peripheral metabolizing block of T4 during the first 24 hours after cardiac arrest.[75, 252]

During the later course of critical illness, peripheral hypothyroidism can advance to transient central hypothyroidism characterized by low total T4 and T3 levels, as well as low serum TSH concentrations.[253] In particular, this phenomenon has been observed in patients with sepsis and referred to as the "euthyroid sick syndrome,"[254] or "non-thyroidal illness syndrome."[253] Although the exact mechanisms of such a hypothyroid state in severe illness is not yet clear, several authors have proposed that decreased peripheral deiodination of T4 and reduced binding by plasma thyroid hormone binding proteins might explain the observed changes in thyroid hormone homeostasis.[255] Clinically, reduced plasma concentrations of T3 and T4 may cause ileus, insulin resistance, impaired triglyceride levels, reduced inotropy, and reduced protein synthesis and metabolism in muscle.[197]

Studies have repeatedly shown that hypothyroxinemia after cardiac arrest and during sepsis was a powerful predictor of mortality in critically ill patients (Fig. 7.5).[256] Notably, free T4 concentrations have been observed to be tightly associated with poor outcome.[257] Thus, T4 levels below 3 mg/dl after admission to the intensive care unit were reported to correlate with a 84% mortality rate. Mortality decreased with increasing T4 levels.[257]

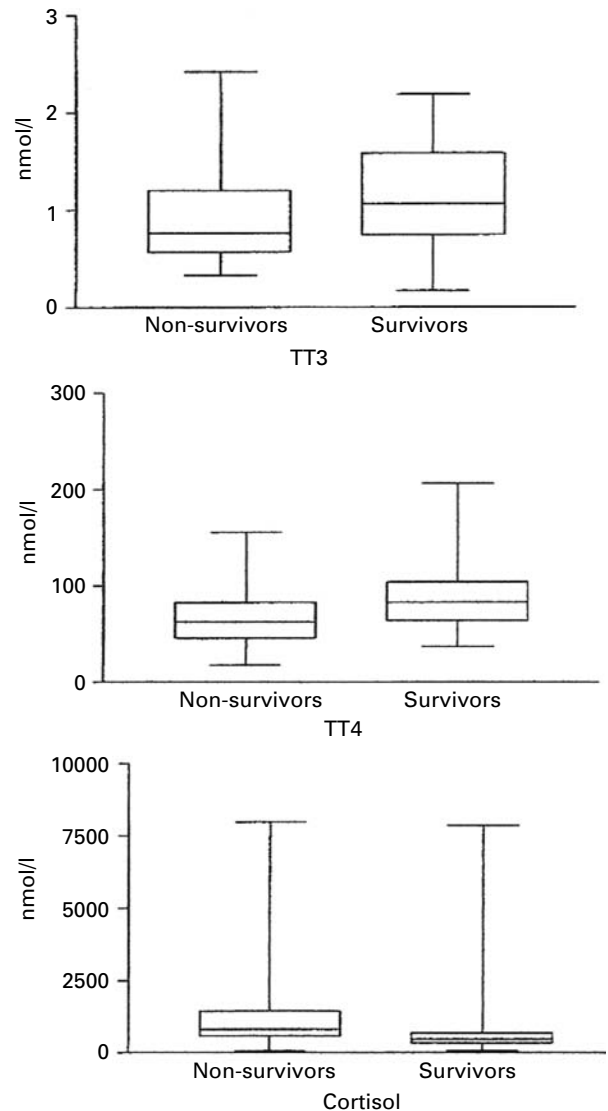
In view of these results, several attempts have been made to substitute thyroid hormones and evaluate changes in patient outcome resulting from such an intervention. One randomized, double-blind study evaluating T3 substitution therapy in cardiac surgery patients demonstrated improved hemodynamic stability, as well as a decrease in postoperative ischemia in patients treated with T3.[258] Similarly, two studies performed in animals after 9 minutes of cardiac arrest reported improved cardiocirculatory and neurologic function after administration of L-T4.[252, 259]


Fig. 7.5. Thyroid hormone concentrations measured on admission to ICU in survivors and non-survivors (range, 25th, 50th, and 75th percentiles).[256]

Administration of thyroid hormones was associated with a significant increase in systemic oxygen consumption.[260] Other studies found that neither hemodynamic variables nor morbidity or mortality were different between thyroid hormone-substituted and not substituted patients.[261, 262] Many authors, however, argue that administration of thyroid hormones to critically ill patients may inhibit TSH secretion and suppress an important mechanism for normalization of thyroid function during recovery.[263]

In conclusion, there is currently no scientific evidence to support subsitution of thyroid hormones in critically ill patients after cardiac arrest. At present, development of

the so-called "euthyroid sick syndrome" can simply be interpreted as an indicator of the severity of disease.

Calcitonin

During the first 24 hours after admission to the intensive care unit, critically ill patients were found to have significantly increased calcitonin serum concentrations. In particular, patients suffering from sepsis had higher calcitonin levels than did non-septic patients ($p < 0.004$). Moreover, calcitonin levels were not only correlated with the APACHE II and the Multiple Organ Failure Score, but also demonstrated a positive correlation with length of stay in the intensive care unit. In the same study, survivors had significantly higher calcitonin concentrations than did non-survivors ($p < 0.03$). Interestingly, serum calcitonin concentrations were not related to the degree of total serum calcium concentrations.[264] In critically ill children, basal serum calcitonin levels were significantly increased and correlated with low concentrations of ionized calcium in blood.[265]

Parathyroid glands

In critically ill patients, both increased and decreased parathyroid hormone concentrations have been reported.[266–268] Carlsted *et al.* reported on significantly increased serum parathyroid hormone levels in a mixed critically ill patient population.[269] In this study, parathyroid hormone levels were related to the severity of disease and also to patient outcome. Similar to a more recent publication,[270] increased parathyroid hormone levels were particularly evident in two specific disease groups, patients with sepsis and patients undergoing major surgery (50–70% of healthy controls). Regardless of the nature of the critical illness, the elevation of parathyroid hormone serum concentrations during the early period of intensive care treatment was an unfavorable prognostic sign.[269]

In studies performed in healthy subjects, catecholamine infusion resulted in altered parathyroid hormone levels, most probably due to a decrease in circulating calcium levels.[270] Nonetheless, increased catecholamine serum concentrations, such as typically found in critically ill patients, could exert a direct action on parathyroid hormone secretion, as β-adrenergic receptors have been detected on parathyroid cells.[271–273] Furthermore, the systemic inflammatory response which inevitably occurs to a certain extent during sepsis or after major surgery, but also after resuscitation from cardiac arrest, seems to further influence homeostasis of parathyroid hormone. Tumor necrosis factor-α and interleukin-1 may impair the responsiveness to parathyroid hormone by downregulating parathyroid hormone receptors in osteoblast-like cells.[273] Interleukin-6

was shown to be a downstream effector of parathyroid hormone, which stimulates bone resorption.[274, 275]

Adrenal glands

Catecholamines

Plasma epinephrine, norepinephrine, and dopamine concentrations are markedly increased during the first 60 minutes after return of spontaneous circulation, even when exogenous epinephrine is not administered during resuscitation efforts. Peak levels of endogenous catecholamines are observed shortly after restoration of circulation and are probably due to "washout" of catecholamines released after arrest onset and during global ischemia.[276]

To date, only one other study evaluated the course of plasma catecholamine levels following conventional resuscitation that included the injection of epinephrine. Prengel and coworkers described the elimination kinetics of epinephrine in patients successfully resuscitated from out-of-hospital cardiac arrest. They failed to demonstrate a correlation between non-invasively determined hemodynamic variables, such as heart rate or mean arterial blood pressure, or glucose and lactate and measured serum epinephrine and norepinephrine concentrations, which consisted of endogenous and exogenous catecholamines.[277]

High plasma catecholamine concentrations persist for prolonged periods after the initial epinephrine and norepinephrine surge and appear to be driven by postresuscitation hypotension. The adrenergic response not only leads to a compensatory increase in systemic vascular resistance, but also to detrimental effects on cardiac function during the postresuscitation period. Accordingly, Niemann *et al.* reported on a negative correlation between norepinephrine plasma concentrations and left ventricular stroke work.[276] This potentially detrimental effect of a presumed adrenergic compensatory response shares some close similarities with chronic congestive heart failure.[278, 279] As in patients with chronic heart failure, a recent investigation examining the effects of β-blockade during the early postresuscitation phase could prove to have a beneficial effect on myocardial function.[280]

After the immediate reperfusion period and postresuscitation phase, catecholamines remain significantly elevated in critically ill patients when compared to healthy controls.[281] Particularly high plasma epinephrine and norepinephrine concentrations have been reported during endoxemia and septic shock.[282] Boldt and colleagues reported significantly higher mortality rates in critically ill patients with high concentrations of plasma

catecholamines. While epinephrine and norepinephrine plasma concentrations were elevated in non-survivors on the day of admission to the intensive care unit and were tremendously increased during the days following, plasma catecholamine concentrations significantly decreased in critically ill patients who survived.[283] Interestingly, in another study analyzing patients with septic shock, not only the absolute height of plasma catecholamine concentrations, but also the adrenal response to a head-up tilt was predictive of poor outcome. During a 60-degree head-up tilt, the increase in plasma norepinephrine levels was significantly higher in survivors than in non-survivors, suggesting an adequate response of the sympathetic nervous system including the adrenal medulla.[284]

Cortisol

A recent study examined the incidence and prognostic value of relative adrenal insufficiency after cardiac arrest. Out of 64 patients hospitalized in the intensive care unit after successful resuscitation of out-of-hospital cardiac arrest, 33 patients (52%) fulfilled the criteria for relative adrenal insufficiency defined as an incremental response of less than 9 μg/dl 60 minutes after administration of 250 μg of tetracosactide. Baseline cortisol concentrations were higher in patients with adrenal insufficiency than in patients without (41 vs. 22.8 μg/dl; $p = 0.001$). A long interval before initiation of cardiopulmonary resuscitation was associated with occurrence of relative adrenal insufficiency indicating a pathogenetic role of hypoxia. Presence of adrenal insufficiency after cardiac arrest was identified as a poor prognostic factor of shock-related mortality ($p = 0.02$).[285]

Adrenal function appears to be strongly dependent on age during critical illness. Adrenal insufficiency occurred 2.5 times more frequently in patients older than 55 years than in younger patients.[286] While patients older than 60 years had paradoxically higher serum cortisol concentrations than did patients younger than 30 years, their response to ACTH stimulation was significantly smaller on both low (1 μg) and standard dose (250 μg) tests.[287]

The mechanisms of adrenal insufficiency after cardiac arrest or major surgery as well as during severe sepsis and septic shock are complex and not yet fully understood. The systemic inflammatory response syndrome, which to a certain extent always accompanies the reperfusion period of global ischemia, results in the release of proinflammatory cytokines (TNF-α, IL-1, IL-6), which in vitro suppress the pituitary response to the hypothalamic corticotropin releasing hormone,[288, 289] and the release of cortisol from ACTH-stimulated adrenocortical cells.[290, 291] Nevertheless, although cortisol synthesis and secretion are impaired

during critical illness, it appears that the function of the entire hypothalamic-pituitary–adrenal axis is also severely impaired.

Moreover, CBG, a liver-derived plasma protein that is the main carrier protein for cortisol (>90%), also appears to be another important regulator of the amount of biologically free cortisol during critical illness.[292] While during the initial phase of reperfusion in septic shock and multitrauma patients, CBG levels were found to be extremely low, reflecting higher levels of free cortisol, protracted critical illness is characterized by increasing and normalizing CGB levels, independent of clinical parameters.[293] Similar results have been observed in patients after major surgery.[294] Several mechanisms have been proposed to explain CBG depletion during reperfusion after shock: increased metabolic clearance, decreased synthesis in the liver, and capillary leakage.[295, 296] In view of the influence of hypoproteinemia on total cortisol concentrations, measurement of free cortisol levels or calculation of a correction factor, the free cortisol index (total cortisol/CBG concentration), has been suggested for assessment of adrenal function.[293, 294]

In the postresuscitation period, suppression of adrenal function can also be caused and aggravated by administration of drugs. For example, transient adrenal insufficiency has been reported after high-dose fluconazol therapy and more than one hypnotic dosage of etomidate.[297]

Renin–angiotensin–aldosterone system

Plasma aldosterone concentrations were reported to be increased in approximately two thirds of critically ill patients when compared to healthy controls. Secondary hyperaldosteronism in the early phase of critical illness, is hypothesized to be mainly due to the stimulatory effects of ACTH or ACTH-related peptides. Thereby, it is considered to be an epiphenomenon of the stress mechanisms of acute critical illness.[298]

Nonetheless, a significant portion of critically ill patients (up to 21% in one study) present with a dissociation of plasma renin activity and aldosterone production.[299] Hyper-reninemic hypoaldosteronism is characterized by normal metabolic clearance of aldosterone, normal production of angiotensin II, appropriate hypercortisolemia, and decreased levels of 18-hydroxycorticosterone, which is an aldosterone precursor. Clinically, this syndrome was reported to be frequently accompanied by hypotension and hemodynamic instability.[300] Such a dissociation is most probably not due to an impairment of angiotensin II production or changes in plasma ACTH or potassium. Pathophysiologically, tumor necrosis factor α and interleukin 1 as well as other cytokines (IGF-1, transforming growth factor β), which are known to stimulate renin

activity, but inhibit aldosterone secretion, may contribute to this state of hyper-reninemic hypoaldosteronism.[301] Some authors have reported increased severity of the underlying disease and increased mortality associated with this syndrome.[299, 300, 302]

In light of evidence of decreased adrenal androgen secretion during severe illness, the dissociation of renin and aldosterone may represent another adrenal adaptation mechanism to promote cortisol production. Nonetheless, inappropriately low aldosterone levels were reported to be associated with high mortality during critical illness. Interestingly, a recent prospective study evaluating the effects of hydrocortisone substitution on patient outcome in patients with septic shock combined hydrocortisone with fludrocortisone substitution (50 μg) and reported a significant improvement in patient survival.[303]

Gonads

The neuroproductive axis is also significantly suppressed during critical illness. The degree of both central and peripheral suppression of the gonads in acute illness has been demonstrated to be related to the severity of the underlying disease. Such a suppression was not attributed to other factors, as age, drugs, head trauma, or hepatic failure, which are otherwise known to alter sexual hormone concentrations independently from critical illness.[217] Both men and women uniformly develop transient hypogonadotropic gonadal insufficiency during critical illness.[304]

Testes

Serum testosterone levels during critical illness fall to prepubertal levels secondary to decreased secretion of gonadotropins and a decreased Leydig cell response to LH. At the same time, serum estrogen concentrations rise as the result of an increased rate of peripheral aromatization.[305] The low testosterone concentrations are not due to reduced sex-hormone binding capacity.[304] Studies evaluating the therapeutic potential of androgen subistution in prolonged critical illness failed to demonstrate conclusive clinical benefit.[306]

Ovaries

Studies of serum levels of female gonadal hormones during critical illness in postmenopausal women showed increased levels of estrone and estradiol, whereas testosterone levels were decreased.[13] Since critical illness suppresses gonadotropin levels,[13, 216] it was suggested that the increase in gonadal hormones in this population reflects an adrenal rather than ovarian origin, presumably a consequence of excess ACTH.[13]

Non-conventional endocrine organs

Endothelium

Plasma immunoreactive endothelin (ET) concentrations in patients following cardiac arrest (5.4 ± 2.3 pg/ml) were not different from those in healthy subjects (5.1 ± 1.2 pg/ml). There was no significant difference in ET concentrations between survivors and non-survivors.[307] However, systemic ET were found to increase during hypoperfusion and all shock forms.[308–310] Particularly high ET serum levels have been reported during septic shock.[310,311] The possible involvement of the ET system in human septic shock is further supported by a clear positive correlation of ET plasma levels and morbidity and mortality in patients with sepsis.[312, 313]

Interestingly, critically ill patients with high ET levels did not have increased systemic vascular resistance. This was hypothesized to be due to prostaglandin E2-mediated vasodilation predominating over ET-mediated vasoconstriction.[308] Furthermore, activation of the ET system has been associated with several pathophysiological conditions complicating septic shock, such as acute respiratory distress syndrome, cardiac dysfunction, splanchnic hepatic and renal hypoperfusion, as well as disseminated intravascular coagulation.[116] Accordingly, high ET-1 levels during the initial phase of critical illness appeared to be a sensitive predictor of death from septic shock.[314]

Recent evidence suggests that persistently high ET serum concentrations in the first 24 hours after cardiac arrest were associated with increased cerebrovascular resistance and delayed cerebral hypoperfusion.[315] Supporting this hypothesis, application of the ET_A receptor antagonist BQ123 during the early reperfusion period after cardiac arrest in rats shortened postischemic cerebral hypoperfusion and accelerated the restoration of the cerebrovascular CO_2 reactivity and recovery of the electrophysiologic function (Fig. 7.6).[316] Furthermore, in the same model, blockage of the ET_A receptor 15 minutes after return of spontaneous circulation following a 12-minute period of cardiac arrest significantly improved neurologic outcome.[317]

Heart

In a study including 401 patients with out-of hospital cardiac arrest, BNP concentrations on arrival at the emergency room correlated well with subsequent patient outcome. Increasing concentrations of BNP were predictive of an increased risk of death in hospital and unfavorable neurologic outcomes at the time of hospital discharge. A multiple logistic regression analysis revealed BNP to be a strong independent factor in survival to hospital discharge.
Fig. 7.6. Measurement of cerebral blood flow by laser-Doppler flowmetry during resuscitation from 12 min of cardiac arrest.[316] Comparison of untreated animals (*filled circles*) with animals treated with the selective endothelin type A antagonist BQ123 (*unfilled circles*) at 15 min after return of spontaneous circulation. Note initial hyperperfusion followed by delayed postischemic hypoperfusion in both groups but faster recovery from postischemic hypoperfusion in treated animals (mean ± sd, statistical significance between treated and untreated groups *P < 0.05, two-tailed analysis of variance for repeated measurements).

Serum concentrations of 100 pg/ml were determined to be the optimal cut-off point for BNP regarding survival to hospital discharge (Fig. 7.7).[318]

Similarly, patients with myocardial dysfunction due to sepsis or septic shock exhibited significantly higher serum BNP concentrations than did patients with adequate myocardial function. BNP levels were also significantly higher on days two and three in patients who died during their intensive care unit stay ($p < 0.05$).[319] In contrast, a study analyzing ANP and BNP plasma concentrations in 178 mixed critically ill patients reported increased plasma concentrations of both hormones compared with those in healthy controls (ANP, 14.3 ± 5.8 vs. 8.8 ± 3.2 pmol/l, $p < 0.05$; BNP, 26.2 ± 10.7 vs. 4.6 ± 2.8 pmol/l, $p < 0.0001$). The relative increases in ANP plasma levels were comparable in all diseases. BNP concentrations, by contrast, showed a wider variation, with largest concentrations in patients undergoing cardiac surgical procedures and with subarachnoid hemorrhage. In this study population, serum concentrations of ANP and BNP did not correlate with the severity of the disease and could not predict patient outcome.[320] Although another study in 78 mixed critically

Fig. 7.7. Association between the B-type natriuretic peptide level and the rate of survival to hospital discharge (primary end point) in all patients and in selected subgroups.[317] CPR, cardiopulmonary resuscitation; ER, emergency room; ROSC, return of spontaneous circulation; VF, ventricular fibrillation; VT, ventricular tachycardia. The range of B-type natriuretic peptide levels was as follows: 2.0–33.8 pg/ml (quartile 1), 33.9–152.0 pg/ml (quartile 2), 152.1–392.0 pg/ml (quartile 3), and 392.1–2620.0 pg/ml (quartile 4). *P* values are for the trend within each group.

ill patients indicated that BNP serum concentrations 24 hours after admission to the intensive care unit were significantly higher in patients with sepsis or septic shock ($p = 0.02$), in patients ≥ 65 years ($p = 0.04$), and in patients with raised serum creatinine concentrations ≥ 110 μmol/l ($p = 0.02$), BNP serum levels neither correlated with intensive care unit nor with hospital mortality.[321]

Kidney

Renin

During critical illness complicated by persistent hypotension, serum renin activities were found to be significantly elevated.[300] In 44 patients critically ill with septic shock, plasma renin activity on admission to the intensive care unit was significantly increased. Although in survivors, plasma renin activity significantly decreased following intensive care therapy, no change was observed in non-survivors.[322]

Erythropoietin

A recent clinical trial analyzed the acute phase response together with the course of erythropoietin plasma concentrations in 22 patients after cardiac arrest. During the intensive care unit stay after return of spontaneous circulation, plasma erythropoietin levels (mean values in healthy, non-anemic volunteers, 17.9 mU/ml; 95% CI, 11–31 mU/ml) increased from 23.5 after cardiac arrest to 26.5 (day 1), 25.5 (day 2), and 31 mU/ml (day 3), but this increase was not statistically significant ($p > 0.05$). At the same time, hemoglobin concentrations fell gradually from a median of 14 g/dl on admission to 12.8 (day 1), 11.6 (day 2), and 10.7 g/dl on day 3. Plasma erythropoietin concentrations in patients surviving with or without a neurologic deficit were not different, but in non-survivors erythropoietin levels were significantly higher on the third day of intensive care therapy after cardiac arrest than in survivors.[323]

Similarly, in 44 patients with septic shock, non-survivors had significantly higher serum erythropoietin levels than did survivors on admission to the intensive care unit.[322] Abnormally high plasma erythropoietin levels have been reported to be a negative prognostic indicator in patients suffering from septic shock in other studies.[324, 325] Analysis of receiver operating characteristic curves showed that a cutoff for serum erythropoietin levels of 50 mU/ml on admission was optimal for predicting death. While in survivors from septic shock, plasma erythropoietin was negatively correlated with blood hemoglobin concentrations ($p < 0.001$), no such correlation was observed in non-survivors.[322]

Although initial plasma erythropoietin levels were significantly increased in a mixed medical and surgical patient population in an intensive care unit, erythropoietin concentrations rapidly decreased thereafter. In the period of prolonged critical illness, erythropoietin diminished to levels that were indistinguishable from those in patients with non-renal anemia.[326] Regardless of the underlying disease, the erythropoietin response to anemia in intensive care patients, particularly during protracted critical illness, seems to be severely blunted.[325, 327] Inadequate erythropoietin production is therefore likely to contribute to the development of anemia in long-term critically ill patients. This phenomenon is assumed to be particularly pronounced in patients with concomitant acute renal failure or sepsis.[327]

Gastrointestinal tract

Insulin

Critical illness, including the postresuscitation phase, is characterized by hyperglycemia and glucose intolerance associated with hyperinsulinemia and insulin resistance.[328] These metabolic alterations have been summarized under the rubric "diabetes of injury."[329,330] Pathophysiologically, the neuroendocrine stress response to global ischemia and/or reperfusion and the systemic activation of the immune system are held responsible for the "diabetes of injury."[330] While catecholamines, cortisol, glucagon, and GH were all shown to affect glucose and insulin metabolic pathways directly, pro-inflammatory cytokines influence glucose homeostasis indirectly, by altering insulin receptor signaling.[330–333]

Until recently, the "diabetes of injury" was widely accepted as a beneficial adaptive response to severe disease and, as such, to be important for survival. In particular, the overall increase in glucose turnover and the fact that hyperglycemia persists despite abundantly released insulin were considered arguments in favor of tolerating moderately elevated blood glucose levels during critical illness. Consequently, blood glucose concentrations of 160–200 mg/dl were recommended to maximize cellular glucose uptake while avoiding hyperosmolarity.[334]

In 2001, however, a large, prospective, randomized, single-center study impressively demonstrated that titration of insulin infusion during intensive care to strict normoglycemia (90–110 mg/dl) reduced the mortality of critically ill patients when compared with conventional insulin treatment aimed to prevent blood glucose levels >200 mg/dl (20.2% vs. 10.6%, $p = 0.005$) (Fig. 7.8).[335] The benefit of intensive insulin therapy in critically ill patients was particularly apparent among patients with prolonged critical illness that required intensive care for more than 5 days, with mortality reduced from 20.2% to 10.6%.
Fig. 7.8. Kaplan–Meier curves showing cumulative survival of patients who received intensive insulin treatment or conventional treatment in the intensive care unit (ICU).[334] Patients discharged alive from the ICU (a) and from the hospital (b) were considered to have survived. In both cases, the differences between the treatment groups were significant (survival in ICU, nominal $P = 0.005$ and adjusted $P < 0.04$; in-hospital survival, nominal $P = 0.01$). P values were determined with the use of the Mantel–Cox log-rank test.

Moreover, strict control of blood glucose levels reduced the incidence of complications, such as severe nosocomial infections, acute renal failure, liver dysfunction, critical illness, polyneuropathy, muscle weakness, and anemia and thus reduced the time that patients were dependent on intensive care. A recently published report confirmed the survival benefit of implementing tight blood glucose control with insulin in a mixed medical-surgical intensive care population.[336]

Intestinal hormones

Thus far, no study has examined plasma concentrations of intestinal hormones in the postresuscitation period after cardiac arrest. Since postresuscitation disease shares similarities with overwhelming systemic inflammation and sepsis, however, it was thought that observations made in animals and patients with sepsis might indicate comparable changes in the postcardiac arrest period.

During endotoxin-induced shock in animals, there are consistent data to show significantly increased plasma concentrations of cholecystokinin and VIP.[337–339] Since VIP is a potent vasodilator, it was postulated to contribute to vasodilatation and hypotension in septic shock. Although Broner *et al*. had established that infusion of VIP resulted in profound hypotension and lactic acidosis,[339] another animal study suggested that endogenous VIP levels may not be responsible for the vasodilatation during sepsis.[337]

In this study, during the first 24 hours of sepsis, VIP was released without a concomitant decrease in blood pressure, suggesting that during septic shock it was released by a direct mechanism rather than as a result of hypotension. Similarly, during peak VIP release, which occurred 2 to 4 hours after induction of sepsis, no decrease in systemic vascular resistance or mean arterial pressure was noted.[337] Zamir *et al*. showed that proinflammatory cytokines were involved in the release of intestinal peptides during sepsis and systemic inflammation. Whereas interleukin-1 did not affect plasma concentrations of gastrin, VIP, peptide YY, and secretin, tumor necrosis factor α induced a significant increase in peptide YY levels.[340]

In human sepsis, a similar increase in VIP serum concentrations was found in five patients with fulminant septic shock. Although none of these patients had VIP levels >2.5 pM before the septic episode, VIP increased >4 pM during the septic episode. Sequentially collected samples from three patients showed rapidly declining VIP levels after initiation of adequate antibiotic and fluid treatment.[341]

Summary

It appears that the differences between the neuroendocrine response to global ischemia/cardiac arrest and

reperfusion/early phase of critical illness are more quantitative than qualitative. During both phases, all components of the neuroendocrine system are significantly altered to adapt to maximal stress. Whereas secretion of adrenomedullary hormones, cortisol, vasopressin, and the pituitary hormones prolactin, ACTH, β-endorphin, β-lipoprotein, and probably GH is significantly increased, thyroidal, gonadal, and endocrine gastrointestinal hormones are not released during the intense stress of cardiac arrest and global ischemia. Likewise, adrenal androgens and presumably mineralocorticoid secretions do not participate in the acute stress response, whereas secretion of pituitary gonadotropin may be actively impaired. Interestingly, during cardiac arrest, but not during critical illness, 73-MSH serum concentrations are elevated significantly. Cardiopulmonary resuscitation itself may be the mechanism for the release of ANP that may simply reflect atrial distension. Whereas most endocrinologic systems are activated during cardiac arrest and also in the early phase of critical illness, it appears that the neuroendocrine system is uncoupled from its stimulators during chronic stress. Thus, during prolonged critical illness, return of stress hormones to physiologic values often results in the occurrence of relative and absolute hormone deficiencies. Immune suppression, limited organ reserves, and severe catabolism may originate in part from these profound changes in the neuroendocrine response to global ischemia and reperfusion during prolonged critical illness.

When summarizing the results of most studies, an adequate neuroendocrine response to cardiac arrest and during the postresuscitation period appears to be tightly connected with beneficial patient outcome, whereas an inadequate stress response seems to be associated with high morbidity and poor outcome.

Introduction

Despite advances in the treatment of cardiac arrest, the development of organ dysfunction following return of spontaneous circulation causes considerable morbidity and mortality. The complex pathophysiologic mechanisms underlying this postresuscitation syndrome likely result from global ischemia, reperfusion, and the triggering of a profound systemic inflammatory response syndrome.[1,2] To understand such mechanisms and to improve therapy for victims of cardiac arrest, it is essential to identify the principal mediators that contribute to this disease process, and to identify their roles in the development of organ dysfunction.[3] By understanding the roles of key inflammatory and immunologic mediators during the resuscitation and postresuscitation periods, it may be possible to improve understanding of the whole-body response to ischemia and reperfusion, and to develop effective therapeutic strategies for patients who suffer cardiac arrest and for those who achieve return of spontaneous circulation.

Systemic inflammatory response

The pathophysiology of cardiac arrest is complex and, like sepsis, induces a profound systemic inflammatory response syndrome.[4–12] Unlike sepsis, however, the systemic inflammatory response syndrome following cardiac arrest results from whole-body ischemia (i.e., low or no-flow) and reperfusion (i.e., restoration of flow following ischemia).[1,13] The development of a systemic inflammatory

response syndrome has been divided into three stages.[14] The first stage occurs in response to an insult, resulting in a local cytokine response primarily intended to evoke an inflammatory response to promote local cellular repair by recruiting cells from the reticuloendothelial and immune systems. The second stage involves release of small quantities of cytokines into the systemic circulation in order to enhance, or magnify, this local response. This acute-phase response is usually tightly controlled by endogenous proinflammatory antagonists, and cytokines and immunologic mediators are kept in check by specific downregulation and antagonism. This local process generally continues until the inciting focus is resolved. Occasionally, however, the third stage develops. This massive systemic reaction results in destruction rather than protection because of an imbalance of pro- and anti-inflammatory cytokines, the formation of oxygen-free radicals, and activation of leukocytes, and if left unchecked, commonly progresses to multiple organ failure and death (Fig. 8.1).

Cytokines and reperfusion injury

Proinflammatory and anti-inflammatory cytokine cascade

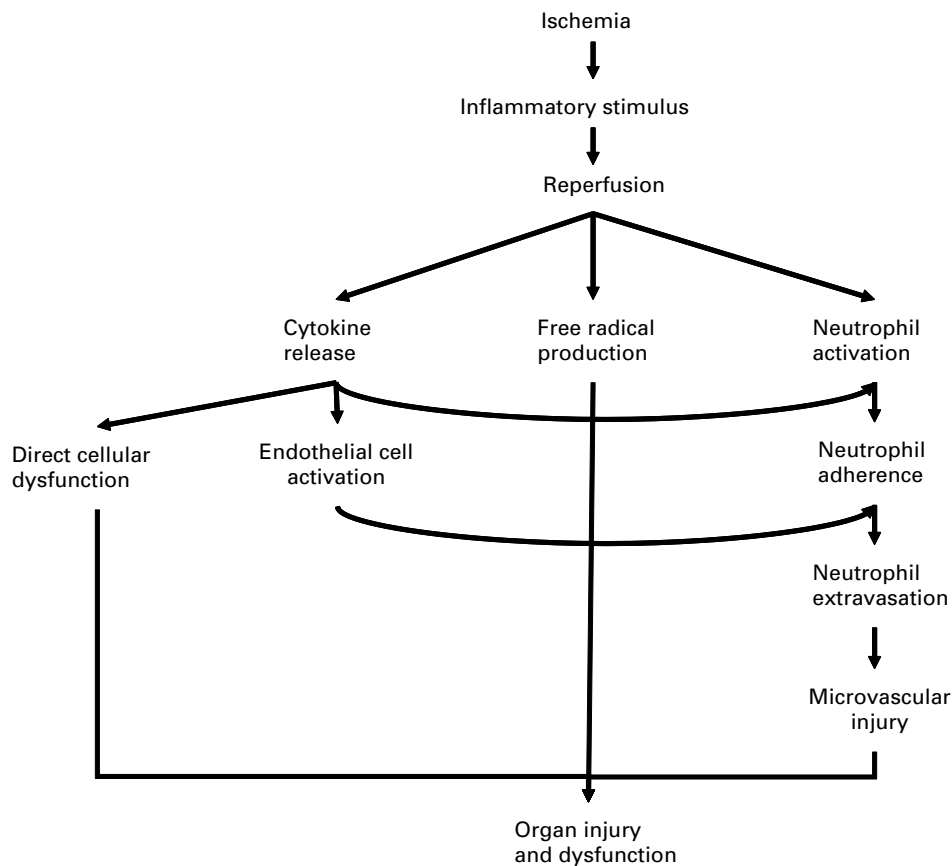
The systemic inflammatory response syndrome is characterized by a complex interplay of molecules and cells, resulting in increased concentrations of systemic inflammatory cytokines, activation of the clotting cascade, release of potent vasoactive substances and adhesion molecules, and activation of the immune system.[15,16] Cytokines are


Fig. 8.1. Mechanism to explain inflammatory process associated with whole-body ischemia and reperfusion and the development of organ dysfunction following cardiac arrest.

soluble, cell-secreted, non-immunoglobulin proteins that, in minute quantities, modulate host cell function and include such diverse molecules as growth factors, interleukins, interferons, and colony-stimulating factors.[17] Altogether, there are at least 30 different cytokines that are generally divided into either pro-inflammatory or anti-inflammatory categories (Table 8.1). Of these, tumor necrosis factor (TNF)-α, interleukin (IL)-1, IL-6, IL-8, and IL-10 appear to play the most significant pathophysiologic roles during reperfusion following ischemia.[1,2,18] While the majority of basic science and clinical research has focused on the roles of cytokines in patients with sepsis, a growing body of literature has focused on their roles during ischemia and reperfusion.[19–23]

Two of the most widely studied proinflammatory cytokines include TNF-α and IL-1β. These two cytokines initiate elaboration and release of other downstream cytokines (e.g., IL-6, IL-8, IL-10, the Fas/Fas ligand system, and the CD40/CD40 ligand system), and stimulate an acute-phase response from the liver. This cascade results

in widespread systemic inflammation resulting in direct physiologic alterations and tissue injury.

Tumor necrosis factor-α

Tumor necrosis factor-α was first described in 1975 for its oncolytic effects on solid tumors.[23] Since then, it has been found to have an abundance of physiologic effects, including but not limited to, triggering the development of fever, shock, myocardial depression, acute respiratory distress syndrome, edema, acute renal tubular necrosis, suppression of erythropoiesis, and disseminated intravascular coagulation.[24] Although several cell types can produce TNF-α, including the cardiac myocyte, it is primarily synthesized by macrophages as a 26-kD membrane protein from which a 17-kD extracellular peptide is cleaved by the enzyme TNF convertase. Three 17-kD peptides become non-covalently associated to form a homotrimeric complex that is biologically active.[25,26] TNF-α is released into the circulation after an insult within minutes and

Table 8.1. Sources and systemic effects of cytokines released during ischemia and reperfusion

Proinflammatory cytokines	Major sources	Systemic effects
TNF-α	Monocytes, macrophages, lymphocytes, neutrophils, endothelium, fibroblasts, and keratinocytes	Myocardial depression, hypotension, leukocyte and endothelial activation, promotion of hypercoagulability, and stimulation of IL-1, IL-6, and IL-8
IL-1β	Monocytes, macrophages, lymphocytes, neutrophils, endothelium, fibroblasts, and keratinocytes	Myocardial depression, hypotension, leukocyte and endothelial activation, promotion of hypercoagulability, and stimulation of TNF-α, IL-6, and IL-8
IL-8	Monocytes, macrophages, lymphocytes, endothelium, fibroblasts, and keratinocytes	Recruitment and activation of neutrophils
Anti-inflammatory cytokines		
IL-6	Monocytes, macrophages, T cells, endothelium, fibroblasts, and keratinocytes	Induction of hepatic acute-phase response, decreases IL-1β and TNF-α

reaches peak concentrations between 90 and 120 minutes, and the serum half-life is approximately 20 to 40 minutes.[27,28] TNF-α is removed from the serum by binding to TNF-receptors and soluble TNF-binding proteins (also known as soluble receptors) and by clearance of the protein complexes by the kidney and liver.[29]

TNF-α interacts with at least two distinct membrane-associated receptors called TNF-R1 and TNF-R2, both of which exhibit similar TNF-α binding affinities. Both receptors are ubiquitous, existing on essentially all cell type surfaces except red blood cells. The two receptors utilize distinct intracellular signaling pathways, however. Both receptors also exist in soluble forms produced by proteolytic cleavage of their extracellular domains. Whereas the mechanism underlying the specific cleavage is not well understood, it is thought that these soluble receptors function to antagonize the effects of TNF-α when concentrations are high. When TNF-α concentrations are lower, soluble receptors stabilize TNF-α in order to slow the spontaneous decay of its bioactivity.[29]

The role of TNF-α in ischemia and reperfusion injury is relatively well documented. Initial studies evaluated its role during re-implantation as well as in models of rat hepatic ischemia and reperfusion.[30] Plasma TNF-α concentrations significantly increased between 30 minutes and 3 hours after reperfusion in these models.

Interleukin-1

IL-1 was first described in the 1940s as a heat-labile protein that when injected into animals induced fever, and was further described as a 10- to 20-kD peptide in the 1970s.[31,32]

It exists in two forms, IL-1α and Il-1β, both of which possess a wide spectrum of inflammatory, metabolic, physiologic, hematopoietic, and immunologic properties. IL-1β, in the setting of endotoxemia, is rapidly transcribed and released extracellularly, with peak concentrations occurring in approximately 3 to 4 hours. Although both forms of IL-1 arise from distinct gene products, both recognize the same cell surface receptors and have overlapping biological effects. Several nucleated cell lineages have been shown to synthesize and release IL-1, including monocytes, macrophages, neutrophils, and endothelial cells.[33]

The physiologic effects of IL-1 are extensive and in many respects parallel those of TNF-α. These effects are not limited to, but include the development of fever, anorexia, and neutrophilia, and the systemic effects of high dose IL-1 after injection into animals include hypotension, depressed myocardial function, and decreased systemic vascular resistance.[24] Additionally, it has been shown that TNF-α potentiates the effects of IL-1, and their synergistic activities seem to be caused by second messenger molecules rather than upregulation of receptors.[33] In experimental settings in which a systemic inflammatory response syndrome was induced in volunteers, serum TNF-α concentrations reached peak levels between 60 and 90 minutes, whereas serum IL-1 concentrations reached peak levels in 3 to 4 hours.[34,35]

Other inflammatory cytokines

More downstream inflammatory cytokines include IL-6, IL-8, and IL-10. IL-6 is considered a weak inflammatory peptide that acts as an endogenous pyrogen and an

inducer of acute-phase responses.[36] IL-8 functions to recruit and activate neutrophils in the development of inflammation and tissue damage. IL-10 is considered an anti-inflammatory cytokine and inhibits the production of TNF-α, IL-1β, IL-6, and IL-8, as well as expression of matrix metalloproteinases, and attenuates neutrophil infiltration at the site of injury.[20]

CD40 is a membrane glycoprotein belonging to the TNF receptor superfamily and is expressed on a relatively diverse line of cells, including lymphocytes, monocytes, macrophages, platelets, and endothelial cells.[37] CD40 ligand (CD40L), also known as CD154, is a cell surface glycoprotein that also belongs to the TNF family of cytokines, which also includes TNF-α and Fas ligand. CD40-CD40L interactions have been most extensively studied in the context of T- and B-lymphocyte interactions, but also more recently have been studied in settings of atherosclerosis and chronic inflammation, and ischemia and reperfusion.[38–40] Although it is unclear to what extent CD40-CD40L signaling plays a role in whole-body ischemia and reperfusion following cardiac arrest, it is known to play a key role in inflammation through the induction of cellular adhesion molecules, tissue factor in endothelial cells, enhancement of the production of proinflammatory cytokines, and activation of platelets.[41,42]

Soluble Fas-ligand (FasL) is cleaved by metalloproteinases from its membrane-bound form on T-lymphocytes and neutrophils, and serum FasL concentrations have been shown to increase dramatically following cardiac arrest.[43] Fas is a widely occurring apoptotic signal receptor molecule expressed by almost any type of cell, and the level of its soluble form has been shown to correlate with the degree of multiple organ dysfunction and survival in critically ill patients.[44]

Nitric oxide (NO) is a relatively stable free radical that has been proposed to contribute to reperfusion injury. NO is produced from L-arginine by the enzyme nitric oxide synthase (NOS), which is found predominantly in endothelial cells where NO has beneficial effects, including the promotion of vasodilation and preservation of endothelial activities. NO reacts with superoxide to produce peroxynitrite, a toxic, highly reactive compound capable of producing irreversible cellular injury. Inhibition of NOS in cardiac arrest models appears to decrease generation of free radicals generation by inhibiting the production of peroxynitrite and reduces the requirements for epinephrine and closed-chest compressions, but has not demonstrated survival benefit.[45–47]

Matrix metalloproteinases (MMPs) are a family of zinc-dependent endopeptidases involved in remodeling of the extracellular matrix during various physiologic and pathologic conditions, including wound healing and inflammation.[48] MMPs are synthesized in a latent, or pro-MMP, form and are activated by proteolytic cleavage or conformational change, and the expression of MMPs is transcriptionally regulated by growth factors, hormones, and cytokines.[48] Recent studies emphasize not only soluble factors but also cell-matrix and cell-cell interactions as key in gene expression of MMPs.[49,50] Inhibition of MMPs has been shown to improve postischemic left ventricular function in models of cardiac stunning after ischemia and reperfusion.[51]

Role of cytokines in the development of postischemic organ injury

Whole-body ischemia and reperfusion injury lead to the synthesis and widespread release of proinflammatory cytokines by macrophages, neutrophils, and endothelial cells. Cytokines play critically important roles by: (1) inducing the expression of cell surface adhesion receptors on a variety of cell types, thus serving to localize phagocytic cells to areas of inflammation; and (2) directly affecting parenchymal cell function (Fig. 8.1).

TNF-α, granulocyte/macrophage colony stimulating factor (GM-CSF), and IL-8 mobilize adhesion receptors on neutrophils, which facilitates adherence of these cells to sites of inflammatory injury.[52,53] Additionally, TNF-α and IL-1 induce the expression of adhesive glycoproteins on endothelial cell surfaces, which serve as receptors for activated neutrophils.[54] Cytokines also induce the expression of adhesion receptors on parenchymal cells. TNF-α, IL-1, and IL-6 induce expression of intercellular adhesion molecule (ICAM)-1 on cardiac myocytes, facilitating neutrophil adherence and activation.[55–57] Thus cytokines are able to induce the expression of adhesion receptors on a variety of cell types, which serves to localize neutrophils and other immunologic cells to areas of inflammation and injury.

Cytokines also directly affect several functions of parenchymal cells. The direct effect of TNF-α on endothelial cells results in suppression of NO production.[58] NO has been identified as an endothelial-derived relaxing factor that also demonstrates potent inhibitory actions on platelet and neutrophil function. Therefore, the cytokine-induced loss of endothelial-derived NO activity may contribute to both platelet and neutrophil adhesion during reperfusion.

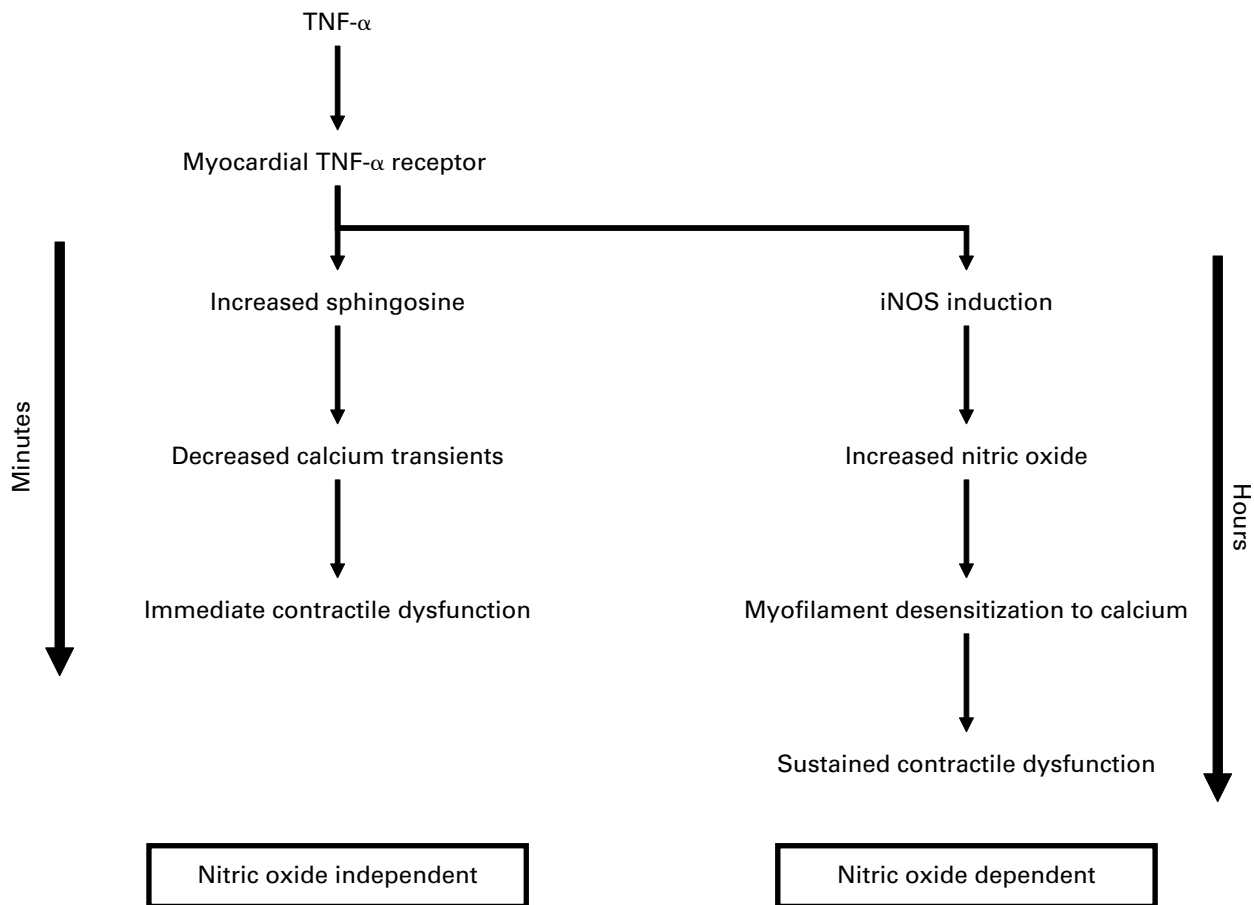
It is also well known that patients who develop the systemic inflammatory response syndrome manifest cardiac dysfunction.[59] The hemodynamic effects of both TNF-α and IL-1 are characterized by decreased myocardial contractility and ejection fraction, hypotension, decreased systemic vascular resistance, and biventricular dilatation.[60–63] Two specific time-dependent phases have been described


Fig. 8.2. Mechanism of tumor necrosis factor-alpha on myocardial contractility (iNOS = inducible nitric oxide synthase).

to characterize TNF-α-related myocardial dysfunction.[64,65] The immediate phase occurs minutes after TNF-α exposure, is nitric oxide (NO)-independent, and is mediated by sphingosine disruption of calcium-induced calcium release by the sarcoplasmic reticulum.[66,67] The late phase occurs over a period of hours after exposure to TNF-α, is temporally associated with inducible NO synthase induction, and is due to NO-induced myofilament desensitization to calcium (Fig. 8.2).[68–71] Additional research supports down-regulation of adrenergic receptors, an independent reduction in their responsiveness and their signal transduction pathways, the formation of free radicals, and apoptosis as contributors to the development of myocardial dysfunction when exposed to TNF-α and IL-1.[72–77] A recent investigation demonstrated an association between elevated serum TNF-α concentrations and myocardial dysfunction in a porcine cardiac arrest model.[78]

Other cytokines appear to exert protective effects on damaged cells. IL-8 prevents neutrophil migration and neutrophil-mediated damage to ischemic myocardium.[79] Also, IL-8 has been shown to inhibit neutrophil adhesion to endothelium and to preserve the ability of endothelium to relax after coronary artery occlusion and reperfusion.[80] Alternatively, transforming growth factor (TGF)-β prevents reperfusion-induced endothelial dysfunction after myocardial ischemia and reperfusion.[81] The protective effects of TGF-β may be related to its ability to decrease neutrophil-endothelial adhesion, suppress the release of TNF-α, or depress the formation of oxidants.[82,83]

In summary, cytokines produced by tissue macrophages, circulating or adherent neutrophils, or endothelial cells in response to ischemia may stimulate the production or mobilization of adhesion molecules on neutrophils, endothelial cells, and parenchymal cells that regulate the entrapment or sequestration of immunologic cells. Proinflammatory cytokines appear also to alter important endothelial functions directly and mediate negative inotropic effects at the level of the myocyte.

The immune system and reperfusion injury

The recruitment of leukocytes to sites of inflammation is critical in the response to tissue injury following ischemia and reperfusion, and the elucidation of molecules mediating the extravasation of leukocytes from the vascular space into the extravascular space is central to the understanding of the complex regulation of the host's response to inflammation. The recruitment of leukocytes from blood to the site of inflammation proceeds through an orderly process that includes: tethering or capture, rolling, activation and firm adhesion, and migration across the endothelium (also known as diapedesis).[84] Each of these steps is mediated by distinct adhesion molecule families that are expressed on the surface of both endothelial cells and adherent leukocytes.

Polymorphonuclear leukocytes and postischemic cellular dysfunction

It is widely accepted that neutrophils contribute to tissue damage following ischemia and reperfusion and several approaches have been used to examine the role of leukocytes in postischemic tissue injury. When blood supply is reduced (ischemia) and then subsequently reestablished (reperfusion), the ability of arterioles to regulate the distribution of blood flow is impaired, many capillaries fail to reperfuse (also known as capillary no-reflow), microvascular permeability is increased, and white blood cells become adherent to and emigrate across the walls of postcapillary venules. Once in the tissues, these inflammatory phagocytes attack parenchymal cells, thereby exacerbating injury induced by ischemia.

One approach to examining the role of leukocytes in postischemic tissue is to monitor the tissue entrapment of radiolabeled leukocytes or to measure granulocyte-specific enzymes, such as myeloperoxidase. Data derived from these techniques indicate that reperfusion of ischemic tissues is associated with massive leukocyte infiltration.[85,86]

Regulation of molecular determinants of leukocyte adherence

The observation that ischemia and reperfusion-induced tissue damage is attenuated by blocking neutrophil–endothelial adhesive interactions not only lends support to the concept that neutrophils directly mediate postischemic tissue dysfunction, but also emphasizes that the initial neutrophil–microvascular endothelial adhesion is the critical and rate-limiting step in later neutrophil–endothelial cell interactions. Adhesion molecules located on both endothelial cells and circulating leukocytes are in large part responsible for guiding the process of leukocyte extravasation.[87] The egress of neutrophils from the vascular lumen to the extravascular compartment, where tissue damage occurs, requires several steps in which the neutrophil first intimately contacts endothelial cells and then becomes firmly adherent. The fact that this adhesive mechanism can be rapidly activated, that it may be rapidly reversed or sustained (depending on the inciting stimulus), and that it may be either site-specific or generalized implies that these adhesion molecules are under tight physiologic control. Research has shown that multiple, differentially expressed adhesion molecules on both the neutrophil and endothelial cell control the complex process of neutrophil adherence.[88]

The molecular events associated with establishing the adhesive interaction between neutrophils and microvascular endothelium appear to involve at least three families of adhesion molecules: (1) the leukocyte β_2-integrins (CD11$_a$/CD18, CD11$_b$/CD18, and CD11$_c$/CD18); (2) the immunoglobulin gene superfamily (intercellular adhesion molecule 1 [ICAM-1], vascular cell adhesion molecule 1 [VCAM-1], and platelet/endothelial cell adhesion molecule 1 [PECAM-1]); and (3) the glycoprotein adhesion molecule family of selectins (leukocyte (L)-selectin, endothelial (E)-selectin, and platelet (P)-selectin).[89–92] L-selectin is expressed on most leukocytes, including neutrophils and monocytes, whereas P- and E- selectins are expressed mainly on the surface of cytokine-activated endothelial cells.[91]

Endothelial activation

It was once thought that vascular endothelium functioned to prevent cellular adhesion and to compartmentalize the intravascular space. Substantial evidence exists to support an adhesive function, however, that is pivotal in modulating the localization of neutrophils to sites of inflammation. Adhesion molecules expressed on the surface of the microvascular endothelium modulate the neutrophil-endothelial interaction associated with inflammation after ischemia and reperfusion. Three of the best characterized endothelial cell adhesion molecules are P-selectin, E-selectin, and ICAM-1.[86,92–95]

P-selectin is normally found in secretory granules within platelets and can also be expressed by endothelial cells. After stimulation with complement, thrombin, or histamine, P-selectin is mobilized to the endothelial cell surface within minutes, remains there transiently, is associated with reversible PMN adhesion, and is rapidly removed by endocytosis.[96,97] In contrast, activation of

endothelial cells by certain oxidants (e.g., hydrogen peroxide) produced during reperfusion results in a sustained rather than transient expression of P-selectin.[98,99] Thus, the failure to reinternalize P-selectin may be caused by an impaired regulatory mechanism when microvascular endothelium is overwhelmed by oxidants produced by reperfusion. It is noteworthy, however, that protein synthesis-dependent P-selectin expression can occur within hours of exposure to appropriate stimuli, thereby providing another route for prolonged expression of this adhesive ligand.

E-selectin is not constitutively present on endothelium, but its expression, which requires new protein synthesis and reaches a maximum within 4 hours of stimulation, is induced by cytokines and by lipopolysaccharides.[91,100,101] The absence of E-selectin on unstimulated endothelium and the time course for its induced expression on activated endothelium suggests that it may target circulating PMNs to ischemic sites at later stages of reperfusion.[93]

ICAM-1 and VCAM-1 are also constitutively present on endothelium, but their expression can be upregulated in a protein synthesis-dependent manner, with maximal expression occurring within 4 to 8 hours after endothelial exposure to cytokines.[86,102,103] ICAM-1 persists on the cell surface for up to 24 hours and plays an important role in firm PMN-endothelial cell adherence.[104]

Leukocyte adhesion

The strength of adhesive interactions between adhesion molecules expressed on the surface of leukocytes and endothelial cells is important in determining whether a neutrophil adheres to the microvascular endothelium. The best characterized of the leukocyte adhesion molecules are L-selectin and the $CD11_{a,b,c}$/CD18 glycoprotein adherence complex.

L-selectin is expressed on the surface of unstimulated neutrophils where it appears to mediate the initial weak adhesion or rolling of neutrophils along cytokine-activated endothelium.[88,105] This form of neutrophil–endothelium interaction is fundamentally different from neutrophil margination as it occurs during inflammatory processes.

An interesting feature of L-selectin expression is the ability of soluble chemotactic substances (e.g., platelet activating factor [PAF] and endothelial IL-8) produced by activated endothelium to cause the rapid shedding (within minutes) or downregulation of the neutrophil L-selectin molecule.[94,106] Although the physiologic relevance of this downregulation is unclear, it may facilitate the transition of subsequent neutrophil-mediated tissue injury, and it is thought that it may help limit the sequestration of

neutrophils at distant sites where injury has not occurred. Alternatively, this downregulation may facilitate the transition of neutrophils from adhesion to tissue extravasation.[107] This downregulation of L-selectin, however, occurs simultaneously with the upregulation of the next phase of neutrophil adhesion, namely, the $CD11_{a,b,c}$/CD18 glycoprotein complex.[94,106] The $CD11_{a,b,c}$/CD18 glycoprotein complex, located on the surface of neutrophils, has been shown to respond to chemotactic peptides (e.g., complement factor $C5_a$) and lipid mediators (e.g., leukotriene B_4 and PAF).[86,95,100] These glycoproteins regulate neutrophil extravasation, oxidant production, and degranulation, all of which have been implicated in neutrophil-mediated tissue dysfunction associated with ischemia and reperfusion.[108–110]

Selectins bind to a variety of glycans or mucins that possess the Sialyl Lewis[x] moiety, a carbohydrate known to play a vital role in cell–cell recognition.[111,112] For example, L-selectin binds to a group of mucins on the activated endothelial cells, including glycosylation-dependent cell adhesion molecule 1. The ligand for P-selectin, P-selectin glycoprotein ligand 1 (PSGL-1), which also contains Sialyl Lewis[x], is found on leukocytes and endothelial cells. PSGL-1, which is expressed constitutively on neutrophils and monocytes, serves as the dominant ligand for P- and E-selectin on endothelial cells.[113] Engagement of PSGL-1 enhances tether strength and stabilizes neutrophil and monocyte cell rolling on endothelial cells. In addition, engagement of PSGL-1 also may regulate gene expression in monocytes. Inhibition of PSGL-1/selectin interactions may be an effective tool to attenuate inflammation.

Coordination of leukocyte adhesion and extravasation

Neutrophils are localized to sites of inflammation by a highly coordinated and dynamic sequence of events in which each of the known adhesion molecules plays a distinct role.[93] The initial adhesive interaction between neutrophils and the endothelium involves upregulation of adhesion molecules (P-selectin, E-selectin, ICAM-1, and VCAM-1) on the surface of endothelial cells adjacent to sites of inflammation. L-selectin, located on the surface of neutrophils, appears to mediate the initial rolling and reversible adherence between non-activated neutrophils and activated endothelium. Weakly bound neutrophils are then activated by triggering substances (e.g., PAF and IL-8) produced by the activated endothelium itself, or by other circulating molecules, including cytokines and complement.[114,115] The $CD11_{a,b,c}$/CD18 glycoprotein complex interacts with ICAM-1, strengthening the neutrophil-endothelium interaction and promoting extravasation.

Table 8.2. Leukocyte adhesion stages and molecular determinants

Stage of migration	Phagocyte molecule	Endothelial cell molecule	Other
Capture or tethering	L-selectin PSGL-1	GlyCAM-1 E- and P-selectin	P-selectin is released by platelets and E-selectin is induced on endothelial cells by TNF-α and IFN-γ
Rolling	L-selectin PSGL-1	GlyCAM-1 E- and P-selectin	
Activation	Increased avidity of integrins		L-selectin shedding induced by chemokines (e.g., IL-8 and MCP-1)
Firm adhesion	CD11$_a$/CD18 CD11$_b$/CD18	ICAM-1 and ICAM-2	
Diapedesis	VE-cadherin PECAM-1	VE-cadherin PECAM-1	

Critical to diapedesis is the binding of vascular endothial (VE)-cadherin or platelet/endothelial cell adhesion molecule (PECAM)-1, both of which are present at the adherence junctions between the endothelial cells and on the leukocytes (Table 8.2). After neutrophil extravasation, oxidant production and degranulation occurs, resulting in tissue damage.

Mechanisms of neutrophil-mediated tissue injury

Activated neutrophils secrete an impressive number of antibacterial and antiseptic agents that are also cytotoxic to normal cells and that dissolve connective tissue.[116] These toxins can be conveniently divided into two groups based on their location with the cell: (1) plasma membrane-bound nicotinamide adenine dinucleotide phosphate (NADPH) oxidase; and (2) intracellular granules.

The NADPH oxidase system enables neutrophils to produce reactive oxygen species. The NADPH oxidase system utilizes NADPH to generate superoxide anion and hydrogen peroxide, both of which damage host tissue but are short-lived and rapidly consumed in other reactions.[117,118] The combination of NADPH oxidase-derived hydrogen peroxide and myeloperoxidase, a constituent of the neutrophil's intracellular granule system, however, produces hypochlorous acid, an oxidizing agent of immense destructive potential.

Activated neutrophils secrete myeloperoxidase, which catalyzes the conversion of hydrogen peroxide and chloride ions to hypochlorous acid. Hypochlorous acid destroys a wide variety of biological molecules, cellular contents, and plasma constituents, and also participates in the production of other chlorinated oxidants, which further impair the host's defense mechanisms against granular proteinases.[116]

Neutrophil proteinases (e.g., elastase, collagenase, and gelatinase) are target-specific enzymes that destroy extracellular matrix proteins, leading, in part, to increased vascular permeability. The simultaneous secretion of both oxidants and granular enzymes produces a synergistic reaction in which the destructive potential of neutrophils can be fully expressed. The cumulative effect of the cascade of cytotoxic reactions associated with neutrophil activation results in damage to structural, contractile, and transport proteins, enzymes, and membrane receptors and causes peroxidation of lipid membranes. As a consequence, normal cellular functions are impaired, membrane fluidity and integrity are lost, and extracellular matrix structure and repair processes are destroyed.

Neutrophils also may contribute to reperfusion abnormalities and tissue damage by occluding capillaries.[119,120] Neutrophils are large, stiff cells that when activated after exposure to hypoxic and acidotic conditions become larger and stiffer, making it more difficult for these cells to traverse capillary beds. Ischemia and reperfusion also reduces capillary diameters by inducing endothelial cell edema and interstitial edema. Such mechanisms create microcirculatory perfusion abnormalities (also known as no-reflow) that may persist despite restoration of normal blood flow. Both neutropenia and blockade of neutrophil adhesion molecules prevent the development of the no-reflow phenomenon.[121] Antibodies against endothelial cell determinants of neutrophil adhesion also effectively attenuate postischemic capillary no-reflow.[122]

Mechanisms of macrophage-mediated tissue injury

Neutrophils, monocytes, and macrophages combine to make up the mononuclear phagocytic system. This system includes promonocytes and their precursors in the bone

Table 8.3. Selected products generated by macrophages

Product	Function
Enzymes	
Plasminogen activators	Inflammatory; tissue repair
Collagenases	Inflammatory
Elastase	Inflammatory
Complement components	Antimicrobial; inflammatory
Coagulation factors	Tissue repair
Arginase	Immunoregulatory
Neutral proteinases	Inflammatory; tissue repair
Acid hydrolases	Inflammatory
Lysozymes	Antimicrobial
Enzyme inhibitors	
α_2 – macroglobulin	Regulation of plasma enzyme activities
Plasminogen activator inhibitor	Regulation of plasma enzyme activities
Cytokines	
IL-1	Inflammatory; tissue repair
TNF-α	Inflammatory; tissue repair
INF-α and β	Antiviral
Reactive oxygen metabolites	
Superoxide (O_2^-)	Microbicidal; inflammatory
Hydrogen peroxide (H_2O_2)	Microbicidal; inflammatory
Hydroxyl radical (OH^-)	Microbicidal; inflammatory
Arachidonic acid metabolites	
Prostaglandin E_1 and E_2	Inflammatory; immunomodulation
Thromboxane A_2	Inflammatory; immunomodulation
Leukotriene C	Inflammatory; immunomodulation

marrow, monocytes in the circulation, and macrophages in tissues. Monocytes remain in circulation for 1 to 3 days, whereas macrophages reside in tissues for up to 3 months.[123]

The mononuclear phagocytic system comprises a critical aspect of host defense against infection, and like neutrophils, macrophages play an important role in host tissue damage in non-infectious diseases, including after ischemia and reperfusion.[124,125] Macrophages secrete an impressive variety of enzymes, oxidants, cytokines, and chemotactic substances that are important for killing microbes, immunoregulation, and modulation of inflammation (Table 8.3).[126]

Monocytes and macrophages are important sources of IL-1, which has a potent effect on the inflammatory response.[33] IL-1 attracts neutrophils, lymphocytes, and monocytes to sites of injury and inflammation and enhances degranulation and adhesion to endothelium.

The ability of IL-1 to activate and thereby induce endothelium to express adhesion molecules may be a means by which distant organs are recruited into a whole-body inflammatory response after cardiac arrest.

TNF-α is another macrophage product responsible for many of the manifestations of inflammation. It has been implicated in the organ dysfunction and multiple organ failure in the setting of sepsis, and has also been associated with reperfusion injury following cardiac arrest.[24]

Therapeutic implications and future research

Resuscitation, postresuscitation, hemodynamic decompensation, multiple organ dysfunction, and survival

Cardiac arrest creates an immediate no-flow state, which produces an immediate systemic inflammatory response syndrome. Therefore, if perfusion is restored, an overwhelming inflammatory response ensues resulting in what many refer to as the metabolic phase of resuscitation.[3] The postresuscitation syndrome is characterized by increased levels of inflammatory cytokines, activation of the clotting cascade, release of potent vasoactive substances, and activation of leukocytes, all of which contributes to altered intracellular oxygen utilization and direct inflammatory injury, resulting in hemodynamic instability, organ dysfunction and failure, and subsequent death if left untreated.[1,2]

In light of the intricately coordinated molecular and cellular events that govern ischemia and reperfusion injury following cardiac arrest, it is not surprising that successful therapeutic efforts directed at the postresuscitation syndrome have been limited.[127] Nonetheless, the significant progress made in the understanding of the molecular and cellular events governing ischemia and reperfusion offers great promise for new therapeutic approaches. For example, ischemia and reperfusion injury following reperfusion after cardiac arrest may be significantly attenuated by inhibition of key inflammatory cytokines (e.g., TNF-α or IL-1) or by inhibition of leukocyte adhesion. Specific cytokines may exert anti-inflammatory effects following reperfusion and consequently offer new therapeutic avenues for those suffering from ischemia-reperfusion injury. The ability of some cytokines to exert protective cellular and tissue effects suggests their possible use as therapeutic agents in reperfusion injury. Alternatively, agents that interfere with the production of, or enhance the removal of, proinflammatory cytokines may provide other therapeutic avenues for treating such injury. A more

broad approach to removing significant inflammatory mediators has recently been reported using high-volume hemofiltration during the postresuscitation period.[127]

One of the most important areas of continued and expanded research will be to identify major mediators released on reperfusion that trigger the sequelae of reperfusion injury. In particular, identification of the most upstream or influential mediators and their subsequent therapeutic attenuation might provide protection, by halting the amplification of the systemic inflammatory response, to individuals and their organ systems following cardiac arrest.[78]

The site specificity of neutrophil and macrophage adhesion at inflammatory sites implies that widespread expression of adhesion molecules by the endothelium occurs during ischemia and reperfusion. Familiarity with mediators of endothelial determinants of neutrophil adhesion suggests additional targets for therapeutic interventions. For example, immunologic intervention before the induction of P-selectin expression may prevent local and generalized organ system dysfunction, whereas later intervention may inhibit the continuous neutrophil recruitment and exacerbation of tissue injury.

Interference with substances released by activated endothelium may provide yet another opportunity to interrupt the cycle of neutrophil activation, adherence, migration, and subsequent tissue injury. In addition, inactivation, by using soluble receptors or antibodies, of systemic molecules (e.g., TNF-α or IL-1) may offer an opportunity to prevent the activation of endothelium or leukocytes, or may attenuate the direct effects of such molecules on organ systems, namely, the direct myocardial dysfunction induced by TNF-α.

A growing body of evidence indicates that the inflammatory sequelae to ischemia and reperfusion can be prevented by antecedent exposure to adenosine, nitric oxide, ethanol or short bouts of ischemia. Understanding the mechanisms whereby these preconditioning interventions induce the development of a preconditioned state, wherein the endothelium undergoes an adaptive transformation to an anti-inflammatory phenotype, may allow for prophylactic treatment of individuals at risk for cardiovascular disease.[128,129]

Conclusions

Although the overall survival rate of out-of-hospital cardiac arrest has remained low and relatively constant over the past four decades, understanding the molecular and cellular events of ischemia and reperfusion has increased substantially, and may, at some point in the future, have an impact on how clinicians treat patients following cardiac arrest. Translation of basic sciences research to clinical research will be the important next steps in determining how to invoke therapies that may improve resuscitation and survival rates for victims of cardiac arrest.

Resuscitation research

Methodology of laboratory resuscitation research

Menekhem Zviman and Henry Halperin

Johns Hopkins University School of Medicine, Baltimore, MD, USA

Up to 1000 cardiac arrests occur every day in the United States alone.[1] The ultimate goal of cardiopulmonary resuscitation (CPR) research is to find ways of improving the survival and post-resuscitation quality of life of the cardiac arrest victim. New CPR techniques may improve survival by various mechanisms, but development of new techniques must be based on a comprehensive understanding of the process of CPR to ensure that the results have a sound basis. Many CPR studies are devoted to understanding the physiologic mechanisms taking place in the patient during CPR and the relationship among the physiologic mechanisms, the technique of resuscitation, and the actions performed by the rescuer.

The sequence of major events during cardiac arrest is shown in Fig. 9.1. Both the actions by the rescuer and the underlying physiology play important roles in the eventual outcome of the resuscitation effort. The patient's status during each intervention can be characterized by hemodynamic, neurologic, biochemical, electrophysiologic, and mechanical properties. Some of these properties, such as blood pressure or arterial blood gases, can be *measured (quantified)* under experimental and clinical conditions. Often, clinicians or researchers utilize *qualitative* properties, such as the size of the pupils or the pulse pressure, that are more easily evaluated but are less likely to provide accurate information. It is unfortunate that many important properties that directly influence the outcome, such as the force of compression and sternal displacement, often are not measured at all, even in animal studies. Measurements during CPR studies are difficult, especially in humans. Even in animal studies, blood flow, pleural pressure, compression force, and other physiologic determinants of flow are difficult to measure.

Measurement of blood flow, for example, requires surgical manipulation of the neck or chest to implant flow probes, which can significantly alter the underlying physiology, making the results potentially suspect. Placement of the transducer for measurement of compression force may interfere with mechanics of delivery of force during CPR. Significant limitations are placed on CPR studies by the necessity of minimizing the downtime and the short time of the CPR procedure itself. In humans, there are serious limitations because cardiac arrest is not a planned event, and it often occurs in places and at times of the day inconvenient for collecting data. In addition, ethical and patient safety considerations, as well as government regulations, limit the extent of measurements that can be made during CPR.

This chapter examines the methodology of measurements and evaluation of measurement errors. Issues pertinent to the specific conditions of measurements during CPR studies will also be discussed. To avoid obscuring the main concepts in complex mathematic equations, we have chosen to use only simple mathematic equations. Table 9.1 lists many of the measurements performed during clinical CPR, human research, or animal research. As representative examples, measurements of compression force, vascular pressures, and blood flow are addressed in detail.

Basics of theory of measurements

Definition of measurement and units of measurement

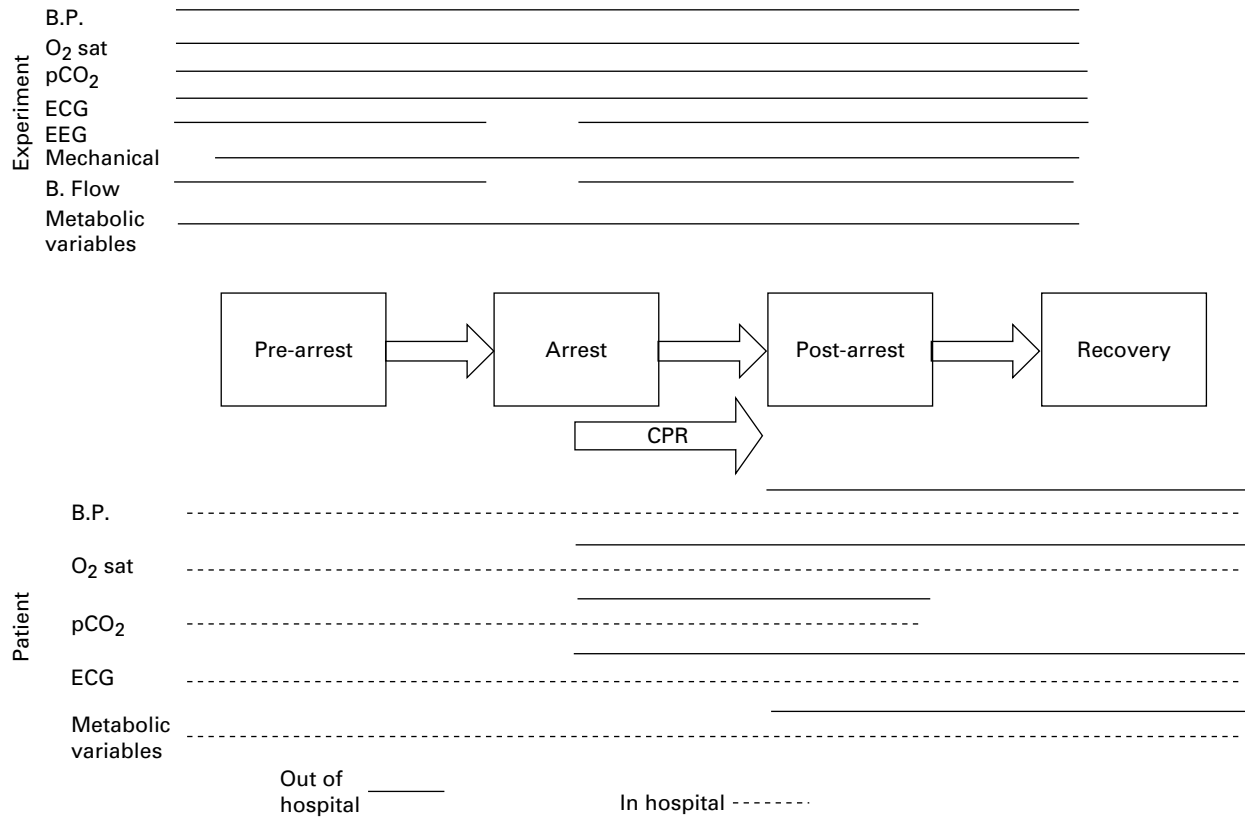
Measurement of "some property of a thing is an operation that yields as an end result a number that indicates how


Fig. 9.1. Data available during the different phases of cardiac arrest.

much of the property the thing has".[2] In physics and engineering the measurements are performed on physical properties that can be expressed as multiples of some unit quantities. For example, blood pressure can be measured as a number of millimeters of mercury (mm Hg) or thousands of pascals (kPa). In clinical research, measurements are also used for such attributes as gender and mortality, as well as for such abstract constructs as coma score[3] or quality of life. This chapter addresses only measurement of physical properties.

Measurements require a system of measuring units. The current international standard is the modern metric system termed the *International System of Units (SI from its French name – Système International d'Unités)*. It is based on seven *base units* (Table 9.2)[4,5] and two *supplementary units* (Table 9.2) that are defined. Units for other physical properties are derived from the combination of basic, supplementary, and other derived units (Table 9.3 contains the most commonly used derived units). To extend the units, SI uses decimal multipliers denoted by prefixes (Table 9.4). In United States medical practice, the SI units are used for most measurements, but some old units, such as mm Hg for pressure, still prevail.

True value, errors of measurement and accuracy

In any measuring process, the true value of the property of interest is sought. The discrepancy between the result of measurement (x) and the true value (τ) is the *error of measurement*:[2]

$$\varepsilon = x - \tau \tag{9.1}$$

The error, or closeness of the measured value to the true value, determines the *accuracy* of the measurement.

The "real" true value is unknown and unknowable[2] since all measurements contain some errors. The value measured by a method accepted by experts as exemplary for the measured property is accepted as the true value.[2,6] For example, in calibrating a measuring instrument, the values measured by the standard instrument are accepted as true values for the tested unit.

Figure 9.2 shows inputs acting on a subject and measurement arrangements. The objects of measurements may be the properties of the treatment or environmental inputs to the subject, the treatment outputs, and/or the subject's physiologic properties. Sources of the measurement errors are (*a*) the variability of the property measured, (*b*) the

Table 9.1. Measurements performed during clinical and research CPR[a]

Properties	Clinical CPR	Human research CPR	Animal research CPR
Mechanical properties			
Sternal compression force	M	Y	Y
Sternal displacement	N	Y	Y
Abdominal movement	N	M	M
Blood pressures			
Heart chamber pressures	M	Y	Y
Aortic pressure	Y	Y	Y
Central venous pressure	M	Y	Y
Peripheral arterial pressure	Y	Y	Y
Peripheral venous pressure	Y	Y	Y
Blood flow			
Aorta blood flow by flow meter	N	N	Y
Peripheral artery blood flow	N	N	Y
Coronary blood flow	N	N	Y
Average organ perfusion flow (microspheres)	N	N	Y
Cardiac output			
By microspheres	N	N	Y
By measuring left ventricular dimensions (ultrasound imaging)	N	E	E
By measuring left ventricular dimensions (ultrasound crystals)	N	N	E
Intracranial pressure	M	M	Y
Pleural pressure	N	N	M
Esophageal pressure	Y	Y	Y
Arterial and venous blood gases			
Blood pH	Y	Y	Y
Blood P_{O_2}	Y	Y	Y
Blood P_{CO_2}	Y	Y	Y
Respiratory parameters			
Airway pressure	M	Y	Y
Respiratory flow	M	Y	Y
End-respiratory CO_2	Y	Y	Y

[a] Y, measurement is or can be performed with reasonable ease; M, measurement may be performed but requires special setup; E, measurement has been performed, but it is error prone; N, measurement cannot be performed.

Table 9.2. International system of units: base and supplementary units

Parameter	Unit	Abbreviation
Base units		
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	Kelvin	K
Luminous intensity	candela	cd
Amount of substance	mole	mol
Supplementary units		
Plane angle	radian	rad
Solid angle	steradian	sr

interaction of the sensor and subject, and (*c*) the measuring instrument. One example of the sensor–subject interaction might be measurement of pleural pressure by a fluid-filled catheter. The thickness of the pleural space is 10 to 50 μm, whereas any catheter inserted into the pleural space has a diameter that is on the order of millimeters. Therefore the catheter distorts the pleural space drastically. In addition, propagation of the pressure from the limited volume of the pleural liquid in the pleural space to the liquid in the catheter is questionable. The error introduced by the measuring instrument depends on such factors as the quality and characteristics of the measuring instrument used the performance of the measuring technique by the operator, and the conditions under which the measurement is made.

Table 9.3. International system of units: derived units

Parameter	Unit	Abbreviation	Equivalent
Frequency	hertz	Hz	1/s
Force	newton	N	kg·m/s^2
Pressure	pascal	Pa	N/m^2
Work or energy	joule	J	N·m
Power	watt	W	J/s
Electric potential	volt	V	W/A
Electric resistance	ohm	$$	V/A
Conductance	siemens	S	A/V
Quantity of charge	coulomb	C	A·s
Electric capacitance	farad	F	C/V
Magnetic flux	weber	Wb	V·s
Magnetic flux density	tesla	T	Wb/m^2
Inductance	henry	H	Wb/A
Celsius temperature	degree	ºC	K

Table 9.4. International system of units: prefixes

Multiplication factor	Prefix	Symbol
10^{18}	exa	E
10^{15}	peta	p
10^{12}	tera	T
10^{9}	giga	G
10^{6}	mega	M
10^{3}	kilo	k
10^{2}	hecto	h
10^{1}	deka	da
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	milli	m
10^{-6}	micro	μ
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f

Fig. 9.2. Block diagram of measurement arrangements.

Depending on the nature of errors, they can be divided into *systematic errors* and *random errors*. A systematic error, or *bias*, is the same for all measurements of the same value by a particular instrument, whereas a random error may differ for every reading. The errors may be further subdivided into *static* and *dynamic errors*. The static error occurs when the measuring signal is constant or changes slowly in time; the dynamic error occurs when the measured value changes quickly.

The error expressed in units of measurement (Eq 9.1) is an *absolute error*. However, it is often more informative to report the error as a *relative error*, that is, as a fraction of the measured value (*reading*).

The relative error ε_r is usually expressed in percents of reading:

$$\varepsilon_r = \frac{\varepsilon}{T}100\% \tag{9.2}$$

Instrument manufacturers routinely quote the allowable maximum error, or the uncertainty (see below) of their instrument as a *percentage of the full-scale reading*. The type of error (systematic or random) is usually not specified. For example, the pressure monitor has the full scale of 300 mm Hg and a quoted uncertainty of ±1%; that means that the error for any measurement will not exceed 3 mm Hg if the instrument is properly used. It is important to emphasize that at the upper end of the scale the relative error of the instrument is close to the full-scale error, whereas at the lower end, the relative error becomes very large. Indeed, when the measurement is 30 mm Hg the error is (3/30)100%, or 10%. A lower, more sensitive scale of 50 mm Hg may have a slightly higher full-scale uncertainty of 2%; that is, the absolute error is not higher than 1 mm Hg. Thus measurement of 30 mm Hg pressure on this scale will have an error of not more than (1/30)100%, or 3.3%. For this reason, many modern measuring devices, such as pressure monitors, have switches that allow alternate full-scale measurements. The scales for extremely low or extremely high limits may have a slightly higher full-scale uncertainty.

Characteristics of measurement instruments and errors of measurement

Measuring instruments are designed to provide *functional relationships* between the value of the input signal and the output signal displayed by the instrument. The ideal characteristic of an element of the measuring instrument is a straight line relating the input (x_{inp}) and the output (y_{out}) variables (Fig. 9.3(*a*)):

$$Y_{out} = S \cdot x_{inp} \tag{9.3}$$

where *S* is a coefficient. The same characteristic is also applicable to a measuring instrument in which the input and output variables have different units. When input and output units are the same, the ideal characteristic is a line of identity ($S = 1$). (Fig. 9.3(*b*)). In an ideal instrument the output would be exactly equal to the measured value. Any discrepancy of the result of measurements from the straight line characteristics is the error of measurements (Fig. 9.3).

The values of properties measured by the instrument are limited by the minimal value (most often zero value) and the full-scale value. Most medical instruments have alternate switchable full scales. The transducer and other elements are limited by the range where their characteristics are linear. When the input signals change very slowly, the characteristics of any instrument can be described by its *static characteristics* and can be expressed using only simple algebraic equations. In contrast, the response of the instrument and its associated elements to fast-changing input signals is described by its *dynamic characteristics* and can only be represented using differential equations. For common measuring instruments the final functional characteristics of the instrument are defined by the superimposition of both its static and dynamic characteristics.[6]

Static characteristics and static errors of measurement

The static characteristic of a unit (an instrument or an element) describes the reaction of this unit to constant or slow-changing input signals.[6–8] As described above, the ideal characteristic is a straight line (Eqn 3, Fig. 9.3). The major parameter of the static characteristics is its sensitivity. *Sensitivity* of either the transducer or the measuring instrument is the slope of the characteristic:

$$S = \frac{\Delta y_{out}}{\Delta x_{inp}} \tag{9.4}$$

For the instrument with input and output values having the same units, sensitivity is equal to one. Sensitivity of the transducer to the primary signal should be many times larger than the sensitivities to interfering and modifying signals.

The smallest incremental quantity that can be measured or can be discriminated is termed *resolution*. An instrument has high resolution when this discriminated value is small. For an instrument to have high accuracy and

(a)

(b)

Fig. 9.3. Characteristics of a measurement instrument or an element of the measuring instrument. (a) Characteristic of a measuring instrument or an element with different input and output units. (b) Characteristic of a measuring instrument with the same input and output units. ε, error.

(a)

(b)

(c)

Fig. 9.4. Sources of systematic errors. (a) Non-linearity. (b) Hysteresis. (c) Zero and sensitivity drift.

precision (the term *precision* is defined in the section on random errors), it must have high resolution. Obviously this condition is necessary but not sufficient, since all errors of a high-accuracy instrument must be small.

Deviation of the real characteristic of an instrument, or an element, from a straight line is termed *linearity* (a more correct term would be non-linearity) (Fig. 9.4(*a*)).

In blood pressure transducers, non-linearity is the result of non-linear deformability of the membrane material when pressure is applied. If the measured value is first increased monotonically from zero to a maximum value and then decreased back to zero, the output signal at some particular value of the input value may be different (Fig. 9.4(*b*)). This difference defines *hysteresis* of the instrument or the element. In a pressure transducer, hysteresis is caused by internal friction in the membrane material during deformation.

Stability and *repeatability* define how accurately the device or sensor repeats the output signal when the input signal is repeated after cycles of input and temperature changes. Repeatability is a short-term specification; stability is a long-term specification.[7]

The characteristics of elements and the instrument change (*drift*) (Fig. 9.4(*c*)) with temperature. Changes can be in the slope of characteristics (*sensitivity drift*) and in zero offset (*zero drift*). To limit the changes in the working range of temperatures, transducers are often temperature compensated.

Sources of systematic errors are non-linearity, stability, and changes of characteristic with temperature, whereas repeatability and hysteresis are the sources of random error. Non-linearity and temperature changes can be measured during calibration. If the instrument contains a microprocessor and a temperature sensor, the characteristics may be stored in the memory and these systematic errors may then be compensated for during measurements. Currently, industry manufactures *smart transducers*, which contain microprocessors and provide such compensation.[7]

Dynamic characteristics

Many properties that are measured during CPR change rapidly. Examples of such properties are sternal compression force, blood pressure, and blood flow. The response of the measuring system to fast-changing input is characterized by a dynamic characteristic of the system that can be represented by differential equations. It is beyond the scope of this book to give detailed mathematic analysis of these equations, which are available elsewhere.[6,8,9]

Many real measurement systems, such as those measuring pressure or force, can be characterized by two parameters, *resonant frequency* and *damping coefficient*. Resonance occurs when the frequency of energy impacting on a system is close to the natural frequency of vibration of this system, resulting in storing of energy and amplification of oscillations. In damping, the system dissipates impacting energy, which results in much lower oscillations. For example, automobile shock absorbers

are designed to dampen (attenuate) the vibrations of the car wheels and to provide a smooth ride, even on bumpy roads. Depending on the combination of the resonant frequency and damping coefficient, the measuring system may amplify the input signals of frequencies close to resonant frequency, and therefore the output magnitude will be larger than the input magnitude. Quite often, the signal will be attenuated, with the output magnitude smaller than the input magnitude.

Periodic signals such as aortic blood pressure can be represented as a sum of sinusoids.[10] In many practical measuring systems the components of different frequencies are amplified or damped to a different degree. As a result, the shape of the signal is distorted. In addition, the pulse pressure swing – the difference between the diastolic and systolic pressure – can be either amplified or damped. When the measuring system is strongly damped, the measured pulse pressure oscillations decrease and the measurement gets closer to showing just mean pressure. Thus the error of measurements of systolic, diastolic, and pulse pressure could be very large, whereas the error of the mean pressure measurement may be small.

To ensure a small dynamic measurement error, the dynamic characteristic of the measuring system should be close to ideal in the frequency range of the input signal components; in technical terms this is defined as a *flat dynamic characteristic* in the necessary frequency range. It is also referred to as a *high-fidelity* characteristic.

The contribution to limitations of quality of a dynamic characteristic can come from any element in the measuring arrangement. It can come from subject-instrument interface, from elements transmitting the signal, from a transducer, from electronics, or from a combination of some of the elements. For example, dynamic limitation of the pleural pressure measurement usually comes from subject–instrument interaction, whereas limitation of the aortic blood pressure measurements comes from the fluid-filled catheter and the fluid-filled transducer dome.

To choose a measuring system that provides sufficiently accurate measurements, the researcher has first to determine the dynamic parameters of the measured property, and second, to choose or design a measuring system with a dynamic characteristic close to ideal in the appropriate frequency range. Determination of the dynamic parameters of the measured property can be based on (*a*) previous experience (including a literature search), (*b*) analysis of the physical nature of the parameter and subject-transducer interaction, and (*c*) measurement of the property by means of a calibrated transducer known to have a dynamic characteristic of sufficient quality in the appropriate frequency range. Dynamic characteristics of the measuring system can be found from analysis of the equipment manufacturer's data and analysis of the complete measuring system, and by dynamic calibration of the measuring systems, that is, by measuring the dynamic characteristics of the system.

Random errors

Multiple measurements of the same true value produce dissimilar results because of random errors of measurement. (Extensive treatment of random errors can be found in refs)[2,4,6,11] An example of multiple measurements could be a set of independently performed measurements of a patient's temperature made over a short period of time with the same electronic thermometer. Although the patient's temperature was constant during this brief measurement period, the measurements made during this period can differ from one another by a few tenths of a degree Celsius. These variations represent random errors in measurement around the true temperature value. If the thermometer also were improperly calibrated, however, the measurements will be offset by a certain amount (i.e., the thermometer will have a systematic error).

If the number of measurements performed was very large, the measurements would comprise a *population* of measurements. A limited number of measurements constitute a *sample* of the population. The measurements (x_i) of the sample are concentrated around the *sample mean* or *average value*:

$$\bar{x} = \frac{\sum_{i=1}^{N} x_i}{N} \tag{9.5}$$

For a particular measurement, the value $\delta_i = x_i - \bar{x}$ (9.6)

is defined as *deviation* (or *residual*).

The magnitude of the random error for multiple measurements of a single value is characterized by the *sample variance*:

$$s^2 = \frac{\sum_{i=1}^{N} (x_i - \bar{x})^2}{N - 1} \tag{9.7}$$

and the *standard deviation of the sample (SDS)* is defined as follows:

$$s = \sqrt{s^2} \tag{9.8}$$

As the number of measurements increases, the values of the sample mean ($\bar{x}$) and the sample standard deviation (SDS) (s) approach their limits, the population or limiting mean (μ) and the population standard deviation (σ). Therefore $\bar{x}$ and s are the estimates of parameters μ and σ respectively.[2] The error of estimating the population mean

(μ) by the sample mean ($\bar{x}$) decreases with the number of independent measurements. It is characterized by the *standard error of estimation of the mean (SEEM)*:

$$\sigma_{\bar{x}} = \frac{\sigma}{\sqrt{n}} \qquad (9.9)$$

Here, σ is the standard deviation as above, which in fact is the standard deviation of a single measurement $(x_i)^2$.

The difference between the mean value (μ) and the true value (τ) is a systematic error of measurements, or bias:

$$\varepsilon_b = \mu - \tau \qquad (9.10)$$

The estimate of bias, or the systematic error, is as follows:

$$b = \bar{x} - \tau \qquad (9.11)$$

The total error for a measurement therefore is as follows:

$$\varepsilon_i = b + \delta_i \qquad (9.12)$$

Many studies of random errors demonstrated that smaller random errors occur more often than large errors.[12] Therefore during multiple measurements most of the measurements are close to the mean value. The closeness of the measurements to the mean value is characterized by the standard deviation. Multiple measurements can decrease error in estimation of the mean value. The systematic error or bias can be found only by calibration of the measurement instrument, that is, by measurement of the same value by an instrument with higher accuracy.

As stated above, the true value is unknown, and therefore, the magnitude of error of a particular measurement is uncertain. Nevertheless, by knowing the distribution of errors it is possible to state with a predetermined probability (*confidence level*) that a true value of a property is located within the defined *confidence interval*[2,4,6,11] from a measured value.

Accuracy, precision, bias, and uncertainty

The closeness of the measured value to the true value defines the *accuracy* of the instrument. The total error of measurements, containing both the systematic and random errors, determines the accuracy of the measurements: the smaller the error of measurement, the smaller the inaccuracy of the measurement and therefore the higher the accuracy of the instrument used. Requirements of accuracy depend on the intended use of the instrument.[2] Of note, the price of the instrument increases with increased accuracy (decreased inaccuracy) of that instrument.

The error of estimation of the true value by the limiting mean is a systematic error, or bias.[2] The systematic error is the result of an imperfection in the instrument.[4] Multiple measurements can improve estimation of the limiting mean; however, the systematic error cannot be corrected by multiple measurements. It can only be determined by calibration of a measuring instrument.

The standard variance and hence standard deviation are measures of the *precision*, or more appropriately imprecision, of the measurement process. Imprecision characterizes a disagreement between repeated measurements of the same true value.[2]

Reports of measurements should contain both the estimation of systematic error and the random error. *Metrology* (science of measuring) recommends reporting not the error but the *measurement uncertainty*.[4,11] The term itself emphasizes the uncertainty of knowing the true value based on the measured value. The measurement uncertainty defines the range of values, usually centered on the measured value, which contains the true value with defined confidence. The uncertainty of a measuring instrument is usually determined by the *instrument calibration*.[4]

Static calibration

Calibration is performed for two reasons: (*a*) to verify the performance of the instrument being tested and (*b*) to adjust the response of the instrument being tested.[4,6] The quality of calibration is ensured by the fact that the standard reference, or the known instrument to which the calibrated instrument is compared, has been previously calibrated against better instruments. This chain of calibration guarantees traceability of the calibration of any device to the national standards. In the United States it means traceability to the National Institute of Standards and Technology (NIST) (previously the National Bureau of Standards) in Rockville, Maryland.

Calibration assures the clinician or investigator of the quality of his or her measurements. Moreover, the law and regulations require calibration of measuring instruments used for the acquisition of data that will be used by regulatory agencies to approve new drugs or medical devices.

Calibration of a measuring instrument or system is a measuring process performed when input values (true values being measured) are known. The input values are varied over some range of values while all other properties are held constant. During static calibration the input signal is changed in stepwise fashion, and time is given for the output to stabilize. The input signal is often changed in increasing and decreasing directions. The input signal is either provided by standards (serving as reference) or measured by standard instruments (test equipment).

Calibration should be performed with standards or instruments that are much more accurate than the instrument being calibrated. An instrument cannot be calibrated

to accuracy better than that of the test equipment. An accepted practice in metrology is that the *ratio of total uncertainties (TUR)* of the unit under test and the standard should be not less than 4:1.[4]

Dynamic calibration

Dynamic errors of the measuring system depend on both the dynamic parameters of the property measured and the dynamic characteristics of the systems. In many cases the measured property can be presented as a sum of harmonics of different frequencies and magnitudes. Knowing the frequency content of the signal allows development of requirements to the measuring system and the choice of a method for its calibration.

If the measuring system is known to have a flat dynamic characteristic in the frequencies exceeding the frequency components of the measuring system, the system can be calibrated statically, and the result can be used for dynamic signal. For example, it is well established that the pressure transducers with the silicon piezoresistive sensors at the catheter tip have flat characteristics far beyond any blood pressure harmonics. As long as the electronics to which the transducer is connected do not distort the pressure signal, it is sufficient to calibrate this system statically.

The methods of dynamic calibration of the particular measuring devices should be chosen according to the physical principles of the property measured. The calibration of the system for measuring vascular pressures and the chest compression force is addressed below.

Notably, however, the measurements of the dynamic properties of the measuring system are usually conducted in somewhat idealized conditions. The system used for real measurement quite often has a lower resonant frequency and higher damping.

Thoracic compression

Sternal compression force measurement

Resuscitation is performed by applying a compression force to the sternum of the patient (Fig. 9.5(*a*)). The compression force is the major determinant of CPR effectiveness; however, in most studies this force is neither measiured nor controlled.

Examples of recordings of compression forces during mechanical and manual resuscitation in a dog are shown in Fig. 9.6(*a*),[13] which also presents the corresponding aortic and right atrial pressures. Figure 9.6(*b*) illustrates the force[14] generated by the mechanical resuscitator Thumper

Fig. 9.5. Direction of application of chest compression force. (a) Compression force (F) perpendicular to sternum. (b) Compression force (F) applied to sternum at an angle different from normal. (c) Components of compression force are normal (F_n) and tangential (F_t).

(Michigan Instrument Inc., Grand Rapids, Michigan), which is used in the practice of CPR.

In measuring the compression force, three issues must be addressed: (*a*) direction of the application of the compression force; (*b*) dynamic properties of the force values; and (*c*) the shape of the force-time curve. The device for measuring force should not interfere with the delivery of CPR, nor should it alter the area and place where force is applied during CPR without the device.

Direction of compression force

Quite often, the rescuer applies the compression force not perpendicular to the sternum, but at some angle (Fig. 9.5(*b*)), in which case the total force can be represented by two components: normal to the sternum and tangential to the sternum (Fig. 9.5(*c*)). Sternal compression is brought about by the perpendicular force. Although tangential force does not directly affect the sternal displacement, this force contributes to changes in the shape of the thorax (what some call chest conditioning), especially in dogs, thereby affecting the mechanical properties of the chest and the effectiveness of the sternal compression.

An ideal assembly for measuring compression force would measure both force components separately, but there are no known devices capable of measuring both components. Devices currently in use measure the main component of the force, the normal component (e.g., a device in reference).[15]

Frequency characteristic of compression force

The analysis of frequency characteristics of the compression signals in Fig. 9.6 showed that for faithful reproduction of compression force, it is sufficient if the measuring system measures the signal of frequency up to 20 Hz without distortion. Some force application, however,

(a)

(b)

as with the ACD (active compression–decompression)
devices being promoted by AMBU, should require much
higher frequency response. Indeed, in the ACD device, the
central part is lifted from the chest and then brought into
contact with the chest with high speed; in other words,
this device provides an impulse load on the sternum.

Additional studies are required to measure the frequency
characteristics of such loading.

Compression force–time course

The force-time curves of compression forces (i.e., the *time
course of the compression force*) can differ (Fig. 9.6). Figure
9.6(*a*) also shows that the time course of compression force
significantly influences the time course of the aortic and
right atrial pressures. The characterization of CPR results
and the comparison of the results of different compression
sequences and different studies thus require characteriza-
tion of the compression forces applied during resuscitation.
Here we introduce the compression force–time course clas-
sification and the nomenclature of parameters describing
most of the usually seen patterns of force–time curves.

Most of the observed time courses of the compression
force can be divided into the following classes.

Class I: Semisinusoidal course
The force rises monotonically until it reaches the maximum
force and then decreases monotonically to the minimum
force (see curves 3 and 4 in Fig. 9.6(*a*)). The pattern of the
force–time curve is similar to a distorted half-sinusoid.

Class II: Time course with plateau
For at least 20 milliseconds the force maintains a constant
value; that is, the force–time curve contains a plateau.
Class 2 can be subdivided into two subclasses.

Class 2A: Time course
The force reaches a plateau asymptotically without exceed-
ing its value (see curve in Fig. 9.6(*b*)).

Class 2B: Time course
The force reaches the maximum value, then decreases to a
plateau level, and then decreases to the minimum force
(see curves 1 and 2 in Fig. 9.6(*a*)).

Some suggested definitions for use in describing the
sternal compression force are given below. An example is
shown in Fig. 9.7, which is the class 2B force–time course
(curve 2 in Fig. 9.6(*a*)).
1. *Compression period (T)* (measured in seconds) is the
   time interval between the moments in two consecutive
   cycles when the rising compression force reaches the
   value of 50 N (Fig. 9A.7(*a*)).
2. *Compression rate* of CPR (*CR*) is the frequency of the
   compressions expressed as number of compressions
   per minute:

$$CR = \tfrac{1}{T} 60 \; Compressions/min \tag{9.13}$$

Fig. 9.7. Nomenclature of time course of compression force. (a) Complete cycle. (b) and (c) Time expansions of compression time course in (a).

3. *Compression duration (t_c)* (measured in seconds) is the time interval from the moment when the rising force reaches 50 N to the moment when the decreasing force returns to 50 N (Fig. 9.7(*a*)).

4. *Duty cycle (D.C.)* expresses what part of the compression period is spent in compression:

5. *Maximum force* (F_{max}) (measured in newtons) is the maximum value of force for class 1 compressions or the maximum value of overshoot for class 2B compressions (Fig. 9.7(*a*)).

$$D.C. = \frac{T_c}{T} 100\% \qquad (9.14)$$

6. *Plateau* is a part of the compression duration where the force is larger than 50 N, and the rate of change in compression force is less than 0.5 kN/s for at least 20 milliseconds (Fig. 9A.7(*b*)).

7. *Plateau force* (F_{pl}) is the average force during the plateau time interval.

8. *Force rise time* (t_r) is the time required for the force to change from the level of 50 N to 90% of peak force for class 1 and 2B compressions or to 90% of plateau force for class 2A compressions.

9. *Force peak time* (t_p) is the time required for the force to change from the level of 50 N to the maximum force–time for class 1 and 2B compressions (Fig. 9.7(*c*)).

10. *Overshoot time* (t_{OS}) is the time interval from the moment when the rising force reaches the level of F_{pl} to the moment when the force decreases to that level (Fig. 9.7(*c*)). This is applicable to class 2B compressions.

11. *Force relaxation time* (t_{Rel}) is the time required for the force to change from the maximum force to 50 N for class 1 compressions or from the plateau force to 50 N for classes 2A and 2B compressions (Fig. 9.7(*b*)).

This nomenclature, although somewhat arbitrary, is based on analysis of many records of compression forces and corresponding vascular pressures. It does not preclude introduction of other parameters that would appear necessary from other studies.

Devices for measuring chest compression force

The compression force can be measured accurately only by placing the appropriate transducer between the compressing element (e.g., rescuer's hands, mechanical piston, or circumferential vest or band) and the place of force application. Both the area of contact between the transducer and the patient's chest and the mechanical properties of the material in contact with the chest can affect the delivery of CPR. The goal of the researcher is to minimize these effects.

All force-measuring devices use mechanical elastic elements that produce mechanical deflection proportional to the applied force. In traditional mechanical devices, this deflection is calibrated in units of force. The modern force-measuring devices, the *load cells*, use flexible elements that focus the effect of a load into an isolated uniform field of small deformations (strain field).[16] The resistance strain-gages attached (bonded) to the flexing surface produce an electric signal proportional to these deformations. Problems may arise in choosing a load cell for measuring the compression force. Many of the industrial cells are designed to be used in such applications when the force is applied perpendicular to their loading surface. Presence of the tangential force causes unpredictable errors in their output. Cells that measure the component along the load cell axis but reject bending and side loads are also available. These cells use elastic devices with parallel linkages.[15–17] Gruben *et al.*[15] reported on an assembly that was specially designed to measure accurately the force component normal to the sternum (Fig. 9.8(*a*)). The assembly uses a coin-shaped force cell placed inside thick wall housing. The cell is isolated from bending moments and side forces by two parallel diaphragms. The industrial unidirectional force cells use

Fig. 9.8. (a) Force measuring assembly that selectively measures perpendicular component of manually applied compression force. (b) Coupled dual–beam spring element of a load cell. (a) From ref. 15. (b) Courtesy of Measurements Group, Inc., Raleigh, North Carolina.

a sensing element (Fig. 9.8(*b*)) that contains two beams joined by relatively massive sections at both sides.[16] With this configuration, tangential forces are counteracted by axial forces in these beams.

The commercial load cells have natural resonance frequency on the order of hundreds and even thousands of hertz and can provide an adequate measurement of dynamic CPR compression forces. Incorporation of additional masses can decrease the natural frequency of the assembly. Thus the device by Gruben *et al.*[15] had a peak error of 14 N at oscillating loading with the force not exceeding 400 N with the frequency of 2.8 Hz.

Attention should be paid to amplifiers used in conjunction with the load cells. Many commercial amplifiers allow their frequency responses to be defined by the settings on the amplifiers. These amplifiers should be set for a range from DC to not less than 50 Hz.

Calibration of force measurement devices

The static calibration of the force-measuring devices can be performed with calibrated weights. Because the forces applied during CPR should not exceed 500 N, calibration for a maximum mass of 60 kg is sufficient, and a load cell of an uncertainty of 5 N is acceptable. Since the standards should be at least more accurate than the device that is being calibrated (recommended TUR = 4:1) the uncertainty of calibrating mass should be less than 0.13 kg. The NIST class F weights have tolerance of 0.01%: for the 60-kg mass, the uncertainty is 6 g.

Static calibration of the force-measuring assembly should be performed before and after every study. The effect of non-perpendicular loading and the dynamic properties of the force-measuring assembly should be tested at least once at the beginning of each series of experiments. Gruben *et al.*[15] describe a simple method for testing the force assembly on an inclined surface and for an off-center loading. Tests of dynamic properties of the cells and the assemblies can be performed on vibration stands.

Deformation measurement

Thoracic compression deforms the thorax resulting in intrathoracic pressure that moves the blood (see Chapter . . .). It is therefore useful to measure both the deformation and the intrathoracic pressure.

Intrathoracic pressure

Pressure in the thorax can be measured using a manometer attached to a fluid-filled catheter. The catheter is terminated with a small fluid-filled balloon (Fig. 9.9). Such a

Fig. 9.9. Fluid-filled catheter for measurement of intrathoracic pressure. A small balloon (latex) is secured to the end of the catheter. By using the syringe, the catheter is filled with saline. Care is taken to insure that no air remains in the catheter.

catheter is then inserted to a cavity in the thorax that does not have direct communication with the blood pool and does not have a route to release the pressure. For example, the esophagus has been used.[18]

MRI

Compression force and sternal displacement measurements do not reveal the complete details of thorax deformation. This is particularly pertinent to circumferential compression. While force and displacement of the anterior surface of the chest might be good measures of manual CPR quality, a fuller assessment of deformation is required to understand the underlying mechanisms that propel blood during CPR. Figure 9.10 illustrates measurements feasible by MRI of the thorax during CPR. Images were acquired using fast gradient echo with and without motion tagging. The acquisition was synchronized to the CPR device and images could be acquired at a temporal resolution of 30 ms during the compression-release cycle. Multiple slices can be scanned such that the whole thorax is imaged. Thus a sequence of volumes can be generated covering the complete compression-release cycle. External measurement of the displacement of the chest during compression yields a one-dimensional measure of chest deformation. Panels (a) and (b) of Fig. 9.10 illustrate the additional measurements provided by MRI. In addition to the anterior-posterior distance (light blue line) volumes of the heart chambers (red, LV) and the thoracic cavity (green) can be calculated. It is also apparent that the simple sternal displacement is not a sufficient parameter to estimate the sternal to spine distance (blue arrow).

The use of motion tagging allows the creation of 4D volumes where strain is mapped during the compression-release cycle. Panels (c) and (d) of Figure 9.10 depict such tags. Tags in a form of a grid are created before compression starts and can be imaged throughout the

Fig. 9.10. Axial MRI images of pig thorax during CPR. Left panels (a and c) are images during relaxed phase. Right panels (b and d) are at peak compression. Panels a and b illustrate the type of measurements that can be performed. The light blue line demonstrates the anterior-posterior distance of the sternum. Areas of the sections through the left ventricle (red) and the intrathoracic cavity (green) can be readily calculated. The image in panel a was taken before compression and panel b at the peak compression (20% AP distance). Deformation of the chest wall, the heart and other organs is clearly visible. Also visible is that the direction of compression was not through the sternum-spine axis (blue arrow), thus shortening at this axis can not be calculated simply from the AP distance. Panels c and d illustrate the use of tagging. MRI images are acquired during multiple phases of the compression-release cycle. Recording the movement of the tagged grid produces a strain map. The complex features of deformations during the circumferentially compressed phase are clear (panel d). (See Plate 9.10.)

compression-release cycle. Following the displacement of the tags results in a strain map. Figure 9.10 (panels (c) and (d)) show an axial slice of an animal chest before and at the peak of circumferential compression.

Blood pressure measurement

The most commonly measured blood pressures in CPR studies are the aortic and the central venous (or the right atrial) pressures. Figure 9.6(*a*) shows examples of recordings of these pressures. The largest difference between the pressures at CPR and the normal pressures of the beating heart is that the right atrial pressure has the same magnitude as the aortic. Sometimes the peak right atrial

pressure is even larger than the peak arterial. Since the pressure generating the blood flow to the myocardium (coronary perfusion pressure) is the difference between the arterial and right atrial pressures, even small errors in measurement of the latter pressures can produce relatively large errors in the estimation in the perfusion pressure. In addition, change of resuscitation techniques may produce large changes in absolute values in the aortic and the right atrial pressures while producing small changes in the heart perfusion pressure. Therefore requirements for accuracy of measurement of blood pressures during CPR are high. The pressure-time curves may have a complex shape with short spikes. Consequently, faithful reproduction of these shapes requires pressure

Fig. 9.11. (a) Transducing a pressure pulse to extravascular pressure transducer with displaying output signaling on a monitor. (b) Extravascular pressure transducer (ARGON CDX) with piezoresistors on microchip. (Used with permission of ARGON, a division of MAXXIM Medical.)

transducers that measure signals of frequency up to 20 Hz without distortion.

Methods of measuring blood pressure

The non-invasive indirect measurement of blood pressure that is common in clinical practice uses an inflatable cuff placed around the upper arm. Systolic and diastolic pressures are determined during deflation of the cuff either by listening to Korotkoff sounds or by utilizing the oscillatory method.[8,19,20] Due to the low peripheral blood pressure during CPR, these methods have limited applicability. Invasive techniques for measuring blood pressure place catheters inside a blood vessel. Measuring arrangements are of two types: either a fluid-filled catheter is connected to the tubing outside the body, which in turn is connected to an *extravascular pressure transducer* (Fig. 9.11),[9–21] or a catheter with a transducer at its tip is placed so that an *intravascular pressure transducer* contacts the blood directly (Fig. 9.12).

Similar to force transducers, a pressure transducer contains a mechanical elastic element (membrane or diaphragm) (Fig. 9.11(*b*) and 9.12). One side of the membrane is exposed to measured pressure, and the other is vented to atmospheric pressure. The deflection of the membrane is converted into an electrical signal by the strain gages. In nearly all modern pressure transducers,

Fig. 9.12. Intravascular pressure transducer. (Courtesy of Millar Instruments, Inc., Houston, Texas.)

the strain gages (sometimes called piezoresistors) are produced on one silicon chip.

Choice of pressure transducers for CPR studies

Blood pressure transducers with direct coupling, the Mikro-Tip Catheter Pressure Transducers (Millar Instruments, Inc., Houston) (Fig. 9.12), have a natural frequency of 50 kHz and provide non-distorted measurements of the blood pressure during CPR.

The transducers used in measurement of blood pressure with fluid coupling by itself have high dynamic quality. The CDX Transducer (ARGON, a division of MAXXIM Medical, Athens, Texas) (Fig. 9.11(*b*)), for example, has a dynamic response in excess of 100 Hz. The combination of mass of liquid in the connecting fluid-filled catheter, the elasticity of the catheter, and the hydraulic resistance of the catheter contributes to resonance within the hydraulic system. The resonance selectively amplifies different frequency components of the blood pressure signal, significantly distorting the signal. Extensive evaluation of the dynamic properties of the system for measuring blood pressure with fluid coupling can be found in References 8, 19–21.

Simultaneous recordings of the same aortic pressure with both types of transducers are shown in Figure 9.13(a) with direct coupling by intravascular Mikro-Tip Catheter Pressure Transducers SPC-470 (Millar, Inc., Houston); and in Fig. 9.13(b)) with fluid coupling by extravascular transducer P23 ID (Statham-Gould, Oxnard, California) and 7 Fr fluid-filled catheter. The Mikro-Tip transducer gives a correct recording of the pressure wave. The resonance of the fluid-coupling system on rising and decreasing fronts of the pressure signal distorts the signal and overestimates pulse pressure. Both measuring systems give similar mean pressure for compression and release intervals. Optimization of the dynamic characteristics of the fluid-coupling system may reduce the resonance but cannot eliminate it.

If the objective of the study is to record the correct vascular pressures, then the application of a pressure measuring system with direct coupling is essential. Because intravascular transducers cost significantly more than extravascular pressure transducers and are much more fragile, intravascular transducers are not readily available and are not a part of routine monitoring in hospitals. Thus these transducers are not already in patients at the beginning of an in-hospital arrest. Placing catheters with transducers during CPR is a difficult task, but it can be done in prolonged resuscitation.[22] In animal studies, however, the use of intravascular transducers should be routine for recording intravascular pressures.

Accuracy of blood pressure measurement

Accuracy of 1 to 2 mm Hg is easily achievable. Blood pressure transducers should be calibrated before each study, if possible, and calibration should be verified after each study. Usually, calibration is performed with mercury manometers, which are readily available in hospitals.

$P_{Maximum}$ = 155 mmHg

$P_{Avg.compression}$ = 123 mmHg

$P_{Avg.release}$ = 68 mmHg

$P_{Maximum}$ = 196 mmHg

$P_{Avg.compression}$ = 124 mmHg

$P_{Avg.release}$ = 70 mmHg

Fig. 9.13. Simultaneous recordings of aortic pressures by two transducers. (a) By intravascular transducer (b) By extravascular transducer. Note ringing at pressure upstrokes and down strokes, which distorts pressure waveforms as compared to waveforms measured with high-fidelity transducer in (a).

With appropriate care, pressure can be established with an accuracy of 0.2 to 0.3 mm Hg. Calibration with electrical means on the monitors or on connecting boxes (for Mikro-Tip Transducers) may add 1 to 2 mm Hg of calibration error.

The biggest challenge in blood pressure measurement is establishing the zero pressure level. External transducers have a port that can be exposed to ambient pressure for establishing zero pressure level, which is generally placed at the level of the right atrium. The same zero level can be established for different extravascular pressure transducers independent of the position of the ends of the attached fluid-filled catheters. The output signal for zero input pressure for intravascular transducers should be established before insertion of the transducer into the vessel and

checked after the experiment. Since the zero level pressure in these transducers depends on the position of the tip of the catheter in the body, this discrepancy can reach 1 to 2 mm Hg. Therefore the post-experiment zero level should be checked in vivo (if the experiment allows).

Blood flow measurement in cardiopulmonary resuscitation

Blood flow is a critical determinant of survival. Blood flow is quantified as the volume of fluid passing through a cross-section of a blood vessel per unit time. If a small volume of blood (δV) has passed through the cross-section in a short time (δt) then the flow is as follows:

$$F = \frac{\delta V}{\delta t} \tag{9.15}$$

The flow can also be related to velocity of liquid in the cross-section. If the velocity is the same across the cross-section, then the volume of liquid that will pass the section in the time interval δt is as follows:

$$\delta V = uA\delta t \tag{9.16}$$

Here, u is a velocity of liquid in the cross-section, and A is the area of the cross-section. From Eqns 15 and 16, it follows that, when velocity is the same across the cross-section, the flow is as follows:

$$F = uA \tag{9.17}$$

When the velocity is not constant across the vessel cross-section, it should be substituted in Eqn 17 by an average across the cross section value of the velocity $\bar{u}(A)$:

$$F = \bar{u}(A) \cdot A \tag{9.18}$$

From Eqn (9.15), it follows that if flow is constant, the volume that passes the cross section in time interval Δt from t_1, to t_2 (i.e., $\Delta t = t_2 - t_1$) is as follows:

$$V = F(t_2 - t_1) \tag{9.19}$$

If the flow is changing in time, then constant flow (F) in Eqn (9.19) has to be substituted for mean (average in time) flow ($\bar{F}$):

$$V = \bar{F}(t_2 - t_1) \tag{9.20}$$

Flow is characterized by both magnitude and direction. *Antegrade blood flow* is usually assigned a positive value, whereas *retrograde flow* (e.g., the valve regurgitation flow) is assigned a negative value. During CPR the blood flow in vessels usually changes direction from antegrade to retrograde during one chest compression cycle. The resulting mean flow defines the blood supply to the organs. The measurement of the *regional tissue blood flows*, or *organ per-fusion*, during CPR provides information on distribution of cardiac output to different organs. Success of CPR depends on sufficient blood supply to the heart and brain.

Methods of measuring blood flow

Both non-invasive and invasive techniques are used for measuring blood flow. An example of a non-invasive technique is the transcutaneous or the intraesophageal ultrasound echo Doppler technique.[23] Some invasive techniques require placement of catheters into blood vessels by transcutaneous or surgical cutdown access; examples are cardiac output measurements by the Fick principle or by thermo dilution.[19,24–27] Other invasive techniques require surgical procedures to access the external surface of the blood vessels to place a flow probe.[19,25,26,28] Measurement of regional blood flow by labeled microspheres requires sacrifice of an animal for acquiring tissue samples.[29,30]

Methods of blood flow measurements can be classified as follows: (*a*) use of tracers of various sorts (e.g., thermodilution or labeled microspheres);[25,26,29] (*b*) utilizing electromagnetic flow probes;[25,26,28] (*c*) methods utilizing transit-time ultrasonic flow probes,[31,32] (*d*) ultrasound echo Doppler technique,[23] and laser–Doppler flow methods.[33–35]

Distinctive features of blood flow measurement

Compression on the chest produces extensive mechanical movement and vibration of the chest, organs, and vasculature inside the chest and abdomen; consequently techniques such as transcutaneous or intraesophageal ultrasound echo Doppler, which require steady positioning of the transducer relative to the blood vessels, cannot be used during CPR.

During cardiac arrest, arterial pressure drops to the level of the mean systemic pressure (7 to 10 mm Hg), causing a significant decrease in aortic and arterial radii. During resuscitation the aortic and arterial pressures increase but still can be much lower than before arrest. Therefore, the arteries will be smaller than before arrest. Such arterial shrinkage will cause changes in mechanical coupling of the flow probes to the aorta and arteries.

During CPR, blood flow is usually substantially lower than in the intact circulation. In addition, during CPR, blood flow in most vessels alternates between antegrade and retrograde directions (Fig. 9.14). While the magnitude of the antegrade *instantaneous flow* (the flow at a particular time moment) can be large, subsequent retrograde flow negates some of it. Consequentially, the mean flow for a

Fig. 9.14. Recording of blood flow during resuscitation by electromagnetic flow meters. (a) Carotid flow during conventional resuscitation. (c) From ref. 50.

whole compression cycle could be rather small. Therefore it is of paramount importance to verify the output signal of the flowmeter when the flow rate is equal to zero.

This section will evaluate current methods of blood flow measurement by microsphere injection and with flow probes.

Measurement of blood flow with microspheres

Measurements of blood flow by known concentrations of tracers in the blood have been used for more than a century. In 1870 Fick introduced measurements of cardiac output by measurements of oxygen or carbon dioxide concentrations in arterial and venous blood and the uptake of oxygen or release of carbon dioxide by lungs. The tracers can be introduced into the bloodstream continuously or as a single bolus injection. Although single-bolus injection is utilized in the clinically popular measurement of cardiac output by thermodilution, this technique is not applicable during CPR because of low blood flow and extensive movement of the body.

Measurement of organ perfusion by injection of radionuclide-labeled microspheres in animal CPR studies was extensively studied by Koehler *et al.*[29] in the 1980s and is now widely accepted. In general, a known amount of tracer (Q) is injected into the bloodstream as a bolus (Fig. 9.15(a)) during a short time interval. Arterial blood is sampled by withdrawal by a syringe with a calibrated rate. To ensure accuracy of blood flow measurement, the tracer should be uniformly mixed with blood (i.e., the concentration [c] of the tracer in any cross-section in a vessel after the mixing chamber is constant); in addition, tracer particles should move with the same velocity as the flow particles.[27] After the bolus injection the concentration of the tracer in the blood distal to the mixing chamber changes with time, as shown in Fig. 9.15(b).

It can be shown[25,26] that if the amount of the tracer is known, the flow can be calculated as follows:

$$F = \frac{Q}{\int c \cdot dt} \tag{9.21}$$

Here the denominator of Eqn 21 ($\int c \cdot dt$) is the area under the tracer concentration curve in Fig. 9.15(b). Thus, if the

Fig. 9.15. (a) Principle of measuring organ perfusion by microsphere injection. (b) Concentration-time curve after fast injection of microspheres.

total amount of the tracer injected into the bloodstream is known, and the concentration of tracer in the blood after the mixing chamber can be measured, then the blood flow can be calculated. This method is used in cardiac output measurements with thermo dilution. During resuscitation, organ flow is measured with 15-μm diameter microspheres. These microspheres are nearly completely trapped in the capillaries, and therefore the rate at which the tracer leaves the organ is negligible. To avoid measurements of concentration of the spheres in the bloodstream, the reference sample of blood is withdrawn from an artery with a constant known flow (F_{sample}) (Fig. 9.15(a)). The syringe that withdraws the arterial blood can be looked on as another organ with known blood flow to it (F_{sample}). Since only the amount of microspheres in the sample is important, withdrawal starts before the microsphere injection and continues until the blood is cleared of spheres. It can be shown that the blood flow to an organ is as follows:

$$F_o = F_{sample}\frac{Q_o}{Q_{sample}} \tag{9.22}$$

In CPR research the amount of microspheres in an organ is measured as the amount trapped in 1 g of tissue. Substituting Q_{100} in Eqn (9.22) for Q_o we get for the blood flow to 100 g of tissue:

$$F\left(\frac{ml}{min \cdot g}\right) = F_{sample}\frac{Q}{Q_{sample} \cdot w} \tag{9.23}$$

where w is the assayed tissue weight in grams.

The number of spheres is measured as the amount of radioactivity or concentration of dye, depending on the type of microspheres that were used.[29,33,35–40] Multiple injections could be performed with microspheres labeled with different radioactive nuclides, different colors or different isotopes. The numbers of each different microsphere in one sample are then determined by differential spectroscopy,[29,30,38] or colorimetry.[36,37,39,40]

Practical considerations

While measuring organ blood flow with radionuclide-labeled microspheres, the spheres are injected into the left ventricle via a catheter. The number of spheres injected should be about 1 to 3 times 10^6. Additional fast flushing of the catheter with 10 ml of saline ensures that no spheres are left in the catheter and improves mixing of the spheres with blood in the left ventricle. The amount of injected microspheres depends on the minimal amount that is required for reliable assay. The estimate of the injection amount can be calculated as follows:

$$n = \frac{n_{min}}{F \cdot S \cdot CO_f} \tag{9.24}$$

where $F \equiv \dfrac{F_{reduced}}{F_{normal}}$; $S \equiv \dfrac{\text{tissue sample weight}}{\text{Organ weight}}$;

$CO_f \equiv \dfrac{\text{normal flow to organ}}{\text{normal cardiac output}}$; n_{min} is the minimal amount required for reliable assay and n is the injected amount.

The reference samples are taken from at least two arteries lying on both sides. Closeness of counts in the two arteries ensures that spheres have been well mixed in the blood. The reference sample withdrawal time should be at least 2 minutes.[29] Instability of blood flow for such a long time would introduce significant errors in estimations of blood flow. Spheres with lower energy emissions (e.g., [113]Sn) should be injected when the flow is greatest; before arrest.

For radioactive microspheres, the numbers of microspheres in blood and tissues are counted on gamma spectrometers. The overlap of counts in tissue from high-energy isotopes into windows of lower-energy emission is

subtracted to obtain a corrected count value for each isotope by differential spectroscopy.[30]

The following factors can cause error.

1. Instability of blood flow during blood sampling time, which should extend for at least 2 minutes.[29]
2. Any interruption of CPR during sampling time.
3. Poor mixing of microspheres in the left ventricle and sedimentation of spheres.
4. Any problems with the pump that withdraws the reference blood sample and discrepancy between counts in two samples (Koehler *et al.*[29] reported a discrepancy on the order of 1.5%).
5. Microsphere shunting across the venous bed and recirculation of spheres (Koehler *et al.*[29] found that shunting across the cerebral bed was $4.1 \pm 2.3\%$ during CPR).
6. Small numbers of spheres in some tissue samples.
7. Pulsatility of blood flow.[24]

Currently, we do not have realistic measurements of accuracy of regional blood flow during CPR by radionuclide-labeled microspheres. We can only estimate that the uncertainty of these measurements is at least 10% of the measurement. If the technique of the investigator is not perfect, the uncertainty can be 20% to 50% of measurement or even much higher.

Non-radioactive microspheres

Non-radioactive microspheres with affixed fluorescent non-leaching labels or neutron-activated isotopes have been added to regional blood flow measurements for four major reasons: (*a*) the cost of disposal of radioactive waste is becoming prohibitively expensive; (*b*) there is a danger to the health of laboratory personnel, however small; (*c*) animals injected with radioactive material are difficult and expensive to maintain; and (*d*) new technology of tissue processing and color analysis is improving in quality and is less costly.

Color

Fluorescent microspheres alleviate the problems associated with using radioactive material in animals. The use of fluorescent and radioactive microspheres is similar. Instead of detecting the amount of microspheres trapped in tissue sample by nuclear spectroscopy, fluorescent microsphere amounts are detected by fluorometry. In order to assay the fluorescence of the microspheres in tissue samples, the tissue has to be processed. Van Oosterhout *et al.*[37] describe a method for extracting the microspheres from the blood and tissue and than extracting the dye from the microspheres so it can be assayed using a luminescence spectrophotometer. It was later shown that fluorescent microspheres were superior to their radioactive counterparts when blood flow was

measured in chronic experiments.[36] Detailed technical discussion of the use of fluorescent microspheres can be found in the manufacturers' documentation.[39,40]

Neutron-activated

The latest microsphere technology is neutron-activated microspheres.[38] Like the fluorescent microspheres, it is not hampered by the use of radioactive material. At the same time, like the radioactive microspheres, it does not require digestion of the tissue. The microspheres are loaded with non-radioactive isotopes. Once tissue is harvested it is rinsed and dried in the investigator laboratory and sent to the manufacturer for assay. The assay procedure involves activation of the isotopes by neutron bombardment and measurements of the decay of the different isotopes in the sample. Currently, 12 different isotopes are available.

Blood flow measurement with flow meters

Blood flow meters contain at least two major parts: a flow probe producing a signal functionally related to the flow (usually proportional) and an electronic unit supplying energy to the flow probe, processing the output signal of the flow probe, and presenting the result to the observer. Blood flow measurement with flow meters requires placing a flow probe in the circulation. The degree of surgical intervention depends on the vessel in which the blood flow is measured and on the design of the flow probes. Independent of the physical principles on which flow measuring is based, we can distinguish three major types of flow probe design: perivascular, cannulating, and intravascular.

The perivascular probe is placed around the vessel. The required tightness of fit of the perivascular probe to the vessel depends on the physical principles of the flow measurement.

The cannulating flow probe is composed of a short tube with a sensor in the middle part. The vessel is transected and the flow probe interposed between the cut ends. Thus the entire volume of blood flowing through the vessel goes through the flow probe. The advantage of the cannulating flow probe is the fixed geometry, which guarantees the fixed velocity profile inside the probe, whereas the major disadvantage is that the anatomy of the vessel is altered, which might alter the hemodynamics.

The intravascular flow probe measures the velocity in the vicinity of the probe rather than the flow. Hence, such flow probes are often termed *velocity meters*. Measurements of the flow by these probes rely on knowing the vessel cross section and the velocity profile in this section and on stability of the cross section and the profile during measurement. Because these conditions are uncertain during CPR,

intravascular flow probes have very limited use during CPR research.

Electromagnetic flow meters

The principle of electromagnetic flow meters is based on Faraday's law; namely, the electromotive force is generated when the conducting medium (blood) moves across the magnetic field (Fig. 9.16). The electromagnet produces the magnetic field with the magnetic flux density (B), across the vessel. Blood moves across the field with velocity (u), and as a result electromotive force (E) is generated in the blood. This voltage is picked up by the electrodes positioned on the walls. In a cannulating flow probe, the tube is made from an isolating material and the electrodes are placed inside the tube so that they are in contact with the flowing blood. In a perivascular flow probe the body of the probe is placed tightly around the blood vessel so that

the electrodes on the internal surface of the probe do not lose contact with the blood vessel.

It has been shown[28] that, under ideal conditions, distribution of the voltages and currents in the flow probes produces the voltage E on the electrodes that is proportional to the average across the cross-section flow velocity

$$\bar{u}(A) : E = dB\bar{u}(A) \tag{9.25}$$

where d is the diameter of the blood vessel and B is the magnetic inductance. Thus it follows from Eqns 18 and 25 that the electromagnetic flow meter generates a signal proportional to the flow. The signal of the flow probe is on the order of microvolts so that the flow meter requires high-quality, powerful amplification. The flow probe produces voltage proportional to flow, as long as flow is axially symmetric. The cannulating flow probe provides the proper flow profile, since it has a tube of sufficient length. The perivascular flow probe measures flow accurately in

Fig. 9.16. Principle of electromagnetic flow meter, B, density of magnetic flux; u, velocity of blood; E, flow-induced electromotive force.

most arteries but not in the aorta, where the profile is non-symmetric.[9] When the perivascular flow probe is implanted and has become attached to the vessel by connective tissue, the shape of the vessel may be distorted, which can cause a non-symmetric flow profile.

Polarization of the electrodes in contact with blood or vessel produces voltages of higher magnitude than that of the flow signal. To exclude the polarization effect, the magnetic fields of the flow probes are produced by alternating electric current.

Some of the flow meters utilize a sinusoidal current of 400 to 700 Hz. In addition to the signal proportional to the flow, these flow probes also generate what is called a *transformer voltage*, which is not flow-related. This voltage is generated because of interaction of the winding of the probe, which produces the magnetic field, with a circuit comprising the electrodes, the blood between them, and the wires leading to the electrodes. The probe winding and this circuit function as primary and secondary windings for an unintentional de facto transformer. It is fortunate that the transformer voltage has a 90-degree phase shift in reference to the flow signal. The flow probe manufacturers reduce the transformer voltage by proper alignment of the wires leading to the electrodes. Nevertheless, complete compensation of the transformer voltage cannot be achieved. The flow meter electronics utilize different schemes of gating to overcome this voltage. Some of the flow meters have a gate knob that can be properly set. The appropriate gate number for the particular flow probe can be either supplied by the manufacturer or measured according to the flow meter manual.

The square-wave flow meters utilize power supplies that deliver constant current into a flow probe for a very short time interval, switching the direction of the current. The transformer voltage in these flow probes has the form of short spikes, which are gated out by the flow meter electronics. These spikes do, however, have the unwanted effect of producing eddy currents in the blood.

The biggest problem encountered with the use of electromagnetic flow meters is a zero flow variation. In sinusoidal flow meters the zero shift is caused by uncompensated transformer voltage and by currents leaking into the electrode circuitry. In square-wave flow meters, the major zero instability is caused by presence of the eddy currents during the field switching. The most reliable zero flow checking is by complete occlusion of the vessel while the flow meter is on. We estimate the uncertainty of flow measurement with electromagnetic flow meters to be 5 to 10% of full scale range.

Transit-time ultrasonic flow meters

A transit-time ultrasonic flow probe manufactured by Transonic Systems Inc. (Ithaca, New York) consists of a probe body, which houses two ultrasonic transducers, and a fixed acoustic reflector (Fig. 9.17). The transducers are positioned on one side of the vessel under study, and the reflector is positioned midway between two transducers on the opposite side.

An electrical excitation causes the downstream transducer to emit a wide plane wave of ultrasound, illuminating the vessel's full width. This ultrasonic wave intersects the vessel in the upstream direction, then bounces off the acoustic reflector, again intersects the vessel, and is received by the upstream transducer, where it is converted into an

Fig. 9.17. Schematic view of perivascular ultrasonic volume flow meter. By means of wide beam illumination, two transducers pass ultrasonic signal back and forth, alternately intersecting flowing blood in upstream and downstream direction. (Courtesy of Transonic Systems Inc., Ithaca, New York.)

Fig. 9.18. Schematic view of ultrasound Doppler echo frequency determination.

electrical signal. From these signals the flow meter derives an accurate measure of the *transit time* taken for the wave of ultrasound to travel from one transducer to the other.

The same transit-receive sequence of the upstream cycle is repeated but with the transmitting and receiving functions of the transducers reversed so that the blood flow is bisected by an ultrasonic wave in the downstream direction. Again, the flow meter derives and records an accurate measure of transit time from this transmit-receive sequence.

During the upstream cycle the sound wave travels against flow, and total transit time is increased by a flow-dependent amount. During the downstream cycle the sound wave travels with flow, and total transit time is decreased by the same flow-dependent amount. The flow meter subtracts the downstream transit time from the upstream transit time and calculates the average velocity of the liquid along the path of the beam.[31] The beam illuminates the vessel's entire cross section, and the flow meter yields volume flow: average velocity multiplied by the vessel's cross-sectional area. Since the transit time is sampled at all points across the vessel, volume flow measurement is independent of the flow velocity profile. An electronic zero-flow reference signal is generated by subtracting two consecutive upstream measurements instead of using an upstream and a downstream measurement. This eliminates the need for clamping the vessel to establish the zero flow baseline.[32]

Transonic Systems Inc. manufactures both perivascular and in-line (cannulating) flow probes. Perivascular probes are non-constricting and allow some misalignment of the flow probe with the vessel. The free space in the probe should be filled with jelly, which serves as an acoustic couplant. The company guarantees high accuracy of the flow probes: for a perivascular probe appropriate for a 4-mm

vessel, the maximum uncertainty of zero offset is 4 ml/min, and the maximum uncertainty of the calibration slope is 10%; for a cannulating flow probe with 3.2-mm internal diameter (maximum flow range, 150 ml/min), the maximum uncertainty of zero offset is 2 ml/min, and the calibration slope is 7%. The zero flow uncertainty is usually smaller for most of the probes, and the slope uncertainty can be reduced by *in situ* calibration.

Ultrasound Doppler flow meters

Ultrasound Doppler flow meters[41] also known as color Doppler sonography have not been commonly used to quantify blood flow during CPR Experiments. Figure 9.18. depicts the principle of the velocity measurements using Doppler effect. The received frequency ($f_{received}$) is:

$$f_{received} = f_{transmitted}\left(1 + 2\frac{V_{blood}}{V_{tissue}}\cos\alpha\right) \qquad (9.26)$$

where V_{tissue} is the velocity of sound in the tissue, V_{blood} is the velocity of the blood, and α is the Doppler angle of incident ultrasound beam.[42] Newer Amplitude-coded Doppler solves problems of aliasing and angle dependence.[42] Unlike older continuous wave monitors, pulsed ultrasound is location-specific. This technology has been widely used in postresuscitation assessment of blood flow and cardiac output.[43,44]

Trans-esophageal echo (TEE) has been used in animals[45] and humans[46] during resuscitation to measure cardiac output. While extravascular probes are difficult to use during resuscitation because the motion caused by compressions, newer intravascular probes might facilitate the use of ultrasound Doppler[47,48] during experiments.

Laser Doppler flow meters

Tissue blood flow can be measured using Laser Doppler flow meter. The principles of operation of laser Doppler are similar to ultrasound Doppler flow meter. Here to the transmitted beam is reflected, or more accurately scattered, by the cells in the blood. The shift in the frequency of the light is than used to calculate velocity. Small probes can be implanted close to an area of interest to monitor blood flow. Nordmark and Rubertsson[34] implanted a probe (Periflux, Perimed) directly over the frontal cortex of piglets via a burr hole to monitor blood flow continuously during CPR.

MRI

Magnetic resonance imaging can be used to measure blood flow by using established clinical protocols. Krep

et al.[49] report additional use of MRI and NMR to assess perfusion and the metabolic state of the brain during CPR. Diffusion-weighted imaging was used to monitor brain perfusion by calculating water diffusion coefficient which is sensitive to intracellular water and cell volume. Proton spectroscopy (^{1}H-NMR) was used to monitor brain lactate as an indicator of metabolic state.

Application of flow meters in CPR research

The specific features of cardiac arrest and the CPR procedure present significant challenges to the use of flow probes. As noted above, the resuscitation process produces significant motion and vibrations in the subject's body. As a result, the acutely placed perivascular probes may move around the vessel, changing their placement position and angle. In addition, the aorta and arteries are smaller during cardiac arrest and resuscitation than they are before arrest. This decrease in the vessel's size exaggerates the flow probe movement. In electromagnetic probes, arterial shrinkage will cause partial or even complete loss of contact of electrodes with the vessel. In ultrasound flow probes, the reduction in vessel size will cause disruption of sound coupling. The vibration can also cause leakage of the acoustic coupling jelly.

The implanted perivascular electromagnetic flow probes have been used by Wolfe *et al.*[50] for aortic and coronary flow measurements (Fig. 9.12(*c*)). Scarring of the flow probe prevents the implanted flow probe from losing contact with the vessel. Vibrations of the subject cause vibrations of the probe in relation to the vessel, however, which may influence the flow measurements. Another concern is that the scarring prevents the vessel from the shrinkage that is natural during CPR (see above). This modification of the vessel anatomy by the flow probe may influence the flow. Of note also, the implanted flow probes should be calibrated *in vivo*.[25,26] Chandra *et al.*[51] used cannulating flow probes to measure carotid flow (Fig. 9.14). Although cannulating probes present significant difficulties in their placement, they guarantee the best accuracy.

As already noted, blood flow during CPR alternates directions in the vessels (Fig. 9.12(a)). High magnitude of the positive and negative flow values requires the use of large full scale ranges. At the same time the mean flow value could be small, on the order of the error of measurement for the chosen scale. Thus measurements of phasic blood flow by flow meters during CPR require continuous development. It is conceivable that transit-time ultrasonic flow meters may provide, in the future, the necessary accuracy.

Air flow

It is of interest to measure the air flow during CPR. Air flow can be measured using a pneumotach. Most pneumotach transducers are low differential pressure transducers. Air is made to flow through some small resistance such as a number of thin glass tubes. At slow flow rates, the difference between the pressure before and after the resistance is proportional to the flow. The pneumotach is calibrated by blowing a known volume of air through it while recording the transducer response. The relationship between the voltage and flow can be calculate as: $V = \int_{t_s}^{t_e} v(t)\,dt$ where V is the volume, $v(t)$ is the transducer voltage, t_s and t_e are the starting and ending times. A pneumotach system that provided heating if the resistive elements is preferred. Heating prevents condensation in the resistive elements and thus prevents changes in the resistance.

Regulatory aspects of calibration in CPR research

In the United States, requirements for proper calibration are clearly spelled out for manufacture of medical equipment[52] and for non-clinical laboratory studies,[53] which are performed to provide the data in support of applications for investigational device exemption[54,55] or marketing permits for medical equipment.[56]

The regulations entitled *Good Laboratory Practice for Nonclinical Laboratory Studies*[53] state that "equipment used for generation, measurement, or assessment of data shall be adequately tested, calibrated and/or standardized," that "written standard operating procedures [are] required," and that "written records shall be maintained of all inspections, maintenance, testing, calibrating and/or standardizing operations." Therefore, any experimental data submitted to the US Food and Drug Administration for approval of a drug or device must have been acquired by use of instruments that meet these criteria.

CPR research uses many measurements performed in clinical laboratories. The quality of measurements in these laboratories is strictly regulated. In the United States, clinical laboratories have to be certified by federal and local governments.[57] To acquire certification, the laboratories must have written procedure manuals for performance of all analytic methods used by the laboratory. Procedure manuals must include, when applicable to the test procedure, calibration and calibration verification procedures. Extensive work for developing calibration procedures for clinical laboratories has been performed by the National Committee for Clinical Laboratory Standards, which has produced many publications on this topic.[58] Both the scientific community in CPR research and the manufacturers

of equipment for CPR should devote more attention to developing standardized methods of static and dynamic calibration of measuring devices used in CPR research.

This chapter is designed to provide a comprehensive, systematic account of the methods of conducting clinical research in resuscitation, in particular, how to set up and carry out a comprehensive and meaningful clinical trial. We will follow the natural conduct of a study, from designing the protocol through data collection to evaluation and interpretation. As an example of some of the difficulties and also the satisfactions of a job well done, in the Appendix we present Professor Wenzel's personal description of the trials and tribulations of determining the role of vasopressin in treatment for cardiac arrest.

Study design

Study objectives

Clinical research in cardiac arrest has developed slowly during the last few decades as compared with other disciplines. The objectives of completed, scheduled, or planned studies can roughly be divided into three categories: (1) epidemiology, i.e., collection of information on prevalence, chance and risks of clinical conditions that require resuscitation attempts; for example, anecdote in the Appendix, elevated endogenous vasopressin levels in survivors of cardiac arrest were found in previous epidemiological studies; (2) evaluation of established treatments and algorithms for resuscitation that are practiced with or without proof of efficacy; for example, in the anecdote, historical data on CPR with vasopressin were available; (3) randomized clinical trials performed to collect evidence on the efficacy and safety of established or new interventions or therapeutic strategies following cardiac arrest; for example, the anecdote describes a randomized clinical trial performed to gain evidence on the efficacy of vasopressin as compared to the established epinephrine injections during out-of-hospital CPR.

Study protocol

For all clinical trials and indeed other experimental studies, a comprehensive protocol is required that summarizes in detail the study objectives and procedures before the study starts. This protocol is the foundation for all decisions of sponsors, ethics committees, review boards, insurance companies or regulators, for conduct, evaluation, and publication. It provides detailed guidelines for study participants (researchers and patients), on how the study must be carried out (for example, recruitment and inclusion and exclusion criteria), and how to deal with potential conflicts. Although time-consuming, a well-designed and well-written protocol will prove invaluable during the course of the study.

Fundamental decisions in study design

When planning a clinical study in resuscitation or in other medical subjects, there are a few basic options that require fundamental decisions. The best choices will depend on the study objectives and on the practical restrictions of the researcher.

External vs. internal validity
Two potentially conflicting goals have to be in accord in a study: (1) Any conclusion from a study is based on some comparison. Usually, these comparisons involve a

reference group or control group that does not exhibit the characteristic or experience the intervention under study. If the study allows a fair comparison to the reference group, the differences between the study groups can be ascribed to the characteristics or interventions under study only; such studies are called **internally valid**. In general, the best method to attain internal validity is by randomization. (2) Usually, the conclusions that apply to a general population or target population are of interest. For this purpose, the study population should be representative of the target population. If representiveness is guaranteed to a sufficient degree, the study is called **externally valid**. Ideally, external validity is accomplished by random selection from the target population. This can be accomplished by a broad selection of study centers in different countries, which may or may not represent all providers of resuscitation.

It is almost impossible to achieve perfect internal and external validity in a single study. For example, registers are usually selections from a target population that are complete for a defined period of time and thus ideally represent that period, but lack internal validity because of several confounding influences. On the other hand, randomized trials allow optimal internal comparisons, but, in order to permit randomization and attain a study of high quality, special centers and patients have to be selected that agree to randomization and fulfill restrictive inclusion and exclusion criteria, resulting in a lack of generalizability of the conclusions to routine health care. Thus, a decision must be made with respect to which goal is more important in the particular study. In epidemiology, external validity is usually considered to be more important in order to receive information from 'the real world' and thus, epidemiologic studies should include at best all patients suffering from cardiac arrest and considered for CPR from a well-defined area. On the other hand, proof of efficacy of a therapy requires high internal validity and would be better targeted in randomized controlled trials. Studies on health care usually try to give equal weight to both aspects.

Observational vs. interventional approach

A decision closely linked to the competing goals of external and internal validity is the choice between observational[7] and interventional[8–11] study approaches. In an observational study, once the study population is selected, patients are simply observed in the natural course of the disease with the therapies that they would receive anyway, regardless of whether they are in a study or not. By contrast, in an interventional study, the treatments under investigation will be allocated to the patients according to some allocation scheme that is designated in the study protocol.

Interventional studies obviously raise serious questions on ethical and practical issues. Physicians or patients may find it difficult to accept that the treatment a patient receives is determined by some arbitrary or random allocation scheme that is not derived from an individual clinical judgment. The justification for interventional studies is methodological. In observational studies, the treatments under study are always allocated in some way according to the characteristics of a patient or his/her disease; thus, it is never known, whether differences between groups are due to the treatment or to the different characteristics confounded with the treatment effect. For example, when comparing patients who receive bystander CPR with those who do not, the former group might be favored by being younger, with fewer co-morbid diseases, and thus bystander CPR might look more favorable in a study than it does in the real world. The differences may be measured and statistically corrected by adjustment, but there will always be some differences between groups in characteristics that cannot be or were not measured, introducing a hidden bias. In principle, this possibility limits the conclusions from observational studies. This problem can be overcome by artificial (optimally random) allocation of the patients to the treatments, so that all treatment groups under comparison have the same chances of success if treatments are equally effective. This argument alone renders randomized controlled trials sufficient and necessary to collect strong evidence on the efficacy of a treatment, despite ethical and practical concerns.

Interventional studies cannot be avoided if a high standard of internal validity is required. On the other hand, a high standard of external validity and reflection of 'real world' performance of a therapy can be accomplished more easily by observational studies. Nonetheless, the choice between the two approaches is determined by the practicability of the study (e.g., recruitment, timing of procedures), the potential participants, conclusions to be drawn, final acceptance in the scientific community and opportunities for publication. It is difficult or seem to be impossible to randomize resuscitation trials, in particular when early defibrillation,[12,13] bystander CRP,[14,15] or early call for ambulance is studied; on the other hand, the published observational studies raise concerns about confounding factors that may have biased the results.

Confirmatory vs. exploratory analysis

At the end of the study, the groups are usually compared for a wide variety of results in order to receive a complete picture of all clinical aspects. While this approach reflects the desire of a physician not to miss anything of relevance,

it has the risk of overinterpretation of chance findings. Thus, the thorough search for differences is "frowned upon" by methodologists as "fishing expeditions." In contrast, to control random effects and error probabilities in a scientific study, the pre-specification of what is called 'primary analysis' is required, consisting of the exact definition of a primary endpoint, statistical hypotheses on the differences between groups, establishing a method of statistical evaluation, and a sample size calculation. The hypothesis to be tested is derived from a therapeutic model and from previous experience. The model is obtained by integrating the assumed mechanism of action of the intervention to the pathophysiology of the disease. Past experience is published from relevant studies of any kind before the start of the new trial. In principle, it is possible to have more than one primary endpoint in a trial, but this requires a larger sample size or a prior ordering of hypotheses that may be wrong, so the restriction to one endpoint is usually recommended.

In general, an analysis as described, with pre-specified hypotheses and evaluation schemes, is called 'confirmatory' since it is performed to confirm a pre-specified assumption. This approach is the only generally accepted way to attain a high level of evidence for a presumption. All other comparisons between study groups are called 'exploratory' since they can only generate new possibilities, but not prove them. Further studies are required to confirm these new hypotheses.

It is of utmost importance when dealing with study results to distinguish those that are confirmatory from those that are exploratory of, for example, a randomized trial. The results of analyses that were not specified before the trial cannot be taken for granted even if they stem from a randomized study.

In the Appendix, a randomized controlled study was performed. It was pre-specified that vasopressin treatment should be compared to epinephrine treatment with respect to survival to hospital admission. No significant difference was found between treatment groups. Surprisingly, better performance was found in patients who received epinephrine after unsuccessful use of vasopressin. Since this comparison was neither pre-specified, nor randomized, however, a new hypothesis that possibly vasopressin and epinephrine should be given in combination was generated, but not proven. This would require a new randomized controlled trial.

Once the objectives of the study are defined and the fundamental decisions are made, study type, study population, endpoints, and sample sizes have to be settled in the study protocol. These partly technical points are discussed below.

Study types

Responses, factors, and covariates

In general, clinical studies are designed to evaluate the influence of certain characteristics, exposures, or treatments (called 'factors' if discrete and 'covariates' if continuous, by statisticians) on clinically relevant endpoints (called 'responses' by statisticians).

The number of variables to be studied in cardiac arrest epidemiology research is substantial. The endpoints mostly deal with aspects of survival, e.g., immediate survival (i.e., return of spontaneous circulation), admitted alive to hospital, alive after 24 hours, alive at hospital discharge, alive at 1 month after cardiac arrest, and alive at 6 months after cardiac arrest, cerebral function, and quality of life. Few studies in the past have been adequately powered to address whether an intervention can increase survival to discharge from hospital. But in the future, more studies should be powered to address this issue and also to address whether it is possible to increase the proportion of patients who survive to hospital discharge with good cerebral function.

Factors and covariates include (a) demographics, (age, sex and co-morbidity), (b) circumstances around the cardiac arrest (witnessed status, place, etiology, presenting rhythm, time of day, week and year), and (c) aspects on treatment (including delay to start of treatment, use of medication, intubation, and so on).

Prospective, cross-sectional, and retrospective sampling

There are three sampling schemes that permit the associations of endpoints and factors to be studied. In cross-sectional studies, a target population is examined for the coincidence of factors and responses. In prospective studies, patients are sampled according to the exposure or treatment of interest, and the subsequent responses are observed. In retrospective sampling, cases (patients with critical outcome) are matched with similar controls without critical outcome, and exposure or treatment is collected from records. Each of the sampling schemes has advantages and disadvantages. Statistical analysis should be oriented according to the sampling scheme.

Observational studies: register, cohort studies, case-control studies

Medical registers document specific health care situations. Thus, external validity is of highest priority. Registers are observational by nature. Complete documentation of all cases or cross-sectional sampling (preferably random sampling) are natural approaches. The limitation of registers is the lack of internal validity because of significant confounding. Hence, registers are sometimes not valued

by scientists who are only interested in first-class evidence for cause–effect relations. Recent experiences with safety problems in licensed drugs, however, have raised awareness that registers are indispensable for pharmacovigilance and optimization of use of principally effective treatments in daily life. In particular, in resuscitation medicine, there is an urgent need for registers, since routine data are collected according to local customs and cannot easily be compared or combined.

While medical registers are well suited to give an overall picture of the epidemiology and practice of resuscitation medicine (objective 1), they may be suboptimal for addressing specific research questions on certain accustomed or newly introduced interventions (objective 2). If suspicion is raised that there is a problem requiring a quick answer, or if study funds are severely limited, case-control studies that apply retrospective sampling, as described above, are good choices. Today, these studies can frequently be performed by selection from existing databases, possibly after linkage of different sources of information. Two limitations of case-control studies cannot be overcome, however: (1) missing data can usually not be retrieved retrospectively; and (2) criteria for choice of controls are usually neither unique nor exhaustive; different choices of controls may affect the result of the study, leaving researchers unable to assess which analysis they should trust.

Within the observational approach, both limitations can be overcome by a prospective study design. The collection of data can be monitored, and there is a natural control group: the unexposed or not treated patients. Two types of prospective studies are common: studies with historical controls, and cohort studies.

If a new treatment is introduced and data are collected, the observed successes can be compared with the previous successes in the same unit before the new treatment was introduced. Such a control group of patients is called 'historical'. For example, the hypothesis that early chest compression prior to defibrillation improves survival stems from a historical control study.[16] In this study a new routine (early chest compression) was introduced and outcome after ventricular fibrillation was compared before and after introduction of this new routine. The limitations of this approach are obvious: other aspects might have changed as well, including the study population, the skilfulness of the ambulance crew, and other treatment regimens. In studies with historical controls, the general medical progress is attributed to the new treatment and takes it piggy-back. Thus, a subsequent randomized confirmation trial will frequently end in disappointment. In consequence, a study with historical controls alone cannot be relied upon if a new treatment is considered for routine application.

In cohort studies, groups are prospectively and simultaneously sampled according to the treatments under study and are subsequently observed by identical procedures. The disadvantage of this study type is that it may be prolonged until a sufficient number of endpoints is reached, and the study may be expensive. On the other hand, this study type produces the most reliable results of all observational studies. Cohort differences in observed baseline variables can be controlled by statistical model building. The resulting adjusted effect estimates should be the primary endpoints. Hidden biases may occur, however, and thus spurious results cannot be excluded even if the cohort study meets high quality standards. Only interventional studies can overcome this limitation.

Interventional studies: randomized controlled trials, superiority, non-inferiority and equivalence trials, cluster-randomized trials

Randomization results in an equal distribution of chances between treatment groups. Thus, effects can be analyzed relying on the laws of probability. Observed group differences that are unlikely in case of no effect can thus be ascribed to the intervention with controlled error probabilities.

While randomization balances the baseline chances, however, a random treatment allocation does not exclude every sort of bias that can occur during the follow-up. For example, it is possible that after randomization the patients in the intervention group are consciously or unconsciously better treated or more thoroughly observed by physicians than are patients in the control group. To avoid such biases, the optimal approach is to keep patient and physician blinded as to the group in which the patient is enrolled. This can easily be accomplished if, for example, the study intervention consists of a drug to be infused, and a saline infusion that looks identical can be given to a control patient. If the intervention consists of the application of a mechanical device or a change in the order of treatments, however, blinding may be impossible. In this case, at least the evaluation of treatment successes should be done by a person blinded to the treatment allocation ('blinded reading').

In planning a randomized controlled trial, the appropriate choice of the control treatment is important.[17] The control may be inactive (e.g., placebo) or active (e.g., traditional intervention). It is particularly important to include three factors: (i) what doctors or other health care providers usually accomplish in their practice; (ii) what is recommended by guidelines; and (iii) the available evidence. If the available evidence does not demonstrate that an already known treatment is efficient, the appropriate choice is

inactive. Therefore it can be argued that, for example, vasopressin in a number of studies has been compared with adrenaline (a treatment without scientific documentation in cardiac arrest) instead of placebo. Naturally, adrenaline has been used because it is recommended in guidelines.

In so-called superiority trials, the intervention must be shown to be better than the control. This is usually the case if the control is inactive or the intervention is supposed to improve the therapeutic efficacy. In some cases, however, the new treatment is not required to be more effective, but only easier to be applied, more tolerable, or safer than is a standard therapy. In this case, only non-inferiority or equivalence with respect to survival is required. Contrary to what would be expected, non-inferiority trials are harder to perform since the new therapy must prove to be not worse than the old one, but it also requires that the trial would have been able to demonstrate a clinically relevant difference, i.e., had a sufficient sample size and quality. Thus, non-inferiority trials require previous knowledge of the effect size of the standard therapy and huge sample sizes, which may explain why non-inferiority trials so far have been rare in resuscitation medicine.

Usually, individual patients are randomized. Sometimes, however, interventions cannot be fitted to an individual patient, but require that a center be reorganized, and the intervention has then to be performed in every patient included in that specific center. In this situation, centers or time periods can be randomized instead of patients. Such trials are called cluster-randomized. They have to be analyzed differently from individually randomized trials since patients of the same cluster will be more similar than patients from different clusters, compromising the usual independence assumption of classical statistics. The statistical quality of such trials is governed by the number of clusters rather than by the total number of patients. A minimum of 30 clusters to be randomized per group is usually postulated. Cluster-randomized trials are thus not very efficient, but frequently this approach is the only way to study complex interventions in the hospital or ICU.

Technically, the best way to randomize is by telephone, which cannot be manipulated in case of local irregularities. Nevertheless, this kind of randomization is expensive and not always practicable. Out-of-hospital studies are sometimes better performed by using randomization envelopes or coded study drugs. Irrespective of the method, however, randomization is crucial in such studies and this must be explained in detail to physicians and patients or their relatives to be accepted. Moreover, it has to be taken into account that some people will wish to crack the codes just because it is forbidden.

Summaries: systematic reviews, meta-analysis, metaregression, pooled analyses

An essential part of clinical research is the regular summary of evidence from studies. This can be done qualitatively as a systematic review, by using formal methods of meta-analyses or meta-regression, or by pooling the individual data of the patients. The last mentioned is the most informative, but also the most elaborate and time-consuming. Quantitative methods rely heavily on advanced statistics and should be performed with great care.

Study population

Criteria for including patients in randomized clinical trials

Study populations can be defined as restrictive, to achieve homogeneity, or liberal, to achieve generalizability. If internal validity is found to be most desirable, homogeneity is advantageous since sample sizes can be reduced and trials will be shorter, but external validity may be compromised. Liberal inclusion criteria allow better generalization but are more expensive. In drug development, restrictive inclusion criteria are applied in phase II, if proof of principle is sought. Liberal inclusion criteria are mandatory in phase III trials to confirm broad clinical efficacy. In principle, similar considerations should apply to resuscitation trials.

Most cardiac arrest trials tend to include cases with a presumed cardiac etiology in order to make the patient groups more homogeneous. Nevertheless, patients with other etiologies, including cerebral hemorrhage, will occasionally be included as well. It will be extremely difficult to evaluate the effects of interventions on subsets of cardiac arrest patients other than those with a presumed cardiac etiology, because these subsets are likely to be very small. Thus, it may be argued that all cardiac arrests should be included regardless of etiology, if there is no reason to assume that the intervention is particularly advantageous for patients whose arrest had a cardiac cause.

When evaluating the impact of a new intervention in cardiac arrest, patients with a prolonged delay between collapse and start of the intervention have not been included. Such a decision is based on the assumption that the chance of resuscitating a patient with a prolonged delay is extremely low, and therefore the inclusion of such patients will only weaken the chance of proving the efficacy of the intervention. Consequently, patients with a non-witnessed cardiac arrest and those with a delay above a certain time limit from either collapse or call for ambulance until start of the intervention are often excluded from participation. Although this might be a wise decision, it is

important not to make the upper time limit too short, as this would limit the proportion of "available" patients to be included and if the intervention turns out to be positive, there will always be problems how eventually to extrapolate the data from the trial to clinical practice.

Similarly, previous interventions often have specifically addressed patients with a variety of rhythms admitted by the ambulance crew. For example, when evaluating the impact of an anti-arrhythmic agent on outcome, it would be logical to study patients in ventricular fibrillation. It has sometimes been argued that patients in asystole are found so late in their course, that the chance for rescue is minimal, even with the best of interventions. Perhaps it is wise to include patients with all types of rhythms in intervention trials, except for those on antiarrhythmic agents, and clearly state in the protocol that a secondary hypothesis will be to analyse separately the results of the intervention in the three major rhythm groups: ventricular fibrillation, asystole, and pulseless electrical activity.

Sample sizes

The requirement of representiveness and the desire to identify prognostically relevant factors or to collect evidence on treatment effects influence sample size requirements of clinical studies on resuscitation, both observational studies and clinical trials. To provide a representative cardiac arrest population, the sample size generally needs to be substantial, owing to the heterogeneity of patient populations. This is particularly true when subset analyses are to be performed, such as a description of men versus women, or patients with a shockable versus a non-shockable rhythm. Nevertheless, clinically relevant treatment effects can be small in a statistical sense and thus require big trials, particularly for survival endpoints in cardiac arrest because of the low survival rates.

If a confirmatory analysis is prespecified, e.g., in randomized controlled trials, a formal power calculation for determination of sample sizes is possible and desirable. The power of a trial is its ability to provide evidence to support the existence of the postulated treatment effect. Therefore, it should not only have sufficient statistical power but also pharmacodynamic power (i.e., optimal dose for a medication, or regimen for a mechanical device) and design power (optimal design). The power of a trial usually refers to statistical power, which indicates the chance that the expected difference could be detected at a pre-specified level of statistical significance. Sample size calculation is implemented so as to have a high chance of detecting a worthwhile effect, if it exists, and concomitantly to be reasonably sure that no such benefit exists if it is not found in the trial. Obviously, the greater the power of the study, the more convincing the trial, but a greater power requires a larger sample. The vast majority of clinical trials aiming at evaluating the impact of various interventions in cardiac arrest have been underpowered, and thus have been too small to detect an improvement in long-term survival, such as discharge alive from hospital. Unless the true treatment effect is large, small trials can yield a statistically significant result only if, by chance, the observed difference in the sample is much larger than the real difference.

Whereas it is evident that a formal sample size calculation is advantageous before start of a trial, the precision of a formal sample size calculation should not be overestimated. Formulae produce exact counts that look (pseudo) precise. But the input to the formulae consists of rough estimates of effect sizes and variances. Clearly, the calculated sample sizes cannot be more precise than the input, that is, previous knowledge from earlier studies. The risk of missing adequate power is always substantial and must be accepted, as inevitable, by the study participants. There is no silver bullet for trial success. Sample size calculations should thus be understood as an instrument to give a rough idea of the required efforts and the risks of a study. Nevertheless, once the sample size is fixed in the protocol, every change has to be justified to avoid the suspicion of manipulation of the results.

Data collection

Data exchange

The classical instrument for data exchange between centers and data management is the Case Record Form (CRF). The development of a CRF is not easy: it must be explicit, unequivocal, unambiguous, and complete; the order must be accurate, clear, concise, and easy to complete. Any mistake in the CRF will subsequently require considerable corrective work, and may result in misunderstanding, data losses, and errors. Frequently, CRFs are produced under pressure since everybody is anxious to begin the study. Nonetheless, we recommend testing the final CRF with a few pilot patients and, if necessary, to improve it.

Today, electronic CRFs, data exchange, and even data entry via the internet are used more frequently. Although electronic media simplify the process and allow immediate plausibility checks, the technical standard at each site must be of high quality to be successful. Data safety and security must be guaranteed. While CRFs are documents that can be

used for source verification and reconstruction of data at any time, files can (and will) accidentally be lost, overwritten, exchanged, or deleted. In particular, in out-of-hospital resuscitation medicine, documentation should be easy to handle independent of the location and time, so classical (non-electronic) CRFs may be preferable in some studies.

Monitoring and auditing, plausibility checks

Data quality is absolutely essential in clinical trials, or medical registers. Thus, monitoring (concomitant assistance in data collection, for example, by study nurses/monitors) and auditing (systematic checks and source validation by an independent institution) are valuable instruments, even if expensive, to guarantee the required level of data quality. Alternatively, peer auditing among centers is possible as described in the anecdotal report, (Appendix) but may be less perfect.

The central database should perform prompt plausibility checks soon after the data are submitted and immediately ask for corrections or completion of missing data. 'Clean file' should be declared before any statistical evaluation starts, unless interim analyses are required for the trial to be continued.

Interim analyses

Interim examination of the data may be performed for safety reasons or for efficacy. Both aspects cannot always easily be separated. For example, mortality differences between study groups should be considered for safety reasons, but may at the same time be the primary efficacy endpoint of the study. These issues are discussed below.

Safety interim analyses

Safety aspects should be considered regularly (e.g., for every 50 patients included) to protect the study participants from harm. They are usually done informally. To avoid early stopping due to chance clusters of adverse events in one of the study groups, however, it is advisable to calculate p values, adjusted for the multiplicity of inspections.

Efficacy interim analyses

At study start, the required sample size is estimated based on limited knowledge. One method to deal with this problem is to define milestones (numbers of patients recruited, intervals in calendar time) when the sample size or even the study design may be recalibrated, taking into regard the last interim results and the growing body of scientific knowledge from other studies. Actions after interim examination of the data may compromise the intended study goals, however. As an extreme example, consider a researcher who examines the new data daily and calculates the primary endpoint. If he stops the trial once the endpoint has crossed the significance border, he will end up with a positive study with a probability far above the significance level, even if there is no treatment effect. This phenomenon is called 'alpha-explosion.' To avoid such pitfalls, such interim analyses of efficacy should be pre-specified and complex calculations of the error probabilities performed in advance. The result will be a group sequential plan or an adaptive design. Sequential or adaptive designs allow early stopping of the trial because of success or futility, as well as prolongation as a result of new power calculations, but only according to the pre-specified rules.

Efficacy interim analyses can only be useful if changes to the study design or conduct are still possible. If recruitment phase and treatment duration are short compared to the follow-up interval, interim analyses are useless. In resuscitation research, however, the recruitment phase is usually long and the follow-up to the primary endpoint is short, and thus efficacy interim analyses are frequently mandatory to avoid longer studies than necessary.

Data and Safety Monitoring Board

The interim monitoring, analyses, and recommendations should be performed by an independent Data and Safety Monitoring Board (DSMB) comprising scientists not otherwise involved in the study, in order to avoid conflicts of interest. Ideally, a committee should consist of an uneven number of members (three or five) for clear decisions, and at least one of them should have statistical expertise.

Evaluation and interpretation

Analysis populations

The choice of the analysis populations will depend on the objectives of the study. In medical registers or observational studies, usually the maximal available dataset will be applied that will be representative of the study population. In randomized controlled trials, a valid superiority conclusion requires an endpoint comparison between the random groups according to the intention-to-treat principle, regardless of the actual treatment, in order to avoid masking of bad outcomes in one of the random groups by treatment switch. In contrast, in non-inferiority trials, the actual treatment groups should be compared, but only with patients who were treated strictly according to protocol. Safety evaluations should be performed with all patients who received one of the study treatments at least once.

Unfortunately, so far, most of the cardiac arrest databases suffer from considerable missing information. A major reasons is that a cardiac arrest is one of the most chaotic events in medicine. Thus, missing data will continue to be a serious challenge during the statistical analysis of the study. Missing values may compromise conclusions even from the primary analysis, in particular if the missing data differ between study groups.[18] Unless the percentage of missing values is so small that it can have absolutely no impact on results, there should be some means of handling the missing data. Neither ignoring them nor excluding patients with missing data will suffice. Instead, the application of different methods of imputation and the report on the results in terms of a sensitivity analysis is recommended. Classical imputation methods like mean replacement or LOCF (last observation carried forward) in follow-up-studies are unsatisfactory. Maximum-likelihood imputation or multiple imputation are methods of choice.

For evaluation of response systems and cardiac arrest programs, accurate time registration is important. Often reconstruction of the time of collapse is necessary. Estimation of time intervals is hard in these circumstances,[19] but an observer who can concentrate on the different time sources and correct them with a standard clock. is most likely to be successful.

Choice of statistical method

In randomized trials with two groups, simple two-sample comparisons will be sufficient. Adjustment for baseline differences may slightly improve the power, but it is not required.[20] Subgroup analyses have to be pre-specified and should be evaluated using so-called interaction tests with p-value adjustment for multiplicity.[21] The statistical analysis plan should be finalized before unblinding the study.

In contrast, in observational studies, adjustments for factors and covariates are mandatory for confounder control. Thus, statistical models have to be applied, particularly for longitudinal analyses/analyses of follow-up data with complicated dependence structure that requires a deeper understanding of modern statistical model-building tools.

Interpretation

Interpretation of study results is a major task, even if there is agreement on the statistical evaluation. It requires the close cooperation of physicians and biometricians since neither group can overlook all the consequences and pitfalls alone. Various plotting techniques are helpful for communication. Effects should be presented with confidence limits to give an account of other possible outcomes that would only differ by chance from the observed one. Conflicting views are frequent and may remain even after a thorough and honest discussion. Convergence of opinions is neither guaranteed nor required (not even in randomized trials) and should be reported in the final publication. In many cases, the result of a study is not what the authors had expected when they started, and thus some may be disappointed in the results. But the impact of a clinical study depends on both confirmation of the expected and/or detection of the unexpected, although the latter will need confirmation in further studies. In this manner, any study, either positive or negative, will contribute to a deeper understanding of the disease or treatment under study and will be reviewed and subjected to meta-analyses. In this sense, a well-performed study is always successful.

Future aspects

Survival in cardiac arrest has remained relatively unchanged during the last decades. One of the main reasons is that clinical research has not contributed much information on the documentation of effects of new interventions. The only hopeful major step forward so far, is research on hypothermia.[22,23]

The solution to this dilemma lies in large randomized clinical trials. If they were introduced it might be possible to forecast a more marked improvement in outcome during subsequent decades.

We need proper interventions to test, however, and most important such trials must be interpreted adequately. This means that the implementation of a new treatment must be based on the results of these trials. Not before all these requirements are fulfilled can we expect to see a more marked improvement in outcome after cardiac arrest.

Appendix: Experience with a large randomized clinical trial in cardiac arrest

It started in the early 1990s, when it was found that survivors of prehospital cardiac arrest had significantly higher endogenous vasopressin levels than did non-survivors.[1] Multiple experiments in the laboratory followed, which confirmed that vasopressin resulted in superior effects compared with epinephrine during CPR;[2–3] further, neurological recovery was excellent even in pigs undergoing prolonged CPR;[2] results from in-hospital- and out-of-hospital CPR with vasopressin were promising as well;[4] therefore, we decided to organize a randomized controlled clinical trial in Europe to determine effects of vasopressin vs. epinephrine during out-of-hospital CPR. First, a team had to be assembled in both Innsbruck, Austria to do the routine work and organize the trial, and abroad to monitor and control efforts. Colleagues from the European Resuscitation Council offered help. The next step was to provide the study protocol, which obviously required important decisions with respect to inclusion/exclusion criteria, sample size (N=1500), randomizing centers (German-speaking countries Germany, Austria and Switzerland proved to be the most appropriate since everybody involved spoke the same language), and study endpoints (hospital admission and hospital discharge). The importance of the protocol should not be underestimated; bad decisions preclude any subsequent success – multiple face-to-face meetings were beneficial in assessing advantages vs. disadvantages of the protocol.

One continuous threat to the study was lack of funding, which was in large part due to the expired patent of arginine vasopressin. Although we were able to organize funds for the study itself, we were never able to pay anybody for personal efforts. One major expense was travel costs; another big expense was the drug we studied. At first, we had to buy hundreds of arginine vasopressin ampoules; we later convinced the manufacturer to donate arginine vasopressin to us; however, even the manufacturer himself had several unanticipated delivery problems. The

study drugs were prepared by a pharmacist in Belgium in a clean-room laboratory in his spare time at night and weekends without pay – he was only reimbursed for expenses for supplies, and a large box of chocolate which he donated to his technicians. From Belgium, the study drugs were shipped to Innsbruck, and sent to the participating centers. During one particularly tense situation with several centers on the brink of running out of study drugs, we had a courier drive the 900 km from Antwerp, Belgium to Innsbruck with the drugs arriving on Christmas Day – they were shipped out to participating centers immediately. The third large expense (~100 Euro/patient) was the patient's insurance to be covered should severe unanticipated complications occur; this was first paid by us, and then sponsored by Pfizer Inc.

Organizing the study itself was the next, exhausting step-two dozen institutional review boards in three countries had to be convinced that the study was worthwhile. Interestingly, many institutional review boards were pragmatic and accepted each other's decision; however, some wanted to have the protocol changed during the study, and one institutional review board did not understand our intention to randomize between treatment arms. Almost all institutional review boards required adaptations of the informed consent form. With the institutional review board's approval, we traveled thousand of kilometers in central Europe to meet and convince colleagues responsible for emergency medical services to randomize patients for the study. This was generally no problem, but it had to be done personally- and many friendships developed.

With the start of the study, the case record form had to be entirely self-explanatory to ensure that the protocol was followed in detail. The study drug kit was self-made, and our medical students were frequent visitors to the local post office hauling material for the study. The study was very well received, and many people supported us who did not benefit from it at all – for example, we first considered black film boxes as containers for the study drugs, and received 1000 of them free one day after a single phone call. Once the study started, grant applications had to be written again: while many applications were rejected, in some cases money surfaced from areas we did not expect; total cost without any salary support was ~250, 000 Euro/US-Dollars.

During the study, we sent to the 44 randomizing emergency medical services in 33 cities packets with coffee with a sticker on each pack entitled "We are unable to pay you for your efforts, but may we invite you for a cup of coffee?" A regular newsletter about any new development ensured continuous updating. Despite all efforts, money was running out in Spring 2002, and we had to stop the study; however, 1219 patients had been randomized. We ensured data quality by doing several cross-checks in the data base (example: did the code of a study drug being sent to Hamburg, Germany, return from Hamburg, Germany?); also, two separate blinded investigators verified that original data were adequately entered into the database. Data analysis should not be underestimated; it is complicated and must be absolutely correct. The database had to be ready to be handed to, for example, Government authorities, who may cross-check any analysis.

These enormous efforts ended up with results indicating no overall difference between vasopressin and adrenaline in terms of survival after out of hospital cardiac arrest. Nevertheless, the study generated several interesting hypotheses: (1) compared with adrenaline vasopressin might improve survival among patients found in asystole; (2) among patients with a more complicated cardiac arrest the combination of vasopressin and epinephrine might be more advantageous than either drug alone;[5,6.] These two hypotheses need to be tested in further prospective clinical trials. Such trials are already being planned (P.Y. Gueugniaud, personal communication).

The special problem of consent for resuscitation research

Introduction

Over 300 000 Americans die each year from catastrophic medical and surgical emergencies.[1,2] New interventions, based on sound research, could save lives. These research studies must be done in an ethical framework that traditionally includes obtaining prospective informed consent from the research subject. The ethical framework for the conduct of Human Research began with the development of the Nuremberg Code[3,4] in 1949. This code states that (1) informed consent of volunteers must be obtained without coercion of any form, (2) human experiments should be based on prior animal experiments, (3) the anticipated scientific results should justify the experiment, (4) only qualified scientists should conduct medical research, (5) physical and mental suffering should be avoided, and (6) no death or disabling injury should be expected from the research study.

The Declaration of Helsinki[5] was issued in 1964 and defines rules for clinical research. It repeats the ethical concerns stated in the Nuremberg Code, but also gives a provision for enrolling certain patients in clinical research without their consent, by using either proxy consent, or waiver of consent in minimal risk studies.

The subsequent Belmont Report,[6] which was published in 1979, is the cornerstone of ethical principles upon which current federal regulations for the protection of subjects are based. The Report conveys the three major premises of ethical conduct of studies: respect for persons, beneficence, and justice. The Report also provides elements used by Institutional Review Boards for evaluating the ethical standards for individual research proposals. The ethical principles presented in both the Belmont Report and the

Declaration of Helsinki have been expanded and clarified in the most recent guidelines published by the Council for International Organizations of Medical Sciences (CIOMS),[7] especially for providing guidelines for applying ethical standards in local circumstances.

A dilemma arises in research studies of interventions for life-threatening emergencies, such as cardiac arrest, catastrophic neurological emergencies, and some instances of major trauma. In these circumstances, a victim may be eligible for a research study, but be unable to give prospective consent because of unconsciousness, or severe alteration in cognition, caused by the life-threatening emergency. Often with such research protocols, the subject must be enrolled immediately so that the potential physiological effects of the experimental intervention can be maximized before the onset of irreversible organ damage.[8,9]

The FDA defines the "therapeutic window" as "the time period, based on available scientific evidence, during which administration of the test article might reasonably produce a demonstrable clinical effect."[10] It is this therapeutic window that is limited or non-existent for research studies of life-threatening emergencies. There generally is not time to seek out a legally authorized patient representative for disclosure and consent. In addition, consent under such emergency circumstances may not meet the standards of informed consent, since there is little time for the investigator to explain the study, and little time for the patient representative to assess the various treatment options available.[11] In addition, the emotional state of the patient representative may eliminate the possibility of reflecting objectively on the situation. Obtaining informed consent is especially difficult in pediatric populations where it has been shown that "the emotional trauma of the

diagnosis decreases a mother's ability to absorb and understand vital information, and the emergent nature of the children's condition and the urgency to begin treatment further compromise informed consent."[12]

Clinical trials involving research on emergency patients who were unable to give prospective informed consent were traditionally carried out in the United States by either receiving a waiver of informed consent from the local IRB, or by deferred consent.[13,14] In 1993, however, the Office for Protection from Research Risks (OPRR) at the National Institutes of Health and the FDA questioned the legality of the deferred consent practice (45 CFR 46.102(i)).[15] Because of problems with obtaining consent in studies of life-threatening emergencies,[16,17] and its impact on performing such studies, a Coalition Conference of Acute Resuscitation and Critical Care Researchers was held in October 1994. Representatives from over 20 organizations participated in discussions that explored informed consent in emergency research and produced consensus recommendations.[18] In 1996, the FDA and the Department of Health and Human Services published regulations (21 CFR 50.24)[19] for the ethically and legally acceptable conduct of emergency research. Emergency research must operate under exemption from consent, either because of no or minimal risk, or through community exception of consent regulations as outlined by the Office for Human Research Protections (OHRP) and the FDA. These guidelines aim to protect patients from participation in a study they would not consent to if they had decisional capacity. For research that is subject to FDA regulation (i.e., conducted under an Investigational Device Exemption (IDE) or Investigational New Drug (IND) permit), exception from consent can be applied to emergency research if explicit criteria are met (Table 11.1): (a) an IDE or IND is in effect; (b) the research involves human subjects who cannot consent because of their emerging life-threatening medical condition for which available treatments are unproven or unsatisfactory; (c) the intervention must be administered before informed consent from the patient's legally authorized representative is feasible; (d) the sponsor has prior written permission from the FDA; (e) an independent data monitoring committee exists; and (f) the relevant IRB has documented that these conditions were met. In addition, the ethical framework for performing such studies mandates that there is an independent assessment of the risks and benefits of the protocol.

For all research that is supported by federal funding (e.g., NIH), even if the study does not use a drug or device regulated by the FDA, similar criteria are required to determine whether exception to informed consent is warranted for an emergency research study. Further, for research that is not supported by federal funding or subject to FDA regulation (e.g., a trial of a novel method of manual cardiopulmonary resuscitation), IRBs generally apply similar criteria to determine whether exception from consent is warranted for an emergency research study.

Prior to the initiation of the study, **Community Consultation** and **Public Disclosure** must be provided for each emergency research protocol for which an exception from informed consent is requested.[19] In March 2000, the FDA issued "Draft Guidance" to help clarify the concepts of community consultation and public disclosure.[10] This report stated: "[C]ommunity consultation means providing the opportunity for discussions with, and soliciting opinions from the community(ies) in which the study will take place and from which study subjects will be drawn." The three primary goals of the community consultation process are: (1) to explain the nature of the research, with its attendant risks and benefits; (2) to state that informed consent will not be obtained from individual subjects prior to study participation; and (3) to explain the process by which potential subjects can refuse to participate in research studies.[10] The FDA guidance defines public disclosure as ". . .dissemination of information about the emergency research sufficient to allow a reasonable assumption that communities are aware that the study will be conducted, and later, that the communities and scientific researchers are aware of the study results."[10]

The regulations indicate that each IRB is to exercise its own discretion in determining appropriate community consultation activities and public disclosure, allowing considerations specific to the local community(ies) to be taken into account. The regulations do not explicitly state the amount or types of community consultation and public disclosure that are required to achieve compliance, although the FDA Guidance document does give some general considerations.[10] These requirements for community consultation and public disclosure, although reasonable, sometimes lead to delays in obtaining approval for research studies that use the emergency exception process. Each IRB may lack experience in determining what types of consultation and disclosure are necessary. In addition, there is ambiguity in the regulations as to how individual IRBs should implement such community consultation and public disclosure. In a study in 2003, Shah and Sugarman examined emergency research protocols at 36 centers and reported that to satisfy the public disclosure requirement the majority of these centers used a one-way disclosure method (press releases, institutional and local newsletters, radio and television announcements). A minority of the centers reported using two-way disclosures with the community, including public forums, telephone polls, and written communications.[20]

Table 11.1. Summary of the exception from informed consent requirements for emergency research (21CFR50.24)

Justifications

(1)   The research involves a medical condition or situation in which:
  (a)   Human subjects are in a life-threatening situation.
  (b)   Available treatments are unproven or unsatisfactory.
  (c)   Evidence is necessary to determine the safety and effectiveness of particular interventions.

(2)   Obtaining informed consent is not feasible because:
  (a)   The subject is not able to give consent due to his or her medical condition;
  (b)   The intervention must be administered before obtaining consent from legal representative is feasible.
  (c)   There is no reasonable way to identify eligible subjects prospectively.

(3)   Participation holds out the prospect of direct benefit to the subjects because:
  (a)   Subjects face a life-threatening situation which requires intervention.
  (b)   Preliminary investigations, including animal studies, and related evidence suggest that this intervention may provide a direct benefit to the individual subject.
  (c)   The risks are reasonable.

(4)   The clinical investigation could not practicably be carried out without the waiver.

Obligations of the investigator

(5)   The proposed study protocol defines the length of the potential therapeutic window, and the investigator:
  (a)   Commits to attempt to contact and, if feasible, to obtain consent from a legally authorized representative for each subject within that window of time; and
  (b)   If a legal representative is not available, commits to attempt to contact within that window some other family member and ask if that family member objects to the subject's inclusion; and
  (c)   Will summarize the efforts made to contact legal representatives and family members and make this information available to the IRB at the time of continuing review.

(6)   Consultation with representatives of the communities in which the research will be conducted.

(7)   Public disclosure to the communities where the research is conducted:
  (a)   Prior to initiation of the trial regarding the study plans, risks and benefits;
  (b)   After completion, of the results and subject demographics.

(8)   Perform the study under a separate investigational new drug application (IND) or investigational device exemption (IDE) from the Food and Drug Administration, even if an IND or IDE already exists.

Obligations of the IRB

(9)   The IRB has reviewed and approved procedures and documents for:
  (a)   Use in situations when obtaining informed consent is feasible;
  (b)   Use when providing an opportunity for a family member to object is feasible.

(10)   The IRB is responsible for assuring that procedures are in place to:
  (a)   Inform each subject, or a legally authorized representative or family member (if the subject is incapacitated) of his or her inclusion in the study and details of the study;
  (b)   Inform each subject or representative that he or she may discontinue participation in the trial;
  (c)   Inform subjects who become competent after initial notification to representatives of incompetent subjects;
  (d)   Inform a legally authorized representative or family member of subjects who die prior to notification about the trial.

(11)   If an IRB determines that it cannot approve a proposed study because it does not meet the criteria for justifying the need for a waiver or for other ethical concerns, the IRB must provide these findings promptly to the investigator and sponsor in writing.

(12)   The IRB must retain the determinations and documentation required by the above regulations for three years after completion of the investigation.

Obligation of the sponsor

(13)   Develop the protocol in collaboration with appropriate investigators.

(14)   Establishment of an independent data monitoring committee to exercise oversight of the clinical investigation.

(15)   If an IRB denies approval of a protocol per item 12, the sponsor of the investigation must promptly disclose this information to the FDA, the clinical investigators and other IRBs that have been or are asked to review the same or a substantially equivalent trial. The sponsor must track all information disclosed and assure that disclosed information in placed on the FDA's public docket.

Effect of 21 CFR 50.24 on study approvals

Standardization of community consultation and public disclosure are necessary because there has been inconsistent interpretation of current procedures for implementing research with the exception of informed consent process. There are significant variations in local IRB's interpretation of what is necessary for fulfilling the FDA requirements for community consultation as well as what constitutes the proper venue for the community to provide feedback. These variations make it difficult for the investigator to "guess" what will be necessary for IRB approval in this section of the regulations and this often significantly prolongs the approval process. IRB membership and experience change over time so that the investigator is faced with an ongoing and evolving set of criteria that needs to be met for initial, as well as, continuing approval. Local IRBs place very different demands on different investigators, sometimes making it so onerous to perform Exception of Informed Consent research in certain circumstances that the research is simply not performed, or is moved outside the USA,[21–23] resulting in a lack of availability of potentially life-saving therapies to the entire population.

In addition, the process of community consultation and feedback can be extremely costly and time-consuming. Current processes vary substantially from institution to institution. Financial implications, therefore, vary widely from investigator to investigator. It is very difficult for investigators to know how much money to include for consultation costs, because the costs vary greatly from one IRB to another.

In one large multicenter trial of 24 sites studying defibrillation approaches, it took up to 404 days (median 108), up to 7 submissions (median 2), and cost up to $13,000 (median $1300) to obtain IRB approval.[24] The types and numbers of activities undertaken at each site to fulfill the community consultation and public disclosure requirements were quite diverse. There were public meetings, press releases, letters, brochures, newsletters, e-mails, radio, television or print advertisements, notices, feature stories, and radio and television appearances. Of over 1000 comments received, 96% were reported as "positive," and only 1% were reported as negative".[24] No IRB rejected the project for approval on the basis of negative comments. The experience from this trial in performing community consultation and public disclosure under Exception to Informed Consent demonstrates that despite numerous, costly, time-consuming, and different methods, there was minimal community input in this multi-center study, and that what negative input was expressed did not prohibit the conduct of the trial.

Effect of 21 CFR 50.24 on the number of research studies performed

A number of groups have completed statistics on the number of research studies performed before and after 21 CFR 50.24 was implemented. One group conducted a MEDLINE search using the strategy: "Heart Arrest" or "Cardiac Arrest" and "Human" not including Case Reports.[25] The results were hand-searched by two reviewers for US cardiac arrest articles that met criteria for Exception from Informed Consent. The group compared the fraction of all publications on research in the US during the 4 years since the promulgation of 21 CFR 50.24 to the 4 years before the moratorium.

Between 1990 and 1993 MEDLINE listed 1 090 395 clinical publications, of which 46 were US cardiac arrest studies meeting exception criteria; between 1997 and 2000 there were 1 288 460 clinical publications, of which 13 met cri-teria ($P < 0.001$).[25] Despite this dramatic drop in the number of studies published, it was noted by the group that publication delay may shift the effect time of these events such that a study performed before the moratorium appeared in the literature after the New Rule took effect. This decrease may also represent a lack of familiarity with the new Rule rather than an intrinsic negative effect of the Rule on emergency research. They concluded, however, that there has been a significant decrease in the number of published US emergency human cardiac arrest clinical trials under the new FDA Rule.

Effect of 21 CFR 50.24 on commercial entities

The effects of delays in obtaining study approvals can be extreme for commercial entities, where each month of delay incurs substantial cost to the commercial entity because of ongoing requirements for operating expenses. Companies that ceased commercial operations, and which were attempting to perform studies to determine the safety and efficacy of unapproved devices include Cardiologic Systems, Inc,[26] and Theracardia, Inc.[23] It is unlikely that the delays in study approval were the sole reason for the demise of those companies, but they may have contributed substantially. Other commercial entities have opted to perform emergency medicine studies in other countries, where approvals can proceed expeditiously. Industry's decision to move many trials on potentially life-saving therapies for diseases where conventional therapies are woefully inadequate to countries with less stringent and ambiguous regulations may deprive the United States population of the possible benefit of these interventions.

Studies with non-approved drugs or devices

IRB approval can be even more difficult if the drug or device to be studied has not been approved for sale by the FDA. The issue for the IRB is that they are asked to approve a research study where a drug or device that has not been approved by the FDA is used on test subjects without their consent, there is likely to be a fatal outcome because of the inherent disease state, and the next of kin will be notified of these details. In many emergency situations, such as cardiac arrest, mortality may exceed 90%. This is obviously why the research is critical. Because of the large numbers of victims of these conditions, even small increases in survival could save many lives. Even if the experimental drug of device would only reduce mortality from 90 to 80% – that would translate into a potential saving of more than 20 000 lives per year for that one therapy. Some IRBs have expressed great reluctance to approve such studies because of fear of liability. They believe that they can be successfully sued for enrolling research subjects into research studies without the subject's consent, even if appropriate federal guidelines have been followed. In general, companies sponsoring studies under an IND or IDE of drugs or devices are required by the study sites (universities, and others) to provide indemnification (insurance). This is a "cost of doing business." Large companies expect this. Small companies are often surprised, and the need for expensive liability insurance can be a substantial barrier to performing studies dealing with emergency research.

Community consultation and public disclosure template

The American Heart Association has published recommendations for implementation of Community Consultation and Public Disclosure.[27] A template is presented that (1) provides for quantification of the minimum requirements that an IRB might adopt, (2) gives examples to help IRBs quickly become familiar with the process of implementing and reviewing studies proposed with Exception to Informed Consent, and (3) proposes that trials of interventions approved by the FDA for the indication being studied should require levels of community consultation and public disclosure different from studies of unapproved interventions. The template gives a common interpretation of the requirements, and provides a list of actions acceptable for the implementation of community consultation and public disclosure.

Ethics

The guiding ethical principle for the template is that there is a range of actions that are acceptable to protect subjects' autonomy, depending on the risk of the study. The risk referred to here is the incremental risk of participation in the proposed study, over and above the risks of having sustained a life-threatening emergency and being treated with standard interventions. The higher the risk of the study, the more stringent are the actions that are required to protect subjects' autonomy. Since there is a range of risk associated with different study interventions, different levels of community consultation and public disclosure can be used to balance subjects' autonomy appropriately with the public good.

A trial of an approved therapy should not require the same level of community notification and consultation as one where non-approved or not-generally-accepted interventions are being introduced for the first time. For interventions that were not approved by the FDA, the risk of the therapy could be incrementally higher, and the level of community consultation and public disclosure for the study should similarly be higher.

It was, therefore, proposed that it is ethically acceptable to stratify the intensity of community consultation and public disclosure based upon the anticipated incremental risks to subjects participating in a research study. It was acknowledged that any research study may have unanticipated risks, but the argument for stratifying community consultation and public disclosure was based on the reasonable and prudent prediction of subject risk.

The proposal regarding stratifying community consultation is analogous to how IRBs currently review research protocols and informed consent documents. For example, IRB review of a protocol that studies unlinked serum samples will not require the same considerations as a project involving the use of a novel immunosuppressive agent in kidney transplantation. The study of unlinked serum samples may be considered to have minimal risk and therefore be eligible for expedited review, while the transplantation study requires standard IRB review. Similarly, the informed consent document may be shorter and simpler for the serum sample study than for the transplantation study. Indeed, for the transplantation study, the IRB may suggest in addition to an extensive consent protocol, the use of supplemental educational material or the involvement of a patient advocate to ensure that subjects fully understand the risks, benefits, and alternatives to participation. The point is that while all emergency research that is not minimal risk requires some level of

public disclosure and community consultation, emergency research studies that have less incremental risk, and are not politically and culturally controversial, may be performed ethically with lesser degrees of community consultation and public disclosure than would be needed for high risk or controversial studies.

Stratification of risk

The template breaks studies into categories of minimal, low, intermediate, and high incremental risk. Any sudden, catastrophic, life-threatening condition places patients at high risk for substantial morbidity and mortality. Instead of paying heed only to the inherent risk of the underlying disease, which is present whether the patient is enrolled in the study or not, we recommend evaluating the incremental risk from participating in the proposed study. That evaluation can then be used to determine the degree of community consultation and public disclosure appropriate for the proposed study.

Certain studies are justifiable without documented consent under minimal risk criteria. Consider the study of a therapy approved by the FDA for the indications being studied being compared to another therapy that was approved or did not need approval (e.g., manual CPR). The study likely would carry a risk that was minimally above the risk of being treated with either approved therapy. In the absence of a research protocol, physicians could ethically and legally choose to treat patients with a life-threatening condition with either of these interventions. The only additional factors introduced by a research study of these interventions are (1) that the patients are being randomized to one of the approved interventions, and (2) the loss of privacy and confidentiality during review of the clinical record after the intervention has been applied. Therefore, if the randomization procedure does not introduce any significant delay in applying the approved therapies, such a study is justifiable without documented consent under minimal risk criteria. The rationale for not having an informed consent document is described in the preamble to the final rule for 21 CFR 50:

The agency thinks that it may not always be possible to develop a meaningful informed consent document for continued participation in the research, because the relevant information may vary significantly depending upon when it becomes feasible to provide the information to the subject or legally authorized representative. The agency is, therefore, not requiring that such a form be developed. The agency notes however that Sec. 50.24 (a)(6) places the responsibility on the IRB to review and approve

"informed consent procedures and an informed consent document" for use with subjects or their legal representatives, and procedures and information to be used in consultations with family members, in situations where use of such procedures is feasible. [Page 51520]

During the comment period for these regulations, the agency received feedback that the subject should be able to choose to continue to participate fully in a study, to continue the intervention but not have their data included in the research database or results, or to discontinue the intervention and use of the subject's data. This was rejected on the following grounds:

FDA regulations . . . require investigators to prepare and maintain adequate case histories recording all observations and other data pertinent to the investigation on each individual treated with the drug or exposed to the device. The agency needs all such data in order to be able to determine the safety and effectiveness of the device. The fact of having been in an investigation cannot be taken back. Also, if a subject were able to control the use (inclusion and exclusion) of his or her data, and particularly if the clinical investigation were not blinded, the bias potential would be immense. (Page 51520)

The factors that can help decide the degree of incremental risk added by a particular study are shown in Table 11.2. It was proposed that IRBs use the following criteria to determine incremental risk: (1) FDA labeling status of the investigational therapeutic drug or device, for studies of interventions; (2) an evaluation of whether the study introduces any additional risk of harm over that of simply using the investigational therapeutic drug or device (such as any delays in applying therapy that may be introduced by the randomization process); (3) the degree of invasiveness and need for real-time clinical decisions, for studies of diagnostics; and (4) the potential sensitive nature of the study from the community(ies)' perspective, including political cultural and religious considerations. For a therapeutic intervention, therefore, the study would have minimal, low, intermediate, or high incremental risk based on the FDA labeling status of the therapy and the assessment of whether there was minimal risk of being in the study (Table 11.2, "Intervention" row), unless it were placed in a higher risk category based on the community(ies)' sensitivity (Table 11.2, bottom row). The same would be true for the study of a diagnostic, where the type of diagnostic would place it in minimal, intermediate, or high risk categories on the basis of the degree of invasiveness, the need for real-time decision-making, and whether the diagnostic is FDA-approved (Table 2, "Diagnostic" row), unless it were placed in a higher risk category by the perceived community(ies)' sensitivity (Table 11.2, bottom row).

Table 11.2. Assessment of incremental risk of research studies

| Study Type | Potential incremental risk added by study | | | |
	Minimal	Low	Intermediate	High
Intervention (Device/drug)	(1) FDA-approved for proposed study indication (2) and/or already in clinical use for study indication (3) and have minimal risk of harm from being in the study. (e.g., Approved mechanical CPR devices standard CPR; amiodarone vs lidocaine)	(1) FDA-approved for proposed study indication (2) and/or already in clinical use for study indication (3) and have higher than minimal risk of harm from being in the study	(1) FDA-approved for clinical use, (2) but not for the study indication.	Not FDA-approved for any indication yet.
Diagnostic (Test/device/ feature)	(1) Non-invasive, (2) and not used for real-time clinical decisions. (e.g.: non-invasive monitor, low volume blood drawing)		(1) Minimally invasive, (2) and not used for real-time clinical decisions. (e.g., transconjunctival oxygen saturation)	(1) More than minimally invasive, (2) or used for real-time clinical decisions, (3) or not FDA approved. (e.g., intracranial pressure monitor)
Community's potential sensitivity (Political, cultural, religious)	Very unlikely to have community sensitivity	Very unlikely to have community sensitivity	Possibly to have community sensitivity	Likely to have community sensitivity

For a therapy, the study would have minimal, low, intermediate, or high incremental risk based on the FDA labeling status of the therapy, and the assessment of whether there was minimal risk from being in the study ("Intervention" row), unless it were placed in a higher risk category based on the community(ies)' sensitivity (bottom row). For a diagnostic: the study would have minimal, intermediate, or high risk categories based on the degree of invasiveness and the need for real-time decision making ("Diagnostic" row), unless it were placed in a higher risk category by the perceived community(ies)' sensitivity (bottom row).

Levels of community consultation and public disclosure

Once the degree of incremental risk is determined, it was proposed that the amount and types of community consultation and public disclosure be guided by Table 11.3. For minimal risk studies, no community consultation or public disclosure is required, although minimal community consultation should be considered. For low incremental risk studies, minimal community consultation would be needed. For example, review and feedback from an appropriate group, committee, panel, or organization representative of the study community could allow appropriate community consultation without excessive time being needed to wait for public comment from a published

advertisement. Alternatively, there could be solicitation through a website or public notices (such as through a mass media piece), with a call-in number and/or web address provided for feedback. For a high incremental risk study, however, more community consultation would be required, including an appropriate number of mass media solicitations, community meetings, and contact with prominent community organizations. Specific examples of community consultations and public disclosures are available at: www.americanheart.org/emergencyexception. It was emphasized that the recommendations of Table 11.3 are simply guidelines. Individual IRBs will set their own standards based on their individual considerations. It was also emphasized that involvement of the community

Table 11.3. Levels of community consultation and public disclosure suggested at different degrees of incremental risk

	Potential incremental risk added by study		
	Low	Intermediate	High
Community Consultation Options	Review and feedback from an appropriate group, committee, panel or organization representative of the study community. Alternatively, consider solicitation through website or public notices (such as through a mass media piece), with a call-in number and/or web address provided for feedback	(1) As in Low (2) Plus consider solicitation through website or public notices (such as through a few mass media pieces). (3) Call-in number and/or web address provided for feedback	(1) Review and feedback from at least one group, committee, panel, or organization representative of the study community, (2) Public forum(s) or presentation at municipal government meeting(s) in the study community. (3) Solicitation via a number of mass media pieces. (4) Call-in number and/or web address provided for feedback
Public Disclosure Options	Single targeted effort deemed most likely to reach study community: This could be through a mass media piece or distribution of information in more focused manner to likely subjects. (e.g., targeted: poster, brochure, or newsletter article in senior citizen center where study will be conducted.)	At least one targeted effort and a mass media piece. Consider website.	Multiple efforts, including both targeted efforts and mass media pieces, as deemed necessary to reach the community adequately. Website recommended.
Patient / family notification of participation	Reasonable attempts required for written communication regardless of patient survival status (e.g., letter, including invitation to meet with investigator or study coordinator to discuss)		

For minimal risk, no community consultation or public disclosure is needed, although a single announcement could be considered. A mass media piece refers to a newspaper article or advertisement, or a radio announcement, or a television spot.

should include attempts to consult with targeted, at-risk, or interested populations.

Definition of Community for Pediatric Studies

There is a unique problem in the definition of what constitutes a "Community" for pediatric studies. For many pediatric populations, the "Community" could be defined to include a group of patients with a specific disease, their families, as well as the appropriate health care providers (especially in the in-hospital environment). In these types of situations, rather than a particular geographic based community, consultation with the "Community at risk"

may be most appropriate. This process should be differentiated, however, from prospective informed consent of all patients at risk, as the latter process may not be feasible because of the potentially large numbers of patients involved.

Definition of Community for Hospital-based Studies

Also there is a unique problem in the definition of what constitutes a "community" for hospital-based studies. For many hospital populations, the "community" could be defined to include a group of patients who present to the

ambulatory, emergency, and wards of the hospital, their families, visitors, as well as the appropriate health care providers. In these types of situations, where it is not feasible to consent every individual who enters the grounds of the hospital, consultation with the "community at risk" may be most appropriate. This process should be differentiated, however, from prospective informed consent of all patients at risk, as the latter process may not be feasible owinge to the potentially large numbers of patients involved.

The situation in Europe

Difficulties in the United States have been mirrored in Europe – at least within the European Union (EU) – although the major problems came later. Differences exist among Member States despite an intention for a uniform approach.

Until relatively recently, emergency research in Europe was conducted in accordance with the terms of the revised Declaration of Helsinki[5] that permitted research involving mentally incompetent subjects subject to appropriate safeguards. The situation changed, however, with a Clinical Trials Directive from the EU in 2001[28] that had to be implemented by all EU countries by May 2004. This Directive reiterated the general principle that research involving medicinal products required the written informed consent from participating subjects, but it did make reference in its Article 5 to the inclusion of incapacitated adults who had neither given nor refused informed consent before the onset of their incapacity. Nine conditions were set out; whilst some of them were unexceptionable, others have put major obstacles in the way of research in emergency situations.

Without the ability to obtain consent from the subject, the Directive stated that informed consent must be obtained from a legal representative, either the next of kin or a suitable person independent of the research team. Considerable uncertainty exists in some parts of the EU about the definition of a legal representative which was intended to be determined by national law. But in any case the stipulation for prior written consent is impractical for emergency research where interventions have to be made either immediately or at least within minutes. These include resuscitation from sudden cardiac arrest, but also treatment of acute heart attacks, stroke, serious head injury, and many forms of shock. Some member states have waived the requirement to seek prior written consent from a legal representative if treatment must be started urgently. Whilst this is outside the strict wording of the Directive, no objections seem to have been raised to this liberal interpretation. The alternative approach has generally been to

seek consent later from any subject who regains mental competence, or otherwise from a legal representative who is preferably a close family member. With this arrangement, ongoing treatment would certainly be halted if consent were refused, but the position is less clear for cases in which it had already been completed: is it then permissible to retain the data for analysis? If not, the possibility of bias is clear. A person whose condition has improved may be more likely to consent to inclusion of data than family members whose relative has not recovered. On the other hand, in some types of study a survivor may be unwilling to continue with treatment, whereas non-survivors would not be in a position to withdraw from participation.

The Directive also stipulates that research without individual consent can be considered only to validate data obtained from persons able to give consent or from other research methods: this does have reasonable flexibility since treatments would hardly be considered unless some previous clinical or experimental evidence is available. An additional clause is, however, more problematic: it states that the research must relate *directly* to the condition from which the subject suffers. Interpreted narrowly this prevents research that involves the general care of incapacitated patients. A relevant example might be research into the rate or volume of ventilatory support in those being treated during or after cardiac arrest, the importance of which was highlighted in recent observational and experimental studies.[29] Such research would not relate directly to the condition causing the cardiac arrest but rather to supportive therapy, and therefore would be unacceptable according to a strict acceptance of this provision from the Directive.

An even greater problem with the European Directive springs from a paragraph that requires an *expectation* that administration of experimental medicinal treatment will produce a benefit outweighing any risk or produce no risk at all. Almost any intervention carries some risk, however small. Moreover, the notion that a treatment under investigation must be more likely than not to offer benefit undermines the whole principle of equipoise that should be an ethical basis for randomized controlled trials!

The Directive has not been implemented in a uniform way by Member States. Variations are not restricted to the interpretation of the term "legal representative" mentioned above. Some Member States have have sought to widen the provisions of the Directive to include not only medicinal products but all research, whereas the legal framework in others is loose enough to impose little restriction on research that most ethicists would accept as legitimate. The variations within Europe have been reviewed by Lemaire and colleagues.[30] Within the United

Kingdom a review has been undertaken of the regulations that implemented the Directive. These were acknowledged by the Government to have been unduly restrictive as they were closely based on the Directive. The anticipated changes in the implementing legislation will thus permit a resumption of emergency research that is currently impossible to conduct lawfully. Curtailment of important studies has existed from the time of the publication of the Directive, 3 years before it became mandatory, because of fears that any on-going studies that remained incomplete by May 2004 may have to be terminated prematurely. The danger to emergency research was foreseen by many active in the field[31] but by then the terms of the Directive could not be changed.

The hope now is that Member States that have interpreted the Directive strictly in their implementing legislation may be prepared to introduce modifications in line with the perceived intention of the Directive to permit some flexibility. The initiative within the United Kingdom may encourage others to follow suit. To give guidance to this approach, a working group assembled in Vienna in May 2005 under the auspices of the Department for Ethics in Medical Research of the Vienna Medical University, in cooperation with other relevant groups, and recommendations have been published.[32]

Conclusions

In conclusion, obtaining informed consent from patients or surrogates is difficult in the setting of serious emergency conditions. Current regulations do allow studies to be performed with Exception to Informed Consent, but ambiguities in implementing studies under current regulations can be onerous for IRBs and investigators, and may discourage research to evaluate promising interventions. The proposed template to help guide IRBs to comply with the Federal Regulations may help with striking an appropriate balance between protecting eligible patients, and preserving the public good in the United States. For the moment, however, a serious barrier to the development of evidence-based treatments for many emergency conditions exists in Europe as in the United States.

The pathophysiology of global ischemia and reperfusion

The etiology of sudden death

Sunil K. Sinha, Arthur J. Moss[1], and Hugh G. Calkins

Johns Hopkins Hospital, Baltimore, MD, USA
[1] and University of Rochester Medical Center, Rochester, NY, USA

Definition

Sudden death is natural death, heralded by loss of consciousness within 1 hour of the onset of acute symptoms. The time and mode of death are unexpected. This definition is meant to satisfy medical and scientific considerations as well legal and social concerns.[1] Included within this construct are four temporal elements: (a) prodromes, (b) onset of terminal event, (c) cardiac arrest, and (d) progression to biological death. Prodromes, if any, are new or worsening symptoms that begin during an arbitrarily defined period of up to 24 hours before the onset of cardiac arrest. The 1-hour time period described in the definition refers to the duration of the terminal event leading to cardiac arrest. Following cardiac arrest – the clinician's synonym for *sudden death*, biological death may ensue within minutes, or alternatively, due to community-based interventions and life support systems, may be delayed for a long period of time and even aborted altogether. Nonetheless, for legal, forensic, and certain social considerations, *biological death* is used as the absolute definition of death.

Epidemiology and Causation

A large prospective cohort study – the Framingham study – observed that over a 26-year period, 13% of all deaths were sudden in nature as defined by death within 1 hour of the onset of symptoms.[2,3] In the Western hemisphere, cardiac causes currently predominate in sudden deaths among adults. One large retrospective analysis of death certificates in the United States reported that 88% of sudden deaths were due to cardiac causes.[4] Hence, an estimated 300 000 sudden cardiac deaths occur annually in the United States, accounting for about 50% of all deaths due to cardiovascular disease.[5,6] Accordingly, the general incidence of sudden cardiac death in the unselected United States population > 35 years of age is 1 – 2/1000 (0.1%–0.2%) per year.

A number of diseases are associated with cardiac and non-cardiac sudden death in adults (Table 12.1). Several subgroups at high risk for sudden cardiac death have been accurately identified. These include those individuals who have already survived a cardiac arrest, those with coronary artery disease (especially prior myocardial infarction), and those with left ventricular hypertrophy or systolic dysfunction.[7] Conventional, modifiable atherosclerosis risk factors such as cigarette smoking, hypertension, diabetes mellitus, dyslipidemia, and obesity serve as readily identifiable markers of increased risk, although their primary significance lies in their link to coronary artery disease, the predominant disease predisposing to sudden cardiac death.[8,9] The clinical dilemma that remains is that *the majority of sudden cardiac deaths occur in people who are not currently recognized as being at high risk* (Fig. 12.1(a), (b)).

Neurological causes, such as large acute ischemic or hemorrhagic stroke and seizures, constitute a distant second leading cause of sudden death. Respiratory compromise leading to hypoxia, catecholamine excess, metabolic acidosis, and asphyxia from a variety of causes may result in a fatal event. Likewise, significant metabolic and electrolyte derangements may cause sudden death. Acute infections may lead to sudden unexpected death due to meningitis, myocarditis, and endocarditis. A variety of toxins, including prescription and non-prescription drugs,

Table 12.1. Acute and subacute causes of sudden death in adults

	c. Pneumothorax
	d. Blunt cardiac trauma (commotio cordis)
	e. Myocardial or aortic rupture

illegal narcotics, and alcohol may yield fatal consequences especially when used in excess. Sudden death due to trauma may ensue from a direct cardiac insult such as blunt cardiac trauma (*commotio cordis*) (Chapter 65), myocardial or aortic rupture, and acute cardiac tamponade, or indirectly from massive exsanguination or the triggering of one or more of the other causal processes mentioned above.

Sudden death in the pediatric and young adult population contains several unique features. In particular, *sudden infant death syndrome* is most likely to strike between birth and 6 months of age and has an incidence of 0.1%–0.3% of live births.[10] Established risk factors for sudden infant death include male sex, premature birth, maternal smoking, bed sharing, gastroesophageal reflux, and prone position.[11–13] This syndrome likely consists of a variety of causes both cardiac (such as cardiac ion channelopathies, high risk atrioventricular accessory pathways) and non-cardiac (central nervous system respiratory dysfunction).[14–18] In contrast to adults, studies indicate that only 19% of sudden deaths in children between 1–13 years of age and 30% of sudden deaths in those 14–21 years of age are of cardiac origin.[19] Among the general population of adolescents and young adults < 30 years of age, the overall risk of sudden cardiac death is estimated to be 1/100 000 (0.001%) per year.[20,21] A significant element of sudden cardiac deaths in this population consists of either familial or spontaneous genetic mutations expressed as hypertrophic cardiomyopathy, arrhythmogenic right ventricular

(a)

(b)
Fig. 12.1(a). Estimates of incidence (percent/year) of sudden death are shown for the overall adult population (**ALL**) and increasingly higher risk subgroups in the United States[5] (**HIGH RISK,** multiple coronary risk factors; **Prior MI,** prior myocardial infarction; **EF < 30%,** left ventricular ejection fraction < 30%; **Prior SCD,** prior resuscitated or aborted sudden cardiac death; **SCD > MI,** resuscitated or aborted VT/VF postacute myocardial infarction).

  (b) Estimates of the total annual number (events/year) of sudden deaths are shown for the overall adult population and increasingly higher risk subgroups in the United States (abbreviated group labels as per Fig. 12.1(a)). The progressively smaller denomination of increasingly higher risk subgroups results in an inverse relationship between the total number of fatal events and the actual incidence of sudden death[5] (as displayed in Fig. 12.1(a)).

dysplasia, cardiac ion channelopathies, and congenital heart disease. Neurological catastrophe, usually seizures, is also an important contributor to sudden death in the young. An analysis of sudden death between 1 and 21 years of age noted that epilepsy accounted for 15% of deaths.[19]

Sudden cardiac death in athletes

Sudden cardiac death in athletes is rare but usually strikes individuals with previously unrecognized cardiac disease.[22,23] In athletes < 35 years of age, hypertrophic cardiomyopathy, with or without left ventricular outflow tract obstruction, represents the most common cause of sudden cardiac death.[24] The second most common cause is due to congenital coronary artery anomalies.[25] In particular, anomalous origin of the left main coronary artery from the right (anterior) sinus of Valsalva, predisposing to kinking at the origin of the coronary artery or compression of the artery between the aorta and pulmonary artery trunk during exercise, engenders a significant risk of sudden cardiac death in athletes.[26] Arrhythmogenic right ventricular dysplasia may present with syncope or sudden cardiac death – often exercise related.[27] Indeed, in Italy, where comprehensive clinical and electrocardiographic screening has effectively excluded most athletes with hypertrophic cardiomyopathy from competition, arrhythmogenic right ventricular dysplasia is the most common cause of sport-related sudden cardiac death.[28] Acute myocarditis, even in the absence of severe left ventricular dysfunction, is another potentially fatal cause.[29] In a report of 19 sudden cardiac deaths among previously screened United States Air Force recruits, eight had evidence of myocarditis at postmortem examination – the majority of whom had their cardiac arrest during strenuous exertion.[30] Other less common causes include premature coronary atherosclerosis, commotio cordis, severe aortic stenosis, dilated cardiomyopathy, deep myocardial bridging of intramural coronary arteries, long QT syndrome – particularly LQTS1, and idiopathic ventricular fibrillation.[31–36] On the other hand, athletes > 35 years of age are most likely to die suddenly from coronary artery disease.[23,37]

Pathophysiology

Pathological studies of victims of sudden cardiac death correspond well with the established epidemiological preponderance of coronary artery disease.[8,38] Autopsy studies have consistently revealed that > 80% of cases demonstrate significant stenosis (> 75%) in at least one major epicardial coronary artery.[39,40] However, < 40% exhibit evidence of recent plaque fissuring, platelet aggregation, and coronary thrombosis.[41,42] Coronary artery spasm as a cause of sudden death is recognizable postmortem in rare cases.[43] The incidence of acute myocardial infarction on necropsy averages 20%–30% and healed myocardial infarction is noted in about 40%–70%.[8,39,44] Additionally, left ventricular

hypertrophy confers an acute mortality risk seemingly independent of hypertension, left ventricular dysfunction, or coronary artery disease.[45]

Clinically, malignant cardiac arrhythmias represent the final step of a complex pathophysiological process usually facilitated by established *structural heart disease* modulated by *functional variations*.[46] In this biological model of sudden cardiac death, structural abnormalities may include chronic coronary atherosclerosis, acute or healed myocardial infarction, ventricular hypertrophy or myopathy, or a congenital ion channelopathy. Functional alterations of abnormal anatomic substrate may result from interactions with dynamic influences, such as acute myocardial ischemia and reperfusion (coronary plaque rupture, thrombosis, or spasm), hypoxia, acidosis, electrolyte imbalance, catecholamine excess, autonomic dysfunction, toxins, and proarrhythmic drugs. The final pathway is the triggering of a fatal arrhythmia – usually ventricular tachyarrhythmias (80%–90%), or less commonly bradyarrhythmias, asystole, or pulseless electrical activity.[47] For example, in athletes with premature coronary atherosclerosis, increased myocardial oxygen demand with a fixed supply may provide a mechanism for exercise-induced ventricular tachyarrhythmia during intense physical activity.[48]

At the level of the cardiac myocyte, ischemia results in an efflux of potassium, influx of calcium, intracellular acidosis, reduction of transmembrane resting potentials, and
Fig. 12.2. Cardiac telemetry strips recorded from a patient 2 days postmyocardial infarction. Initially, the patient is in sinus rhythm at 70 beats per minute (bpm) with the first premature ventricular contraction (PVC) falling upon the T wave resulting in a compensatory ventricular pause. The second PVC upon the latter aspect of the T wave results in ventricular tachycardia, however, which soon progresses to ventricular flutter at 300 bpm (top strip), which in turn devolves in to coarse ventricular fibrillation (second strip from top) until an external 300 joule monophasic shock restores sinus rhythm (bottom strip).

an often heterogeneous enhancement of automaticity. Additionally, formation of superoxide radicals, fatty acid metabolites, adrenergic stimulation, and alterations in autonomic tone may contribute to electrical instability.[49,50] The resultant susceptible myocardium is prone to slow conduction and unidirectional block and, in the setting of premature impulses (premature ventricular contractions), can manifest a *re-entrant* ventricular tachyarrhythmia leading to ventricular fibrillation (Fig. 12.2). Furthermore, heterogeneously *enhanced automaticity* may trigger rapid bursts of depolarization and uncoordinated conduction leading to ventricular fibrillation.

Failure of normal sinus node and atrioventricular node function with concomitant failure of subordinate automatic activity to assume pacemaking function is the basis of the electrophysiological mechanism of bradyarrhythmias and asystole. At the cellular level, increased extracellular potassium concentration, anoxia, acidosis, shock, and hypothermia may result in partial depolarization of pacemaker cells in the His-Purkinje system, decreasing the slope of spontaneous phase 4 depolarization with loss of automaticity.[51] This phenomenon is likely to be more common in hearts with pre-existing His-Purkinje system conduction abnormalities due to *Lenegre's disease* (primary fibrosis) or *Lev's disease* (secondary mechanical injury).[52,53]

Pulseless electrical activity represents electrical depolarization of myocardium in the absence of effective mechanical myocardial contraction. Secondary pulseless electrical activity (pseudo-electromechanical dissociation) is caused by near or complete cessation of cardiac venous return due to large pulmonary embolism, cardiac tamponade, and massive exsanguination. Primary pulseless electrical activity results from a *failure of electromechanical coupling.*[54] The cellular mechanism for failure of electromechanical coupling probably includes abnormal metabolism of intracellular calcium, intracellular acidosis, and depletion of adenosine triphosphate. This usually occurs in the setting of end-stage heart disease, acute ischemia, or electrical resuscitation from a prolonged cardiac arrest.

Conclusions

Death is inevitable. Nevertheless, a thorough understanding of its multifaceted etiology holds the key for designing successful community- and patient-based strategies to delay its grim arrival. Familial clusterings of sudden cardiac death may provide us with the key to success by allowing us to delineate accurately specific genetic abnormalities that predispose to sudden cardiac death and target therapies accordingly.[55–58]

Introduction

Sudden, unexpected death claims nearly 1000 lives each day in the United States and is the fifth leading cause of all deaths in the western world.[1,2] Cardiac arrest occurs over 300 000 times per year both in the United States and Europe with the risk for persons 35 years and older estimated at 1 per 1000. In those patients resuscitated from cardiac arrest, nearly 60% die from a neurological cause. Despite every effort, only 3%–10% of all resuscitated patients are able to resume their former lifestyles.[3]

To date, there are no clinically effective pharmacologic tools for amelioration of brain damage by ischemia and reperfusion. Clinical trials conducted more than a decade ago utilizing postresuscitation treatment with barbiturates[4] or calcium antagonists[5] were disappointing. More recently, clinical treatment of stroke with a radical scavenger (trilazad),[6] intercellular adhesion molecule-1 antagonist (Enlimomab),[7] glutamate receptor antagonist (Aptiganel, gavestinel),[8,9] glutamate release inhibitor (Lubeluzole),[10] ganglioside administration (GM1),[11] calcium channel blockade,[12] or upregulation of the GABA receptor (Clomethiazole)[13] were all found ineffective. This suggests that our understanding of the mechanisms involved in damage and repair in neurons remains incomplete and further therapeutic progress will require the delineation of the primary mechanisms involved in neuronal injury and repair.

Although the picture is still incomplete, a few things are clear.

1. The majority of damage occurs not during ischemia but during reperfusion. Nevertheless, the two processes work sequentially to increase neuronal damage (i.e., lipolysis during ischemia potentiates the radical-mediated peroxidation of polyunsaturated fatty acids (PUFAs) during reperfusion).
2. Since in practice the initial ischemic damage has already occurred, suppression of further damage and promotion of acute repair is the key to minimizing permanent neurological injury.
3. Regulation of calcium influx or its intracellular release plays a sequential role in neuronal pathology.
4. Postischemic competence for protein synthesis is crucial to the neuron's ability both to limit and to repair damage during early reperfusion.
5. Competence for both antioxidant defense and membrane synthesis and repair in terminally differentiated brain neurons is regulated at a fundamental level by selected growth factors and proto-oncogenes.

Experimental models of global cerebral ischemia

Because the brain is particularly vulnerable to even short periods of ischemia, rapid defibrillation of the heart and restoration of spontaneous circulation are extremely critical. With each passing minute of cardiac arrest, the magnitude of neuronal injury progressively increases. For example, experimental studies in dogs have shown that increasing ischemic duration beyond 8 minutes results in progressively worse neurologic deficits.[14,15,16] Examination of brain histology, however, reveals that certain neuronal populations are injured after periods of ischemia as short as 5 minutes, whereas others can survive 30 or more minutes of ischemia.[17–23] Indeed, partial recovery of metabolism and electrophysiologic function is possible

after 1 hour of ischemia.[24,25] In addition, selective neuronal populations do not die immediately, raising the possibility of a temporal therapeutic window. Considerable effort has been directed at understanding the mechanism of delayed neuronal death that typically occurs 1 to 3 days after the insult. The mechanisms by which ischemia causes neuronal death are multifactorial and vary by brain region and by connectivity of specific neuronal populations.

When evaluating the large body of literature concerning cerebral ischemia, it is critical to consider the severity, duration, and distribution of reduced blood flow in the particular experimental model used in each study. Although ventricular fibrillation produces zero blood flow throughout the body, cardiac arrest is not used in many experimental models of cerebral ischemia because of the difficulty of cardiac resuscitation after prolonged arrest and the need for intensive care in animals with impaired brain-stem and thalamic function. Models of complete cerebral ischemia (zero blood flow) include ventricular fibrillation,[26,27] aortic occlusion with preserved coronary blood flow,[28,29] brachiocephalic and subclavian arterial occlusion plus arterial hypotension (to reduce inflow from spinal accessory arteries),[25,30] neck cuff inflation,[31,32] and compression models in which intracranial pressure is elevated above arterial pressure by ventricular fluid infusion.[33,34] Models of nearly complete global forebrain ischemia have been developed in which blood flow to cortex, striatum, and hippocampus is reduced to extremely low levels (0–5 ml/min per 100 g), whereas blood flow to caudal structures is adequate for preserving respiratory and cardiovascular stability. Global forebrain ischemia models include the four-vessel occlusion model, in which vertebral arteries are permanently occluded and carotid arteries are reversibly occluded,[35] and the carotid occlusion plus arterial hypotension model.[36] These two models of global forebrain ischemia have been the most widely used because they are relatively easy to prepare, particularly in the rat, and require less postoperative care than do cardiac arrest models. In addition, gerbils are sometimes used because the Circle of Willis is incomplete and carotid occlusion without hypotension produces near-complete forebrain ischemia. The nature and topography of injury in global models of cerebral ischemia, in which the duration of cerebral ischemia is typically less than 20 minutes, differs from focal ischemia models of stroke, in which a spatial gradient of blood flow reduction is produced for durations typically greater than 1 hour, and in which an inflammatory response occurs that leads to infarction. Therapies that are effective in experimental stroke may not necessarily be effective after cardiac arrest.

Cardiac arrest as well as other neuronal injury-triggering processes can lead to selective and delayed neuronal death.[37] Postischemic recovery depends on the type and the duration of the ischemic insult, which correlates with the level of cellular damage during reperfusion.[38] Cell death after global cerebral ischemia can be due to apoptosis or necrosis, depending on the duration of the insult and the quality of postischemic reperfusion.[39,40] If cardiac arrest times are exceedingly long or return of spontaneous circulation (ROSC) is not robust, then primary brain necrosis results. Resuscitation and cerebral reperfusion with shorter time periods may lead to cellular restitution or a delayed type of cellular death (apoptosis). The term *apoptosis* was promulgated by Kerr and Wylli to describe a cell death process without necrosis.[41,42] Specific morphological and biochemical features distinguish apoptosis from necrosis.[43] Necrotic cell death begins with a swelling of the cell body and the mitochondrial elements. Soon thereafter cell membranes disintegrate. The release of cytoplasmic contents triggers inflammatory reactions in the surrounding tissue. In contrast, apoptosis is a well-regulated process. Apoptotic cells take an active part in their own "shut down," packing, and dismantling process.[44] The highly regulated physiological "programmed cell death" process is characterized by specific morphological features such as changes in the plasma membrane, condensation of cytoplasm and nucleolus, and internucleosomal cleavage of DNA. Intracellular processes degrade the cells without rupture of the plasma membrane. At the end of the apoptotic process, shrunken cells become fragmented into "apoptotic bodies."[45] Finally phagocytic cells eliminate these cell fragments without significant inflammatory damage to the surrounding cells. The newest research results indicate that postischemic neuronal death most likely involves a combination of both apoptosis and necrosis even at the level of individual neurons.[46] Furthermore, both forms of cell demise seem to represent the extremes of a continuum.[37,47]

Energy metabolism, ion fluxes, tissue pH, and cerebral circulation

Energy metabolism and ionic fluxes during ischemia

High-energy phosphates in mature brain are derived primarily from oxidative metabolism of glucose. With sudden cardiac arrest, high-energy phosphates are depleted more rapidly in brain than in most other organs. Both the tissue freeze-clamp technique and the phosphorus magnetic resonance spectroscopy (MRS) technique demonstrate
Fig. 13.1. Percent changes in phosphocreatine and ATP concentrations obtained from neocortex frozen at different times after cardiac arrest in rats. Note the rapid decrease in phosphocreatine, followed shortly by a decrease in ATP. The time of anoxic depolarization corresponded to an ATP concentration of 30–40% of control. (From ref. 59.)

that phosphocreatine is largely depleted within 1 minute and ATP is almost completely depleted within 2 to 3 minutes of the onset of complete cerebral ischemia.[34,48–50] Consciousness is lost within 10 seconds, and electroencephalographic (EEG) activity becomes isoelectric within 20 seconds.[51,52] As shown in Fig. 13.1, the decline in ATP over time is not linear because: (1) phosphocreatine initially acts to buffer the decrease in ATP[49,50] (2) EEG silence reduces ATP demand and the rate of decline in tissue PO_2, whereas subsequent cell depolarization increases ATP demand[53,48] and (3) anaerobic metabolism of tissue stores of glucose and glycogen produces small amounts of ATP for several minutes.

Recordings from ion-sensitive microelectrodes in brain interstitial space reveal two phases in the temporal ionic response.[54,55] During the initial phase after cardiac arrest, interstitial K^+ concentration gradually increases from 3 to approximately 10 mM. Moderate increases in intracellular Ca^{2+} also occur during this early phase of anoxia.[56,57] Magnetic resonance measurements of Na^+ and water diffusion constant also suggest an early influx of Na^+ and water.[48–59] Spontaneous electrical activity is lost during this phase (Fig. 13.2), although evoked responses can still be generated. Within 2 minutes of cardiac arrest, interstitial

K^+ activity begins to increase at a progressively faster rate, resulting in cell membrane depolarization of neurons and glia (anoxic depolarization), increases in ion conductance, and further increases in interstitial K^+ activity to 60–100 mM. The onset of this second phase is associated with rapid decreases in interstitial Na^+, Cl^-, and Ca^{2+} activity and shrinkage of the interstitial space as these ions and water move intracellularly.[59,60] At this time, tissue ATP levels are reduced to approximately 30% of normal and are inadequate to maintain Na^+–K^+ ATPase at maximum activity.[48] The large influx of Ca^{2+} leads to activation of proteolytic enzymes and phospholipase A_2 and to a consequent rise in free fatty acid levels in tissue.[49]

Therefore, complete cessation of cerebral blood flow
Fig. 13.2. Recordings of intracellular pH (pH_i), membrane potential (mp), and intracellular calcium activity (Ca_i^{2+}) from a triple-barreled microelectrode inserted into a cell in CA1 region of hippocampus. Extracellular potassium activity (K_e^+) was recorded from a microelectrode in the contralateral hippocampus, and electrocorticogram (ECoG) activity was recorded from frontal cortex. Global forebrain ischemia was produced in the rat (at the first arrow) and PO_2 in separately recorded tissue fell to zero (at the second arrow). After a transient alkaline shift, pH_i progressively decreases due in part to ATP hydrolysis. ECoG is rapidly lost. At about this time, small increases in Ca_i^{2+} and K_e^+ occur. After an approximately 2-minute delay, large increases in Ca_i^{2+} and K_e^+ occur and the membrane depolarizes. Thus, changes in Ca_i^{2+} are detectable before membrane depolarization. (From ref. 64.)

results in a very rapid sequence of physiologic and metabolic events, involving: (1) loss of consciousness, (2) loss of EEG activity, (3) small increases in interstitial K^+ and intracellular Ca^{2+} activity, (4) membrane depolarization when ATP is approximately 30% of normal, and (5) a large influx of Ca^{2+}, Na^+, Cl^-, and water and an efflux of K^+. This sequence of events can be delayed to a small extent by increasing tissue glucose stores with preischemic hyperglycemia[63] or by decreasing the rate of ATP utilization with barbiturates,[61] and to a greater extent with preischemic hypothermia.[62]

Energy metabolism during early reperfusion

When cerebral perfusion is fully reinstituted after 3 to 12 minutes of global ischemia, transcellular ionic gradients for K^+, Na^+ and Ca^{2+} are largely restored within several minutes.[48,55,57,63–65] Tissue levels of ATP also recover rapidly.[66] Recovery of Na^+ and K^+ gradients, however, precedes full recovery of ATP,[48,63] presumably because the affinity constant of Na^+–K^+ ATPase for ATP is lower than when ATP levels are normal. Hence, much of the ATP initially produced during reperfusion is utilized for restoration of ionic gradients and high ATPase activity delays recovery of ATP concentration.

When ischemia is prolonged beyond 15 minutes, recovery of ionic gradients and ATP becomes progressively slower.[67–70] Furthermore, steady-state recovery of ATP is 20%–40% below normal.[71,72] Slower ATP recovery may be the result of depressed mitochondrial function[73,74] secondary to acidosis,[75,76] formation of oxygen radicals,[77] degradation of mitochondrial phospholipids,[78] increased Ca^{2+} load, and opening of mitochondrial permeability transition pores.[79] Recovery of oxidative metabolism after prolonged ischemia might also be limited by loss of adenosine base through the adenosine deaminase pathway,[80,81] by defective production of NADH,[82] by heterogeneous patches of poor reflow and oxygenation,[33,83,84] and by sustained ionic membrane leaks that cause wasteful utilization of a limited ATP supply for ionic pump activity. In addition, initial recovery of ATP after prolonged ischemia might be followed by a secondary decline in ATP, as loss of adenosine, loss of NADH, and microcirculatory stasis worsening over a period of several hours.[85]

With short periods of ischemia, full restoration of transcellular ionic gradients and high-energy phosphates in tissue should not be taken as evidence that metabolism is completely restored throughout the cell. Critical abnormalities may persist in dendritic processes far removed from the cell body, particularly at synaptic sites. Postsynaptic microregions deluged by neurotransmitters are expected to show an imbalance in second messenger systems, with effects that will persist into reperfusion. Astrocyte processes responsible for ATP-dependent uptake and metabolism of neurotransmitters, such as glutamate, require restoration of their Na^+ gradient for inward glutamate transport. Presynaptic neuronal processes depleted of neurotransmitters during anoxic depolarization might also be active in reuptake and synthesis of neurotransmitters and synaptic vesicles.[86] Consequently, defects in neurotransmission can persist. Appearance of spontaneous EEG activity can be considerably delayed after restoration of ionic gradients and ATP, and if the duration of ischemia is prolonged, the EEG may remain abnormal.[27,51,87] Furthermore, the amplitude of evoked potentials may remain depressed even after brief ischemia. Thus, functional neurotransmission can remain impaired despite recovery of global oxidative metabolism and ionic gradients.

Cerebral acidosis during ischemia and reperfusion

Because acidosis has traditionally been assumed to play an important role in ischemic injury, it is useful to understand the factors that influence cerebral pH during ischemia. Normal intracellular pH in brain is approximately 7.1, and normal extracellular pH is approximately 7.3.[88,89] This transcellular pH gradient is the net result of intracellular production of acids, proton and bicarbonate antiporters, and membrane voltage.[88] With the onset of complete cerebral ischemia, intracellular pH falls rapidly to approximately 6.1–6.2 within 6–10 minutes.[48,90,91] Extracellular pH decreases in parallel with the decrease in intracellular pH, but appears to remain more alkaline than intracellular pH.[92,93]

One major source of protons during complete ischemia is the hydrolysis of ATP and other nucleoside triphosphates.[94,95] The net hydrolysis of ATP stores (0.3 mmol/kg) in brain is expected to produce approximately 2–4 mmol/kg of protons, depending on Mg^{2+} concentration and pH.[95] Another source of protons is anaerobic glycolysis, whereby 1 mole of glucose forms 2 moles of ATP and 2 moles of lactate anions. When these 2 moles of ATP are eventually hydrolyzed, approximately 2 moles of protons are produced. During complete ischemia, the amount of protons produced depends on glucose and glycogen stores in the tissue, which to a large extent, depend on the history of plasma glucose concentration before the onset of ischemia.[96] During incomplete ischemia, proton production also depends on continued delivery of glucose to the brain and, hence, on arterial glucose concentration.[97]

Ordinarily, changes in intracellular pH are passively buffered by proteins, particularly those with abundant

histidine groups (pka 6.9), and by inorganic phosphate (pka 6.7) and bicarbonate ions (pka 6.1). Because extracellular protein concentration is low in brain, extracellular pH is buffered primarily by bicarbonate ions. In addition, active regulation of intracellular pH that accompanies changes in acid loads is mediated by various proton and bicarbonate antiporters.[88,98] During complete ischemia, CO_2 is not cleared and bicarbonate ions become an ineffective buffer. Marked changes in Na^+ and Cl^- gradients during ischemia render extrusion of acid equivalents by antiporters unfavorable. Upon full reperfusion, CO_2 is cleared within a few minutes and tissue pH increases by approximately 0.3–0.4 unit.[55,91,92] Full recovery of tissue pH requires from 15 to 60 minutes, however[31,48,67,99,100] depends on the duration of ischemia, and lags behind recovery of calcium,[101] sodium,[48] and ATP. The delay in pH recovery might be due to (1) persistent anaerobic glycolysis and production of metabolic acids from other sources during early reperfusion, (2) the need for re-establishment of Na^+ and Cl^- gradients for appropriate function of proton and bicarbonate transporters, and (3) the magnitude of the buffered and unbuffered proton load that must be extruded out of the brain.

Influence of acidosis on ischemic injury

Major evidence that acidosis contributes to ischemic injury is largely derived from studies in which tissue pH is manipulated by varying blood glucose levels to influence the magnitude of anaerobic glycolysis during ischemia.[102,103] Induction of hyperglycemia before global ischemia augments histopathologic damage.[104,105] The most severe damage with hyperglycemia has been reported in models of incomplete global ischemia, in which blood flow is reduced by at least 75% and the duration of ischemia is extended to at least 30 minutes.[106,107] In this case, intracellular pH falls to values in the 5–6 range[97] and is not restored during reperfusion. Additional consequences of these events include: temporary recovery of energy metabolism,[102,108,109] glial and endothelial swelling during early reperfusion,[107,110] patchy, heterogeneous reperfusion,[111] and large areas of necrosis.[104] Conversion of the histopathologic injury from one of selective necrosis of individual neurons typically seen after normoglycemic ischemia to one of microregions of overt necrosis after hyperglycemic ischemia, probably depends on the presence of critically low levels of tissue pH. An alternative mechanism of injury that involves elevated corticosterone during hyperglycemia has been proposed.[112]

In addition to the importance of severity of intraischemic pH, acidosis during reoxygenation might promote from damage oxygen radicals. Postischemic hyperglycemia can delay pH recovery[113] and worsen neurologic deficit.[114] Furthermore, imposing carbonic acidosis during early reperfusion depresses electrophysiologic recovery,[91] whereas antioxidant treatment accelerates pH recovery and improves electrophysiologic recovery.[115]

The mechanism whereby acidosis augments ischemic injury remains unclear. It is generally assumed that, by altering protein charge, acidosis affects functions of a wide array of enzymes, receptors, ion channels, and intracellular messenger systems. Acidosis in the absence of ischemia does not produce neuronal and glial injury, unless it is severe (pH $<$ 6) and prolonged.[98,116–121] Therefore, if acidosis contributes to normoglycemic ischemic injury, it presumably interacts synergistically with other mechanisms that come into play after the loss of oxygenation and depletion of energy.

One way by which acidosis might augment ischemic injury is by augmenting increases in free intracellular Ca^{2+}.[122] This might occur via indirect effects on endoplasmic reticulum and mitochondrial Ca^{2+} sequestration sites, rather than on effects of acidosis on N-methyl-D-aspartate (NMDA) channels. Extracellular acidosis inhibits Ca^{2+} influx through NMDA channels in vitro,[123] and induction of metabolic alkalemia by infusion of carbicarb before incomplete cerebral ischemia depressed the recovery of energy metabolism through an NMDA channel-sensitive mechanism.[124] Acid-sensitive ion channels permit influx of cations, including Ca^{2+}, and blocking these channels protects the brain from focal cerebral ischemia.[125] The role of these acid-sensitive channels in brain injury from cardiac arrest remains to be elucidated.

Another mechanism by which acidosis might augment ischemic injury is through interactions with oxygen radical mechanisms. Iron-dependent lipid peroxidation is promoted by metabolic acidosis,[126] but not by carbonic acidosis.[127] This difference raised the possibility that lactic acid attacks iron that is bound to protein by carbonate bridges, such as occurs on transferrin, whereas carbonic acidosis acts to stabilize these carbonate bridges.[127] Mobilized iron, found in the brain after cardiac arrest,[128,129] will enhance the formation of reactive oxygen species during reoxygenation. The percent of iron bound to low-molecular-weight species after ischemia can be augmented in cerebral cortex by increasing acidosis with hyperglycemia.[130] Moreover, superoxide formed during reperfusion might mobilize additional iron from ferritin[131] and enhance lipid peroxidation.[132] Once abundant free iron is present, free radical production may proceed at a rapid rate and deplete endogenous antioxidants. Because tissue pH during reperfusion usually remains acidotic for 15 to 60 minutes,

persistent acidosis during reperfusion might continue to augment this adverse process. An interaction of metabolic acidosis with oxygen radical damage is supported by evidence that shows that the depressed metabolic recovery associated with enhanced lactic acidosis during hyperglycemic ischemia[97] is ameliorated by treatment with an iron chelator[133,134] or an antioxidant,[135] whereas enhancing carbonic acidosis during ischemia does not depress metabolic recovery despite intra-ischemic pH falling to 5.7.[136] The importance of this mechanism in normoglycemic cardiac arrest is unclear, however because both carbonic acidosis and metabolic acidosis contribute to the drop in tissue pH when there is no blood flow to clear CO_2.

Intra-ischemic acidosis augmented by hyperglycemia affects protein kinases and protein phosphorylation during recovery in a manner different from acidosis augmented by hypercapnia and from normoglycemic ischemia.[137] Other potential mechanisms of acidotic damage include changes in gene expression and protein synthesis and activation of endonucleases, leading to DNA damage.[138] Therefore, the precise mechanism of interactions between acidosis and other mechanisms of ischemic injury remains uncertain and appears to depend on the nature of the acid load (metabolic acid vs. CO_2), the range of pH during ischemia, the range of pH during reperfusion, and the severity and duration of the ischemic insult.

Bioenergetics during chest compression CPR

In most experimental studies of global cerebral ischemia, reperfusion is initiated by rapidly restoring cerebral perfusion pressure to normal levels and producing a hyperemic response in the vasodilated vascular bed. In the typical clinical setting of cardiac arrest, however, a variable period of chest compression CPR, which generates subnormal levels of arterial blood pressure, occurs before the return of spontaneous circulation. Because the increase in intrathoracic pressure during each chest compression increases intracranial pressure,[139,140] cerebral perfusion pressure during CPR is considerably lower than arterial blood pressure. For example, cerebral perfusion pressures in the range of 15–30 mmHg averaged over a chest compression cycle have been measured in standard CPR.[141] At these low levels of cerebral perfusion pressure, cerebral blood flow is expected to be less than 50% of the normal value, which is insufficient to restore cerebral ATP and pH.[142] On the other hand, a low level of reperfusion achieved with experimental CPR does not worsen intracellular pH (Fig. 13.3), which might be of concern if the low level of blood flow restored glucose delivery without concurrently providing sufficient oxygen for aerobic energy
Fig, 13.3. Recovery of cerebral intracellular pH measured by phosphorus MRS during prolonged CPR started at 6 minutes of ventricular fibrillation in dogs. When cerebral perfusion pressure (arterial minus sagittal sinus pressure) was regulated at 80 mmHg during vest CPR and cerebral blood flow (CBF) was near normal (57 ml/min/100g), intracellular pH recovered to near prearrest levels. When cerebral perfusion pressure was regulated at 30 mmHg by adjusting the inflation pressure of a pneumatic thoracic vest, intracellular pH did not recover in a group with a CBF of 29 ml/min/100 g, despite partial recovery of ATP. In a group with poor CBF (8 ml/min/100 g at 12 minutes and lower flow thereafter), intracellular pH did not decrease further during CPR. Recovery of intracellular pH requires normal levels of CBF, but trickle flow does not worsen tissue acidosis. (Curves drawn from refs. 121 and 192.)

metabolism. With advanced CPR techniques that permit higher levels of cerebral blood flow (50%–100% of normal) to be generated, cerebral ATP partially recovers, but energy supply is insufficient to restore cerebral pH (Fig. 13.3) unless blood flow is near the normal level.[90,142] Most importantly, brief delays in the onset of CPR after cardiac arrest have a major effect on the level of cerebral blood flow that can be generated (Fig. 13.4). As the delay in the onset of CPR is increased from 0 minutes to 12 minutes, the relationship of blood flow to perfusion pressure progressively shifts to higher perfusion pressures.[143,144] Consequently, the ability to regenerate ATP becomes markedly impaired (Fig. 13.4). The increase in the zero-flow intercept on the pressure axis might be related to progressive swelling of astrocyte processes that surround capillaries, limiting flow at low perfusion pressures. Aquaporin-4 water channels are preferentially localized on astrocyte foot processes near blood vessels and appear to contribute to ischemia-induced swelling.[145,146] Additional delivery of water into the microcirculation that accompanies low perfusion might lead to additional astrocyte swelling and further shifts in the pressure–flow relationship.
Fig. 13.4. Left. Forebrain blood flow generated during CPR vs. cerebral perfusion pressure (arterial minus sagittal sinus pressure) when CPR was started at different times after cardiac arrest in dogs. Cerebral perfusion pressure was regulated by adjusting inflation pressure of a pneumatic thoracic vest during a continuous epinephrine infusion. Note the progressive decrease in blood flow at a particular perfusion pressure when the CPR is delayed from 0 minutes to 1.5, 3, 6, and 12 minutes. Right. Percent recovery of cerebral ATP becomes progressively lower when CPR is delayed from 0 minutes to 6 and 12 minutes at a particular level of perfusion pressure. (Curves drawn from refs. 192 and 195.)

Therefore, intermediate levels of blood flow during reperfusion generate intermediate levels of ATP recovery, but recovery of tissue pH appears to require near normal levels of blood flow and near normal levels of ATP recovery. Consequently, it can be speculated that clinical CPR provides partial recovery of energy metabolism, at least after relatively short arrest times (6 minutes), but that cerebral acidosis persists until return of spontaneous circulation. After longer arrest times, however, metabolic recovery is likely to be poorer. These observations emphasize the importance of early defibrillation.

Cerebral circulation after return of spontaneous circulation

With return of spontaneous circulation and normal cerebral perfusion pressure after complete ischemia, cerebral blood flow initially increases to above normal levels and then decreases to below normal levels. The mechanism of initial vasodilatation is multifactorial and includes elevated extracellular concentrations of potassium,[147] adenosine,[148] and nitric oxide,[149,150] decreases in extracellular pH and calcium, and possibly trigeminal sensory afferent activation.[151] The magnitude of the flow changes might also depend on estrogen.[152] Studies with iodoantipyrine in rats[33] and with stable xenon in dogs[153] indicate that

initial hyperemia is relatively heterogeneous among brain regions. The microvascular pressure required to start reflow of a non-Newtonian fluid in individual capillaries might be greater than the pressure required to maintain flow, particularly if swollen astrocytes reduce capillary diameter sufficiently to impede the flow of red cells and the less deformable white cells.[154] Thus, reperfusion at subnormal perfusion pressure is expected to result in poor reflow capillaries. Reperfusion accompanied by hypertension and hemodilution for several hours has been used to promote reflow and has been found to improve neurologic recovery in animals.[26,155] The existence of brain capillaries with true zero blood flow at a time when perfusion pressure is normal after resuscitation remains uncertain, however, because the spatial resolution of most blood flow techniques employed after ischemia[33,153] does not resolve individual capillary red cell flux.

Postischemic hyperemia typically lasts 5 to 40 minutes and depends on the duration of ischemia.[34] This hyperemic phase is followed by a period during which cerebral blood flow falls to subnormal levels and is termed "delayed hypoperfusion." The transition from hyperperfusion to hypoperfusion has been assumed to depend on the gradual clearance of vasoactive metabolites, although some evidence suggests that the transition can occur abruptly.[156] Delayed hypoperfusion does not appear to be the result

of neurogenic vasoconstriction[157] or loss of neurogenic vasodilatation.[30] Both cerebral blood flow and oxygen consumption are reduced in comatose cardiac arrest victims during the first 6 hours after resuscitation[158] and can remain depressed in those with persistent coma.[159] Postischemic reductions in oxygen consumption are also observed in most experimental models of complete ischemia.[34,91,160] Therefore, reduced metabolic demand may contribute to hypoperfusion. Nevertheless, increases in oxygen extraction observed by some investigators[153] suggest that postischemic reductions in metabolic rate do not fully account for postischemic reductions in blood flow.

Delayed hypoperfusion generally lasts 2 to 6 hours. In a 1989 study, patients who regained consciousness after cardiac arrest had normal cerebral blood flow before regaining consciousness, whereas those who died without regaining consciousness surprisingly exhibited increased cerebral blood flow by 24 hours after resuscitation.[161] The pathologic significance of delayed hypoperfusion remains uncertain because its severity does not necessarily correlate with the neurologic outcome in animals,[162] and treatment with nimodipine to reduce delayed hypoperfusion did not improve outcome in patients[163] or animals.[164,165]

On the other hand, perfusion defects in individual capillaries have been observed[84] and could result in neuronal damage. Leukocytes, which are much less deformable than red cells and can be a major source of oxygen radicals, may contribute to hypoperfusion by plugging compressed capillaries.[166] Endothelium-dependent vasodilatation is impaired in pial arterioles[167] by an oxygen radical-dependent mechanism,[168] and this impairment in female animals is augmented by the loss of estrogen.[169,170] Furthermore, cerebral blood flow responses to CO_2 are largely impaired, whereas flow responses to hypoxia and changes in blood pressure are only modestly affected [28,171–173] Oxygen radicals appear to be involved in loss of CO_2 reactivity.[168,174] Delayed hypoperfusion is attenuated by antioxidant treatment after cardiac arrest,[175,176] but not by osmotic or thrombolytic therapy.[177] Therefore, selective abnormalities in vascular regulation occur during the delayed hypoperfusion period at both the macrocirculatory and microcirculatory levels. The consequence of hypoperfusion on neuronal injury, however, remains unclear.

Mechanisms implicated in selective vulnerability

The selectively vulnerable areas of the brain are the hippocampus CA1 region, the cerebral cortical layers 3–5, and the cerebellar Purkinje cells. The phenomenon of selective neuronal vulnerability can be explained by two main hypotheses: the excitotoxic neurotransmitter hypothesis, based largely upon events during ischemia, and the free radical hypothesis, primarily due to events during reperfusion. The excitotoxic neurotransmitter theory suggests that the selectively vulnerable cell bodies and dendrites receive afferent projections that release large amounts of amino acid neurotransmitters (i.e. glutamate) during ischemia-induced depolarization.[178] There are two classes of glutamate receptors, one being the inotropic receptors, which are the ligand-gated ion channels, and second the metabotropic glutamate receptors (mGluR), which are coupled to cellular effectors via GTP-binding proteins. On the vulnerable neurons glutamate may bind to the two inotropic receptors that are distinctively activated by either N-methyl-D-aspartate (NMDA) or α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA). NMDA receptor activation opens a Ca^{2+} channel, allowing Ca^{2+} influx, and AMPA receptor activation opens a Na^+ channel, allowing Na^+ influx. The increased intracellular Na^+ concentration (Na^+_i) is thought to induce reversal of normal Ca^{2+} extrusion through a $3\,Na^+/Ca^{2+}$ antiporter, thereby also resulting in increased intracellular Ca^{2+}_i. Studies with brain slices and cell cultures suggest that the mGluRs are coupled to several second messenger systems in situ, including those involved in activation of phosphoinositide hydrolysis, regulation of cAMP formation, and ion (calcium and potassium) channel modulation. The mGluR agonists have two unusual effects. First, they reduce transmission of excitatory amino acid (glutamate) and reduces inhibitory postsynaptic potentials (probably via decreased GABA release). Second, in the hippocampal CA_1 region mGluR agonists induce long-term synaptic potentiation (thought to be how memory is formed), probably mediated by protein kinase C-induced escalation in NMDA receptor currents.[179] Intraocular injection of the metabotropic receptor agonists protects against retinal damage induced by NMDA, but intra-hippocampal injections of mGluR agonists caused massive hippocampal damage in some rat strains.[180,181]

There is convincing evidence for glutamate release during complete global ischemia.[178] The resultant calcium influx stimulates even more glutamate release from presynaptic vesicles.[182] In addition reuptake of glutamate is inhibited by arachidonic acid[183] and other products of lipid peroxidation.[184] Magnesium, which inhibits synaptic transmitter release and, as a natural calcium antagonist also inhibits cell death in vitro.[185,186] Nevertheless, NMDA receptor antagonists have generally failed definitively to salvage neurons after complete global ischemia. There is little evidence for sustained exposure to elevated glutamate during reperfusion, calling into question whether glutamate plays

a role in the progressive neuronal reperfusion injury. Further, the hydrogen ions that accumulate intra- and extracellularly during ischemia have been shown to inhibit the NMDA receptor.[187] There is however more promising evidence that AMPA receptor blockade is neuroprotective following complete global ischemia.[188] Excitotoxic mechanisms mediated at this receptor may play a larger role in complete global ischemia and reperfusion injury than that mediated by the NMDA receptor. In total this evidence reinforces the role of ischemia-induced Ca^{2+} overload as a principal mechanism in neuronal death.

The free radical hypothesis of selective vulnerability asserts that neurons are more susceptible to radical-induced damage (specifically lipid peroxidation) during reperfusion because (1) they are deficient in glutathione peroxidase,[189] and (2) they are surrounded by oligodendrocytes that have iron stores which are released during ischemic reperfusion and catalyze formation of free radicals.[190,191] Indeed, White *et al.* reported direct histochemical evidence that during the first 90 minutes of reperfusion following a 10 minute cardiac arrest in rats, lipid peroxidation was concentrated in the selectively vulnerable zones.[192] In particular the lipid peroxidation products localized to the area of the Golgi apparatus, an important site of membrane recycling, and in the apical dendrite, an area rich in mitochondria.[193,194]

Since the two theories primarily involve different phases in an injury continuum (*i.e.*, ischemia then reperfusion), the glutamate and free radical hypotheses are by no means mutually exclusive. Furthermore substantial evidence exists for membrane damage caused by both calcium activation of phospholipases and generation of free radicals during reperfusion. Later in the chapter we will explore the idea that damage to membrane lipids plays a central role in postischemic brain injury. In the next section we will explore the loss of calcium homeostasis as mediated by both energy depletion and glutamate receptor activation during ischemia.

Calcium flux and calcium activated proteases

Disruption of neuronal Ca^{2+} homeostasis during global brain ischemia and reperfusion

In vivo microelectrode measurements of hippocampal CA1 pyramidal neurons indicate that cytosolic $[Ca^{2+}]$ increases from a baseline of 60–90 nM to 20–200 μM within 8 minutes of transient forebrain ischemia.[195,196] If reperfusion occurs after brief to moderate durations of ischemia, cytosolic $[Ca^{2+}]$ returns to baseline within 20 minutes.[65,21,22] A

secondary increase in cytosolic Ca^{2+}, however, is detected as early as 4–6 hours after reperfusion.[197] Unfortunately, no direct measurements of cytosolic Ca^{2+} beyond 6 hours have been reported. Less quantitative histochemical techniques have demonstrated a transient increase in mitochondrial Ca^{2+} by 10 minutes of reperfusion that returns to baseline within 1–2 hours.[198–200] Secondary increases in mitochondrial Ca^{2+} appear 24 hours after reperfusion in the hippocampal CA1 sector prior to evidence of ATP depletion or the morphologic appearance of cell death.[201] In contrast to the cytosol and mitochondria, endoplasmic reticulum Ca^{2+} is persistently depleted in postischemic CA1 pyramidal neurons.[202] Ultimately, total tissue Ca^{2+} in the CA1 hippocampus begins to increase 48 hours after reperfusion and reaches a peak at 72 hours corresponding to histopathological evidence of neuronal death.[203,204]

Overall, these measurements show that cytosolic and mitochondrial Ca^{2+} overload observed during ischemia and early reperfusion is reversible, but sustained ER Ca^{2+} depletion and delayed secondary cytosolic and mitochondrial Ca^{2+} overload occur in neurons that eventually die. Understanding the mechanism of delayed secondary disruption of Ca^{2+} homeostasis is essential to discovering the cause of delayed postischemic neuronal death. Dysfunction of a number of Ca^{2+} regulatory proteins has been implicated, including plasma membrane Ca^{2+}-ATPase, the L-type voltage-gated Ca^{2+} channel, NMDA receptor, AMPA receptor and transient receptor potential melastatin (TRPM7)[205–212] and endoplasmic reticulum proteins including endoplasmic reticulum Ca^{2+} ATPase, the IP_3 receptor and the ryanodine receptor.[32,213]

The calpain/calpastatin system

Calpains (EC 3.4.22.17) are a family of non-lysosomal neutral cysteine proteases. Their activity is absolutely dependent on Ca^{2+} and is regulated by a specific endogenous inhibitor calpastatin.[214,215] The two ubiquitous calpain isoforms are μ-calpain (calpain I) and m-calpain (calpain II). Immunohistochemical studies have demonstrated that μ-calpain is concentrated in neurons, while m-calpain appears to be relatively more abundant in glia, and calpastatin is evenly distributed between the two cell types.[216–219] μ-Calpain and m-calpain are heterodimeric proteins that have nearly identical substrate specificity, but require different Ca^{2+} concentration ($[Ca^{2+}]$) for activity.[41] The $[Ca^{2+}]$ required for in vitro proteolytic activity of μ-calpain is 3–50 μM and for m-calpain is 200–1000 μM.[220] The two isoforms have unique 80-kDa catalytic subunits with only 50% sequence homology, but share a common 30-kDa regulatory subunit. The catalytic subunits of μ

calpain and m-calpain undergo N-terminal autoproteolysis at a [Ca^{2+}] slightly greater than that required for substrate proteolysis. The result of autoproteolysis is a decreased Ca^{2+} requirement for subsequent proteolytic activity (0.6–0.8 μM for μ-calpain and 50–150 μM for m-calpain).[221–223] This reduced Ca^{2+} requirement of autolyzed calpains may be a mechanism of potentiated proteolytic activity in response to recurrent intracellular Ca^{2+} overload such as occurs in postischemic neurons.

In vivo calpain activity is measured by demonstrating autoproteolysis and/or substrate degradation. Autoproteolysis of calpain I reduces the mass of the 80-kDa subunit first to 78-kDa and then to 76-kDa, and these forms can be resolved by SDS-PAGE and detected by Western blotting.[224] Autoproteolysis of the 80-kDa calpain II subunit reduces the mass to 78-kDa, but this usually cannot be resolved by SDS-PAGE. Calpain substrate degradation is detected by the loss of intact protein or the appearance of calpain-specific degradation fragments, the latter of which is much more sensitive. For the cytoskeletal protein α-spectrin, antibodies have been generated that bind specifically to the α-spectrin fragment uniquely generated by calpain proteolysis.[225,226] This method appears to be the most sensitive way for detecting in vivo calpain activity in rodent models of brain ischemia.

Calpains are physiologically involved in regulation of the cell cycle, mitosis, motility, signal transduction, gene expression, long-term potentiation, and synaptic remodeling.[41,42,227,228] Functional knockout of both ubiquitous isoforms is achieved by knockout of the common regulatory subunit and is embryonically lethal.[229,230] Knockout of m-calpain is also embryonically lethal,[42] whereas μ-calpain knockout mice survive and are fertile.[231] Honda et al.[232] recently reported that RNAi-mediated knockdown of m-calpain but not μ-calpain caused aberrant mitosis and abnormal chromosome alignment. Taken together these results strongly suggest that the two isoforms have unique physiologic roles despite their common substrate profile. Under physiologic conditions, calpain activity is likely to be stimulated by transient localized increases in cytosolic Ca^{2+} and to be tightly regulated by the presence of calpastatin. In contrast, the massive unlocalized increase in cytosolic Ca^{2+} that occurs during brain ischemia is likely to overwhelm endogenous regulatory systems and thus result in pathologic calpain activity.

Neuronal calpain activity during global brain ischemia and reperfusion

The initial increase in cytosolic Ca^{2+} during severe brain ischemia is clearly adequate to cause increased μ-calpain

activity and autoproteolysis based on in vitro kinetic data. We have demonstrated μ-calpain autoproteolysis and calpain substrate degradation within 10–20 minutes of cardiac arrest in rabbits.[233,234] Yamashima et al.[235] used immunohistochemistry with an antibody specific to the 76-kDa autolyzed form of calpain I to demonstrate the appearance of autolyzed μ-calpain in the cytosol of CA1 and cortical pyramidal neurons after 20 minutes of global brain ischemia in monkeys. In our rat model of transient forebrain ischemia, a transient increase in calpain-mediated α-spectrin cleavage product is detected in the CA1 hippocampus 1 hour after reperfusion followed by a ten-fold greater rise beginning between 24 and 48 hours after reperfusion.[236] This result is consistent with that published by several other investigators using different models or species.[52,53,237]

Studies with calpain inhibitors provide evidence that neuronal death following both global and focal brain ischemia may be caused by increased calpain activity.[238–244] However, these studies must be interpreted with caution, because all synthetic calpain inhibitors effective in vivo have significant activity against other proteases[245,246] including cathepsins, which have also been mechanistically implicated in postischemic neuronal necrosis acting downstream of calpains.[247,248] Furthermore, studies of calpain inhibitor cannot elucidate the relative role of μ-calpain and m-calpain because all known calpain inhibitors are effective against both isoforms. Bendarski et al.,[249] reported, however, that anti-sense-induced translation suppression of μ-calpain in cultured neurons decreased spectrin proteolysis and improved recovery of evoked synaptic responses after NMDA-induced injury. This observation supports the hypothesis that μ-calpain is primarily responsible for pathologic calpain activity in postischemic neurons.

Nitric oxide

Nitric oxide (NO) is a free radical generated from the conversion of arginine to citrulline by the three isoforms of the enzyme nitric oxide synthase (NOS). Constitutive isoforms are regulated by calcium and calmodulin and are located in endothelium, periarterial nerves,[250] and in approximately 2% of parenchymal neurons,[251,252] whereas a calcium-independent isoform can be induced in microglia, macrophages, and astrocytes. Parenchymal NOS neurons are highly arborized,[253] permitting NO to diffuse to many neighboring neurons, where it can stimulate soluble guanyl cyclase.[254] The activity of neuronal NOS, anchored by postsynaptic density proteins, is coordinated by

calcium entry through NMDA receptors.[255,256] In addition, activation of AMPA, kainate, and metabotropic glutamate receptors can result in stimulation of NOS activity.[257–261] Overstimulation of these glutamate receptors during and after ischemia is thought to lead to an overproduction of NO in neurons.[262,263]

Nitric oxide can form reactive peroxynitrite anions, nitrosonium cations and nitroxyl anions, and alterations of metalloprotein redox state.[264,265] Most important, ischemia and reperfusion increase superoxide production which, in the presence of increased NO availability, rapidly generates excess peroxynitrite anion.[266] In the presence of carbon dioxide, peroxynitrite forms the nitrogen dioxide intermediate, which leads to nitration of tyrosine residues and altered protein function, nitrosylation of sulfhydryl groups on proteins, and hypochlorous acid.[264,267] Peroxynitrite can form hydroxyl radicals without a requirement for iron, leading to DNA damage[268,269] and lipid peroxidation.[270] Reduced NMDA toxicity and reduced ischemic damage by both Cu,Zn-superoxide dysmutase overexpression and NOS inhibitors are consistent with a peroxynitrite-mediated mechanism.[253,271] Damage to DNA causes activation of the nuclear repair enzyme poly(ADP-ribose) polymerase (PARP). Overactivation of PARP, however, causes caspase-independent cell death by stimulating translocation of apoptosis-inducing factor from the mitochondria to the nucleus[272] and possibly by depleting NAD^+.[273,274] Inhibitors of PARP reduce toxicity from NMDA and from NO donors in neuronal culture.[269] Translocation of apoptosis-inducing factor into the nucleus has been described in hippocampal neurons after global ischemia.[275]

The role of neuronally derived NO in ischemic damage is largely supported by evidence from focal ischemia in male animals, in which administration of NOS or PARP inhibitors or gene deletion of neuronal NOS or the PARP-1 isoform reduce infarct size.[276–279] Unexpectedly, this mechanism appears to differ in female animals that are subjected to focal ischemia.[280] In contrast to focal ischemia, the role of NO in global ischemia in vivo is less convincing. Studies in gerbil,[281,282] rat,[283] and cat[284] with NOS inhibitors failed to detect an improvement in histopathology, although some reports have described a positive effect.[285] Moreover, endothelial NOS exerts protective effects in focal ischemia by promoting blood flow and limiting platelet aggregation and inflammation. The use of inhibitors that act on both neuronal and endothelial NOS could result in offsetting effects. In contrast to the pharmacologic strategy, neuronal NOS-deficient mice were found to have reduced hippocampal neuronal cell loss in the CA1 region after global cerebral ischemia.[286] Moreover, the PARP-1 isoform appears to be important in neuronal injury from global ischemia, because PARP-1-deficient mice had improved neuronal viability in striatum and hippocampus after cardiac arrest and resuscitation.[287] Therefore, genetically altered mice support a link among neuronally derived NO, PARP activation, and hippocampal injury after global ischemia, but more robust biochemical and molecular evidence will be required to substantiate that the observed effects are not related to developmental effects of gene deletion. Furthermore, additional work is required to elucidate how these mechanisms may differ in the female, where injury in the hippocampus, but not striatum, after cardiac arrest appears to be linked to gender and where overexpression of superoxide dismutase has no additional protective effect.[288]

Because the inducible isoform of NOS (iNOS) is calcium independent, it can produce a large amount of NO continuously if substrate is available. Induction of iNOS has been studied in experimental focal ischemia, where induction in microglia and astrocytes in the peri-infarct region increases over a 48-hour period.[289] The iNOS inhibitor aminoguanidine given as late as 24 hours after focal ischemia can attenuate the progression of the infarction.[290] A role for iNOS in the infarction process is also supported by the reduced infarct size seen in iNOS null mice.[291] But the role of iNOS in neuronal injury that arises from global cerebral ischemia in which infarction does not occur has not been well studied. In one study of four-vessel occlusion in the rat, aminoguanidine was shown to reduce the nitrite and nitrate metabolites of NO at 24 hours of reperfusion in hippocampus, restore long-term potentiation in the hippocampus, and improve performance on a short-term memory task.[292] In another study, aminoguanidine was found to increase the number of viable pyramidal neurons in the hippocampus and reduce the number of NADPH-diaphorase-positive cells (presumed to represent iNOS in activated microglia and macrophages) over 14 days of reperfusion.[293] Therefore, increased activity of iNOS over many days of reperfusion may contribute to the delayed neuronal loss in the hippocampus after global ischemia.

Membrane Damage by Brain Ischemia and Reperfusion

Enzymatic lipolysis during brain ischemia and reperfusion

ATP stores in the brain are depleted within 4 minutes of complete ischemia. This depletion is associated with loss of the normal transmembrane gradient of Ca^{2+} the resultant increase in Ca^{2+}_i catalyzes lipolysis during ischemia. (The

subsequent free fatty acid (FFA) release metabolism generates superoxide radicals ($\cdot O_2^-$) during reperfusion.) Initially, phospholipases are activated during early ischemia.[294–296] The phospholipases are a ubiquitous family of enzymes, found in the cytosol, plasmalemma, and mitochondrial membrane, that hydrolyze functional groups from phospholipids.[297,298] Of particular interest is phospholipase A_2, which has an absolute requirement for calcium[299,300] and cleaves fatty acyl chains from the β-position of phospholipids. Arachidonic acid in mammalian cells is esterified almost exclusively at the β-position. Thus, lipolysis during ischemia results in accumulation of free fatty acids, especially arachidonic acid, whose metabolism during reperfusion produces $\cdot O_2^-$. Cyclooxygenase catalyzes the addition of two molecules of O_2 to an unsaturated fatty acid, like arachidonic acid, and produces prostaglandin PGG, which is rapidly peroxidized to PGH with concomitant release of $\cdot O_2^-$ [182] There is evidence that the rate of lipolysis in the selectively vulnerable zones is significantly greater than it is in other areas of the brain.[296]

The release of FFA appears to continue during reperfusion.[301] Enzymatic lipolysis and lipid peroxidation may act synergistically in membrane destruction during reperfusion, as erythrocytes damaged by lipid peroxidation are lyzed more rapidly by phospholipase than are normal membranes.[302,303] Thus, fatty acids that have been peroxidized are better substrate for phospholipase and some products of lipid peroxidation stimulate phospholipase.[304,305] In addition to the lipid peroxidation, there is evidence of substantial inhibition of the lipid repair enzymes, lysophosphatidylcholine acyltransferase and fatty acyl CoA synthetase during reperfusion.[306] Lipid hydroperoxides, a product of lipid peroxidation, also interfere with the reacylation (salvage pathway) of neuronal phospholipids.[307]

Lipid peroxidation during brain reperfusion

The morphological progression of injury during reperfusion led to the hypothesis[308] that accelerated structural damage is a consequence of excessive generation of oxygen radicals followed by lipid peroxidation. The resultant changes in the conformation or configuration of the fatty acids alters the permeability and fluidity of the membrane leading to compromised receptors and ion channels.

Lipid peroxidation comprises a set of radical-mediated chemical chain reactions whereby the double bonds in the unsaturated fatty acid side chains are rearranged.[309] The cell membrane contains a large number of unsaturated fatty acids in a monolayer and is a favorable environment for a lipid peroxidation chain reaction.[310] The divinyl hydrogens in the PUFA side chains of membrane lipids are

particularly susceptible to attack by oxidizing chemical species.[311] After initial abstraction of the divinyl hydrogen and rearrangement of double bonds in the PUFA to form a conjugated diene, the consequent lipid alkyl radical reacts with O_2 to form the lipid peroxyl radical, which then abstracts a divinyl hydrogen from a second PUFA, yielding a lipid hydroperoxide and another lipid alkyl radical. In the presence of a transition metal, the lipid hydroperoxide can be converted to a lipid alkoxyl radical, which is electrophilic enough to initiate further lipid peroxidation.[312] This allows geometric expansion of the chain reactions. PUFA hydroperoxides and alcohols undergo a number of subsequent catabolic reactions that generate several aldehydic products, including malondialdehyde.[313]

The identity of the initiating oxidizer remains unclear despite intense investigation,[309,314] although it is well established that the presence of a transition metal is required as a catalyst. Iron is undoubtedly the biologically relevant transition metal catalyst. The brain glia have abundant stores of oxidized (ferric) iron,[315] mostly in ferritin and transferrin[316] which is unable to act as a catalyst for oxygen radical reactions. Nonetheless, $\cdot O_2^-$ promotes reduction of ferric and release of ferrous iron from ferritin,[132] a reaction possible only during reperfusion. Iron delocalization into low-molecular weight species is seen in the brain during postischemic reperfusion.[129] Kinetic modeling has shown that membrane lipid peroxidation can be initiated in the presence of 1 μM iron by reduction via $\cdot O_2^-$ [317]

Membrane lipids are extensively peroxidized by iron-dependent radical reactions during reperfusion.[318–323] Sakamoto *et al.* demonstrated increased in vitro formation of *N*-tert-butyl-*a*-phenyl-nitrone (PBN – a radical spin trap) spin adducts during reperfusion following 10 to 20 minutes of carotid occlusion in rats, and interpreted this as representing a burst of free radical production.[322] They found that the PBN adduct reached a peak at 5 minutes of reperfusion, and this peak increased with longer ischemic time. Furthermore, they noted products of lipid peroxidation were increased as early as 30 minutes after 10 minutes of ischemia, and the degree of lipid peroxidation also increased with longer ischemic time. Bromont *et al.* found brain lipid peroxide levels were selectively increased in the hippocampus, striatum, and cortex between 8 and 72 hours of reperfusion after 30 minutes of 4-vessel occlusion in the rat.[321] In our work, by 8 hours of reperfusion, there was loss of 30% of the lipid double bond content and ultrastructural evidence of large gaps in the neuron plasmalemma.[324] At this point, the neurons were no longer able to maintain ionic homeostasis. The biochemical effects we observed were significantly inhibited by treatment with deferoxamine during the first 15 minutes of reperfusion.[325]

We have utilized a rat model of 10-minute cardiac arrest and resuscitation[326] to study cellular localization of reperfusion-induced lipid peroxidation. By 90 minutes postresuscitation, reperfusion-induced fluorescent products of the reaction between thiobarbituric acid and lipid aldehydes formed by lipid peroxidation are found in the pyramidal neurons in the infragranular layers of the cerebral cortex, including layers 5 and upper layer 6, and in the pyramidal layer of Ammon's horn in the hippocampus. Our observations are consistent with the chemical data on lipid peroxidation during reperfusion and verify the study of Bromont *et al.* showing that the selectively vulnerable neurons are damaged specifically by lipid peroxidation during early reperfusion.

These reactions also appear to be involved in the genesis of the postischemic hypoperfusion phenomenon, which is inhibited by superoxide dismutase and deferoxamine[327] or U74006F,[328] a lipid peroxidation chain terminator.[329] Thus, there is now evidence implicating membrane damage by reperfusion-induced lipid peroxidation in both histological damage to neurons and in the genesis of the postischemic hypoperfusion syndrome.

Protein synthesis and brain ischemia and reperfusion

At the onset of reperfusion following global ischemia, protein synthesis is inhibited in neurons throughout the entire brain,[330] but it recovers over a 6–24-hour period in neurons more resistant to ischemic damage. In the brain region most vulnerable to transient ischemia, the CA1 of the hippocampus, normal levels of protein synthesis never recover during reperfusion even after relatively brief durations of ischemia.[331] Indeed, a number of investigators have suggested that persistent suppression of protein is a marker for neurons destined to die in the reperfused brain. Because proteins have such fundamental roles in the cell, including enzymatic reactions governing intermediary metabolism, transport, and storage, as well as intracellular signaling and cellular structure, significant changes in the ability of neurons to produce and maintain proteins would be expected to have considerable effects on the capacity of the cells to survive. The brain has a substantial requirement for protein synthesis just to maintain homeostasis. It expresses the largest percentage of its DNA of any organ, and its protein turnover is approximately equal to 100% of its protein content every 48 hours. Additionally, as a result of ischemia and reperfusion, there is a significant need for replacement of proteins damaged by calpain-mediated proteolysis and membrane lipid peroxidation (neuronal

membranes are ~50% protein). We will first review the regional and temporal pattern of protein suppression occurring as a consequence of brain ischemia and reperfusion and then review the pathophysiological mechanisms responsible.

Patterns of protein suppression in reperfused brain

Postischemic suppression of protein synthesis was first reported in 1971 by Kleihues and Hossman.[332] When cats were given ^{14}C-labeled amino acids intravenously during reperfusion and the protein was extracted from brain homogenates 30 minutes later, a 30% decrease in label incorporation was observed after 4 hours of reperfusion following 30 minutes of ischemia. Evidence now indicates that in the selectively vulnerable neurons the post-ischemic suppression of brain protein synthesis is severe and prolonged. Cooper *et al.* measured [14C]phenylalanine incorporation by in vitro translation utilizing the postmitochondrial supernatant from rat brain homogenates.[333] Incorporation was normal in the homogenates derived from rats after 15 minutes of ischemia, but had fallen 80% after 15 minutes of reperfusion. They concluded that the reduction of protein synthesis was a consequence of reperfusion. Nowak *et al.* found that in vitro amino acid incorporation by the postmitochondrial fraction prepared from gerbil brain homogenates was normal after 30 minutes of ischemia without reperfusion.[334] After 10 minutes of recirculation, however, protein synthesis had decreased 90% and slowly recovered to 60% of baseline by six hours of reperfusion. Moreover, these studies show that as little as 3 minutes of ischemia triggers suppression of protein synthesis during reperfusion. The degree of suppression was dependent on the duration of the ischemia for ischemic periods of less than 5 minutes; longer ischemic times did not result in any additional suppression. Recovery of protein synthesis was not affected by the duration of ischemia in this model. In contrast, Dienel *et al.* found that increasing the duration of ischemia delays the recovery of in situ protein synthesis in the surviving areas.[335]

Translational competence in the brain after ischemia/reperfusion is not regionally homogeneous; the cortex, hippocampus, and caudate show severe and prolonged suppression of protein synthesis, while the brainstem and midbrain structures are relatively unaffected.[336] Araki *et al.*, using a bilateral carotid occlusion model in the gerbil, demonstrated regional differences in L-[methyl-^{14}C]methionine incorporation and corroborated the existence of an ischemic threshold for suppression of protein synthesis.[331] They found that 1 minute of ischemia did not suppress protein synthesis during reperfusion. After 2

minutes of ischemia, however, there was a severe, but reversible suppression, and 3 minutes of ischemia produced a severe loss of protein synthesis in the neocortex, striatum, the whole hippocampus, and the thalamus that slowly recovered during the following 5–24 hours; the CA1 region of the hippocampus never recovered its ability to incorporate label. These areas are also the ones most susceptible to delayed neuronal death following ischemia, indicating that a prolonged deficit in postischemic protein synthesis correlates with the selective vulnerability of these areas to ischemia and reperfusion.

Mechanisms of protein suppression in reperfused brain

Although the patterns of postischemic suppression of protein synthesis in the brain are well described, the mechanisms that cause it are still under investigation. Protein synthesis is a complex process requiring (1) high energy phosphates, (2) intact DNA, (3) intact transcription machinery, (4) processing and transport of mRNA from the site of transcription to the site of translation, and (5) intact translation machinery. Each of these steps is a potential site of disruption following ischemia and reperfusion.

Energy supply

Because protein synthesis requires energy, depletion of ATP/GTP stores is responsible for its cessation during ischemia. Nowak *et al.* showed that the postmitochondrial supernatant fraction isolated from ischemic brain would incorporate amino acids into polypeptides if a source of high-energy phosphates was added.[337] High-energy phosphate depletion cannot account for the prolonged suppression of protein synthesis seen during reperfusion, however, ATP, phosphocreatine, and GTP, all essentially zero after 5 minutes of ischemia, are normal by 15 minutes of recirculation.[334]

DNA stability and transcription

When a particular protein is to be made, the nucleotide sequence from the appropriate section of the chromosomal DNA is first transcribed into an RNA molecule. These transcripts are then subjected to a series of processing steps that includes capping on the 5′ end, removal of intron sequences by splicing, and polyadenylation on the 3′ end before the messenger RNA is permitted to exit from the nucleus and be translated into protein.

Brain DNA does not accrue any significant damage by either endonucleolytic or free radical mechanisms during cardiac arrest or during early reperfusion. We developed sensitive assays able to detect low levels of damage (1 radical-mediated single-strand nick in 200 000 base pairs), but found no evidence of radical-mediated base damage nor of strand scission in brain genomic or mitochondrial DNA after a 20 minute cardiac arrest followed by up to 8 hours of reperfusion.[338,339] Furthermore, neither thymine glycols nor thymine dimers, formed by free radical mechanisms and known to cause premature termination of transcription, were seen in the same model. Hours later, however, apoptosis can be triggered in neurons, and as a part of that response, Ca^{2+}/Mg^{2+}-dependent endonucleases are activated that cleave DNA into the characteristic 200-base pair pieces.

mRNA processing

Following synthesis by RNA polymerase II, the 5′ terminus of the nascent transcript is modified by the addition of a 7-methylguanosine (m^7G) cap; this cap helps the RNA to be properly processed, exported, and attached to a ribosome for translation. After capping, the pre-mRNA enters the splicing pathway where the introns (sequences of bases interspersed between coding sequences) are removed and the transcript is brought to its mature sequence. In animals, all mRNAs, except histone mRNAs, are terminated on the 3′ end by a polyadenylate tail [poly(A)$^+$], 100 to 200 nucleotides in length, which increases the stability of the message and appears to act as a signal for transport to the cytoplasm.

Intron-containing mRNAs are tightly bound to the nuclear matrix, most likely by the splicing system, which appears to be an integral part of matrix structure. Transit through the splicing pathway seems to be a prerequisite for transport of at least some transcripts out of the nucleus. Nuclear placement of a single cDNA coding for the 16S mRNA of SV40 results in normal transcription, processing, and cytoplasmic transport of the message only if there is at least one intron contained in the gene.

There is some evidence that splicing, and presumably the resulting proteins, are altered in neurons following a transient ischemic event.[340] Splice-site selection depends on the relative concentration of splicing regulatory proteins. When C57BL/6 mice were subjected to transient focal cerebral ischemia for 1 hour and various recirculation times, splicing regulatory proteins tra2-β1 and SAM68 changed their intracellular localization from the nucleus to the cytoplasm in neurons. This relocalization was an active process and not the result of a non-specific breakdown of the nuclear envelope; the splicing factor rSLM-2 and ribosomal RNA complexes remained in the nucleus, and there was no evidence of apoptosis. These

effects seem to be specific, because the splicing patterns of *Bax*, *Bcl*, and *SERCA2* genes were not affected. The changes in pre-mRNA splicing pathways caused by the relocalization of proteins that regulate splice-site selection were due to a change in the calcium concentration associated with ischemia.[341] Alternative splicing has also been shown to be a regional phenomenon. Neurexin IIIα mRNA is up-regulated in postischemic CA3 and contained the insert corresponding to the fourth splicing site, whereas the transcripts in postischemic CA1 neurons and control CA3 neurons lacked the insert.

The effects of alternative splicing are unknown, but may be profound. The transcripts of most genes that encode apoptotic regulators are subject to alternative splicing, which can result in the production of anti- or pro-apoptotic protein isoforms. Daoud *et al.* studied the *ICH-1* gene that can generate two isoforms: ICH-1L, which promotes apoptosis, and ICH-1S, which prevents apoptosis.[342] In C57BL/6 mice subjected to transient focal cerebral ischemia, the ischemic episode stimulated inclusion of an alternative exon and the formation of the ICH-1S form. Conversely, a study of Bax κ, a splice variant of Bax, found that expression of Bax κ mRNA and protein was up-regulated in the hippocampus after cerebral ischemic injury. The increased Bax κ mRNA was distributed mainly in selectively vulnerable hippocampal CA1 neurons that are destined to die after global ischemia. In vitro, overexpression of Bax κ protein in HN33 mouse hippocampal neuronal cells induces cell death.

Non-intron-containing transcripts are not affected because they do not require splicing, but there is some evidence suggesting that translation of these transcripts depends upon the sequence of the 5′ leader.

Nucleocytoplasmic transport of mRNA

To reach the cytoplasm, the mRNA must transit through a nuclear pore complex (NPC), which spans the nuclear envelope and serves as a gateway of communication between the nucleus and cytoplasm.[343] The pore is a huge structure with 50 individual nuclear pore proteins that allows proteins of less than 5-kDa to pass unimpeded, but large molecules must be actively transported. Correctly processed mRNAs interact with the NPC in the form of large ribonucleoprotein complexes (mRNPs) rather than the naked mRNA molecule. mRNP complexes contain nuclear mRNAs, the cap binding proteins CBP20 and CBP80, general RNA binding proteins, splicing factors (for those mRNAs derived from spliced precursors), and other factors involved in pre-mRNA processing. In general mRNA export does not depend on a specific nucleotide motif.

A group of evolutionarily conserved proteins known as nuclear export factors (NXFs) is responsible for exporting the majority of cellular mRNAs to the cytoplasm. Recruitment of export factors to nascent mRNA starts cotranscriptionally and involves elaborate systems of quality control. NXFs mediate the interaction between the mRNA export cargo and components of the NPC required for translocation. Presumably, export factors can load onto mRNA in both a relatively non-specific way as well as via splicing-coupled mechanisms.

Release of mature mRNA from the nuclear matrix requires ATP and DNA topoisomerase II and is the rate limiting step in mRNA nuclear translocation. Mechanical disruption of the nuclear membrane does not increase mRNA efflux; as immature (intron-containing) mRNA remains matrix-bound. Transport of poly(A)+ mRNA requires hydrolysis of ATP or GTP, and is mediated by a nucleoside-triphosphatase (NTPase) that is associated with the inner nuclear membrane and the nuclear lamina. The NTPase is stimulated in situ by poly(A)+ mRNA, but not by poly(A)− mRNA; an effect that is mediated by a pore-associated poly(A)+ binding protein.[344]

There are some observations suggesting that newly synthesized mRNA does not efficiently reach the cytoplasm following ischemia and reperfusion. Autoradiograms of pulse-labeled RNA in gerbils reperfused after 5 minute forebrain ischemia showed accumulation of newly synthesized RNA in the nucleus with little appearing in the cytoplasm.[345] Moreover, there are normal levels of newly synthesized mRNA in the nucleus and mitochondria during reperfusion but decreased new mRNA in the microsomal and ribosomal fractions. Similarly, there is apparent retention of RNA in the nucleus during reperfusion by using acridine orange staining. Together, this indicates a reduction in mRNA transport from nucleus to cytoplasm has occurred, and an increased population of messages is being retained in the nucleus.

To study poly(A)+ mRNA transport and NTPase activity, we prepared nuclear envelopes (NEVs) from dog brain cortices after a 15-minute cardiac arrest followed by up to 6 hours of reperfusion.[346] The rate of ATP-dependent poly(A)+ mRNA export from NEVs was examined after ³-H-uridine-labeled poly(A)+ mRNA was incorporated in NEVs during their preparation. The kinetic constants for ATP hydrolysis by the brain NEVs were not significantly affected by ischemia and reperfusion. Furthermore, appropriate poly(A) stimulation of the rate of ATP hydrolysis occurred without significant differences between animal treatment groups. In vitro exposure of the NEVs to hydroxyl radical completely abolished NTPase activity. Similarly, the rate of poly(A)+ mRNA egress was stimulated by ATP in all

samples, and the ATP-stimulated egress rates were unaffected by ischemia and reperfusion. Thus, brain ischemia and reperfusion do not induce direct inhibition of nucleo-cytoplasmic transport of poly(A)$^+$ mRNA, although micromolar quantities of hydroxyl radical completely inhibit the NTPase. Therefore postischemic inhibition of protein synthesis and reduced brain nuclear mRNA egress is not caused by direct damage to the poly(A)$^+$ transport system of the nuclear membrane. Similarly, we found that the nucleocytoplasmic translocation system for the poly(A)$^-$ *hsp-70* mRNA at the nuclear membrane is intact during postischemic brain reperfusion.

mRNA following ischemia and reperfusion

Although total RNA synthesis is normal during reperfusion,[347] several studies have used gene arrays to show that there is considerable variation in individual mRNA expression after both focal[348] and global brain ischemia.[349] Nonetheless, caution is required in extrapolating changes in mRNA expression to changes in protein levels. In a meta-analysis of studies comparing mRNA expression levels and protein levels for 2044 molecules, Greenbaum *et al.* reported a poor correlation ($r^2 = 0.43$).[350] In yeast, Gygi *et al.* found that that similar mRNA expression levels could be accompanied by up to 20-fold difference in protein levels, and in some instances similar protein levels were accompanied by a 30-fold difference in mRNA levels.[351] Given this lack of correlation between mRNA and protein levels, it is not possible to predict protein expression levels from quantitative mRNA data. For example, during reperfusion, cells of the CA1 sector of the hippocampus express massively increased amounts of *hsp*-70 mRNA with little or no accumulation of HSP-70 protein. Eukaryotic mRNA has a half-life estimated at several hours and there is no evidence of a generalized increase in mRNA degradation during ischemia and reperfusion nor in other processes characterized by disaggregation of polyribosomes. Thus, taken together the data suggest a dissociation of transcription and translation that does not involve either failed transcription or an acceleration of mRNA degradation. We will now turn our attention to translation.

Translation

Translation of mRNA into protein requires the presence of functional ribosomal subunits, translation factors, aminoacyl-tRNAs, amino acids, an energy supply, and an appropriate ionic environment. Ischemia and reperfusion appears to alter significantly some but not all of these components. For example, ischemia does not alter the

intracellular levels of amino acids.[352] Levels of aminoacyl-tRNAs, required for chain elongation, fall to no less than 64% of control values during reperfusion, and the energy supplies normalize upon circulatory return. Ribosomes can tolerate prolonged periods of ischemia without apparent functional impairment. Nowak *et al.* demonstrated stable in vitro incorporation of amino acids by brain polysomes after 1 hour of decapitation ischemia.[337] Marotta *et al.* reported that human brain ribosomes obtained 2–6 hours postmortem could synthesize proteins in vitro.[353] Dienel *et al.* found that polysomes isolated from rat brains subjected to 30 minutes of ischemia and 3 hours of reperfusion qualitatively produced the same protein patterns, with the addition of heat shock proteins, on 2D-PAGE gels as polysomes isolated from non-ischemic rat brains.[354] Our own work demonstrated that the rate of in vitro translation by purified ribosomes was not inhibited after 20 minutes of cardiac arrest or by 2 or 8 hours of reperfusion,[355] a time when protein synthesis is suppressed both in vivo and by in vitro translation systems utilizing an unfractionated postmitochondrial supernatant. The above evidence argues against any significant damage to the ribosomes themselves.

Several lines of evidence are consistent with the hypothesis that protein synthesis may be suppressed at initiation during early reperfusion, thereby deranging the "assembly line" involved in transport of mRNA. Ribosomal sedimentation profiles obtained from reperfused brains show a preponderance of monomeric ribosomal subunits suggesting a block in the formation of the initiation complex. In the study by Cooper *et al.* using an in vitro translation system, the addition of a chain initiation inhibitor (polyinosinic acid) decreased protein synthesis 63% in control animals as expected.[333] Polyinosinic acid had no effect on in vitro translation with the postmitochondrial supernatant obtained after 15 minutes of reperfusion, however, indicating that translation initiation was already maximally inhibited.

Formation of the translation initiation complex

The rate limiting step in translation is initiation.[356] This step entails the formation of the initiation complex (Fig. 13.5) which involves over 140 proteins and requires the coordinated assembly of the 40S and 60S ribosomal subunits, the mRNA to be translated, and the charged amino-acyl tRNA coding for the first amino acid (always methionine in eukaryotic cells). The process is orchestrated by a family of proteins collectively known as eukaryotic initiation factors (eIFs), and several eIFs are altered as a consequence of brain ischemia and reperfusion.

The initiation complex begins with free 40S ribosomal subunits; however, under normal physiologic conditions,
Fig. 13.5. Translation Initiation Complex

formation of inactive 80S ribosomes is favored. Binding of eIF6 to the 60S subunit and of eIF3 plus eIF4C to the 40S subunit act to keep the subunits disassociated. Next, eIF2 joins GTP and the initiator tRNA into a ternary complex (eIF2/GTP/Met-tRNA$_i$) which binds via eIF3 to the 40S subunit. The mRNA to be translated binds to eIF4E, which recognizes the m^{7}G cap at the 5′ end of the mRNA. eIF4A, eIF4E, and eIF4G form a complex which, together with eIF4B, unwinds the mRNA near the cap structure and binds it via eIF3 to the 40S subunit. At this point, the combined complexes migrate along the mRNA in the 5′ to 3′ direction to locate the AUG start codon. Once the appropriate match is made, eIF5 triggers the hydrolysis of the bound GTP molecule and the release of eIF2/GDP. A conformational change occurs such that the 60S subunit joins the 40S subunit to complete the 80S initiation complex.

Initiation is primarily regulated by modulating the degree of phosphorylation of the initiation factors required for the formation of the ternary complex (eIF2) and the recognition of mRNAs (eIF4E and eIF4G).

Cells determine which mRNAs bind to the ribosome by modulating phosphorylation of the mRNA cap binding protein, eIF4E. Cellular mRNAs vary greatly in their binding efficiency to eIF-4E, and increasing the activity or availability of the limited amount of eIF4E in cells appears to favor translation of those mRNAs that compete poorly for the mRNA-specific initiation factors. eIF4E is found in the nucleus as well as the cytoplasm and may play a role in post-transcriptional processing as well as translation initiation. Brain ischemia has been variably reported to induce transient dephosphorylation of eIF4E that normalizes rapidly with reperfusion.[357,358]

eIF4G is phosphorylated at multiple sites, which is thought to correspond with increased binding of eIF4E and enhanced protein synthesis. We found that μ-calpain (a calcium-activated protease) is activated during brain ischemia and proteolyzed eIF4G;[359] eIF4G is also a target of caspase-3, which cleaves it at multiple sites, but leaves

a stable 76-kDa "middle fragment." In our model, multiple fragments of eIF4G persist in the forebrain at 90 minutes of reperfusion following a 10-minute cardiac arrest.[357] Martin de la Vega *et al.* confirmed proteolysis of eIF4G during ischemia and showed reduced eIF4G levels (~ 65% of control) in the vulnerable CA1 region at 4 hours of reperfusion.[360]

Nonetheless, we[357] and others[334] have found little or no inhibition of the overall rate of in vitro translation in brain homogenates after up to 30 minutes of complete global ischemia without reperfusion despite eIF4G degradation during ischemia. The surprisingly limited effect of eIF4G degradation on in vitro protein synthesis by brain homogenates obtained after ischemia without reperfusion suggests that either the residual amount of eIF4G is adequate to support translation initiation or that proteolytic fragments of eIF4G may be active in supporting initiation of translation. In either case, the proteolytic degradation of eIF4G may have major implications for message selection.[361] Fragmented eIF4G causes failure of the docking of eIF4E-bound m^{7}G-capped mRNAs to the small ribosomal subunit during initiation of translation and favors translation of messages that contain "Internal ribosome entry sites" (IRES).

Cells downregulate the overall rate of global protein synthesis primarily by decreasing the initiation rate via phosphorylating serine 51 on the α subunit of eIF2. Phosphorylated eIF2α [eIF2α (P)] is a competitive inhibitor of eIF2B, the factor that exchanges GTP for GDP once the eIF2/GDP complex is released after the start codon has been located. Because the ratio of eIF2 to eIF2B is approximately 5:1 in the brain, initiation translation will be nearly completely inhibited when ~20% of eIF2 contains a phosphorylated α-subunit.

Postischemic brain reperfusion induces a very rapid and large increase in eIF2α (P)[362] that is seen in highly vulnerable as well as less vulnerable neurons throughout the entire brain. After 10 minutes of reperfusion following a 10-minute cardiac arrest, phosphorylated eIF2α in brain homogenates has increased ~20-fold and represents ~23% of the total eIF2α. This extent of eIF2α phosphorylation will inhibit almost all protein synthesis. This level of eIF2α (P) remains relatively stable throughout the first 4 hours reperfusion. We used immunohistology to study the regional and cellular distribution of eIF2α (P) in normal, ischemic, and reperfused rat brains.[362] The small amount of eIF2α (P) in normal brains is predominantly localized to astrocytes, which lose their eIF2α (P) during ischemia, presumably due to unopposed action of phosphatases. In the early minutes of reperfusion, heavy eIF2α (P) immunostaining appears in the cytosol of neurons, and is most

pronounced in the vulnerable neurons in cortical layers 3 and 5 and in the hilus and CA1 of the hippocampus; eIF2α (P) also appears in ischemia-resistant neurons of the dentate gyrus during early reperfusion. By 1 hour of reperfusion eIF2α (P) is largely undetected in ischemia-resistant neurons but remains prominent in vulnerable neurons, which also now display intense nuclear eIF2α (P) staining. By 4 hours of reperfusion, the pattern of nuclear eIF2α (P) immunostaining in vulnerable neurons suggests nuclear condensation consistent with the early stages of apoptosis. In addition, although eIF2α (P) is initially localized exclusively in neuronal cytoplasm, we found that by 1 hour of reperfusion, there is a substantial amount of eIF2α (P) only in the nuclei of vulnerable neurons; phosphorylated eIF2α was never found within the nuclei of neurons in the ischemia-resistant areas of the brain. These observations raise questions whether eIF2α is phosphorylated in the cytoplasm and migrates to the nucleus or is also phosphorylated in the nucleus itself. This could reflect a conformational change in eIF2α (P) that exposes the RRRIR nuclear localization signal adjacent to the Ser-51 phosphorylation site, and suggests the possibility that the nuclear localization of eIF2α (P) in vulnerable neurons by 1-hour reperfusion has important consequences for transcription.

Insulin and insulin-like growth factors administered during post-ischemic brain reperfusion substantially reduce both neuronal death and the final extent of neurologic disability independent of any hypoglycemia.[363] Insulin has several effects on the translation initiation system that, in general, increase protein synthesis; in particular, insulin rapidly decreases eIF2α phosphorylation, increases eIF2B activity and the association of eIF4E with eIF4G. We investigated the effect of insulin on protein synthesis during reperfusion utilizing immunostaining for eIF2α (P) and autoradiography of in situ[35] S amino acid incorporation.[364] After resuscitation from 10 minutes of cardiac arrest, rats were given 0, 2, 10 or 20 U/kg of intravenous insulin and reperfused for 90 minutes. Controls had abundant protein synthesis and no eIF2α (P) in neurons of the hippocampal CA1 and hilus. Untreated reperfused brains had intense staining for eIF2α (P) and little protein synthesis in these neurons, and animals receiving 2 or 10 U/kg of insulin, however, demonstrated little improvement. All animals treated with 20U/kg of insulin, however, had complete clearing of eIF2α (P) and extensive label incorporation in vulnerable neurons. Interestingly, insulin did not block phosphorylation of eIF2α of the neurons after a 5-minute reperfusion. This is a direct demonstration that it is possible to reverse the phosphorylation of eIF2α (P) and the loss of protein synthesis in vulnerable neurons during early reperfusion.

Role of eIF2α (P) in message selection

The modifications to eIF2α induced by brain ischemia/reperfusion last for at least several hours and affect not only the rate of protein synthesis, but also the repertoire of peptides actually synthesized from the available mRNAs. High levels of eIF2α (P) cause a generalized decrease in global rate of translation, whereas lower levels of eIF2α (P) play a role in message selection. Because eIF2α (P) competitively inhibits the reaction needed to recycle eIF2, translation does not completely cease, and there is always some capacity for residual translation. There are at least two alternative translation initiation pathways, bypass scanning and IRES-mediated initiation, that exist and either of these can have profound influences on message selection.

Bypass scanning is a form of residual translation that occurs when the 5' untranslated region of an mRNA contains upstream open reading frames (uORF).[365] In situations where there are high levels of eIF2 α (P), there is inefficient delivery of the initial methionine tRNA to the ribosome. Thus the ORF that is translated under normal conditions may be bypassed because of the lack of an initiator tRNA at the time when the scanning ribosome reaches the start codon. If an initiator tRNA becomes available at a later point as the ribosome scans the remainder of the mRNA, translation can be initiated on a downstream, normally untranslated, ORF. Upstream open reading frames are important control elements of growth and differentiation of cells. Although less than 10% of vertebrate mRNAs contain an uORF, about two thirds of mRNAs encoding vertebrate growth-regulatory proteins have uORFs. This paradoxical eIF2α (P)-induced enhancement of translation has been shown to occur for the pro-apoptotic proteins CHOP and ATF4, and may contribute to directing reperfused neurons down a cell death pathway.

Initiation of translation from the vast majority of cellular mRNAs occurs via scanning; the 40 S ribosomal subunit binds to the m7G-cap and then moves along the mRNA until an initiation codon is encountered. Nevertheless, the 5' untranslated region of some mRNAs contain regions, called internal ribosomal entry sites (IRES), and cellular stress can stimulate translation from some cellular IRESs via a mechanism that requires the phosphorylation of eIF2α.[366] It is thought that some mammalian mRNAs use IRES-mediated translation to provide cells with proteins essential for survival when the nutrient supply is limited.[367] Although cellular stress can stimulate translation from some cellular IRESs via a mechanism that requires the phosphorylation of eIF2α, there are distinct regulatory patterns for different cellular mRNAs that contain IRESs

within their 5′-untranslated regions. Thus it will be crucial to determine if, for example, APAF-1 (Apoptosis-Activating Factor-1), which is produced only by an IRES-mediated mechanism and serves to maintain sufficient levels of APAF-1 even when cap-dependent translation initiation mechanisms are compromised, is being synthesized after brain ischemia/reperfusion.

The combination of bypass scanning and IRES-mediated translation initiation means it is not possible to predict precisely which peptides are being made from examining changes in mRNA in the reperfused brain. An elevation in capped mRNAs does not mean that they will get translated under conditions of IRES-mediated translation initiation. Furthermore, even in the subset of IRES-containing mRNAs, it will be impossible to determine which ORF is being used from study of the available mRNAs by bypass scanning.

Mechanisms to hyperphosphorylate eIF2a following transient global brain ischemia

Protein synthesis is downregulated by phosphorylating eIF2α in response to a wide variety of cellular stresses, including transient brain ischemia.[362] It appears that specific eIF2α kinases have evolved that directly sense specific cellular stresses and respond by regulating translation. There are four known eIF2α kinases, GCN2, HRI, PKR, and PERK that, either individually or in combination, could mediate eIF2α phosphorylation in the reperfused brain. Because many of the stimuli that signal for inhibition of protein synthesis occur as a consequence of transient brain ischemia, it remained to be determined which eIF2α kinase(s) was activated under these stresses; in one in vitro system, at least three of the eIF2α kinases were activated simultaneously in response to a single chemical insult.

Although all four kinases share homology in the kinase catalytic domain, their regulatory mechanisms are quite different. GCN2 (general control non-derepressible-2), which is expressed in mammalian brain, is activated in response to amino acid starvation in mammalian cells. During ischemia, lowered ATP levels in neurons make it possible that uncharged tRNAs accumulate thereby activating GCN2. However, Munoz *et al.* were unable to demonstrate GCN2 activity in PC12 neurons following in vitro ischemia.[368] HRI (heme-regulated inhibitor) coordinates globin synthesis with heme availability in erythroid cells, but it can be activated by transition metals and reactive oxygen species both of which are characteristic of post-ischemic brain reperfusion. Little, if any, HRI is present in brain, however.[369] PKR (double-stranded RNA-activated protein kinase) can be activated in neuronal cell

culture by calcium overload induced by the calcium ionophore A23187. In addition, PKR can be activated upon its cleavage in vitro by recombinant caspase-3, caspase-7, and caspase-8. Calcium overload and caspase activation are well-known events in reperfused brain, and Burda *et al.* have suggested that PKR was responsible for increased eIF2α (P) during reperfusion.[358] Although PKR can be activated by calcium overload, it is not required for increased eIF2α phosphorylation or inhibition of protein synthesis in response to amino acid deprivation or endoplasmic reticulum stress. PERK (also known as PEK) is an endoplasmic reticulum transmembrane protein that couples protein folding in the endoplasmic reticulum to translation initiation rates in the cytoplasm.[370] Hypoxia can induce PERK activation and subsequent phosphorylation of eIF2 in fibroblasts.[371] Previously, we have shown that PERK is present in the brain and is activated early in reperfusion following transient ischemia.[372]

The development of knockout mice has allowed us to address the question of which kinase is responsible for the dramatic increase in eIF2α (P) during reperfusion. Previously, we have shown that mice with homozygous functional knockouts for the gene encoding either GCN2, HRI, or PKR had large increases in brain eIF2α (P) following ischemia and reperfusion similar to wild type mice;[372,373] this argues against one of these kinases being solely responsible. Nevertheless, in a transgenic mouse line with targeted disruption of the *Perk* gene, we found that phosphorylated eIF2α is absent in the non-ischemic mice.[374] This implies that PERK is the kinase chiefly responsible for modulating the basal level of eIF2α (P). More important, there was only a minimal change in phosphorylated eIF2α levels and there was a substantial rescue of protein translation in the reperfused transgenic mice compared to the wild type. Together, these data demonstrate that PERK is responsible for the large increase in phosphorylated eIF2α early in reperfusion that suppresses protein synthesis following transient global brain ischemia.

It is possible that increased phosphorylation of eIF2α could also result from a loss of an eIF2α (P) phosphatase activity, but we found no reduction in eIF2α (P) phosphatase activity in reperfused brain homogenates.[373]

An alternative mechanism was suggested by a series of studies by Gupta and colleagues which identified a 67-kDa glycoprotein (p67) that binds to the γ-subunit of eIF2 and protects its α-subunit from phosphorylation.[375] Depletion of p67, either by preincubation of brain homogenates with antibody against p67 or by antisense-mediated reduction of p67 in KRC-7 cells results in greatly increased eIF2α phosphorylation. In p67-depleted KRC-7 cells, eIF2α (P) approached 100% of eIF2α and was associated with a

three-fold reduction in protein synthesis, and induction of apoptosis. The binding of p67 to eIF2 is regulated by glycosylation of p67; when deglycosylated, p67 is unable to prevent phosphorylation of eIF2α.

Because glycosylated p67 is present in rat brain, these findings suggested at least two testable hypotheses might explain the large and prolonged increase in eIF2α (P) in vulnerable neurons during reperfusion. First, activation of the p67 deglycosylase and subsequent deglycosylation of brain p67 might occur during ischemia and/or early reperfusion and be more extensive in vulnerable neurons. Second, the vulnerable neurons, such as those in the CA1, could normally express smaller amounts of p67 than more resistant neurons, such as those in the CA2. We found no reperfusion-induced loss of total or glycosylated p67 by Western blots or by immunohistochemical staining in vulnerable neurons, however.[376] Thus the mechanism by which eIF2α is phosphorylated during reperfusion is due solely to the activation of PERK.

Role of PERK in the UPR

PERK is activated only by the ER stress signaling system termed the unfolded protein response (UPR).[377] Thus, inhibition of protein synthesis following brain reperfusion is likely to be part of a more comprehensive cellular response that contributes to the ultimate fate of reperfused neurons.

The UPR is activated to overcome ER stress by temporarily slowing accumulation of new proteins in the ER lumen, while simultaneously upregulating transcription of genes for ER-resident chaperones and enzymes that abate the effects of ER stress.[377] In higher eukaryotes, prolonged activation of the UPR can also activate pro-apoptotic mechanisms. PERK contributes to a pro-survival response by attenuating accumulation of new protein in the ER through phosphorylation of eIF2α leading to a generalized decrease of protein synthesis. Several studies have presented evidence of ER dysfunction following ischemia and reperfusion.[372,378] Thus, we have hypothesized that regional differences in expression of the UPR in brain may contribute to selective vulnerability following ischemia and reperfusion.[379]

The primary effectors of the UPR in mammalian brain are three ER-transmembrane proteins: PERK, IRE1α, and ATF6, and it is thought that activation of all three is required for a full response to ER stress.[379] In transient focal cerebral ischemia, Paschen *et al.* found a marked increase in processed *xbp1* mRNA levels during reperfusion, indicating activation of IRE1α, that was most pronounced after a 1-hour occlusion of the right middle cerebral artery.[380] The rise in processed *xbp1* mRNA was not paralleled by a

similar increase in its cognate protein levels, however, because transient ischemia induces severe suppression of translation. In contrast, our data indicates that there is dysfunction in the UPR during global brain ischemia and reperfusion.[381] In rats subjected to 10 minutes of global brain ischemia, PERK was maximally activated at 10 minutes of reperfusion, which correlated with maximal eIF2α phosphorylation and protein synthesis inhibition. Neither ATF6 nor IRE1α show evidence of activation, however. IRE1α's substrate, *xbp1* mRNA, had not been processed nor was there expression of the UPR effector proteins XBP1 (55-kDa), CHOP or ATF4. In other systems, failure to mount the UPR results in increased cell death.

Translation in late reperfusion

Finally, during the later reperfusion period, other mechanisms may be responsible for continued inhibition of translation. Apoptosis can inhibit protein synthesis via the caspase-dependent cleavage of initiation factors eIF4G, eIF4B, eIF2α and the p35 subunit of eIF3.[382,383] Substantial shifts in potassium, magnesium, and calcium occur that could affect translation. Ribosome activity is very sensitive to concentrations of potassium and magnesium, both of which are important for assembly of the ribosomal subunits. Decreased Mg^{2+} concentrations result in disaggregation of polysomes, increased missense errors, and decreased protein elongation. Normal pH and tissue concentrations of Na^+, K^+ and Ca^{2+} are recovered early in reperfusion. However, a secondary loss of ionic homeostasis is seen by 8 hours of reperfusion following a 15-minute cardiac arrest in dogs with concomitant loss of 30% of the lipid double bond content and ultrastructural evidence of large gaps in the neuron plasmalemma.[324] Finally Liu *et al.* have shown evidence of irreversible aggregation of translational components after prolonged ischemic times.[384]

Thus, the evidence we have reviewed suggests that postischemic suppression of protein synthesis in the brain has different etiologies depending on the time examined. During ischemia, suppression of protein synthesis is due to the lack of high energy phosphates needed to support the energy-requiring synthetic process. Although the high energy phosphate level quickly returns to normal during early reperfusion, there is inhibition of formation of the translation initiation complex secondary to the phosphorylation of eIF2α by PERK. Nuclear retention of newly synthesized mRNA probably reflects a "backup" of mRNA traffic. Later in the reperfusion period, lipid peroxidation eventually destroys the integrity of the plasmalemma for ionic partitioning, and after this time protein synthesis will

be halted because the cell can no longer maintain the requisite ionic milieu.

Surprisingly, it is not clear that restoring protein synthesis in the reperfused brain is beneficial. There is contradictory evidence from studies with mutant variations of eIF2α and PERK as to whether activation of PERK, phosphorylation of eIF2α, and inhibition of translation are protective,[385] pro-apoptotic,[386] or neutral.[387] While the conflicting conclusions in the above studies could be ascribed to different insults administered to different cell lines, we theorize that there may be some time points following an insult where translation is protective, while at other times it may induce death. During early reperfusion, eIF2α(P)-mediated inhibition of translation may well be a protective response to cope with ischemia-induced ER stress. It is clear, however, that at some stage protein synthesis must be restored to ensure survival.[388] The contribution of postischemic inhibition of cerebral protein synthesis inhibition to neuronal death is a crucial issue that has yet to be resolved.[389,390,391]

Mitochondria: membrane potential, cytochrome

As previously stated, since the contribution of apoptosis to postischemic neuronal death appears to have enormous therapeutic relevance, the following reflections will focus on apoptosis. Two apoptotic pathways have been identified: the extrinsic, death receptor protein-mediated pathway, and the intrinsic, mitochondria-mediated, pathway.[392] In neuronal ischemia both pathways may be activated. Apoptosis is an energy-dependent, programmed form of cell death.[41,45] Mitochondria have long been considered as subcellular targets of ischemia. Disturbed mitochondrial function appears to be a key player in the pathogenesis of post ischemic neurodegeneration and a critical factor in the cellular "life-or-death" decision.[393–396] Mitochondrial dysfunction is a trigger for development of necrotic as well as apoptotic neuronal death.[397] In general, relatively mild mitochondrial injury results primarily in apoptotic cell death, whereas more extensive injury leads more toward necrosis. Thereby, alterations in mitochondrial oxidative phosphorylation, Ca^{2+} transport, free radical generation, and release of apoptotic factors[394,398,399] are major events in the damaging process. Two of the earliest events that can tip the balance toward neurodegeneration following transient ischemia are the accumulation of Ca^{2+} and generation of ROS by mitochondria. It is generally accepted that the mitochondrial membrane potential ($\Delta\Psi_m$) is an important factor in the maintenance of mitochondrial homeostasis:

both the influx of Ca^{2+} and production of ROS are attenuated following a decrease in $\Delta\Psi_m$.[394,395,399] Under normal conditions, more than 90% of the available cellular oxygen is consumed by the mitochondria during oxidative phosphorylation.[400,401] Which is driven by the electron donors NADH and FADH. These electron carriers enter the mitochondrial electron transport chain via complex I (NADH) and complex II (FADH). Electrons are transferred to oxygen via cytochrome c oxidase and other components of the electron transport chain.

Cytochrome oxidase, located in the inner mitochondrial membrane, is composed of 13 subunits. To function properly this complex requires intact catalytic, regulatory and structural subunits as well as maintenance of the inner mitochondrial membrane environment.[402]

Cytochrome c is a vital component of the mitochondrial electron transport chain. It is a water-soluble protein whose primary function is to transport electrons between coenzyme Q and cytochrome c oxidase. Cytochrome c resides in the mitochondrial interspace where it interacts with the redox partners of complexes III and IV. The entire process generates an electrochemical proton gradient across the mitochondrial membrane driving ATP synthesis by complex V.[403] Electron transport along the electron transport chain and ATP synthesis are closely related, in this case respiration is functionally "coupled."

The disturbance of energy dependent processes during early ROSC is thought to have a major influence on the development of temporary and permanent neurological deficits. As previously noted, ischemia results in rapid loss of high-energy phosphate stores. The amount of available ATP becomes insufficient to sustain normal function of active transport systems and to maintain proper ionic gradients.[404–406] Inadequate oxygen supply but also insufficient amounts of available electrons (donated from NADH or FADH) influence the cellular redox state and lead to mitochondrial damage.[403,407] The ability to produce ATP via oxidative phosphorylation is impaired in the integrated cellular substrate pathway (NADH, complex I).[408,46] Initially, brief periods of ischemia damage complex I in the proximal electron transport chain followed by damage to complex III.[402] Disturbances of the electron transport chain may cause a reduced cellular redox state even under normal oxygen concentrations.[408–410] Electron transport and ATP synthesis become "decoupled." Decoupled mitochondria reduce cell viability,[411] may result in further disturbances of electron transport,[46,412,413] produce reactive oxygen and nitrogen species,[414,415] and can lead to free radical damage.[46] Initially these changes are reversible, but the release of cytochrome c and the opening of the mitochondrial permeability transition pore pave the way to irreversible damages

and finally to cell death. Opening of the mitochondrial permeability transition pores causes depolarization of the mitochondrial membrane potential ($\Delta\Psi_m$) and transforms mitochondria from ATP producers to ATP consumers by reversing ATP synthesis in an attempt to maintain $\Delta\Psi_m$.[416] In addition, prolonged membrane dysfunction can lead to excessive water influx, matrix swelling and outer mitochondrial membrane rupture. The release of proapoptotic molecules, including cytochrome c and Apaf-1, triggers cell death via caspase-dependent as well as caspase-independent mechanisms.[416] Therefore, increased mitochondrial permeability and reduction of $\Delta\Psi_m$ are key factors in triggering apoptosis in a variety of cell types.[417]

Mitochondria under normal conditions generate small amounts of cytotoxic reactive oxygen species (ROS), like hydroxyl radicals ($^\bullet OH$), superoxide anions ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), nitric oxide (NO), peroxynitrite ($ONOO^-$) and other radical substances.[402,418] ROS production is essentially a toxic by-product mainly generated by complex III of the mitochondrial electron transport chain. As reactive oxygen species may damage cellular components, cells have developed various strategies to dissipate free radicals and remove their oxidation products.[40] Superoxide dismutase (SOD), glutathione peroxidase (GSHPx), and catalase constantly scavenge physiological amounts of free radicals.[419] SOD specifically processes $O_2^{\bullet-}$ into H_2O_2. Catalase and GSHPx deactivate H_2O_2 into H_2O and O_2, which is especially important as hydroxyl radicals may be generated from H_2O_2 through the Fenton reaction.[400] Unfortunately, during oxidative stress, cytochrome c oxidase generates greater amounts of ROS.[400] Under these conditions, up to 2% of the consumed oxygen can be converted to free radicals.[397] The degree of ROS production depends on the type of the cell, the available substrate and the polarization of the mitochondrial membrane. The resulting overload of free radicals may cause cerebral damage during ischemia as well as reperfusion.[418,419,420] Permeabilization of the mitochondrial membrane caused by these reactive oxygen species is one of the basic underlying mechanisms of active cell death.[421] Mitochondrial membrane permeabilization can lead to an increased translocation of Bax from cytosol to the mitochondria,[422,423] and a release of cytochrome c and apoptosis inducing factor (AIF). Translocation of mitochondrial cytochrome c to the cytoplasm has been reported to be a key step in the initiation and/or amplification of the intrinsic pathway of apoptosis.[392,424,425] Release of cytochrome c into the cytosol leads to the formation of a complex comprising apoptotic-protease-activating factor-1 (Apaf-1), procaspase-9, and ATP. This complex ultimately cleaves and activates pro-caspase-9, activating the intrinsic pathway for the induction of apoptosis.[426–429] Additionally, cerebral ischemia

causes and activates the neuronal form of nitric oxide synthase (nNOS) and triggers the expression of the inducible iNOS in glia cells, both of which result in the production of an excessive amount of nitric oxide (NO).[430] Nitric oxide is a diffusable free radical that may prevent or promote cell death depending on cell type and NO concentration. NO interacts directly and indirectly with mitochondria. Binding of NO to cytochrome c oxidase causes respiratory inhibition.[431] As a result, NO may trigger apoptosis by one of the following mechanisms: decreased mitochondrial membrane potential, release of cytochrome c from mitochondria, direct activation of several caspases, degradation of caspase-activated DNAse inhibitors, and activation of caspase-activated DNAse.[430] Several homozygous e/i/nNOS knockout mice mutants have been developed to investigate the role of NO in intra- and postischemic pathophysiology.[418] By using these knockout models, a substantial reduction in lesion size after focal ischemia was noted in nNOS knockouts[432–434] as well as the influence on the blood flow-dependent development of cerebral lesions noted in eNOS knockouts.[435] Other studies indicate that NO produced by iNOS in non-neuronal cells may contribute to cerebral ischemic damage.[436]

Cell signaling: Bcl-2, .. caspases

Release of cytochrome c, apoptotic protease activating factor 1 (Apaf-1), and caspase-9 from mitochondria are central mechanisms for triggering the caspase cascade and therefore for inducing apoptosis. Cysteine-requiring aspartate directed proteases (caspases or cell death proteases) and Bcl-2 family proteins represent core components of the apoptotic process.[45] Recently, it has been suggested that "caspase-mediated-cell death" might be a more accurate description than "apoptosis" for the ischemia triggered programmed cell death.[45] Fourteen distinct caspases have been identified thus far, although two of them (caspase-11 and caspase-12) have no identified human counterparts.[45] Under normal conditions caspases are expressed as zymogens composed of an N-terminal prodomain, a large subunit and a small subunit, which undergo proteolytic processes upon apoptotic stimuli.[437] The subunits within some or the procaspases are separated by small linker peptides. Activation results from proteolytic cleavage of the procaspase into its three component parts, usually by other activated caspases.[438] Caspases can be subdivided into two broad groups: those of the interleukin-1 converting enzyme family (caspases-1, -4, -5, -11, -12, and -14) that are involved in the maturation of cytokines and the induction of inflammation and those

caspases directly involved in apoptosis (caspase-2, -3, -6, -7, -8, -9, and -10).[439,440] By using functional aspects, the latter caspase proteins can be classified into upstream "initiators" (caspase-2, -8, -9, and -10) that act as signal transducers and downstream "effectors" (caspase-3, -6, and -7).[442] The initiator caspases have long prodomains that interact with the death domains of other transmembrane and intracellular proteins involved in initiating apoptosis and thus translate a range of pro-apoptotic stimuli into proteolytic activity. In contrast, the effector caspases have short prodomains and are directly responsible for the cleavage of cellular substrates that are in turn responsible for most of the morphological and biochemical features of apoptosis.[45,441] There are two main pathways of caspase activation: death receptor-mediated and mitochondria mediated. The extrinsic pathway is triggered by Fas and TNF-1 and leads via the formation of a "death-inducing signaling complex" to the activation of the

initiator caspases-8 and -10.[391,441] Binding of death receptors by their cognate ligands causes trimerization of the receptors and interaction between cytoplasmic death domains in these receptors and intracellular adapter proteins.[439] The mitochondrial pathway of caspase activation can be initiated by several proteins. Central to this pathway are proteins in the Bcl-2 family. The Bcl-2 family proteins are central modulators of intracellular apoptotic processes by regulating the cytochrome c-dependent pathways of caspase activation. Bcl-2 family proteins are either members of the anti-apoptotic (Bcl-2, Bcl-X_L, Bcl-w) or the pro-apoptotic (Bax, Bak, Bad, Bid) faction.[441] Post-translational modification can change anti-apoptotic members to pro-apoptotic forms.[442] The degree of formation of homo- and heterodimers of these proteins coincides with either cell death or survival. Unfavorable alterations in the ratio of anti- and pro-apoptotic caspases accelerate programmed cell death.[443] Anti-apoptotic members of the Bcl-2 family, including Bcl-2 and Bcl-X_L, are associated with the mitochondrial outer membrane and can inhibit the release of cytochrome c.[444] In contrast the pro-apoptotic protein Bax promotes apoptosis by forming oligomers onto the mitochondrial outer membrane and creating a channel for the release of cytochrome c and other apoptotic substances.[417] Another pro-apoptotic protein Bad binds to Bcl-2 and Bcl-X_L and inhibits their anti-apoptotic functions.[444] Some of the Bcl-2 family proteins are regulated directly by caspases. Therefore the caspase-mediated effects on Bcl-2 family proteins provide a link between the death receptor and mitochondrial pathways for apoptosis.

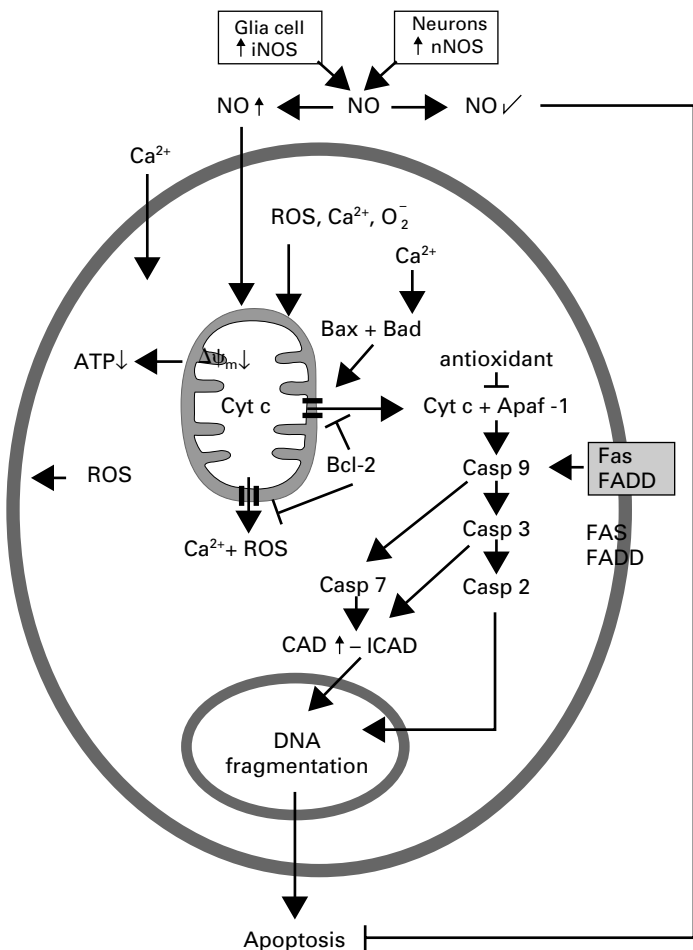
It was suggested that, after dephosphorylation, interactions of Bad with Bcl-2 and Bcl-X_L on mitochondria may initiate the opening of mitochondrial permeability transition pores and the consequent release of cytochrome c.[444] Cytochrome c together with Apaf-1 and dATP can activate the initiator caspase-9 by activating pro-caspase-9[446].[392] Cytochrome c, Apaf-1, and caspase-9 are responsible for the formation of the apoptosome. The apoptosome cleaves and activates procaspase-3 the key effector of caspase-mediated cell death. The critical nature of caspase-3 activation to apoptosis is demonstrated nicely by the decreased neuronal damage in caspase-3 knock-out mice.[437,445] Following these two steps of apoptotic activation other caspases such as caspase-2, -6, and -7 are activated. Activation of the caspase cascade results in cell death through disassembly of the nuclear envelope, degradation of DNA repair enzymes, inactivation of the inhibitor of caspase-activated DNase (ICAD), and the release of caspase-activated DNase (CAD) leading to the apoptotic fragmentation of nuclear DNA.[44,446] The mechanisms of apoptosis is summarized in Fig. 13.6


Fig. 13.6. Mechanisms of cerebral ischemia-induced neuronal apoptosis; modified from refs. 9,10,52.

Competence of neurons for antioxidant defense and repair of membrane damage

Regulatory control of the cell cycle may affect the capacity for endogenous defense and repair and may be critical in surviving ischemia and reperfusion. Terminally differentiated, therefore non-replicating cells, such as those in the glomeruli, the myocardium, and the central nervous system, are quite sensitive to damage by ischemia and reperfusion. Traditionally, it was postulated that non-replicating cells without stem cell support were irreplaceable. Nevertheless, there are data suggesting that non-replicating status is associated with chronic downregulation of (1) the transcription promoter binding complex called activator-protein-1 (AP-1), known to act at promoter regions of a family of antioxidant enzymes, and (2) lipid synthesis that would be important for efficient membrane repair.

Cell replication status and membrane synthesis

The theory that DNA replication and membrane synthesis were linked would be easily explained since both are required for cell replication. This idea is supported by evidence from both prokaryotic and eukaryotic systems, including cultured human cell lines. In prokaryotes experimental manipulations that specifically inhibit lipid synthesis block DNA replication,[447] and blocked DNA replication is associated with down-regulation of phospholipid synthesis.[448] Fewer studies have addressed such questions in eukaryotic cells; however, in a human promyelocytic cell line, sterol and phospholipid synthesis are markedly decreased following induction of myeloid differentiation. Although lipid synthesis before and after neuronal differentiation has not been studied in detail, it is known that there is a 90% decrease in cholesterol synthesis in neurons after completion of differentiation in fetal rats. There is also important evidence that the degree of differentiation is directly related to susceptibility to radical oxidant-induced death in many cell culture lines.[449] Tumor cells, in which replication machinery is fully switched on, are not easily killed by lipid peroxidation.[450] It appears that terminal differentiation is associated with a substantial reduction in the capacity for lipid neogenesis and membrane synthesis.

This theoretical approach predicts that terminal differentiation of neuroblasts to neurons should be associated with a significant increase in susceptibility to cell death induced by membrane damaging mechanisms such as free radical induced lipid peroxidation. We have observed substantial enhancement of radical-induced death in

neuroblastoma B104 (NB104) cells after neuronal differentiation,[451] induced by dibutyryl cyclic AMP and theophylline. Electron microsopic examination of the differentiated cells after radical damage confirms significantly increased ultrastructural injury. Of note, the altered Golgi morphology was nearly identical to that observed in vulnerable neurons of reperfused brains.[452]

Fundamental cellular regulatory systems in neuronal ischemia and reperfusion

Cell growth, proliferation, and differentiation are regulated, in part, by growth factors.[453] The brain has receptors for several growth factors, including insulin,[454,455] fibroblast growth factor (FGF),[456] and nerve growth factor (NGF),[457] all of which have been found in the selectively vulnerable hippocampal and cerebral cortical neurons. Similarly, transforming growth factor beta (TGF-),[458] insulin-like growth factor-1 (IGF-1),[459] and epidermal growth factor (EGF)[460] have been found in the brain and elsewhere in the central nervous system. Receptor proteins for all these growth factors characteristically include a ligand-activated tyrosine kinase at the inner surface of the plasmalemma.

The mechanisms by which these growth factors influence cellular growth and differentiation are not completely understood, particularly with respect to control of synthesis of membrane components. The general consensus, however, is that the effects are mediated through receptor kinase-induced "phosphorylation cascades" leading to transcription of the immediate-early genes,[461] which include the proto-oncogenes c-*fos* and c-*jun*. Proteins of the cFOS family form heterodimers with proteins of the cJUN family to constitute the AP-1 complex that binds with high affinity and specificity to DNA transcription factor binding sequences upstream of target genes.[462]

Brain ischemia and reperfusion elicit the production of both growth factors and proto-oncogene products in at least some neuronal populations. Examples of growth factor responses following ischemia are an increase in basic FGF in the rat hippocampus, caudate, putamen, and cortex;[463] increased production of mRNAs for brain-derived neurotrophic factor and NGF in rat dentate gyrus and in the rat hippocampus CA_1 and CA_2 regions;[464] and increased levels of IGF-1 in the lateral cortex, hippocampus, striatum, thalamus, and pyriform cortex.[465]

With regard to proto-oncogene products, c-*fos* and c-*jun* transcripts are elevated in brain homogenates within 30 minutes of postischemic reperfusion both in rats[466] and gerbils.[467] In situ cytochemistry has shown, however, that

within 1 hour after cortical ischemia, the cFOS protein found in rat cerebral cortex is higher in layers II and VI than in the selectively vulnerable layers III-V.[468] Delayed c-*fos* transcription[469] and translation[470] were also observed in the selectively vulnerable CA$_1$ layer of the rat hippocampus, with transcripts appearing at 24 hours reaching peak at 72 hours of reperfusion. Examination of various cell types during early reperfusion showed that c-*fos* mRNA is transcribed in large amounts in the damage-resistant dentate granule cells, whereas only modest expression was found in CA$_1$ and CA$_3$ pyramidal layers of the hippocampus.[471] Wessel *et al*, using in situ hybridization, studied c-*fos* and c-*jun* transcripts in the rat brain following 20 minutes of transient ischemia.[472] There was strong expression of both genes within 30 minutes of reperfusion in the dentate gyrus; however, expression in the CA$_1$ region of the hippocampus was delayed 1–2 hours and showed a biphasic response. The initial moderate peak had returned to baseline by 6 hours, followed by a weaker response at 24 hours of reperfusion.

There are important links between induction of c-*fos* and the translation of important stress proteins.[473] Heat shock proteins (HSPs),[477] can be induced by a wide variety of insults and are highly conserved from prokaryotes to humans. HSPs appear to facilitate correct folding of proteins[474] and rRNA,[475] dissociate clathrin baskets in the presence of ATP (which is a presumed requirement for cell membrane recycling),[476] interact with cellular tumor suppressor p53,[476] have a calmodulin binding site,[478] are proposed to be involved in membrane synthesis[479] appear to protect cultured neurons from glutamate toxicity,[480] and are induced by insulin in a human tumor cell line.[481] Heat shock messages[482] and proteins[483] are expressed in the brain during reperfusion. After an ischemic insult, the selectively vulnerable neurons in the hippocampus and cortex transcribe large quantities of *hsp-70* mRNA, but translation of *hsp*-70 is considerably decreased when compared to surviving areas of the hippocampus (i.e., the dentate gyrus).[482] The c-*fos*/c-*jun*/*hsp* system is directly activated by ionizing radiation,[484] presumably by hydroxyl radical-mediated events. Also, there is evidence that the HSP response is induced in the presence of free radicals,[485] but not by increased intracellular calcium alone.[486] Clearly, an interesting case can be made that the heat shock response is primarily a free radical defense.[487] The selectively vulnerable brain neurons that display delayed expression of c-*fos* correspond to those with poor translation of *hsp*-70 transcripts. These results suggest the important association of early transcription and translation of c-*fos*, c-*jun*, and *hsp-70* with neuronal survival.

The activator protein library: defense against neuronal damage

The evidence for brain reperfusion-induced transcription of *fos* and *jun* led us to conduct a comprehensive literature search for proteins known to have in their genes' promoters or enhancers sequences responsive to transcriptional regulation by the AP-1 heterodimer.

General observations
On its DNA promoter sequence, the AP-1 complex binds the protein that recognizes the "TATA box" and thus facilitates initiation of transcription.[488] AP-1 DNA binding is modulated by a few known mechanisms, which include regulatory phosphorylation and antagonism by the glucocorticoid receptor. Inhibitory protein-1 (IP-1) inhibits AP-1 binding to DNA, and this inhibition is blocked when IP-1 is phosphorylated by protein kinase C (PKC).[489] Protein phosphatase A$_2$ (a serine-threonine phosphatase) activates AP-1 DNA binding by a dephosphorylation reaction with Jun,[490] but tyrosine phosphatases decrease AP-1 activation of transcription.[491] Both ligand-activated glucocorticoid receptors and retinoic acid-receptors block the DNA binding activity of AP-1.[492,493] In particular the glucocorticoid receptor and AP-1 appear antagonistic for DNA binding; for example, in the promoter region of the genes for α-fetoprotein[494] and insulin-like binding protein 1[495] there are overlapping and mutually exclusive sequences for the glucocorticoid receptor and AP-1. This antagonism could explain the general failure of glucocorticoids and the 21-aminosteroids ("lazaroids") to protect neuronal soma.

Activator protein library
Our search identified 42 proteins with AP-1 sites and 31 with AP-2 sites in the promoter regions of the genes. Most of these genes fall into groups related to (1) antioxidants, (2) growth factors and their receptors, (3) cytokines and their receptors, (4) lipid management, (5) structural proteins, (6) neurotransmitter management, (7) phosphorylation regulation, (8) protease regulation, and (9) electrolyte and water management (Table 13.1).

Theoretical speculation about what the *fos-jun* reperfusion response means
This list of AP-regulated genes makes it difficult to believe that the reperfusion-induced *fos-jun* response is not intended for cell salvage. In particular, the AP-1 and AP-2 systems stimulate production of a family of enzymes that one investigator group has characterized as belonging to an "electrophile counterattack." For AP-1 these include glutathione transferase, NAD(P)H quinone reductase, epoxide

Table 13.1.

AP-1	AP-2
Antioxidants	
Glutathione transferase	Glutathione peroxidase
NAD(P)H quinone reductase epoxide hydrolase	S-adenosylmethionine decarboxylase
UDP glucuronsyltransferase heme oxygenase I	
S-adenosylmethionine decarboxylase	
Growth factors and receptors	
Insulin-like GF-2	Fibroblast GF receptor
Insulin-like GF-1	IGF-1 receptor
IGF binding protein 5	Insulin receptor
Nerve GF	TGF β 2 and 3
IGF binding protein 1	Vascular endothelial growth factor
Fibroblast GF receptor	IGF binding protein 5
TGF β1	
Vascular endothelial GF	
Cytokines and receptors	
Interleukin 2	TNF α 1
Interleukin 6	IL7 receptor
TNF α	
IL7 receptor	
Nuclear Factor-Kappa B	
Interleukin 1 type 1 receptor	
Lipid management	
Apolipoprotein CIII	5-Lipoxygenase activating protein
	Acetyl CoA carboxylase
	Branched chainα-ketoacid dehydrogenase-E1α
	BCαKAD E2 dihydrolipoyl transacylase
Structural proteins	
α-Actin	Elastin
vimentin	Neurofilament light protein
lysosomal membrane glycoprotein 2	Calreticulin
N-Cell Adhesion Molecule	Nidogen
I-CAM	
Cytoactin	
Neurotransmitter management	
NO synthetase	Glutamate dehydrogenase
Tyrosine hydroxylase	NO synthetase
Glutamate dehydrogenase	Aromatic amino acid decarboxylase
Cholecystokinin	Phenylalanine hydroxylase
Phosphorylation regulation	
Protein kinase C	Germ cell alkaline phosphatase
	Protein tyrosine kinase (SRC homolog)
	cAMP-dependent kinase
Protease regulation	
HSP 47 (serine protease inhibitor)	Cathepsins H and L (cysteine proteases)
Stromolysin 1 (metalloproteinase) 92 kDa collagenase	Cathepsin D
Electrolyte and water management	
Atrial natruiretic protein	
Na/H exchanger	
Miscellaneous	
c-jun and c-fos	ADP ribosylation Factor II
α-fetoprotein	α -subunit mitochondrial ATP synthase
Histone H 3.2	
α-subunit pyruvate dehydrogenase amyloid precursor protein	

hydrolase, and UDP glucuronyl transferase, and transcripts for these enzymes are induced by a large number of electrophiles. Glutathione peroxidase and S-adenosylmethionine decarboxylase have AP-2 binding sites in the 5′ promoter region. A search for the SOD and catalase promoters reveals that both of these classic radical scavenging enzymes are regulated by SP1[496] (housekeeping) promoter sequences and have neither AP-1 nor AP-2 promoter sequences.

This suggests that, since the activator proteins are significantly involved at the level of the cell cycle, there are a group of important antioxidant enzymes that are upregulated during DNA replication. The potential evolutionary rationale could be that relaxed repair of electrophilic DNA damage is acceptable during non-division states, but DNA damage during replication could lead to nonsense copies. Upregulated DNA synthesis and growth factor stimulation of the activator proteins suggests that neurons may respond to ischemia and reperfusion with a augmented transcription of both antioxidant and membrane repair competence. This would potentially explain the resistance to free radical damage conferred by growth factors in primary neuron cultures. Because it has long been known that pretreatment with barbiturates induces substantial resistance to brain damage by ischemia and reperfusion, it is interesting that phenobarbital induces transcription of glutathione transferase and NAD(P)H reductase[497] through a radical-mediated mechanism (quite possibly related to cytochrome p450 metabolism of barbiturates).

The second theory is derived from reports[498] of interactions between cytokines and growth factors inducing phosphorylation of a 91-kDa constitutive protein (STAT-91) that marks it for nuclear localization, DNA binding [to the SIE sequence-*fos* promoter][499], and transcription initiation. Further the AP library has multiple positive feedback loops between promotion of cytokines, growth factors, and growth factor receptors. This system may represent a co-ordinated mechanism for stimulating growth factors, receptors, regulatory tyrosine phosphorylation, transcription machinery, and the "electrophile counterattack." It may be possible to manipulate these activities by administration of growth factors.

Growth Factors

Since growth factors are involved in cellular reproduction, including transcription of the AP-1 components and most probably membrane synthesis and repair, it is not surprising that the administration of growth factors has improved post-ischemic neuronal survival.[500] Fibroblast growth factor substantially inhibits glutamate receptor-mediated neuronal damage.[501] Nerve growth factor administered either before or after 5 minutes of carotid occlusion in Mongolian gerbils significantly reduced the loss of hippocampal CA_1 neurons.[502] Treatment with IGF-1 2 hours after an ischemia–hypoxia insult in rats reduced cortical neuronal loss.[465] Treatment with insulin, either pre- or postischemia in the rat, reduced cortical and striatal neuronal necrosis and reduced infarction in the cerebral cortex, thalamus, and substantia nigra pars reticularis.[503,504]

Insulin

The observed role of insulin in prevention of postischemic brain injury is particularly interesting. The improvement in neurologic outcome seen with postischemic administration of insulin is independent of any hypoglycemic effect,[503] a predictable outcome as glucose transport to the brain is insulin-independent. The poorer neurologic outcome observed with hyperglycemia prior to brain ischemia was commonly attributed to increased lactic acidosis.[106] However, the involvement of acidosis in tissue injury appears unlikely, however, because generation of the same low tissue pH by hypercarbia did not cause any evident damage. The effects previously ascribed to hyperglycemia are equally plausible as alternative interpretations involving insulin; that is, hyperglycemic experimental animals (typically fasted rats made ischemic and hyperglycemic) do not do well, potentially due to either fasting-induced insulin deficiency or downregulation of insulin receptors.

Insulin effects are complex and affect fundamental cell regulatory functions well beyond the management of glucose. For example, insulin receptor-mediated protein phosphorylation cascades have many actions: they stimulate transcription of c-*fos*/c-*jun*, increase mRNA efflux from the nucleus, induce enzymatic systems for *de novo* lipogenesis, activate the mitochondrial pyruvate dehydrogenase complex, modify the phosphatidylinositol transcytoplasmic signaling system, and stimulate the heat shock response.[389]

The actions of insulin are mediated by a membrane receptor tyrosine kinase that shares homology with other growth factor receptors. The initial effect of insulin receptor activation is tyrosine autophosphorylation and activation of the intrinsic tyrosine kinase. Secondarily, other proteins are phosphorylated by activated kinases or dephosphorylated by activated phosphatases. It is the modulation of the phosphate content of specific proteins that appears to direct cellular regulation. A germane example involves the Ca^{2+}-calmodulin complex, which activates phospholipases; calmodulin is phosphorylated by the insulin receptor,[505] thereby reducing its ability to bind calcium, a reaction that potentially modulates insulin's antilipolytic effects.

Selectively vulnerable neurons, including specifically the cortical pyramidal ones and those in the CA_1 hippocampus, show marked elevation of the level of both insulin receptors and phosphotyrosine-containing proteins, which co-map extensively.[506] Furthermore, phosphotyrosine-containing proteins show the highest concentrations in the nuclei of these selectively vulnerable neurons,[506] consistent with a transcriptional regulatory function.

This evidence suggests that the postischemic neuroprotective effects of insulin are modulated during reperfusion by kinases, phosphatases, and prompt transcriptional regulation mediated by protein tyrosine–phosphorylation. Indeed, we have reported a reperfusion-specific insulin-induced ~10-fold increase in tyrosine phosphorylation on a 90-kDa brain nuclear protein and Sullivan *et al.* have shown a significant decrease in $eIF2\alpha$ phosphorylation with supranormal recovery of protein synthesis with insulin administration at ROSC.[507] The insulin-induced neuro-protective responses are likely specifically to include (1) activation of appropriate early transcription for the components of AP-1 in the vulnerable zones with subsequent upregulation of antioxidant defenses; (2) inhibition of calcium-calmodulin-activated lipolysis; (3) stimulation of the lipid synthesis systems vital to membrane repair; and (4) insulin-dependent promotion of the heat shock response.

The data regarding the involvement of insulin in neuronal salvage raise may explain in part the observed increase in ROSC, but no improvement in neuronal recovery.[508] Catecholamines, such as epinephrine, cause prompt and prolonged inhibition of insulin secretion by the pancreas[509] and reduce the tyrosine kinase activity of the insulin receptor by cAMP-induced phosphorylation of serine and threonine residues on the receptor.[510] These difficulties may be further aggravated by epinephrine-induced glucocorticoid secretion with consequent ligand activation of glucocorticoid receptors and interference with transcriptional activation by AP-1. Moreover, catecholamines, including dopamine, norepinephrine, and epinephrine, promote iron-mediated lipid peroxidation[511] and neuronal death[512] in vitro. We have carried out a preliminary examination of the interrelationships of insulin and epinephrine levels during the first 3 hours postresuscitation in cardiac arrest patients.[513] We have observed, as have others, very high endogenous levels of catecholamines in patients during cardiac arrest. In resuscitated patients we have observed two distinct subgroups; in one, insulin and C-peptide were initially high and then significantly decreased over time, and in the other, insulin and C-peptide were initially normal with a trend for C-peptide levels to increase with time. An obvious trend is noted for epinephrine levels to be higher at all times (~10-fold higher at ROSC) in the group with falling insulin levels. These results suggest that very high epinephrine levels are associated with a progressive decrease in insulin and C-peptide levels during reperfusion. Further the stroke and critical care literature provide data that bolsters this theory. The Capes *et al* meta-analysis reveals that an elevated initial glucose predicts an increase in mortality by 3-fold in non-diabetic cerebro vascular accident (CVA) patients.[514] The TOAST study reports initial hyperglycemia predicts poor outcome from CVA. Further, Parsons *et al.* proved by MRI and MR spectroscopy a mechanistic link between acute hyperglycemia and increased infarct volume and lactate production,[515] and that persistent hyperglycemia is an independent predictor of increased stroke volume and poor neurologic outcome.[516] Insulin use in diabetics with acute myocardial infarct (AMI) decrease morbidity and mortality,[517] and strict glucose control with insulin decreases ICU mortality from 8% to 4.6%.[518]

Summary

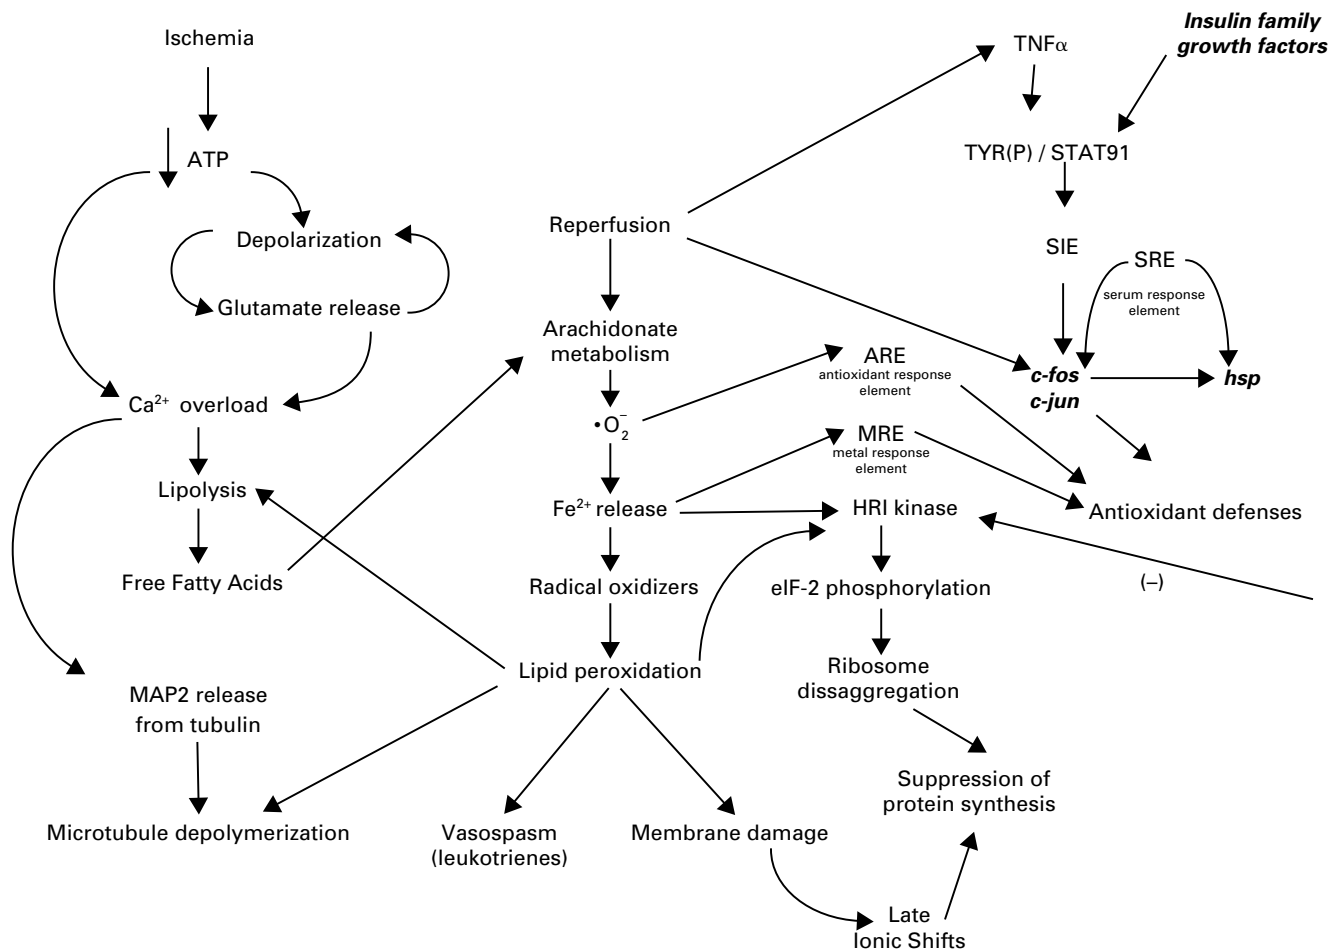
We have tried diligently to summarize the existing evidence related to brain injury by global ischemia and reperfusion (Fig. 13.7). Ischemia results in rapid loss of high energy phosphate compounds and generalized depolarization. Selectively vulnerable neurons are characterized by their dendritic fields receiving large amounts of glutamate released by the general depolarization during ischemia. Under these circumstances, both voltage-dependent calcium channels and glutamate-regulated calcium channels allow a massive increase in intracellular calcium to occur. This takes place in concert with initiation of lipolysis, a process that occurs more intensely in the selectively vulnerable neurons. Early during reperfusion, there is a burst of excess oxygen radical production and iron release from storage proteins. The availability of this transition metal allows initiation of lipid peroxidation. This process preferentially occurs in the selectively vulnerable neurons. The vulnerable neurons respond with transcription products for heat shock proteins and immediate-early genes, a response that appears directed toward enhancing antioxidant and membrane repair competence. Unfortunately, translation initiation is significantly depressed and thus the transcriptional response does not lead to translation of the appropriate protein products. Under these circumstances, the processes of membrane damage during reperfusion proceed unchecked, leading to loss of integrity in partitioning ions and cell death. Growth factors represent a physiologically based intervention strategy to enhance


Fig. 13.7. Schematic of the major mechanisms involved in neuronal ischemia and reperfusion.

appropriate transcriptional responses and translation competence. Antioxidant drugs reduce the rate of membrane damage, but do not alter the ultimate outcome in the absence of an effective physiological response by the neurons. The role of high levels of adrenergic agonists in this process is not yet completely worked out, but it appears likely that these compounds may act to enhance the damage and impede the appropriate physiologic response. We believe that based on appreciation of these fundamental principles, it will be possible to design effective clinical strategies to improve neurologic outcome significantly following cardiac arrest and resuscitation.

Reperfusion injury in cardiac arrest and cardiopulmonary resuscitation

Thomas Aversano

Johns Hopkins Hospital, Baltimore, MD, USA

Except for a single group of papers written in the mid-1980s[1–3] and a more recent preliminary report,[4] there are no studies and no literature on myocardial reperfusion injury in the setting of cardiac arrest and cardiopulmonary resuscitation (CPR). From this perspective, the following discussion may be, as Iago claims Cassio's soldiership to be in Shakespeare's *Othello*, "mere prattle without practice." It is to be hoped, however, that this discussion will serve to identify cardiac arrest and CPR as a setting in which reperfusion injury may occur; that it will point out where reperfusion injury may be relevant mechanistically and therapeutically in this particular clinical circumstance; and, ultimately, that it will encourage basic and clinical research in an area that remains largely unexplored.

Reperfusion injury

The primary therapy for myocardial ischemia is reestablishment of normal blood flow. Yet despite the proven benefit of reperfusion in ischemic syndromes such as acute myocardial infarction,[5–7] evidence shows that some of this benefit may be lessened by injury caused by reperfusion itself.[8]

The term *reperfusion injury* includes a number of potentially deleterious effects of reperfusion after a period of ischemia, including myocardial stunning, reperfusion arrhythmia, and reperfusion-related myonecrosis.[9] Depending on the particular setting in which ischemia and reperfusion occur, these several types of reperfusion injury may be present alone or in combination.

Clinical settings in which reperfusion injury is thought to be important include postcardiopulmonary bypass, heart transplantation, and acute myocardial infarction treated with either thrombolytic therapy or immediate angioplasty.[10] Although generally not recognized as such, cardiac arrest with CPR is clearly an instance, albeit a very complex one, of ischemia and reperfusion; and, as argued in what follows, reperfusion injury may very well play an important role in determining its course and outcome.

Cardiac arrest and cardiopulmonary resuscitation: a setting for reperfusion injury

Cardiac arrest results in myocardial ischemia. Initiation of CPR may result in reperfusion if coronary perfusion pressure is sufficient to provide normal or near-normal coronary blood flow. However, CPR may not provide an adequate coronary driving pressure, either because the developed aortic–right atrial pressure gradient is inadequate or because of coronary artery stenoses. Even minimal coronary stenoses may lead to marked reduction of coronary flow during CPR, particularly in the endocardium.[11] Further, the heart is often fibrillating during CPR, so that levels of coronary flow that might be adequate in the diastolically arrested heart may be insufficient to meet the higher oxygen demands of the fibrillating heart. Thus how long ischemia (defined as the mismatch between myocardial oxygen supply and demand) lasts during cardiac arrest and CPR is often unclear and depends on the time delay between the onset of cardiac arrest and the initiation of CPR and on the adequacy of CPR in restoring a level of coronary blood flow sufficient to meet metabolic demand. As a result, reperfusion may occur once CPR is instituted, once spontaneous circulation is established, or perhaps only after sufficient pharmacologic or mechanical

hemodynamic support allows for development of adequate coronary perfusion pressure. To make matters more complex, the setting of cardiac arrest and CPR often involves multiple, recurring episodes of ischemia and reperfusion and obviously requires administration of a number of pharmacologic agents, which may influence coronary flow and myocardial oxygen consumption.

These considerations make it likely that the full spectrum of reperfusion injury may be seen in the setting of cardiac arrest and CPR. It is important to reiterate that, except for the three studies mentioned above, no studies have been performed to date specifically addressing the question of reperfusion injury in this setting.

The potential importance of defining the extent of reversible or preventable dysfunction or injury caused by reperfusion in this very special setting cannot be overstated. Therapies aimed at *preventing* reperfusion injury may preserve cardiac function and muscle mass and minimize recurrent arrhythmias, critical determinants of survival in the early and late postresuscitation period. Further, *treatment* of reperfusion injury with effective therapeutic modalities utilized for the proper duration can mean the difference between long-term survival and death.

This chapter will review what is known about myocardial reperfusion injury and attempt to relate information gleaned from these studies to the setting of cardiac arrest and CPR, keeping in mind that most of what is known comes from studies meant to examine experimental or clinical circumstances *other than* cardiac arrest and CPR.

Myocardial stunning

Definition

As first reported by Heyndrickx *et al.* in 1975,[12] myocardial stunning refers to the prolonged but reversible ventricular dysfunction that follows a relatively brief, non-lethal ischemic period. The key features of stunning are that myocardial dysfunction occurs despite normal blood flow, that this dysfunction is reversible, and that it occurs in the absence of significant myonecrosis.

Recognition of stunning after cardiac arrest and CPR is important since the associated dysfunction is reversible. Failure to recognize this possibility may adversely and wrongly affect the physician's assessment of the patient's prognosis in the immediate postresuscitation period. Further, as potential treatments for stunning are developed, particularly those directed at its prevention, they may be applied to this clinical situation.

Stunned myocardium in animal models

The original description of stunning involved regional ischemia and reperfusion[12] in the dog. Since then, many studies have shown that the degree and duration of postischemic dysfunction depend on the duration of ischemia (Fig. 14.1(a)).[12–15] Five minutes of ischemia may be followed by 3 hours of reduced systolic wall thickening, and 15 minutes of ischemia may be followed by 24 hours of reduced function.[14] In one of the few studies that directly relates to CPR, Cerchiari *et al.*[15] studied the effect of cardiac arrest of 7.5-, 10-, and 12.5-minute duration on ability to resuscitate, mortality, neurologic deficit scores, and cardiac function. There was no difference in any category except that cardiac output was depressed for more than 12 hours after CPR and more severe arrhythmias occurred in the animals with cardiac arrest of 12.5-minute duration (Fig. 14.1(b)).[15] The prolonged depression of cardiac output with a gradual return toward normal probably represents myocardial stunning, the extent and duration of which are functions of the duration of the ischemic episode. Moreover, the degree of postreperfusion dysfunction is directly related to the reduction of blood flow reduction during the ischemic period[16] and consequently can be influenced by collateral flow.

Repeated brief episodes of ischemia followed by reperfusion periods can also lead to stunning.[17,18] Deterioration of systolic function is greatest after the first occlusion-reperfusion period and reaches its nadir after the third repetition.[17,18] The reason functional deterioration does not continue is unclear, but it appears to be related to a "preconditioning" effect of a first, brief period of ischemia that protects the myocardium from further functional deterioration and adenosine triphosphate (ATP) loss[19] and minimizes myonecrosis[20] in subsequent ischemic periods.

Stunning has also been observed in the isolated heart after brief periods of global ischemia followed by reperfusion in a number of species.[21] Although global ischemia might be considered a better model of cardiac arrest and CPR than regional ischemia models, many such models fail to document a full return of function since the preparation most often used, the isolated heart, deteriorates significantly over time.[21]

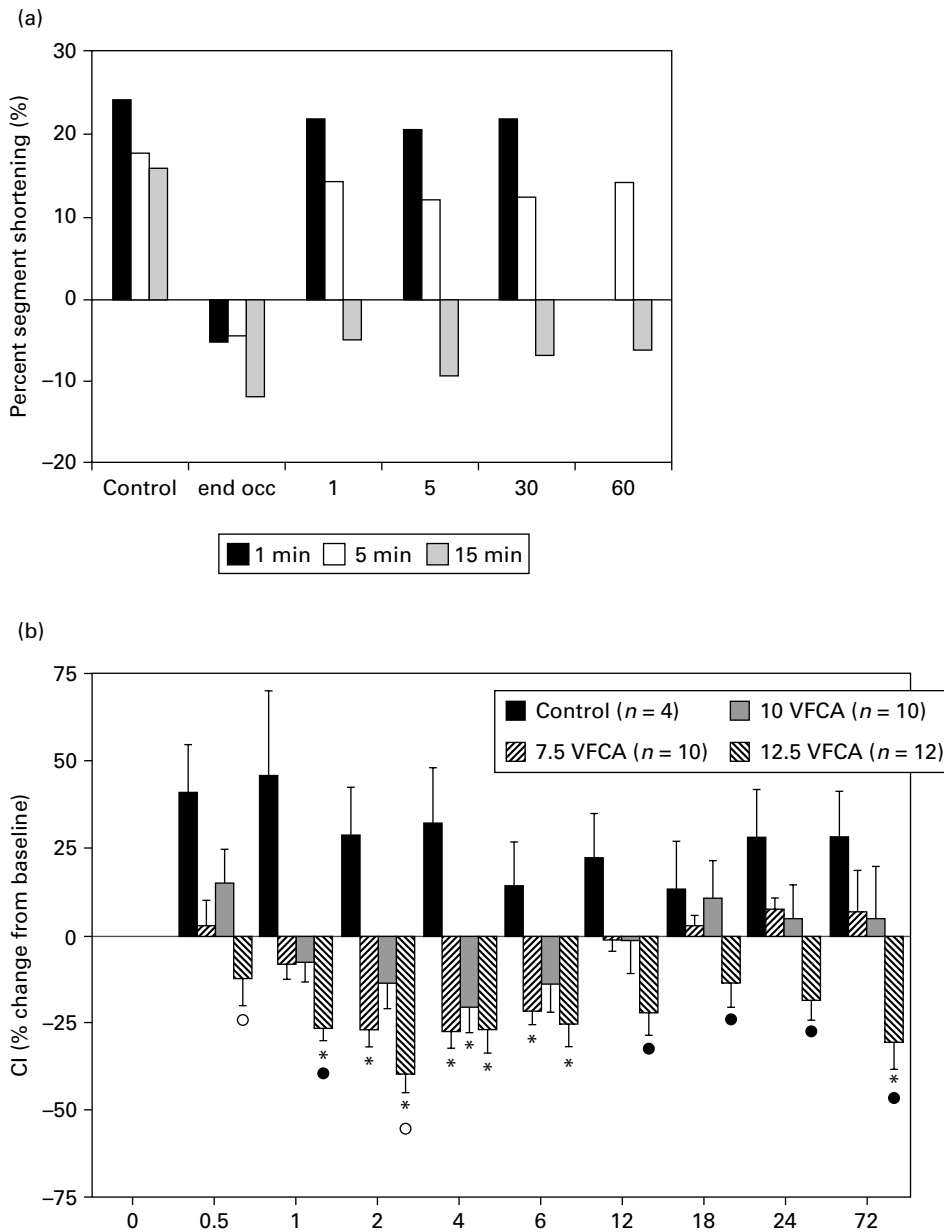
In addition to systolic dysfunction, it has been appreciated more recently that diastolic dysfunction can also occur in stunned myocardium. In previously ischemic regions, the rate and degree of diastolic wall thinning were reduced for several hours after a 15-minute coronary occlusion in the conscious dog.[22]


Fig. 14.1. (a) Effect of ischemic duration on regional myocardial function after reperfusion in dogs. (b) Effect of time to initiation of CPR in dogs. *VFCA*, minutes in ventricular fibrillation circulatory arrest before CPR initiated. In both cases, the longer the ischemic duration the longer and more profound the dysfunction in the reperfusion period. (a) Adapted from ref. 14.) (b) Adapted from ref. 15.)

Interestingly, cessation of coronary blood flow is not necessary to produce stunning: transient dysfunction has been noted after exercise-induced ischemia. For example, Homans *et al.*[23] have shown progressive deterioration in wall thickening in dogs with critical coronary stenoses made to exercise for 10 minutes with 60-minute rest periods between. Thus it is ischemia *per se* (i.e., the mismatch between myocardial oxygen supply and demand), not how it is produced, that when followed by reperfusion results in myocardial stunning.

Finally, factors other than ischemia may produce stunning. Particularly important to the setting of cardiac arrest
Fig. 14.2. Ventricular fibrillation (*VF*) is associated with, (a) a transient rise in intracellular Ca^{2+} and (b) a postfibrillation reduction in cardiac function (stunning) recorded as a reduction in developed pressure (*DP*). (From ref. 24.)

and CPR, ventricular fibrillation alone, in the absence of ischemia, may produce prolonged ventricular dysfunction after its cessation (Fig. 14.2).[24]

Stunned myocardium in humans

Clinical settings in which stunning may occur include reperfusion therapy for acute myocardial infarction (whether pharmacologic or mechanical), following cardiopulmonary bypass, cardiac transplantation, and even after ischemia-producing exercise in patients with coronary artery disease.[9]

Ellis *et al.*[25] have shown that with prolonged ischemia sufficient to produce subendocardial infarction, followed by reperfusion, non-necrotic myocardium surrounding infarcted myocardium is probably stunned and function in this region returns gradually over a 2-week period. By analogy, after thrombolytic therapy for acute myocardial infarction, several studies have shown a gradual return of function over days to weeks.[26] Whereas some functional recovery may be due to infarct healing and the effect of drugs and other factors, recovery of stunned myocardium is a likely additional factor.

Perhaps the best clinical example of stunning is the transient myocardial dysfunction that follows cardiopulmonary bypass (Fig. 14.3). Although a number of factors may play a role in postbypass dysfunction, including the prolonged metabolic effects of hypothermia and effects caused by handling of the heart during surgery, it is likely that much is due to reperfusion injury.[27] Systolic

dysfunction[28,29] and diastolic dysfunction[30] have been reported in the early hours after bypass, with complete recovery within hours, days, or, in some instances, weeks.[31]

As in animal models, it is ischemia *per se*, the mismatch between coronary flow and myocardial oxygen demand, rather than cessation of coronary flow, that results in stunning. Exercise-induced stunning has been demonstrated in studies that reveal transient regional dysfunction after an exercise period that provoked ischemia in patients with coronary artery disease.[32]

Mechanisms of stunned myocardium

A number of mechanisms have been proposed for stunned myocardium, including a decline in myocyte ATP levels, alterations of Ca^{2+} metabolism, change in subcellular organelles, and production of free radicals.

Stunned myocardium is characterized by a persistent reduction in ATP level and in the total purine nucleotide pool[33] for a variable time following reperfusion. In stunned myocardium, less ATP synthesis can occur via the salvage pathway because of loss of the requisite precursors during ischemia. Therefore *de novo* purine precursor resynthesis is required to replenish ATP, a process that may require several days.[33] The parallel reduction in myocardial function and ATP levels and their gradual, parallel return toward normal levels in stunned myocardium strongly suggest a causal relationship between the two. A number of studies have shown, however, that myocardial function and the level of ATP can be dissociated in stunned
Fig. 14.3. Evidence for prolonged dysfunction following cardiopulmonary bypass in a patient for more than 48 hours after being taken off bypass. Δ *Wth*, change in wall thickening. (From ref. 29.)

myocardium. For example, function can be increased and sustained at normal or supranormal levels with catecholamines or postextrasystolic potentiation in stunned myocardium[18] without changing ATP levels. Conversely, ATP levels can be increased to near normal levels in stunned myocardium by administration of requisite precursors without reversing dysfunction.[34] Thus the prolonged but reversible dysfunction that characterizes stunned myocardium is not related to myocyte ATP levels.

Strong evidence suggests that at least part of the prolonged dysfunction after reperfusion in stunned myocardium is mediated by abnormalities of calcium homeostasis. Intracellular calcium levels rise during ischemia and during early reperfusion.[35] The mechanism for the increase in cytosolic Ca^{2+} appears to be a metabolic inhibition of the sarcolemmal Na–K ATPase with a consequent rise in intracellular Na^+. At reperfusion the Na–Ca exchange mechanism, which usually pumps Ca^{2+} out of the cell in exchange for Na^+, reverses direction in response to relative intracellular Na^+-loading, now extruding Na^+ in exchange for Ca^{2+}.

That the transient rise in intracellular Ca^{2+} is causally related to stunning is supported by several lines of evidence. Reducing the rise in intracellular calcium with acidosis[36] or perfusion with low calcium[37] minimizes stunning. In addition, other non-ischemic maneuvers that result in intracellular calcium loading such as perfusion with high calcium concentration perfusate[38] or following a period of ventricular fibrillation[24] mimic ischemia-mediated stunning functionally and histologically.

How this transient rise in intracellular Ca^{2+} leads to depressed function is unclear. Nevertheless, systolic dysfunction in stunned myocardium is associated with a decline in maximal calcium-activated force production

and a decrease in the sensitivity of the myofilaments to calcium.[39,40] Similarly, the mechanism of postfibrillation dysfunction has been related to intracellular Ca^{2+} overload and a resulting decline in the sensitivity of myocyte contractile elements to Ca^{2+}.[24] It is possible that increased intracellular Ca^{2+} may activate protein kinases, which may then phosphorylate and therefore alter the function of contractile proteins.[41] Finally, reduced uptake of calcium by sarcoplasmic reticulum has been observed in stunned myocardium[42] and may be related to both impaired systolic and diastolic function. Impaired diastolic relaxation may also be caused by abnormal myofilament relaxation, perhaps secondary to changes in intracellular inorganic phosphate.[43]

Paradoxically, despite a decline in ATP levels and a parallel reduction in function, myocardial oxygen consumption is increased in stunned myocardium.[44,45] This mismatch between oxygen consumption and function is related neither to uncoupling of oxidative phosphorylation nor to a rise in basal (non-contractile-related) myocyte oxygen requirements.[46] Instead, it appears to be caused by a reduction in the calcium sensitivity of myofilaments in the postischemic period,[47,48] noted above.

Evidence also exists that oxygen-based radicals are important mediators of stunned myocardium. Within 1 minute of reperfusion there is a marked production of free radical species including O_2, H_2O_2, and OH,[49] which, while declining rapidly, is sustained for several hours after reperfusion.[49] Treatment with superoxide dismutase (SOD) (which prevents production of O_2) and catalase (which prevents production of H_2O_2 and OH) minimizes free radical production[49] and minimizes the degree of postischemic dysfunction as well.[50] The relationship between degree of dysfunction in the reperfusion period and the degree of

blood flow reduction during the ischemic period noted above may reflect the close association between the degree of ischemia and the level of oxygen radicals subsequently produced during reperfusion.[51] The only literature that actually specifically addresses reperfusion injury in the setting of cardiac arrest and CPR involved administration of the iron chelator deferoxamine to inhibit generation of oxygen radicals by inhibiting the Haber–Weiss reaction.[1–3] Interestingly, deferoxamine was given 5 minutes *after* return of spontaneous circulation and therefore after reperfusion[2,3] and after the expected early, large burst of free radical generation; yet inhibition of free radical generation at this relatively late time still appeared to have a marked beneficial effect as measured by *late survival*: in the deferoxamine-treated group, late neurologically intact survival was twice that of controls.[2,3]

It is likely that the pathogenesis of stunning involves both free radical–mediated injury and calcium-mediated injury; the two mechanisms are not mutually exclusive.[41,52] Although a number of ways the two mechanisms may work together to effect myocardial stunning have been suggested,[41,52] their complex interrelations remain to be elucidated.

Clinical issues relevant to cardiac arrest and cardiopulmonary resuscitation

The critical aspect of stunning important to the setting of cardiac arrest and CPR is that stunning may lead to profound, prolonged, but *reversible*, myocardial dysfunction despite restoration of normal coronary blood flow and preservation of cerebral function. The clinician must be aware that stunned myocardium *will* recover if given sufficient time and that support of the stunned heart, often for protracted periods of time, may be required. Better methods to identify viable but dysfunctional myocardium could be of obvious value in the postarrest setting.

Minimization of arrest time before initiation of CPR and restoration of adequate coronary blood flow would be important since the degree of stunning is directly related to the duration of ischemia. Clinical studies have repeatedly demonstrated a direct relationship between early and late survival and minimization of the time between cardiac arrest and institution of CPR.[53,54] Clearly, while rapid institution of CPR may minimize myocardial stunning, other beneficial effects are probably as, or even more, important.

During CPR, maintenance of the highest perfusion pressure possible is of clear importance since stunning depends in part on the degree of ischemia. The requisite pressure can be significantly higher than that required for cerebral perfusion, because the elevated oxygen consumption of the fibrillating heart and the presence of coronary artery stenoses increase the aortic pressure required to maintain adequate coronary blood flow. Since stunning depends on an imbalance between oxygen supply and demand, improvement of this balance in the course of CPR might minimize stunning. Epinephrine, which is often used in high doses to improve coronary perfusion pressure during CPR, can also increase myocardial oxygen demand. If the improvement in flow fails to match the increase in demand, then the setting exists for myocardial stunning. In a recent animal study the combination of phenylephrine and propranolol resulted in lower myocardial lactate levels and higher myocardial ATP levels than either high-dose epinephrine or phenylephrine alone.[55] Presumably, phenylephrine allowed for an increase in aortic pressure during CPR, while propranolol reduced myocardial oxygen consumption, suggesting that use of this combination of drugs during CPR may minimize subsequent stunning. Whether this will translate into a useful therapeutic strategy remains to be seen.

Following restoration of spontaneous circulation, the postarrest heart may be stunned and require support, either mechanical[31] or pharmacologic.[18] Left ventricular assist devices[31] and peripheral bypass are both potential forms of therapy. Stunned myocardium can be made to develop normal contractile performance pharmacologically by use of inotropic drugs, such as catecholamines.[18] The duration of support can be quite extraordinary (Fig. 14.4): one patient undergoing coronary artery bypass surgery was reported to have an ejection fraction of 6% postoperatively (50% preoperatively).[31] After more than
Fig. 14.4. Dysfunction caused by stunned myocardium may be profound and prolonged, requiring pharmacologic and mechanical support for a protracted period of time. *IABP,* intraaortic balloon pump. (Adapted from ref. 31.)

2 weeks of mechanical and pharmacologic (inotropic) support, cardiac function recovered and the (unsupported) ejection fraction was 38%.[31] The clinician caring for the postarrest patient must recognize the potential for stunned myocardium to recover over such protracted periods of time.

In the future, further study of the mechanisms of stunning in cardiac arrest and CPR may lead to other ways of preventing its occurrence. Thus inhibition of free radical formation with SOD and catalase administered during CPR may prevent or minimize postarrest myocardial dysfunction. Inhibition of the transient postischemic rise in intracellular Ca^{2+} or reversal of its longer lasting effects on target proteins or subcellular structures could also be a future preventive strategy.

Reperfusion arrhythmias

At one time, arrhythmias, including ventricular tachycardia and fibrillation, were thought to herald successful reperfusion after thrombolytic therapy for acute myocardial infarction. Closer study of large numbers of patients, however, revealed that reperfusion arrhythmias are insensitive and non-specific markers of reperfusion in this setting.[56,57] Nevertheless, reperfusion arrhythmias have been repeatedly demonstrated in animal models of ischemia and reperfusion. It is interesting that reperfusion after brief (5 to 20 minutes) ischemic periods may be associated with more frequent and more severe ventricular arrhythmias than more prolonged periods (hours).[9] A discussion of reperfusion arrhythmias is warranted for at least two reasons. First, as will be discussed below, reperfusion arrhythmias can be the proximate cause of cardiac arrest. Second, since the ischemic period associated with cardiac arrest and CPR is usually relatively brief (minutes not hours), the reperfusion that attends restoration of adequate coronary flow either from CPR itself or from the return of spontaneous circulation may create the electrophysiological milieu associated with reperfusion arrhythmias.

Animal models of reperfusion arrhythmias

Reperfusion arrhythmias have been documented in several species, and in general their frequency and severity depend on the duration of ischemia.[58] This relationship is not linear, however. Very brief episodes of ischemia lead to no or infrequent reperfusion arrhythmias; longer periods of ischemia that end before the onset of significant irreversible injury are associated with the highest frequency and most severe ventricular arrhythmias; and very long ischemic periods

(long enough to lead to irreversible myonecrosis) again lead to less frequent and less severe ventricular arrhythmias.[58] The exact timing of these events depends on the species and the model (intact or isolated heart) examined. In the isolated rat heart, for example, reperfusion ventricular fibrillation occurs infrequently after less than 5 or more than 30 minutes of ischemia but occurs in virtually all animals after 15 minutes of ischemia.[58] In the intact dog, ischemic durations less than 5 to 10 minutes or greater than 60 to 90 minutes infrequently lead to reperfusion fibrillation, whereas more than 50% of animals fibrillate on reperfusion after 20 to 30 minutes of ischemia.[58] In addition to the duration of ischemia, development of serious ventricular arrhythmias appears to be related to the level of collateral flow and high-energy phosphates: the higher the collateral flow during the ischemic period, the less likely arrhythmias follow reperfusion.[59]

Reperfusion arrhythmias in humans

As noted above, prolonged ischemia followed by reperfusion, as occurs in acute myocardial infarction treated with thrombolytic therapy, is sometimes but not usually associated with ventricular arrhythmias. One large study of 500 patients with acute myocardial infarction, some treated with and others without thrombolytic therapy, showed no increase in ventricular arrhythmias in patients treated with reperfusion therapy,[60] suggesting that these arrhythmias, when they occur, are not necessarily related to reperfusion.

In other clinical settings, brief periods of ischemia followed by reperfusion have been shown to be associated with development of serious ventricular arrhythmias. For example, Previtali et al.[61] studied a group of patients with Prinzmetal's variant angina. Continuous Holter monitoring identified a subgroup of these patients who had ventricular arrhythmias either during ST segment elevation (during ischemia) or after resolution of ST elevation (reperfusion). Of the group who developed ventricular arrhythmias, the arrhythmia was associated with reperfusion in one-third (10 out of 27).[61] Similarly, Myerburg et al.[62] described a small group of patients with transient, silent ST segment elevation associated with life-threatening ventricular arrhythmias, 40% (two out of five) of whom developed the arrhythmia during resolution of the preceding ST segment elevation (i.e., during reperfusion).

From these observations it is clear that reperfusion arrhythmias occur in humans, particularly after brief episodes of ischemia. It is also clear that reperfusion arrhythmias can be the initiating event in cardiac arrest.

Mechanisms of reperfusion arrhythmias

Re-entry, increased automaticity, and triggered activity have all been suggested as potential mechanisms of reperfusion arrhythmias.

The ionic and electrophysiologic consequences of ischemia and reperfusion are complex and incompletely understood; the nature and degree of these alterations depend on the duration of ischemia and on the model used for study. Since reperfusion ventricular arrhythmias seem to occur most often after relatively brief durations of ischemia (15 to 30 minutes in most species), this discussion will center around changes that occur in that time frame.

Ischemia rapidly leads to an increase in extracellular K^+ and a rise in intracellular Na^+, in part a result of metabolic inhibition of the sarcolemmal Na–K ATPase pump. The myocyte transmembrane potential becomes depolarized, and action potential duration is shortened. On reperfusion, there is a rise in intracellular Ca^{2+} mediated, in part, by the Na–Ca exchanger mentioned above. Extracellular K^+ is washed out and returns toward normal or subnormal levels, and action potential duration returns to normal or becomes prolonged.

Restoration of coronary blood flow returns the electrophysiologic properties of ischemic myocardium toward normal. However, since coronary blood flow is restored in a non-homogeneous manner, with islands of high and low flow, restoration of the normal ionic and electrophysiologic milieu is also not homogeneous. Hariman et al.[63] showed that in the dog, reperfusion after 20 minutes of ischemia was associated with a marked spatial heterogeneity of regional blood flow, extracellular K^+ concentration, and electrogram duration within the reperfused zone in the first minutes of reperfusion. Similarly, Coronel et al.[64] demonstrated marked heterogeneity of extracellular K^+ and action potential duration between reperfused and normal myocardium in early reperfusion after 10 minutes of coronary occlusion in the isolated pig heart.

This heterogeneity leads to a dispersion of refractoriness, which forms the ideal substrate for re-entry. Although various studies differ on the precise nature of the electrophysiologic changes involved, most support the notion that reperfusion is marked by a dispersion of refractory periods either within the previously ischemic region or between the reperfused and normal regions. For example, Levites et al. demonstrated a marked dispersion of refractoriness in dog hearts subjected to 15 to 30 minutes of coronary occlusion followed by reperfusion.[65] After shortening during the ischemic period, the refractory period was prolonged in the previously ischemic region within 3 minutes of flow restoration.[65] They concluded that the dispersion of refractoriness and its temporal relation to the onset of ventricular arrhythmias suggested re-entry was an important mechanism of reperfusion arrhythmia.[65] Naimi et al. also demonstrated a dispersion of effective refractory periods in ischemic and reperfused dog hearts following either 5 or 15 minutes of regional ischemia.[66] In this study the effective refractory period was actually shortened in the first minute of reperfusion; the increased dispersion of refractory periods between normal and reperfused myocardium led to a large electrical gradient between the two regions.[66]

Although re-entry constitutes a common, if not the most common, mechanism for production of reperfusion arrhythmias, other mechanisms are also likely to be operative. For example, reperfusion arrhythmias have been attributed to triggered arrhythmias: early and delayed afterdepolarizations.

Priori et al. demonstrated, in an in vivo cat model of 10 minutes of coronary occlusion followed by reperfusion, that early afterdepolarization occurs in early reperfusion and can be an important mechanism of reperfusion arrhythmias.[67] Rozanski and Witt[68,69] showed that in isolated cardiac Purkinje fibers recovering from ischemia like conditions (hypoxia, high external K^+, and acidosis), action potential duration is prolonged, setting the stage for early afterdepolarizations (Fig. 14.5). Further, generation of such depolarizations was critically dependent on intracellular acidosis.[68] The ionic basis for early afterdepolarizations is not completely clear but may involve an inward current carried by Ca^{2+} through sarcolemmal voltage-gated Ca^{2+} channels,[70] which, in part because of prolongation of action potential duration, have time to recover from their inactive state and reopen at or near the plateau potential. Alternatively, the ionic current could be carried by Na^+ through Na^+ channels or may be caused by a reduction or delay in outward, repolarizing current.[68] The requirement for a preceding intracellular acidosis suggests that Ca^{2+} may be important in creating the conditions necessary for early afterdepolarizations. That is, the rise in intracellular Ca^{2+} after reperfusion may depend on an increase in intracellular Na^+; and the rise in intracellular Na^+ may depend not only on metabolic inhibition of the Na–K ATPase pump but also on Na–H exchange. The rise in intracellular Ca^{2+} occurs on reperfusion when the Na–Ca exchanger pumps out Na^+ and takes in Ca^{2+}. These reperfusion-associated changes in intracellular Ca^{2+}, although transient, may lead to longer-lasting alterations in membrane electrophysiologic properties,[68] just as they lead to longer-lasting changes in function in the case of myocardial stunning.

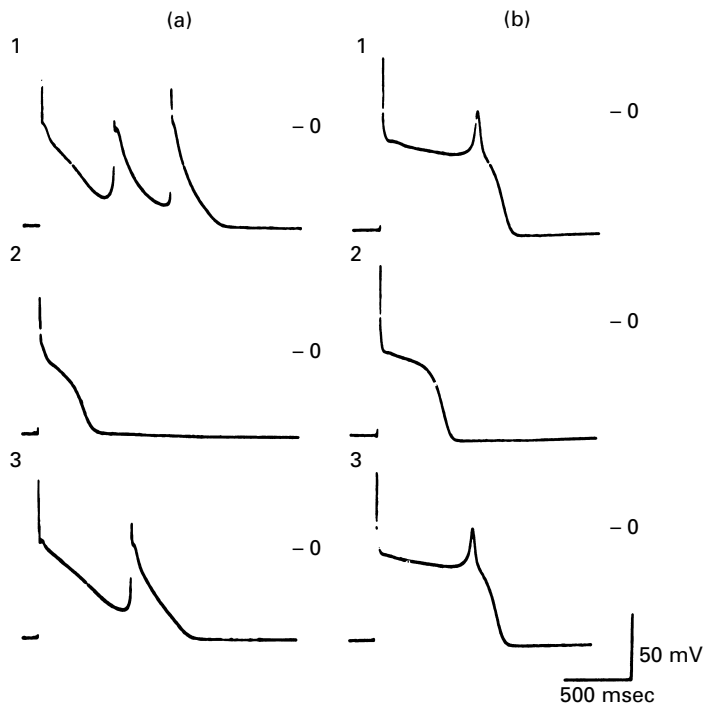
Delayed afterdepolarizations have also been suggested as a cause of reperfusion arrhythmias. Delayed


Fig. 14.5. Early afterdepolarizations and triggered activity in a model of ischemia and reperfusion. Inhibition by lidocaine. (From ref. 68.)

afterdepolarizations are related to spontaneous oscillations in intracellular Ca^{2+} caused by release from the sarcoplasmic reticulum.[70] Increases in such release, as may be seen with the relative calcium overload that occurs with ischemia and reperfusion, can be associated with such depolarizations. In a model consisting of isolated, superfused canine papillary muscle–Purkinje fiber preparations, Ferrier *et al.* demonstrated that "reperfusion" following ischemia-like conditions (hypoxia, acidosis) resulted in a stereotyped sequence of events: first hyperpolarization, then progressive depolarization, and then a return to control membrane potential.[71] During the depolarization phase, delayed afterdepolarizations could initiate extrasystoles,[71] but whether or not they actually can initiate repetitive ventricular activity in the setting of in vivo ischemia and reperfusion is unclear.

Similar to altered cardiac function following ischemia and reperfusion, changes in the electrophysiologic properties of reperfused myocardium have been attributed to alterations in Ca^{2+} homeostasis and changes caused by free radical damage. Relevant changes in Ca^{2+} homeostasis were outlined above.

The extent to which electrophysiologic changes are the result of free radical injury is more difficult to determine, and the relationship between free radical–induced injury and reperfusion arrhythmias remains unclear. Some studies suggest that the time course of changes in electrophysiologic properties such as action potential duration is too slow to be associated with reperfusion arrhythmias,[72] whereas other studies suggest changes can occur within 1 minute of exposure to free radical–generating systems.[73] And although some studies have shown a reduction in ventricular arrhythmias associated with reperfusion after treatment with free radical scavengers such as SOD and catalase,[74,75] others have failed to show such a benefit.[73,76] Thus, although free radicals are generated in the first moments of reperfusion, their relationship to arrhythmias in this period remains uncertain.

Other potential mechanisms involved in reperfusion arrhythmias include α-adrenergic activation[77] and angiotensin II production.[78] Blockade of α-adrenergic activation with phentolamine[77] and angiotensin converting enzyme (ACE) inhibition[78] has been reported to reduce the frequency and severity of ventricular reperfusion arrhythmias in animal models.

Influence of comorbid conditions and common drugs on reperfusion arrhythmias

Comorbid conditions that affect cardiac arrest victims, such as hypertension and diabetes, may influence reperfusion arrhythmias. Isolated hearts from hypertensive rats subjected to 10 minutes of regional ischemia followed by reperfusion have a higher incidence of ventricular fibrillation than do normal hearts.[79] On the other hand, diabetic rats (streptozotocin-induced) appear to have a somewhat lower incidence of sustained ventricular fibrillation after 10 minutes of regional ischemia followed by reperfusion,[80] perhaps because these hearts have a higher content of free radical–scavenging enzymes, prolonged action potential duration, and reduced activity of Na^+–H^+ and Na^+–Ca^{2+} exchange.[80]

Concomitant drug administration can also influence reperfusion arrhythmias. The incidence and duration of ventricular fibrillation are increased in isolated rat hearts made globally ischemic for 25 minutes and reperfused after administration of ouabain,[81] probably because of ouabain-induced augmentation of Ca^{2+} overload. Other drugs may have a beneficial effect. For example, ACE inhibitors have also been shown to reduce the incidence, severity, and duration of reperfusion arrhythmias.[82] Still other drugs have a mixed action. Glibenclamide, an oral hypoglycemic, has been shown to increase the frequency of delayed afterdepolarizations and triggered activity in eperfused myocardium;[83] yet it also appears to reduce

re-entrant ventricular tachycardia and fibrillation in the same setting.[83,84]

Clinical relevance of reperfusion arrhythmias to cardiac arrest and cardiopulmonary resuscitation

Reperfusion arrhythmias may initiate cardiac arrest, as noted above, and may be an important cause of sudden death. In addition, reestablishment of coronary flow by CPR, either by creating an adequate coronary driving pressure or restoration of spontaneous circulation, results in reperfusion, which may in turn lead to reperfusion arrhythmias either during CPR or in the early postresuscitation period.

The approach to these arrhythmias is standardized and directed for the most part at treating re-entry, the mechanism that is probably most common and for which there is strongest evidence. Thus lidocaine, bretylium, and magnesium sulfate, in that order, are used for serious ventricular arrhythmias in the setting of CPR. In addition, lidocaine has been reported to be effective in suppressing both early[85] and delayed[86] afterdepolarizations, making it a drug of first choice in this setting. At present, no specific therapies can be aimed at *preventing* these arrhythmias.

It is clear that the ability to identify mechanisms of reperfusion-related arrhythmias beside re-entry at the bedside may be important in the future when specific therapies for these arrhythmic mechanisms are available. In addition, methods of modifying the effects of increased intracellular Ca^{2+} or minimizing the ionic and metabolic disturbances that lead to Ca^{2+} overload and its lingering aftereffects may be available in the future and used for prevention. Finally, to the extent that free radicals mediate reperfusion arrhythmias, treatment with free radical scavengers during CPR may minimize postresuscitation arrhythmias.

Myonecrosis and vascular injury

Definition

Reperfusion-related myonecrosis occurs after more prolonged ischemic periods. Ischemia alone obviously can produce irreversible injury, but this reperfusion-related myonecrosis extends this injury and produces additional cell death.

Whereas myocardial stunning and reperfusion arrhythmias are important to both therapy and a fundamental understanding of cardiac arrest and CPR, whether the myonecrosis caused by reperfusion after more prolonged ischemic periods is relevant in this setting is much less clear. Indeed, whether this type of reperfusion injury occurs at all in any setting remains unresolved. Further, since a more prolonged ischemic insult is required to produce lethal myocyte injury, the relevance to the setting of cardiac arrest and CPR is less clear: an arrest time greater than a few minutes is incompatible with meaningful neurologic recovery.

Nevertheless, it is possible to imagine a circumstance in which CPR was begun soon after cardiac arrest and produced an adequate coronary perfusion pressure. However, if one or more coronary arteries had critical stenoses, then the regional ischemic period could be relatively long if CPR is continued for a prolonged period; this could be sufficient to produce irreversible injury. On return of spontaneous circulation and better coronary perfusion pressure and flow, reperfusion injury could occur and result in additional myonecrosis.

Reperfusion-related myonecrosis in animals

The most direct evidence for reperfusion injury comes from a study of Becker *et al.*[87] Dogs were subjected to 90 minutes of coronary occlusion followed by variable periods of reperfusion. Electron microscopic evidence for irreversible injury was assessed in biopsies taken from ischemic regions reperfused for 0, 5, 90, or 180 minutes. Nearly all biopsies from ischemic regions with very low flow ($<0.05\,ml/g$ per min) showed irreversible injury independent of the reperfusion period. In biopsies from ischemic regions with less severe flow reduction ($>0.05\,ml/g$ per min), however, irreversible injury increased as a function of reperfusion period, with more samples showing irreversible injury as reperfusion time increased. These results are consistent with reperfusion injury. Whether this injury was inevitable and would have occurred whether or not reperfusion had occurred cannot be gleaned from this study.

Rather than demonstrating reperfusion injury directly, most studies attempt to demonstrate reperfusion-related myonecrosis by trying to minimize it. Such studies rely on using some agent or maneuver to reduce reperfusion injury compared to a control condition. Infarct size (mass) is the most common outcome variable measured: if the agent reduces reperfusion injury, infarct size will be smaller in the treated than in the control group. A critical conceptual issue in such studies is that most interventions designed to reduce reperfusion injury may minimize infarct size in other ways as well and therefore are not absolutely specific.

Review of the numerous agents used in such studies is beyond the scope of this chapter. Agents that appear to reduce infarct size by minimizing reperfusion-related myonecrosis include (*a*) those that interfere with neutrophil sequestration in the reperfused region or neutrophil function,[88–90] (*b*) agents that interfere with free radical formation,[1,3,91,92] and (*c*) other agents that work through various or uncertain mechanisms.[93–95] All such studies demonstrate, at best, an association between a reduction in infarct size and the agent's use but do not prove that the mechanism has any connection with limitation of reperfusion injury. Further, for each of these approaches, studies that fail to show benefit exist as well. For this reason the issue of reperfusion-related myonecrosis remains controversial and unresolved.

Evidence for reperfusion-related myonecrosis in humans

No direct or indirect evidence exists of reperfusion-related myonecrosis in humans. Two agents that have been shown to reduce infarct size in animal models of ischemia and reperfusion (presumably by limiting reperfusion injury), SOD and the perfluorochemical Fluosol, had no beneficial effect when administered just before reperfusion in recent trials of patients undergoing thrombolysis or angioplasty for acute myocardial infarction.[96,97]

Mechanisms of reperfusion-related myonecrosis

The potential elements involved in reperfusion-related myonecrosis are numerous, complex, interrelated, and incompletely understood. The leukocyte, endothelial cell, platelet, cytokines, free radicals, Ca^{2+}, and other factors all may be involved in a complex and interconnected way.

The polymorphonuclear leukocyte (PMN) is sequestered in the reperfused region shortly after reestablishment of flow by the action of specific adhesion molecules that allow for adherence of the PMN to the endothelial cell and subsequent diapedesis into the interstitial space.[98] Deleterious effects of these PMNs include release of lysosomal enzymes and free radicals, which cause both myocyte and endothelial cell damage, and direct plugging of the microvasculature.

Free radical production occurs from sequestered PMNs and also from endothelial cells on reperfusion,[99] resulting in both muscle and microvascular injury.[87] Experiments demonstrating that inhibition of free radical formation limits infarct size support this as a potential mechanism but do not identify the source of radical formation directly.

Clinical relevance of reperfusion-related myonecrosis in cardiopulmonary resuscitation

Since the existence of reperfusion-related myonecrosis is itself controversial, its relevance to cardiac arrest and CPR is tenuous indeed. Nevertheless, to the extent that reperfusion-related myonecrosis may be important, therapeutic strategies that are currently being designed and tested in animal models may be appropriate potential therapies in the setting of prolonged CPR. These include antineutrophil therapies designed to interfere with neutrophil sequestration in reperfused myocardium and inhibition of free radical formation.

Summary

Cardiac arrest and CPR provide a setting in which reperfusion injury can occur (Fig. 14.6). Relatively brief episodes of ischemia lasting less than 10 to 20 minutes followed by reperfusion are probably relatively common and may be regional or global, depending on the time between circulatory collapse and initiation of CPR, the adequacy of CPR in restoring coronary blood flow, the presence of coronary stenoses, the time to recovery of spontaneous circulation and normal hemodynamics, and the pharmacologic agents administered.

Durations of ischemia in this range can be followed by two types of reperfusion injury, myocardial stunning and

Fig. 14.6. The course of CPR and associated events potentially associated with reperfusion injury. *CBF,* coronary blood flow; ROSC, re turn of spontaneous circulation.

reperfusion arrhythmias. One common mechanism underlying the functional and electrophysiologic derangements in these two types of reperfusion injury is altered Ca^{2+} homeostasis. The transient Ca^{2+} overload that characterizes ischemia and reperfusion is related to the rise in intracellular Na^+ that occurs secondary to inhibition of the sarcolemmal Na–K ATPase pump and to intracellular acidosis with subsequent Na–H exchange that occurs during ischemia. On reperfusion the rise in intracellular Na^+ results in a rise in intracellular Ca^+ as Na^+ is extruded in exchange for Ca^+ via the Na–Ca exchanger. This transient rise in intracellular Ca^{2+} leads to longer-lasting derangements in the functional and electrophysiologic properties of the cardiac myocytes by as yet undermined mechanisms, perhaps involving alteration of myofilament or membrane proteins through activation of protein kinases. As a result, reperfusion after brief ischemic periods can result in prolonged cardiac dysfunction and a dispersion of refractoriness, which lead to myocardial stunning and re-entrant reperfusion arrhythmias.

Other mechanisms of stunning and reperfusion arrhythmias may exist, such as free radical injury. Although experimental support for the importance of free radical–mediated injury in animal models of stunning is strong, the relationship of free radical generation to reperfusion arrhythmias is less clear.

Whether more prolonged ischemia can lead to reperfusion-related myonecrosis and whether this is really applicable to the setting of cardiac arrest and CPR are more difficult to assess.

Current therapeutic considerations center around recognition and treatment of the potentially prolonged dysfunction that may occur in stunned myocardium and the important discrimination of stunned from irreversibly injured heart. Pharmacologic and mechanical support of the postresuscitation stunned heart can be protracted but ultimately can be rewarded with improved functional survival. Re-entry is probably the most common mechanism for reperfusion arrhythmias, which appear to be appropriately treated with currently recommended agents.

Future therapies will attempt to prevent or minimize reperfusion injury. Altered Ca^{2+} homeostasis may be prevented by limiting the entry of intracellular Na^+ during ischemia or reversing the effects of intracellular Ca^{2+} accumulation on target proteins and subcellular structures once these are identified. Restriction of the effects of such agents to injured tissue may be the biggest challenge to their development. Free radical generation could be limited by treatment with free radical scavengers during CPR and for some time after return of spontaneous circulation to prevent the

functional and electrophysiologic consequences of their formation.

Conclusions

Cardiac arrest and CPR constitute a setting in which reperfusion injury in its various forms may occur. Almost nothing is directly known about myocardial reperfusion injury in this circumstance, because studies to date have been designed to model other clinical settings, such as cardiopulmonary bypass or myocardial infarction treated with thrombolytics. Nevertheless, knowledge gained from these models can be applied to cardiac arrest and CPR to speculate on how reperfusion injury might occur in this setting. Recognition of the potentially critical role that reperfusion injury may play in the course and outcome of cardiac arrest and CPR will, it is hoped, stimulate research in an area that has remained largely unexplored. Until then our speculations, although perhaps at a level just above "mere prattle," remain "without practice."

Visceral organ ischemia and reperfusion in cardiac arrest

Kevin R. Ward and Andreas W. Prengel

Department of Emergency Medicine Virginia Commonwealth University and Virginia Commonwealth University Reanimation Engineering Shock Center
Department of Anesthesiology, Critical Care Medicine and Pain Therapy, Ruhr University Hospital, Bochum, Germany

During CPR, therapy focuses primarily on restarting the arrested heart and ensuring cerebral perfusion. For the splanchnic and renal circulation, the period of CPR represents a time of very low perfusion. When vasopressors are given during CPR in order to increase vital organ perfusion, splanchnic and renal blood flow may come close to zero.[1,2]

Negovsky[3] and Safar[4] have long maintained that self-intoxication from visceral organ ischemia as a result of cardiac arrest delays or prevents full neurologic recovery and may be a secondary cause of neuronal injury. Nevertheless, the effects of visceral organ ischemia and reperfusion (I/R) on the postresuscitation syndrome, which is characterized by a systemic inflammatory response similar to that observed in other systemic inflammatory conditions such as sepsis,[5] are not fully understood.

In the non-cardiac arrest setting, the two major directions of research on visceral organ ischemia are the contribution of individual visceral organs to development of secondary organ dysfunction and multiple organ failure; and studies of visceral organ injury, surgery, or transplant-ation resulting in or requiring ischemia. This chapter reviews the mechanisms of ischemia and reperfusion injury of the visceral organs; puts them in the context of cardiac arrest, the period of resuscitation (CPR), and the postresuscitation period; and considers how visceral organ ischemia may contribute to the postresuscitation syndrome.

Splanchnic circulation

Splanchnic circulation refers to the vasculature that brings blood to and from the major abdominal organs including the liver, spleen, stomach, pancreas, and small and large intestine. The splanchnic vascular system is regarded as the major blood reservoir containing 20% to 40% of total blood volume, and making the splanchnic circulation the primary source for mobilizing blood during critical situations. While transient reduction of splanchnic perfusion may be life-saving under certain circumstances, splanchnic hypoperfusion may contribute to the pathogenesis of systemic inflammation and multiple organ dysfunction via several mechanisms, including I/R injury, increased mucosal permeability for endotoxins and bacteria, and activation of inflammatory mediators.[6]

Regardless of the organ studied, all organs share a similar complex response to oxygen deprivation from I/R. The relative contribution of ischemia versus reperfusion to the final injury is an area of great debate and is probably related to the period of initial ischemia.[7] If the ischemic insult is not severe enough to cause massive cell death resulting in organ failure, several mechanisms of injury are postulated to exist during the period of reperfusion that contribute to further damage.[8–11]. These involve complex molecular, neural, hormonal, and immunologic responses that cause secondary ischemic damage not only to the involved organ itself, but also to other organ systems (Fig. 15.1). The degree of contribution of each of these mechanisms is unknown and likely varies among organs.

Intestines

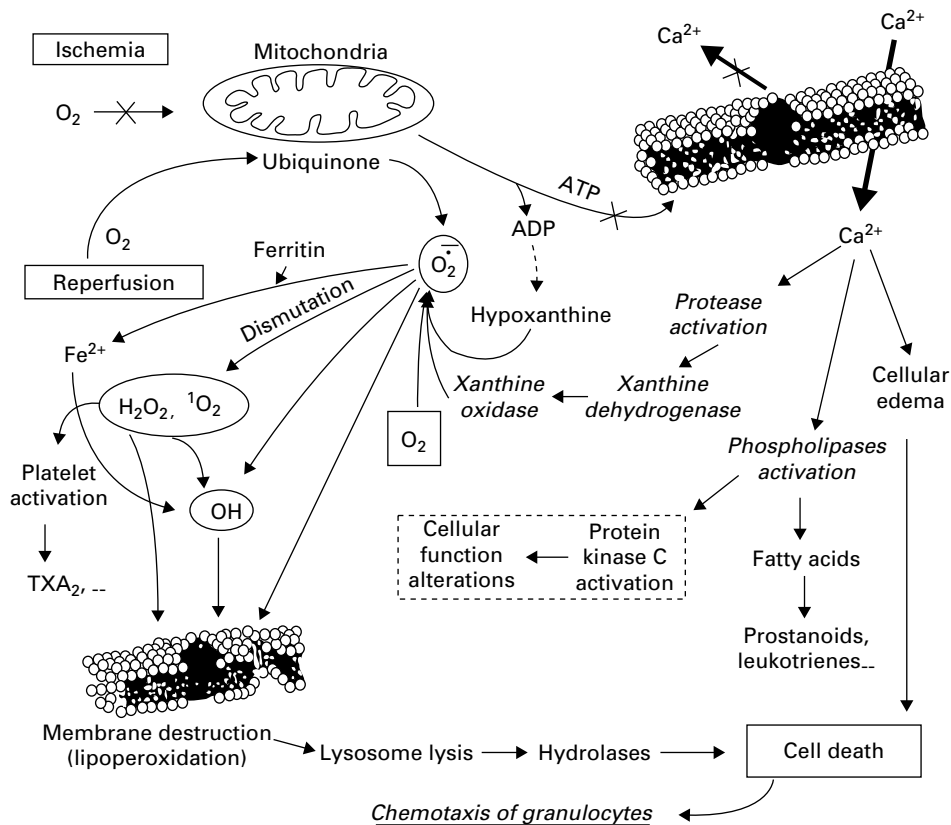
The mesenteric circulation receives 10% to 15% of the body's normal cardiac output, which provides a resting intestinal blood flow ranging between 50 and 70 ml/min/ 100 g of tissue.[12] The mucosal and submucosal layers receive about


Fig. 15.1. General scheme of biochemical events responsible for I/R cellular damage. Extent to which each of the mechanisms is responsible for damage is unknown. Complex interaction of cytokines not shown. (From Pincemail J- Biochemical alterations in ischemia and reperfusion, In Vincent, J.L., ed. Yearbook of intensive care and emergency medicine. Berlin: Springer-Verlag, 1992:104. Copyright Springer-Verlag; Gmbh & Co, KG.)

70% of this flow, and the muscularis and submucosal layers receive the rest.[12] Regulation of mesenteric flow is complex: beside metabolic and myogenic control, intricate neural and hormonal factors affect flow.[13] Activation of both neural and systemic circulating humoral vasoconstrictors results in disproportionate vasoconstriction of the splanchnic vascular bed, which, although helping to redistribute blood to the heart, brain, and kidneys, causes selective splanchnic ischemia itself.[14,15] Table 15.1 lists a number of these agents.

Of particular interest are the vasoactive peptides vasopressin and angiotensin II. Vasopressin primarily affects the splanchnic resistance vasculature, with the response being disproportionately greater than that of the systemic vasculature.[14,15] Receptors for the potent vasoconstrictor angiotensin II exist on splanchnic vascular smooth muscle. The splanchnic circulation is hypersensitive to non-pharmacologic levels of angiotensin II compared to the rest of the circulation,[12, 13] as demonstrated by studies of shock.[14, 15]

The main findings from studies of intestinal ischemia are more easily interpreted if the severity and duration of the insult to the intestine are known. Studies have revealed that oxygen extraction is maintained when flow is kept above a critical level (about 25 ml/min/per 100 g tissue).[16, 17]. Because of compensatory mechanisms, even 2-hour reductions in flow result in little or no detectable injury as long as O_2 consumption is maintained above 50% of normal.[17] When ischemic damage occurs, it begins at the villous layer of the mucosa. For any given reduction in blood flow, mucosal hypoxia is amplified because of the countercurrent exchange of oxygen at the base of the villus. This mechanism results in the villous base remaining oxygenated at the expense of the tip of the villus.[16, 18]

Few studies have examined the response of high-energy phosphates to levels of I/R and correlated them with degree of histologic damage. One study with phosphorus 31 (^{31}P) magnetic resonance spectroscopy reported complete loss of phosphocreatine and adenosine triphosphate

Table 15.1. Effects of vasoconstrictor agents on splanchnic circulation

Agent	Dose	Action*	Significance
Autonomic nervous system			
Sympathomimetics			Mediates non-selective arteriolar vasoconstriction
Norepinephrine	0.01-1.0 μg/kg/min	1	Mediates ambient arteriolar tone
Epinephrine	0.1-1.0 μg	1	(does not mediate selective vasoconstriction)
Dopamine	5-20 μg/kg/min	1	Mediates postcapillary venous vasconstriction
Sympatholytics (propranolol)	0.1 μg/kg bolus	2	Blocks ambient β-vasodilator tone
Parasympatholytics (atropine)	50 μg/kg bolus	2	Blocks ambient cholinergic vasodilator tone
Parasympathomimetics			
Physostigmine	0.15-0.9 μg/kg/min	2	Blood flow reduction 2% to muscular contraction
Vasoconstrictor peptides			
Vasopressin	0.7-50 mU/kg	1	Potent, selective, important to shock
Angiotensin II vasoconstriction	0.01-0.05 μg/kg/min	1	Very potent, highly selective, primary mediator of selective splanchnic
Gastrointestinal polypeptides			
Vasoactive intestinal peptide	1.75-175 ng/min	?2	Many act via renin release
Glucagon	50 μg/kg/hr	?	Usually a dilator; may act as a constrictor
Miscellaneous peptides			
Prolactin	0.6 μg/hr	?	Unknown
Thyrotropin releasing hormone	2 mg/kg	?	Unknown
Arachidonic acid metabolites			
Prostaglandin F_{2a}	12.5-50 μg/min	1	Potent, selective
Prostaglandin B_2	12.5-50 μg/min	1	Selective
Prostaglandin D_2	0.1-0.3 μg bolus	1	Selective
Thromboxane (U46619)	0.01-0.1 μg bolus, i.a.	?	Selective
Leukotrienes C_4 and D_4	0.3-3.0 μg bolus, i.a.	?	Selective
Indomethacin	8 mg/kg bolus	2	Blocks ambient vasodilator tone

(ATP) after 20 minutes of ischemia, with significant recovery after 60 minutes of reperfusion.[19] In contrast, direct biopsies revealed that complete ischemia reduced ATP levels to 40% of baseline after 30 minutes, with no further depletion even after 120 minutes.[20] The reasons for these discrepancies are unclear. The exact role of high-energy phosphate depletion in the final amount of tissue damage remains to be elucidated. Since studies show histologic damage within 10 minutes of ischemia and that damage is reversible after 60 minutes of complete ischemia, this suggests that high-energy phosphate loss is only one of many factors contributing to I/R injury.[16]

As with other organs, it is likely that further damage to the intestine is caused after return of blood flow and that this injury is affected, at least in part, by generation of oxygen free radicals. Nevertheless, the functional importance of the injury that occurs during reperfusion is unclear. If ischemia times are 1 hour or more, injury from the initial insult may be so severe that no further exacerbation can occur.[18] There appears to be a window of time during which reperfusion contributes to total organ damage (Fig. 15.2).

Much attention has been given to the role of xanthine oxidase in I/R injury of the intestine. The intestinal mucosa is one of the richest sources of its precursor, xanthine dehydrogenase.[9] There is no doubt that the oxidase can produce toxic free radical species, but it is unclear if these species directly harm the cell. Rather, the enzyme and the free

radicals it produces may act mainly as chemotoxins in recruiting polymorphonuclear white blood cells (PMNs) that promote the major portion of free radical damage (Fig.15.3).[9] Studies reveal that intestinal xanthine dehydrogenase is converted to the oxidase between 1 and 120 minutes of intestinal ischemia.[9, 21] Administration of allopurinol prevents reperfusion injury when given before ischemia or when reperfusion is initiated.[9,10] It was assumed that allopurinol acts by competitively inhibiting xanthine oxidase. Nevertheless, some studies indicate that allopurinol may reduce damage by acting as a free radical scavenger itself or by stabilizing mitochondrial membranes.[22]

Although lipid peroxidation by free radicals is implicated as a cause of intestinal I/R injury, it is unclear if its inhibition will prevent injury to the intestinal mucosa. In rats treated with U74389F no decrease in mucosal damage was detected.[9, 22, 23]

The role of the PMN is currently under investigation as a cause not only of injury to the intestine itself during I/R, but also of subsequent injury to distant organs.[24] PMNs are capable of producing free radicals as well as proteolytic enzymes, such as elastase, in the intestine in response to I/R. What triggers this response of PMNs already in the intestine and subsequent sequestration of additional PMNs from the systemic circulation is unclear. Free radicals produced by xanthine oxidase and lipid peroxidation as

well as substances produced by phospholipase A_2 may act as potent chemoattractants and chemoactivators of PMNs.[9,25] This influx of PMNs and release of their toxins increase microvascular permeability and dysfunction of the mucosal barrier of the intestine.[11,25, 26] The mechanisms underlying PMN adhesion in the intestine are unknown but may involve complement and the selectin family of glycoproteins. Antagonism of PMN elastase with secretory leukocyte protease inhibitor (SLPI) and inhibition of activation and adhesion with IL-1ra and tumor necrosis factor (TNF) binding protein do not prevent local intestinal injury after 60 minutes of ischemia and 4 hours of reperfusion.[25]

Activation of phospholipase A_2 in the ischemic intestine may also cause reperfusion injury.[9] When inhibitors of this enzyme, such as quinacrine and hydrocortisone, are used, some studies showed decreased damage and others showed no change.[23]

The role of nitric oxide (NO) in I/R injury of the intestine is also unclear. Exogenous sources of NO, such as nitroprusside and L-arginine, are found to reduce I/R-induced intestinal permeability. This occurs even though NO does not increase intestinal blood flow. NO may counter superoxide and reduce PMN-mediated injury.[27]

Toxic factors in the lumen are also implicated in causing intestinal injury during ischemia.[28] Hydrochloric acid, bile salts, proteases, and lipases normally secreted during digestion are likely to induce further injury to the mucosa. Studies in which the pancreatic duct is ligated or protease

inhibitors are administered intraluminally showed reduced injury to the intestine during ischemia.[28]

Bacterial overgrowth is commonly observed in states of ischemia. Under normal conditions several mechanisms keep more than 500 species of bacteria in the intestinal tract and not in the systemic circulation.[29] These mechanisms include the resident mesenteric lymph nodes and PMNs in the intestine, as well as the Kupffer cell system of the liver and the alveolar macrophage system of the lungs.[29,30] The mechanisms operate in series, and thus there are several opportunities to remove intestinal toxins before they reach the systemic circulation. Both aerobic and anaerobic species are capable of producing various toxins, with the majority of gastrointestinal infections caused by aerobic organisms. *Enterobacteriaceae* organisms release the endotoxin lipopolysaccharide, which can produce profound local and systemic effects. Despite normal defenses, intestinal ischemia is known to promote translocation of bacteria and endotoxin from the intestine to the systemic circulation.[29,31] Endotoxin can also be recovered in the peritoneal cavity, suggesting an additional mechanism of translocation. It is thought that in the early stages of ischemia, intestinal permeability increases, which allows molecules such as endotoxin (but not bacteria) to leak into the peritoneal cavity. Such endotoxins potentiate translocation of intestinal bacteria into mesenteric lymph nodes, which results in increasing levels of circulating endotoxin. These levels further raise the rate of

bacterial translocation into mesenteric lymph nodes, because they are potent activators of inflammation, which increases permeability. Endotoxin also stimulates macrophage-released cytokines. This activates PMNs to adhere to endothelium and by diapedesis and phagocytosis to detroy bacteria by lysosomal production of free radicals and non-oxidative enzymes.

The exact role of endotoxin in PMN priming is not known; indeed, it may not be needed.[32] Free radical production is usually counteracted by the scavenger superoxide dismutase (SOD) also produced by the PMN. Although this usually occurs only intracellularly at the infection site, when massive and persistent endotoxemia persists, free radical production overcomes SOD protection.[30] This in turn leads to an out of control inflammatory response in multiple organs and finally to tissue destruction and dysfunction. In the intestines, increased destruction of the mucosal barrier evolves,[29–31] which facilitates escape of bacteria directly through the damaged mucosa and through the portal vein into the liver. Injury caused by toxins, bacteria, and proteases may well depend on the extent and duration of the ischemic period. This general theory is outlined in Fig. 15.4.

Although the effects of intestinal ischemia of sufficient duration will obviously be most prominent in the intestine itself, extraintestinal consequences of such ischemia are now recognized. Ischemia insufficient to cause transmural intestinal infarction can nevertheless be devastating to other organ systems. Once the mucosal barrier is compromised, portal and systemic absorption of bacteria, endotoxins, digestive enzymes, and inflammatory mediators may take place, which is thought to be a major inciting factor leading to the systemic inflammatory response syndrome and multiple organ system dysfunction and failure. The intestines are now thought to serve as the "motor" for multiorgan dysfunction and failure in many forms of shock.[33]

Hepatic injury following intestinal I/R is characterized by acute increases in serum hepatocellular enzymes, reduction of bile flow, and PMN sequestration. After 120 minutes of intestinal ischemia followed by 60 minutes of reperfusion, hepatocytes are exposed to oxidant stress as demonstrated by increased levels of oxidized glutathione.[34] Nevertheless, lipid peroxidation products do not increase significantly despite increases in the number of PMNs, suggesting that hepatocellular injury is reversible in this setting. Moreover, sufficient intestinal I/R induces TNF and IL-1 production by the hepatic Kupffer system, which in turn activates various other mediators and PMNs.[25] Hepatocellular injury can be ameliorated by administering various free radical scavengers such as SOD and catalase. Rendering animals neutropenic or administering agents that inhibit activation and adhesion of PMNs as well as

secretion of PMN elastase also decreases intestinal I/R-produced hepatocellular damage. I/R of the intestine also impairs Kupffer cell function, which enhances the toxicity of translocated endotoxin and bacteria.[35]

Intestinal I/R also appears to be very damaging to the pulmonary system by similar mechanisms. Circulating xanthine oxidase from the ischemic intestine has been shown to mediate sequestration of PMNs in the lung after intestinal I/R. Treatment with allopurinol decreases the level of circulating enzyme and results in decreases in pulmonary PMNs.[36,37] In addition, elevated levels of cytokines, eicosanoids, and other inflammatory mediators act as potent chemoattractants for PMNs. Neutropenia before intestinal I/R and treatment with SOD, catalase (CAT), SLPI, IL-1ra, and TNFbp reduce pulmonary capillary leak.[11,25,38] With the exception of TNFbp these treatments also reduce the level of PMN sequestration in the lungs. ATP levels in pulmonary endothelium were reduced when cells were incubated with plasma from reperfused ischemic intestine, but the mechanism is currently unknown. The time of peak ATP depletion correlates with the known time sequence of peak procoagulant activity, cytokine synthesis and release, and expression of the adhesion molecules.[39] The role of endotoxin in lung injury is unclear, but the effect may be indirect.[40]

Cardiac contractile dysfunction has also been demonstrated after periods of intestinal ischemia for only 20 minutes and reperfusion for 2 hours.[41,42] Left ventricular pressure is decreased, together with a right-ward shift in the left ventricular function curve and decreased responsiveness to Ca^{2+} perfusate. Allopurinol given before I/R prevents this dysfunction, providing evidence that free radicals played some role.[43] Prior treatment with pentoxifylline, which decreases PMN adhesion, also prevents dysfunction.[43]

Different end points have been used as a measure of intestinal ischemia, ranging from morphologic changes to functional changes in mucosal and capillary permeability. One hour of local hypotension (30 to 40 mm Hg) with blood flows of 5 to 15 ml/min/100 g tissue followed by 1 hour of reperfusion results in increases in capillary perfusion but no histologic damage even in the superficial mucosa.[10,16,44]

With complete ischemia for 1 to 4 hours and 30 minutes of reperfusion, the degree of mucosal permeability and villous damage is proportional to the time of ischemia. Free radical scavengers given before treatment apparently fail to prevent the injury, which suggests that under these conditions the majority of injuries are not caused by reperfusion. Prolonged hypoperfusion with perfusion pressures of 25 to 35 mm Hg without reperfusion, however, causes villous tip necrosis, which is exacerbated by reperfusion at

normal flows and can be prevented to a large degree by free radical scavengers.[45] In an in vivo perfusion model, Chiu et al. demonstrated that although complete vascular occlusion for 1 hour produced total destruction of villi, it took 4 hours of perfusion at 5 ml/min/kg to produce the same findings. Perfusion at 15 ml/min per kg for 4 hours produced no demonstrable histologic changes.[44] Rats subjected to intestinal strangulation showed transmucosal necrosis after 4 hours. The viability of the muscularis was largely preserved with antibiotics and fluids. This integrity of the bowel wall was largely maintained, and the mucosa eventually regenerated.[46,47]

In summary, the degree of injury appears to be related in large part to the duration and completeness of the initial ischemic insult. Complete occlusion produces the most rapid injury, from increased permeability at 30 minutes to complete loss of villi at 60 minutes to transmucosal necrosis and infarction at 4 hours. After complete ischemia of 1 hour, administration of free radical scavengers is not effective, indicating a window of therapeutic effectiveness.[47]

The recovery of intestinal mucosa after an ischemic injury is remarkable. After 45 to 60 minutes of complete ischemia, variable mucosal repair occurs within 3 hours of reperfusion, with only rare defects remaining at 24 hours. At 90 minutes of ischemia, mucosal repair at 18 hours is complete. No visual histologic difference from controls exists. Mucosal reconstitution takes place by migration of nearby mucosal cells to cover mucosal defects.[16,44,46,47]

Liver

Blood flow to the liver is supplied by the hepatic arteries and portal vein. The liver is probably susceptible to ischemic injury in part because 70% of its blood is supplied by venous effluent from the gut via the portal system. The liver contains 25 to 30 ml of blood per 100 g of tissue and, therefore, 14% of the total blood volume.[35] In shock, parallel drops in both arterial and venous portal flow occur, which probably reflect selective vasoconstriction of both the hepatic and mesenteric arterial vasculature mediated largely by an increase in sensitivity to angiotensin II.

Damage to the liver parenchyma is a combination of ischemic hypoxia, free radicals, lipid peroxidation, and inflammatory mediated injury if reperfusion is restored within certain time limits. The effects of these events on such responses as production of heat shock protein and programmed cell death are being vigorously studied.[11]

During complete ischemia, ATP levels drop to 25% of normal within the first 10 minutes. After 60 minutes of ischemia, ATP levels are decreased to 5% of control with no

further decrease to 120 minutes, at which time the total adenine pool has decreased to 22% of control, and lactate levels reach 20 times control values. After 15 minutes of ischemia, followed by 120 minutes of reperfusion, ATP and lactate levels return to normal. After 60 minutes of ischemia, lactate levels are normalized after 120 minutes of reperfusion, but ATP levels are not completely restored. After 120 minutes of ischemia and 120 minutes of reperfusion, lactate levels decrease but do not normalize, and ATP levels only increase to 17% of control values.[48, 49]

The role of Ca^{2+} in I/R hepatic injury has been clearly demonstrated by marked reductions in hepatic I/R damage after administration of various Ca^{2+} channel blockers such as verapamil and diltiazem during warm I/R.[50] The exact mechanisms for this are unknown but probably involve a combination of blocking of Ca^{2+} channels that leads to a reduction in protease activation and free radical production, and to vasodilatory effects that improve reperfusion flow.

Large contributions to liver I/R injury are thought to be made by free radicals produced within the liver itself from hepatocytes, Kupffer cells, neutrophils, and the endothelium. Regardless of the source, evidence that free radicals cause damage is in part based on observations that glutathione (GSH), which is particularly abundant in the liver, is reduced during I/R. If GSH is experimentally depleted before I/R, hepatic damage is greatly exacerbated and products of lipid peroxidation are increased.[51]

In common with other organs, the molecular source of these free radicals has been debated. With loss of ATP during ischemia, these free radicals are thought to be produced from the activity of xanthine oxidase, although the rate of xanthine dehydrogenase conversion to the oxidase varies. In one study, up to 60 minutes of ischemia was necessary for conversion of 50% of the dehydrogenase to the oxidase.[52] Other investigators have found even smaller rates of conversion, raising the question of the importance of xanthine oxidase as a cause of hepatic cellular injury.[53] If indeed xanthine oxidase is produced in the liver and released, it might cause system injury by contributing to local PMN-induced injury and injury to distant organs.[9,10,36] Regardless of the source, administration of various free radical scavengers such as SOD and α-tocopherol decreases I/R hepatic damage, giving additional evidence that these reactive oxygen species are responsible in part for some of the hepatic damage and dysfunction caused by I/R.[54]

Lipid peroxidation occurs in the liver in response to I/R, as demonstrated by increases in products of lipid peroxidation.[55] These changes are ameliorated by administration of substances known to reduce lipid peroxidation such as α-tocopherol.[55] The total contribution of lipid peroxidation to the final damage is unknown.

PMNs, Kupffer cells, and the inflammatory mediator eicosanoids, peptide cytokines, platelet activating factor (PAF), and complement all appear to play a major role in hepatic I/R injury and are intricately related.[56,57] It is unclear whether they cause injury to the hepatocyte directly or via microcirculatory damage. It appears that I/R primes Kupffer cell-induced oxidant stress and also primes Kupffer cells and PMNs for increased production of oxygen free radicals by activation of the complement system.[57] PMN infiltration and adhesion in the liver also are apparently mediated by the complement system rather than the CD-18 mechanism since blockade of CD-18 receptor does not result in decreased neutrophil adhesion.[58] Complement depletion results in significantly fewer hepatic PMNs during I/R.[57] Superoxide radicals produced during I/R have also been shown to be responsible for PMN accumulation.[56] The damage done by PMNs in the liver is likely due to a combination of free radical and protease production and plugging of the microvasculature.[59]

PAF produced by Kupffer cells during I/R appears to be responsible for much of the late-phase hepatocellular damage by its ability to attract and activate PMNs. Endotoxin from intestinal I/R is thought to have a similar effect.[60]

Peptide cytokines, probably produced by I/R-activated Kupffer cells, are also likely to play a role in hepatic I/R injury. After 60 minutes of ischemia followed by reperfusion, TNF was produced and reached peak levels after 30 minutes. IL-6 was also detected, independent of TNF. Administration of TNF antiserum decreased hepatic damage from I/R.[61] TNF is known to cause production of PAF by Kupffer cells. The presence of endotoxin is not necessary for production of liver TNF.[61]

Irrespective of the degree of damage imposed by the above mechanisms, all affect the microcirculation. Whereas 60 minutes of flow-controlled reperfusion significantly reduces hepatocellular damage, pressure-controlled reperfusion causes massive cell death. By microscopic visualization, fewer sinusoids conducted flow during the pressure-controlled method, which depends entirely on intrahepatic vascular resistance. Thus reperfusion injury may simply represent more ongoing ischemia.[59]

The function of the reticular endothelium system is also greatly affected by ischemic injury; in the liver, hypoxia and acidosis can reduce clearance by this system by 20% to 25%.[35] This is important because the liver clears the portal vein, which drains the intestines. Since velocity of blood flow and tissue perfusion are inversely related to reticular endothelial system function, some injury other than hypoperfusion is at least partially responsible for

its dysfunction. Depression of the reticular endothelial system in hepatic ischemia is probably multifactorial. Epinephrine, norepinephrine, angiotensin II, vasopressin, and cholinergic and histamine antagonists all decrease the phagocytic function of the system. Hepatic ischemia itself, depletion of opsonic glycoprotein fibronectin, and release of a reticular endothelial system depressant factor from other splanchnic sites have also been implicated.[35]

I/R injury to the liver is also thought to effect injury to distant organs, including the lung and heart. Several models have demonstrated that I/R of the liver itself of 60 minutes' duration can produce cardiac dysfunction,[60] possibly by mechanisms similar to those of the intestine. The lungs are also damaged by hepatic I/R injury, and this damage is likely to be mediated through PMN activation by a variety of mechanisms, such as production of TNF and PAF. [62,63]

The exact limits of hepatic ischemia are unknown and probably depend on whether other organ systems are concomitantly injured. In isolated hepatic ischemia of 30 minutes followed by reperfusion, no hepatic cell necrosis is detected at 24 hours. If ischemia is extended to 60 and 90 minutes, focal necrosis is seen, but the majority of the hepatocytes are intact. After 2 to 3 hours of complete ischemia, more than two-thirds of the liver is necrotic at 24 hours.[35,59] Hepatic parenchymal cells can regenerate via mitosis if not severely damaged.[35]

Pancreas

The mechanism of pancreatic I/R is much less clear than that of the intestines, liver, and kidney. As an exocrine and endocrine organ, even the structure of its microcirculation is controversial. The pancreas comprises about 98% acini by weight, which receive up to 90% of blood flow, whereas the remaining 10% of flow is directed to the islet system. The magnitude of total pancreatic flow (40 to 120 ml/min per 100 g tissue) is similar to that of the other splanchnic organs.[35,63] Blood flow and oxygen consumption of the pancreas are under complex neurohormonal control: blood flow can be severely reduced with vasoactive agents such as epinephrine, norepinephrine, dopamine, vasopressin, and angiotensin II.[13]

In models of hemorrhagic and endotoxic shock, the pancreas becomes disproportionately hypoperfused compared to other splanchnic organs, but it appears to be quite resistant to isolated ischemia per se for up to 1 hour. Hypoperfusion to 20% of control values appears to be tolerated,[63] probably because the pancreas can increase oxygen extraction by metabolic and myogenic autoregulation.[35] States of hypoperfusion that affect multiple organ systems

appear to place the pancreas at greater risk for ischemia, possibly by activation of the renin-angiotensin system.[13] Nevertheless, ischemic pancreatitis is not usually included in the picture of multiorgan failure.

The exact mechanisms whereby ischemia produces pancreatic injury and the part played by reperfusion injury are unclear. Among multiple etiologies suggested as causing ischemic pancreatitis are trauma, hypovolemia, splanchnic vasoconstriction, and hypercalcemia.[35] Intracellular release of lysosomal enzymes and zymogen hydrolases may speed up necrosis. Perfusion of the isolated pancreas with a perfusate high in amylase after a period of ischemia exacerbates damage.[35,63] Some involvement of free radicals in the I/R process is suggested by studies showing a decrease in I/R damage by administration of allopurinol.[35] Pancreatic proteases are known to be capable of converting xanthine dehydrogenase to its oxidase form. Protease inhibitors such as α_1-antitrypsin are probably overwhelmed during periods of ischemia when significant leakage from damaged cell membranes occurs. Other factors, such as TNF, may increase pancreatic edema.[35]

There appears to be little doubt that, regardless of the mechanisms, the microcirculation is adversely affected. Studies reveal better pancreatic function and less damage by optimizing the rheologic properties of the blood by hemodilution with agents such as dextran 62, thereby enhancing oxygen delivery to the pancreas.[64]

I/R damage to the pancreas likely affects distant organ systems such as the heart and lung in a manner similar to other visceral organs. Of particular interest is the release of a myocardial depressant factor that is thought to be produced from a compartmentalized protein by cathepsins. Zymogen granules and lysosomes are thought to release trypsin and cathepsins in response to hypoxia; in turn, trypsin activity promotes phospholipase A, causing further release of cathepsins. This myocardial depressant factor appears to compromise cardiac output, which further jeopardizes subsequent perfusion to the visceral organs.[35,65]

Kidney

Partial or complete I/R can disrupt the homeostatic and excretory function of the kidney. Much debate exists on the extent to which components of vascular changes, tubular obstruction, and tubular cell death and necrosis itself cause ischemic renal failure.[48]

As renal perfusion is decreased, blood flow shifts from the outer cortical nephrons to the medullary nephrons. The renal cortex depends primarily on aerobic metabolism with

ketones, lactate, fatty acids, and glutamine as its primary fuel. The renal medulla, however, has a small amount of O_2-independent glycolysis,[48] as illustrated by the finding that renal cortical ATP levels fall by 65% to 75% within several minutes, whereas medullary ATP levels fall by 19% to 33% in the same period. Lactate increases up to 3.7-fold in the cortex, whereas it increases by up to 8.3% in the medulla, demonstrating the greater capacity of the medulla for anaerobic glycolysis.[48] Overall, during complete renal ischemia, ATP levels decrease to between 20% and 50% of control after 10 minutes but decline more slowly thereafter to between 13% and 30% of control after 40 minutes.

Review of the transplant literature indicates that the kidney may function normally after 60 minutes of warm ischemia followed by an additional 72 hours of cold ischemia. On final reperfusion, ATP levels are regenerated to various degrees, but these levels do not correlate closely with the total ischemic time. Consequently ATP content or adenylate charge itself at the end of the ischemic period has not been found to correlate with ultimate recovery of renal function. The ability to use ATP in critical functions after the ischemic period may be a more important indicator of post-I/R function.[66]

Mitochondrial swelling occurs at rates correlating with durations of ischemia up to 120 minutes and is attributable to increases in permeability of the inner mitochondrial membrane to electrolytes. It is reversible if ATP is added. After 2 to 4 hours of warm ischemia, however, swelling is not reversible, possibly because alterations in the phospholipid membrane increase the level of free fatty acids in mitochondria and inhibit electron transport.[48]

With loss of volume regulation by ongoing ATP depletion of the ischemic cell, free cytosolic Ca^{2+} is elevated from both extracellular and intracellular sources such as the mitochondria, and increased Ca^{2+} activates phospholipases and proteases that are involved in free radical production. Many models have shown improved renal tolerance and function to ischemia when calcium channel blockers are added before the ischemic insult or on reperfusion.[48]

With several exceptions, many studies have indicated that after 30 minutes of ischemia, xanthine dehydrogenase is converted to the oxidase in the kidney and during reperfusion as a result of sulfhydryl oxidation and Ca^{2+}-induced proteolysis and that the oxidase is an important source of the superoxide free radical.[67] The proximal tubular cells, as well as the endothelial cells, are a major source of oxidase-derived free radicals.[68] Administration of allopurinol confers protection presumably by inhibiting xanthine oxidase activity, although this has not been conclusively proven since allopurinol itself is a free radical scavenger.[69] Further, allopurinol is relatively insoluble at physiologic pH, raising doubts whether it has access to the xanthine oxidase in cells.[69]

On the basis of observations that inhibition by catalase and glutathione peroxidase causes larger increases in hydrogen peroxide production and reduced function in I/R of renal cells, it is thought that other radicals such as the hydroxyl radical also promote reperfusion injury.[68,70] Further, iron chelators such as deferoxamine have been shown to be protective, presumably by preventing hydroxyl radical formation by the Harber–Weiss reaction[68,70] The amount of damage caused by free radical–induced lipid peroxidation is unclear, but damage is decreased and function improved by administration of the 21-aminosteroid U74006F during reperfusion after 45 minutes of ischemia.[71]

The role of the PMN in renal I/R damage is less clear than that in the intestine and liver. PMNs can perturb the microcirculation by their adherence to endothelial cells and accumulation in the ascending vasa recta in the outer and inner medullas.[68,72] The addition of PMNs during perfusion of an isolated kidney after ischemia worsens functional and histologic injury. It appears, however, that these PMNs may require "priming" by such substances as lipopolysaccharide, phorbol myristate acetate, PAF, TNF, and interleukins. These primed PMNs may then be fully activated in the ischemic kidney by release of chemotactic phospholipid or other products of phospholipases, including leukotrienes or prostaglandins, that are released by the injured renal cell. Once activated, PMNs then may release free radicals, elastases, and other harmful substances that have been shown to cause significant degradation of the glomerular basement membrane. Nevertheless, some activation of unprimed PMNs within the renal parenchyma is likely to occur. These mechanisms may account in part for the high incidence of renal failure in the setting of relatively mild renal hypoperfusion.[72]

Phospholipase A_2 activity has been studied in the setting of renal I/R. Mitochondrial and microsomal phospholipase A_2 activity increases during ischemia, but cytosolic phospholipase A_2 does not. With reperfusion, phospholipase A_2 activity increases in all fractions. Since mitochondrial membranes are composed of 65% unsaturated fatty acids, they are good targets for phospholipase A_2.[73]

How all of these mechanisms affect glomerular hemodynamics is controversial. Production of eicosanoids by free radicals likely plays a role. PGE_2, $PGF_{2\alpha}$, 6-keto-$PGF_{1\alpha}$, and TXB_2 are produced by renal cells in response to exposure to free radicals and phospholipase A_2 activity resulting from Ca^{2+} influx.[74] In addition, a newly reported

non-cyclooxygenase–produced prostaglandin, 8-epi-PGF$_{2\alpha}$, has been detected after I/R in the kidney.[74] These substances may increase arteriolar resistance, with resulting decreases in glomerular ultrafiltration. Although PGI$_2$ has hemodynamic effects opposite to TXB$_2$, increases in PGI$_2$ and PGE$_2$ may cause increases in cyclic adenosine monophosphate (cAMP) within the cells of the glomeruli.[75] This in turn may stimulate renin synthesis, with local formation of angiotensin and resultant extended renal hypoperfusion, long after the initial insult. Of interest, administration of atrial natriuretic factor (ANF) may increase PGI$_2$, thus altering the TXB$_2$:PGI$_2$ ratio to favor vasodilation rather than constriction.[76]

The role of NO in renal I/R is unclear. Whereas some authors have shown that it contributes to sustained ischemic renal failure and increases PAF, others think that it may have a protective effect by reducing vasoconstriction.[68]

Although evidence for reperfusion injury appears to be overwhelming, one model has demonstrated that ischemia with intermittent reperfusion actually reduces renal functional and morphologic damage.[77]

The role of the cytokines TNF and IL-1 that are increased after I/R of the kidneys is not fully understood, but they are likely to worsen function by augmenting both production of cyclooxygenase-mediated products and PAF and PMN adhesion. They seem to have a greater effect when renal I/R is accompanied by additional concurrent organ I/R. Administration of the immunosuppressant FK 506 before I/R reduces TNF and renal damage by an as yet unknown mechanism.[78] It is likely that a combination of humoral-mediated vasoconstriction, mechanical obstruction by vascular congestion (erythrocytes and PMNs), and endothelial and tubule cell swelling (by Ca^{2+} and free radical damage) is responsible for the observed low or no-flow phenomena in the kidney after I/R.[79]

Adrenal glands

Virtually no work has been performed on the mechanisms of adrenal I/R. Adrenal dysfunction can lead to cardiovascular collapse refractory to conventional treatments and also to electrolyte imbalances.[80,81] Cortisol and catecholamines act synergistically to augment vascular tone and myocardial contractility.[80,81] The majority of shock states produce increased levels of circulating cortisol, thus demonstrating an intact hypothalamic–pituitary–adrenal axis.[82] Circulating catecholamines are also increased, which likely represents an outpouring from the adrenal gland.[82] Apparently adrenal failure caused by various

forms of shock is rare, possibly because the adrenal gland can preserve flow to itself secondary to the local action of adrenergic receptors and endogenous catecholamines on its vasculature.[83] When I/R damage occurs, it probably shares previously discussed mechanisms of damage.

Visceral organ ischemia in the context of cardiac arrest

Under the conditions of low systemic perfusion, blood flow to vital organs is maintained at the expense of the perfusion of visceral organs.[84–89] Despite a large capacity to increase oxygen extraction,[90] prolonged splanchnic ischemia results in increased mucosal permeability[91] and finally in tissue damage and necrosis. Increased mucosal permeability allows endotoxin and other bacterial products to pass through the gut wall into lymphatic and systemic circulation[92–94] and to cause injury to distant organs.[95] Multiple organ failure and death have been associated with such changes.[96, 97] Thus, long term survival after cardiac arrest is determined not only by the duration of circulatory arrest, but also by the ability to ensure adequate organ perfusion during CPR as well as during the postresuscitation phase.

While individual visceral organs can tolerate complete ischemia of 1 hour, in CPR models, the time from actual arrest to the time of beginning CPR ranges from beginning resuscitation immediately after arrest up to waiting 20 minutes thereafter.[98] Typical downtimes for models of pre-hospital cardiac arrest range from 7 to 13 minutes. The actual time of resuscitation to the point of return of spontaneous circulation (ROSC) also varies with the particular model, but the maximum time of no flow (downtime) and low flow (CPR) rarely exceeds 20 minutes before ROSC. Most models of CPR are studied within this time period in order to assess (*a*) the effects of a particular drug or CPR technique on cerebral and myocardial perfusion pressures and blood flow, (*b*) the rates of ROSC from a particular drug or CPR technique, and (*c*) the neurologic or cardiovascular function after ROSC in response to a drug or CPR technique or post-ROSC modality.

With regard to visceral organs, important factors in the context of cardiac arrest and CPR are the amount of blood flow during CPR, the impact of drug therapy during CPR on the splanchnic circulation, and possible development of systemic inflammatory response syndrome and multiorgan dysfunction similar to those of other shock states due to I/R. The most important question in this context is whether visceral organ I/R injury of cardiac arrest does affect outcome.

Visceral organ blood flow during cardiopulmonary resuscitation

Only a few cardiac arrest studies have been performed for specifically examining blood flow to visceral organs during or after CPR. Visceral organ blood flow is generally measured using radiolabeled microspheres. The technique is problematic during low flow for several reasons, the most pertinent of which is microsphere quantification. As flows get lower, the accuracy of quantifying microspheres also decreases. A minimum of 400 spheres per tissue sample is needed to achieve 95% accuracy with repetitive measurements.[99,100] This becomes a problem for visceral organs since their flow is particularly low during CPR. Dramatically increasing the number of injected spheres to achieve adequate microsphere deposition and accuracy to compensate for the low flow would increase expense and create problems in disposing of the animals after experiments because of radiation concerns.

In the few cardiac arrest studies in canine and swine models reporting intestinal blood flow, the durations of no flow before CPR ranged from 0 to 10 minutes.[100,101] Baseline blood flows have been between 20 and 60 ml/min per 100g tissue; flows during standard external CPR without intervention were between 0 and 10 ml/min/100 g tissue. In efforts to enhance flow, use of interposed abdominal compression (IAC)-CPR did not increase blood flow compared to standard CPR;[102] with simultaneous compression ventilation (SCV)-CPR, however, intestinal blood flow was significantly increased when the abdomen was bound and no epinephrine was given, but it decreased to standard CPR levels over time. With SCV-CPR without abdominal binding but with standard dose epinephrine no significant increase in intestinal blood flow occurs.[103] When SCV-CPR is combined with abdominal binding and epinephrine, no increase in intestinal flow over standard CPR is seen,[101] nor is flow increased with combined standard CPR and abdominal binding.[104]

Regardless of technique, blood flow decreases over time.[104] Administration of various vasoconstrictors such as epinephrine, phenylephrine, angiotensin II, and vasopressin not only failed to increase intestinal blood flow during CPR but, depending on the study and dose, further decreased intestinal blood flow compared to CPR alone.[103,105,106]

Perhaps the most compelling evidence of the limited improvement in intestinal blood flow during CPR is provided by studies by Linder *et al.* on the effects of vasopressin on organ blood flow during CPR.[105] In a 4-minute swine model of ventricular fibrillation cardiac arrest, open chest CPR only produced intestinal blood flows between 2 and 26 ml/min per 100 g tissue. Administration of epinephrine, 0.045 mg/kg, with continued internal massage did not increase blood flow. Administration of vasopressin, which increased blood flow to brain, heart, and kidney, resulted in significantly decreased blood flow to almost non-detectable levels in the small intestine.

In a closed chest cardiac arrest model in swine, after 3 minutes of CPR, blood flow to the small intestine was approximately 10 ml/min per 100 g during CPR before drug administration, and did not change after administration of epinephrine 0. 2 mg/kg. After administration of different doses of vasopressin (0.2, 0.4, or 0. 8 U/kg), intestinal blood flow was below 1 ml/min per 100 g tissue.[107]

The level of intestinal blood flow in the postresuscitation period has been investigated in only a small number of studies. Among factors likely to affect blood flow are pre-existing intestinal disease, length of arrest, amount and type of vasopressors used during CPR, and the state of the cardiovascular status on ROSC. In one study designed specifically to examine splanchnic and renal blood flow after CPR with epinephrine and vasopressin in pigs, blood flow to the small intestines was measured with radiolabeled microspheres and was not significantly impaired after 30, 90, and 240 minutes after CPR in comparison to pre-arrest control values.[108] In another study in pigs, blood flow through the superior mesenteric artery was measured with an ultrasound flow probe. After CPR, including the administration of either epinephrine 0.045 mg/kg, or vasopressin 0. 4 U/kg, superior mesenteric artery blood flow was significantly lower after vasopressin compared with epinephrine at 5 minutes after ROSC (332 vs. 1087 ml/min), and at 15 minutes after ROSC (450 vs. 1130 ml/min).[109]

Only a few measurements of liver blood flow during CPR have been reported.[101,103,104,108,110] Baseline flows in these studies range between 40 and 50 ml/min per 100 g tissue, compared with between 0.1 and 10 ml/min per 100 g tissue during CPR. SVC-CPR with or without abdominal binding and epinephrine failed to increase hepatic artery blood flow compared to standard CPR.[101,103] Standard CPR with abdominal binding also did not increase hepatic blood flow.[103]

Postresuscitation hepatic blood flows after a 5-minute arrest without epinephrine were not depressed from baseline, whereas with longer periods of arrest, hepatic flows were significantly lower than prearrest baseline.[111] When hepatic blood flow was measured by means of a constant infusion of indocyanine green[108] or with a hepatic artery ultrasound flow probe[109] after 4 minutes of cardiac arrest, postresuscitation blood flow was not significantly different in animals that received epinephrine 0.045 mg/kg or vasopressin 0. 4 U/kg.

Pancreatic blood flow during CPR, including IAC- or SVC-CPR, has been measured to be, for all practical purposes, zero.[101–103,112] Postresuscitation flows are significantly decreased from prearrest baselines after only 5 minutes of arrest without epinephrine administration.[110,111] With administration of vasopressors during CPR, pancreatic blood flow at 30 minutes after CPR is reduced by 50% with epinephrine, and by 70% with vasopressin, respectively.[108] It is not known whether postresuscitation blood flow is sufficient to meet the organ's demand.

In contrast to the other visceral organs studied, where blood flow is further reduced by administration of vasopressors during CPR, blood flow to the adrenal glands is increased. Adrenal blood flows during normal sinus rhythm have been measured to be between 140 and 500 ml/min/per 100 g tissue,[83,102,108] and during CPR, flow decreased to between 5 and 128 ml/min per 100 g tissue. In a swine model of cardiac arrest, however, administration of epinephrine or angiotensin during CPR increased blood flow to normal sinus rhythm baseline;[83] administration of both agents decreased CPR blood flow to 50 ml/min per 100 g tissue. Simultaneously measured renal blood flows were very low during CPR and were further reduced after administration of epinephrine or angiotensin II or both agents. In a pig model of CPR, both vasopressin and epinephrine produced significantly higher medullary and cortical adrenal gland perfusion during CPR than did a saline placebo, but vasopressin resulted in significantly higher medullary adrenal gland blood flow when compared with epinephrine.[113] On ROSC, adrenal blood flow was substantially higher than in baseline controls despite lower than normal renal flows.[108] Thus, adrenal blood flow seems to be preserved during CPR with and without use of vasopressor drugs.

Renal blood flow during closed chest CPR of various durations without any vasopressors is between zero and 75 ml/min per 100 g of tissue as determined in both dogs and swine,[99,103,104,106,112,114–116] compared with baseline flows between 50 and 500 ml/min per 100 g of tissue. In all studies the flows produced by CPR are far below that required to meet the oxygen requirements of the kidney. IAC-CPR, vest CPR, and standard CPR with abdominal binding also failed to increase renal blood flow significantly compared to baseline CPR.[101–104,117] SVC-CPR performed with abdominal binding and without epinephrine administration[103] did show some increase in flow, but after 20 minutes flow returned to levels equivalent to standard CPR. Active compression-decompression CPR has been shown to increase renal blood flow over standard CPR, but downtimes in this study were very short. It is unclear

how long these increases can be sustained and whether these levels will prevent damage.[118]

Studies with various doses of vasopressors including epinephrine, angiotensin II, and vasopressin revealed that renal blood flow is significantly decreased or unchanged compared to CPR alone.[2, 106, 114–116, 119, 120] Linder *et al.* examined blood flows in a swine model of open chest CPR in the presence of angiotensin II and vasopressin.[105, 120] Baseline renal blood flow was 190 ± 77 ml/min per 100 g of tissue. With open chest CPR after 4 minutes of cardiac arrest, renal flows were reduced to between 17 and 25 ml/min per 100 g of tissue. When angiotensin was administered, renal blood flow decreased to 4. 6 ml/min per 100 g of tissue after 90 seconds and further decreased to 1.1 ml/min per 100 g of tissue after 5 minutes. When standard dose epinephrine was given, renal blood flow decreased from 17 ml/min/ 100 g of tissue to 14 ml/min per 100 g of tissue 90 seconds after drug administration and further decreased to 8 ml/min per 100 g of tissue. With vasopressin, blood flow decreased from 24 ml/min/per 100 g of tissue to between 14 and 19 ml/min/per 100 g of tissue 90 seconds after drug administration but increased to 34 to 40 ml/min/per 100 g of tissue 5 minutes after administration. Of note, these measurements were made during open chest CPR, which is a superior mode of reperfusion.

Few data exist on the postresuscitation renal blood flows after cardiac arrest. With prearrest baselines of 170 to 265 ml/min per 100 g of tissue and arrest times of 10 minutes, postresuscitation blood flows measured at 5 and 15 minutes after ROSC ranged from 17 to 90 ml/min per 100 g of tissue.[83, 100, 119] With arrest times of 4 minutes and administration of epinephrine 0.045 mg/kg, or vasopressin 0.4 U/kg, renal blood flow in pigs ranged from 450 ml/min per 100 g of tissue in control animals to 370 ml/min per 100 g (vasopressin), and 300 ml/min per 100 g (epinephrine) at 30 minutes after ROSC.[108] With arrest times of 5 minutes without vasopressors, post-ROSC renal flow is not depressed.[111]

On the basis of the available data, it does not appear that blood flow to the intestines, liver, pancreas, and kidney can be sufficiently increased by current CPR techniques and vasopressors. Current efforts to improve myocardial and cerebral blood flow with high doses of vasopressor agents will likely further reduce flow to these organs during CPR. Even open chest CPR appears to produce blood flows below those needed to reverse ischemia, especially if the descending aorta is cross-clamped.[2,120] Since with isolated visceral organ ischemia, most organs are tolerant for up to 60 minutes of warm ischemia, it does not appear that increasing visceral organ blood flow during CPR would be advantageous. It is probably more valuable

to use techniques that shorten the duration of ischemia before ROSC, thus restoring visceral organ blood flow as soon as possible, even if these techniques further reduce visceral organ blood flow during CPR. The exception to this may be the use of pharmacologic agents that increase cerebral and myocardial blood flow at the expense of visceral flow after ROSC.

To summarize, the period of arrest before institution of CPR represents a time of complete ischemia. The period of CPR with or without administration of vasopressors represents a time of extremely low perfusion. Flows to the visceral organs during CPR, especially the intestines, liver, and pancreas, are likely to be close to zero for the most part, especially if vasopressors are needed. The ability to increase oxygen extraction in such extreme conditions is likely to be unhelpful during arrest and CPR since oxygen delivery to these organs is close to zero. The period of CPR should probably be considered additional complete ischemia time for the visceral organs.

In models of isolated visceral organ ischemia, organs experience periods of reduced flow on reperfusion for various reasons, but which may be largely the result of reperfusion injury. The time course for this decrease in flow during reperfusion has not been clearly delineated for each organ. In the limited reports of arrest times of 10 minutes, it appears that post-ROSC blood flow to all visceral organs except the adrenal glands is reduced. Whether there are periods of heterogeneous no-flow or very low flow in areas within the individual visceral organs on reperfusion after ROSC is not known.[121,122] The need for post-ROSC vasopressors and the body's natural response to shunt blood from the visceral organs to preserve flow to the heart and brain, however, may account for most of the decreases in post-ROSC blood flow to the visceral organs, rather than actual reperfusion injury in each individual visceral organ tissue bed. Recent clinical studies on global body oxygen delivery and consumption measured using lactate levels and mixed venous blood gas indicate that blood flow is not sufficient.[123,124]

It has been well documented in animals and humans that endogenous levels of epinephrine, norepinephrine, angiotensin, and vasopressin are all elevated during CPR and in the post-ROSC period.[125–127] Although these levels may not correlate with post-ROSC blood pressure or heart rate, the visceral organ vasculature is hypersensitive to these elevated endogenous levels, which may exacerbate microvasculature failure and increase I/R damage by jeopardizing oxygen delivery (DO_2) and oxygen consumption (VO_2). Further visceral organ I/R might be expected with the addition of exogenous vasopressors to maintain blood pressure.

Visceral organ damage from cardiac arrest

Organ dysfunction may cause considerable mortality and morbidity after restoration of spontaneous circulation. It was not until Cerchiari *et al.* examined the effects of visceral organ damage from cardiac arrest and CPR on neurologic outcome that there was any systematic attempt to examine visceral organ function after cardiac arrest.[128] This study was performed on dogs placed in arrest for periods of 7.5, 10, and 12.5 minutes. After resuscitation, all animals received standard postresuscitation intensive care and had various visceral organ functions as well as neurologic measures assessed up to 72 hours. Transient visceral organ dysfunctions were found in all groups, with most functions returning to normal over time. Although trends were noted, no correlations existed among arrest times, visceral dysfunction, and neurologic outcome.

Intestines

When systematically examined in the canine model of cardiac arrest with complete ischemia times of 7.5, 10.0, and 12.5 minutes devised by Cerchiari *et al.*, no alteration in cerebral outcome could be attributed to intestinal ischemia.[128] Each group contained 13 dogs. Despite negative blood cultures before arrest, all but five dogs at 6 hours after ROSC and all but two dogs at 24 hours after resuscitation had positive blood cultures. At 6 hours after ROSC, cultures were generally positive for a single organism whereas multiple organisms were found at 72 hours. Most organisms were enteric aerobic gram-negative bacilli, of which *Enterobacter* was the most common. When poor neurologic outcomes did occur in these animals, sepsis caused by bacteremia was not present. Histopathology of these animals 72 hours after ROSC revealed diffuse petechial hemorrhages in the mesentery and intestinal serosa in only one of nine animals arrested for 7.5 minutes and three of nine animals arrested for 12.5 minutes.

Although ulceration, intractable acidosis of intestinal origin, bloody diarrhea, and sepsis have been reported in the post-ROSC period, this does not appear to be a uniform problem.[124,129] Only one human study has specifically examined the incidence of intestinal dysfunction and failure as exemplified by bacteremia and diarrhea after cardiac arrest.[130] In this study, of 39 patients resuscitated from out-of-hospital arrest, 12 had fetid diarrhea several hours after admission and subsequently developed bacteremia with positive blood cultures for enteric organisms, including streptoccocus D, *Escherichia coli, Pseudomonas aeruginosa, Acinetobacter*, and *Enterobacter*, which were

also recovered from the stool. Interestingly, the average dose of epinephrine given during the resuscitation did not differ between bacteremic and non-bacteremic groups (mean dose range, 9 to 13 mg). Both groups had similar CPR times of 6 minutes, but no estimate of downtimes before CPR was given. Although all patients who developed diarrhea died, none of these patients was thought to have died from sepsis. The results clearly provided evidence of ischemia-induced bacterial translocation. No comment was made, however, about the hemodynamic course and use of vasopressors in both groups after ROSC; therefore, it is difficult to know why some but not all patients developed diarrhea and bacteremia. In another study, gastrointestinal hemorrhage after in-hospital cardiac arrest was reported: [129] of 63 patients 25 developed some type of upper or lower gastrointestinal hemorrhage. These complications were not associated with increased mortality.

Liver

In the same canine ventricular fibrillation cardiac arrest model of Cerchiari *et al.*, no permanent liver damage was detected histopathologically 72 hours after cardiac arrest.[128] Hepatocyte swelling and occasional centrilobular necrosis were seen, but this was not severe enough to impair liver function. Serum bilirubin and glutamyl-transpeptidase (GTP) levels were normal throughout the postresuscitation period in all three groups. Aspartate aminotransferase (AST) was significantly elevated up to 72 hours after arrest, whereas alanine aminotransferase (ALT) was significantly elevated in all three groups only up to 24 hours after arrest, but since these enzymes are not specific for liver damage, the elevations may have been due to myocardial injury. Ammonia levels were significantly elevated at 24 hours in the 10-minute arrest group but not at 72 hours; in contrast, the 12.5-minute arrest group demonstrated significantly elevated ammonia levels only at 72 hours. Animals that regained consciousness had significantly lower ammonia levels than those that did not, although the standard deviation was high. However, there were no significant differences in neurologic outcome between arrest time groups.

Interesting patterns in the amino acid profiles were noted in this model. The branched chain amino acids were significantly increased in dogs with poor outcome but were unchanged in those with good outcome. Although the aromatic amino acids increased in both groups, they were significantly higher in those animals with poor neurologic outcome. The branched chain:aromatic amino acid ratio was worse in animals with poor outcome. None of these

patterns, however, was significantly correlated with arrest times. In addition, the authors of this study point out that liver dysfunction cannot account for all of this imbalance since the elevated levels of aromatic amino acids (metabolized by the liver) were not accompanied by decreased levels of branched chain amino acids, which are utilized by skeletal muscle. These patterns of ammonia and amino acids were not reflected by worse neurohistopathology.

Only one clinical study examined hepatic function after in-hospital cardiac arrest.[129] In this study, 18 of 63 patients had some elevation of liver function tests. However, eight of these patients were in congestive heart failure before arrest and had some elevation of liver function tests at that time. An additional smaller number were found to have passive liver congestion on autopsy. It is therefore difficult to ascribe the abnormal liver function in this study to hepatic ischemia and necrosis from the ischemic time of the cardiac arrest itself. Since animal and clinical studies suggest that livers can be successfully harvested and transplanted from donors after cardiac arrest that involved warm ischemia times from 30 to 60 minutes, complete ischemia of moderate duration cardiac arrest apparently does not impose insurmountable injury.[131]

Pancreas

No formal animal or human studies have examined pancreatic function after cardiac arrest. Clinical pancreatitis has not been reported as a common postresuscitation complication. Up to 39% of pancreatic donors who have undergone some period of ischemia have hyperamylasemia.[132] Pancreatitis secondary to ischemia is, however, extremely difficult to diagnose.

An interesting finding that may have bearing on neuronal salvaging is that insulin production by the pancreas appears to be blunted in the early postresuscitation period. Whether this is secondary to the ischemia of cardiac arrest itself or to the exogenously administered epinephrine given during CPR is not known.[133]

Kidneys

When systematically studied in the canine animal model of Cerchiari *et al.*, renal function is found to recover promptly after only transient periods of anuria and oliguria.[128] Histopathologic examination 72 hours after cardiac arrest in this model revealed scattered renal infarcts that were more consistent with iatrogenic emboli from indwelling catheters than ischemic insults. Blood urea nitrogen

(BUN), creatinine, serum osmolality levels, and serum electrolytes were all reported to be normal at 6 hours after resuscitation.

After CPR including the administration of vasopressors, in the postresuscitation phase neither urinary output nor calculated renal function indices differed significantly between animals after having received epinephrine or vasopressin.[109] Calculated glomerular filtration showed no difference between groups and calculated fractional excretion of sodium was elevated in both groups at 60 minutes after ROSC, with an ongoing elevation in the vasopressin group for 2 hours after ROSC. Relationship of osmolarity between urine and plasma was not impaired at any time point during the postresuscitation phase. In summary, with respect to renal blood flow and renal function after ROSC, there was no significant difference between either vasopressor given during CPR.

Only one study to date has specifically examined the prevalence of acute renal failure in humans following CPR;[134] 30% of patients who were resuscitated from in-hospital cardiac arrest developed acute renal failure. Analysis revealed that the group developing acute renal failure had a significantly longer duration of actual CPR (12 minutes vs. 7 minutes), although the estimated downtime before institution of CPR was not reported. It was also found that the group developing acute renal failure received larger doses of epinephrine (1.8 mg vs. 0.9 mg) and the frequency of preexisting congestive heart failure, coronary artery disease, and compromised renal function was significantly higher in this group. As expected, the group with acute renal failure had significantly worse long-term survival compared to the group without such failure (6.3% vs. 47.5%). More patients who recovered renal function had cardiac arrest secondary to ventricular fibrillation than did those who developed renal failure. The report does not mention which patients required post-ROSC vasopressor blood pressure support or what measures were taken to avoid postarrest renal failure. No study has reported post-ROSC electrolyte disturbances that could be attributed to renal I/R.

In contrast to the intestines and liver, preexisting renal insufficiency is common in cardiac arrest patients and thus is likely to affect renal outcome after arrest. Volume status and renal function are normal in virtually all current animal models of cardiac arrest, thus making these factors, which are common in the clinical setting, difficult to study experimentally unless altered by design.

Many examples exist in which kidneys have been successfully harvested and transplanted from non-resuscitated donors after cardiac arrest times approaching 60 minutes.[135] It appears therefore that complete ischemia from cardiac arrest of moderate duration does not impose an insurmountable insult to the kidneys if they were not significantly impaired before arrest

Adrenal gland

Adrenal function during cardiac arrest has recently been evaluated in both the laboratory and clinical settings. One study found that cortisol concentrations in human victims of cardiac arrest were lower than those reported in other stress states.[82] In this study there was an apparent association between cortisol levels and at least short-term survival from cardiac arrest. Increases in cortisol levels were observed by 6 hours after ROSC but not at 24 hours. Adrenocorticotropic hormone (ACTH) levels were increased, but they decreased 6 hours after ROSC. There was no significant response to cosyntropin stimulation at 6 and 24 hours, suggesting that low levels of cortisol may represent primary adrenal dysfunction, the etiology of which is unclear. Interestingly, increased levels of cortisol have been found in dying intensive care unit (ICU) patients and in patients who suffered cardiac arrest in the ICU and underwent immediate CPR.[136] In cases of sudden cardiac death, it is unlikely that cortisol levels would be increased before arrest. Even if the adrenal gland were capable of responding during CPR it is possible that the volume of distribution of the cortisol is too low, secondary to the low flow of CPR, and thus any advantage it would impose on the catecholamine response, for example, would be lost. Nevertheless, secondary causes of cardiac arrest may be preceded with stress states, such as cardiogenic shock or sepsis, in which the adrenal gland increases cortisol production and flow is sufficient to distribute it. In the study by Schultz *et al.*, patients achieving ROSC tended to have higher cortisol levels,[82] as well as shorter arrest times, and more presented in pulseless electrical activity. Therefore the underlying etiology of the arrest may affect adrenal function and vice versa. Despite ROSC, many individuals did not achieve cortisol levels greater than 30 μg/dl in this stressful state, thus indicating some ongoing adrenal dysfunction after ROSC, possibly secondary to I/R damage caused by the prolonged downtimes and resuscitation times. Again no significant response to cosyntropin stimulation at 6 or 24 hours indicated some primary adrenal dysfunction, possibly in the form of a "stunned" adrenal cortex.

In a pig model of cardiac arrest including the administration of epinephrine 0.045 mg/kg or vasopressin 0.4 U/kg during CPR, ACTH and cortisol plasma concentrations were measured before arrest, during CPR before drug

administration, and at 90 seconds and 5 minutes after drug administration.[137] ACTH and cortisol concentrations remained unchanged in epinephrine-treated animals, but increased significantly after administration of vasopressin and were significantly higher (12.5 μg/dl) than in epinephrine-treated animals 5 minutes after drug administration (5.5 μg/dl). Vasopressin is a potent stimulus for ACTH secretion during CPR. The increased plasma cortisol concentrations caused by the enhanced ACTH release after vasopressin may be one factor contributing to the improved outcome repeatedly observed with vasopressin in animal models of CPR.

Future models of cardiac arrest examining visceral organ I/R may require modifications to mimic the clinical setting more closely, such as longer downtimes and resuscitation times, larger epinephrine doses, and predetermined pauses between ROSC and institution of postresuscitation intensive care.

Relationship among visceral organ I/R of cardiac arrest, systemic inflammatory response syndrome, and multisystem organ dysfunction or failure

Although no exact numbers exist, some resuscitated patients will develop multiorgan dysfunction syndrome and failure, leading to death. This has been termed the postresuscitation syndrome.

The mechanism underlying this postresuscitation disease involves a whole-body-ischemia and reperfusion syndrome, and shares many features with systemic inflammatory response syndrome (SIRS) and sepsis, including plasma cytokine elevation with dysregulated cytokine production, the presence of endotoxin in plasma, coagulation abnormalities, and adrenal dysfunction.

The SIRS and resulting organ dysfunction represent a response to injury; four general events can incite this response: infection, perfusion deficits, inflammation, and dead or injured tissue. These inciting events may overlap. Free radicals, inflammatory mediators, immunologic factors, and neurohormonal factors all play a role in SIRS and its progression to MODS. These mediators are probably produced from the visceral organs as a result of the inciting events. The SIRS response generally reaches a peak in 3 to 4 days and abates in 7 to 10 days, and the patient recovers. If SIRS continues, however, MODS develops and may eventually lead to death.[11]

Drastic increases in mortality from 40% to as much as 100% may occur after the transition of SIRS to MODS. The postresuscitation response of an organ or organism after any insult is based on multiple factors, including the severity of the initial injury, the patient's organ reserve, the time interval from insult to resuscitation, and the adequacy of resuscitation. Failure to control infection or correct perfusion deficits, for example, will convert a stable SIRS patient to one with MODS progressing to failure and death.[11]

Recently, TNF has been detected 6 hours after ROSC in patients resuscitated from cardiac arrest, indicating an inflammatory response and possible SIRS. TNF was not found in patients surviving less than 4 hours.[138] Patients surviving longer than 20 days in this study had no TNF detectable at 6 hours, although TNF did eventually appear. Patients surviving for more than 12 hours, but who died within 72 hours, had the highest levels.

In other models of shock and I/R, TNF has been found to reach a peak between 30 and 180 minutes after reperfusion.[139] The different time lags for detection of TNF between these states and the cardiac arrest study discussed above suggest that the stimulus for TNF may not be the initial ischemia time of cardiac arrest and CPR, but rather the postresuscitation course that follows ROSC. There is good evidence that derangements of oxygen delivery and consumption exist long after ROSC, and these may underlie the majority of visceral organ injuries that occur in the postresuscitation state.[123,124]

Cytokines and soluble receptors increase in the circulation as early as 3 hours after cardiac arrest. Plasma concentrations of interleukin-6 (IL-6) show greater elevations in non-survivors than in survivors and were higher in patients requiring vasopressor therapy. IL-6 and soluble TNF receptor II are closely correlated with plasma lactate concentrations, suggesting a relation among ischemia, reperfusion injury, and inflammatory responses. Elevated levels of plasma endotoxin within 2 days after successful resuscitation may be explained by translocation of endotoxin through sites of gut-wall ischemia. Increased soluble intercellular adhesion molecule-1, soluble vascular-cell adhesion molecule-1, and P and E selectins were found after successful CPR, suggesting neutrophil activation and subsequent endothelial injury in patients with SIRS, including patients after recovery from cardiac arrest, however, hyporesponsiveness of circulating leucocytes has been observed, and may allow protection against overwhelming dysregulation of the inflammatory process, but may also induce immune paralysis with an increased risk of subsequent infection.

The relationship between the SIRS progression to MODS of other shock states and that of cardiac arrest may depend on the etiology of arrest as well as postarrest events. Cardiac arrest from trauma or sepsis would likely have been preceded by some degree of SIRS. In addition, lung or

liver trauma caused by CPR, infectious foci occurring secondarily, such as catheter-related infections or sepsis, and aspiration pneumonitis might induce SIRS not due to the primary ischemia. Because of these complex relationships, it remains questionable whether the primary ischemia of cardiac arrest itself, or cofactors in the context of CPR may induce a sepsis-like syndrome after successful resuscitation from cardiac arrest.

The oxygen debt incurred during the cardiac arrest itself is not likely to represent a lethal insult in producing postresuscitation mortality and the development of multisystem organ failure. Studies of critically ill surgical patients demonstrate little or no mortality from development of multisystem organ failure when oxygen debt is less than $4100\,ml/m^2$. Mortality increases to 50% and 95% when cumulative oxygen debt is $4900\,ml/m^2$ and $5800\,ml/m^2$, respectively.[140] In contrast, for a 70-kg individual with a baseline oxygen consumption of $120\,ml/min/m^2$, a 30-minute cardiac arrest would create an oxygen debt of $3600\,ml/m^2$. Postresuscitation hemodynamic derangements may cause further accumulation of oxygen debt to more lethal ranges.

The preponderance of evidence indicates that ischemia of cardiac arrest per se may not promote a systemic inflammatory response leading to the multiorgan dysfunction syndrome of the postresuscitation syndrome unless ischemia times are extremely prolonged. Rather, it seems more likely that protracted hemodynamic derangements, many of which may be iatrogenic in nature (often from neglect), in the post-ROSC period are mainly responsible.

Treatment

Little work has been performed specifically to prevent postresuscitation visceral organ damage. Therapies should probably be aimed at reducing injury at reperfusion and at preventing further I/R injury in the postresuscitation state, keeping in mind that the majority of visceral organ injury may occur in the post-ROSC phase. Several strategies aimed at stabilizing cells, inhibiting molecularly mediated damage, correcting derangements of oxygen transport, and reducing complications of visceral organ injury will be examined.

Prevention of free radical and inflammatory mediator injury

Since primary ischemia from most cardiac arrests is less than 1 hour, there is likely to be a window of opportunity for inhibition of various molecularly mediated causes of I/R injury. Many agents have been studied with the hope of limiting damage not only to the individual visceral organ itself, but also to distant organ systems.

Many potential antioxidant therapies have been proposed because they were used to demonstrate that a particular oxidant was responsible for the injury. In numerous instances, however, this required that the antioxidant be given before the ischemic insult or at the start of reperfusion. Consequently, although the antioxidant may have proved beneficial in these cases, extrapolation to the clinical setting of cardiac arrest has numerous problems. This again relates to the concept of a window of opportunity for these therapies to be effective (Fig. 15.2). No agent has been shown to make a clinically significant difference in outcome and is in routine use. Table 15.2 lists the exogenous antioxidant agents that may be useful in limiting visceral organ I/R damage. If the postresuscitation phase of cardiac arrest is considered a period of ongoing ischemia, administration of these agents may be helpful.

If antioxidant therapy becomes a clinical reality, its use in the cardiac arrest patient will require examination of dose-response curves and timing of administration. Administration during CPR would offer no advantage before ROSC, because of the short half-lives of many of these agents and because their distribution would be limited by the low blood flow to the visceral organs. On the other hand, sufficient concentrations of antioxidants in the circulation would permit their rapid delivery to the visceral organs after ROSC. Administration of these agents to patients who are immediately at risk for sudden cardiac death, such as those who present with an evolving myocardial infarction, might be of greater benefit. If the patient arrests and is resuscitated, antioxidant therapy will then be available for maximal effect. Even if these individuals do not arrest, many will develop a protracted and difficult course of cardiogenic shock, which will produce varied degrees of visceral organ I/R injury.

Other therapies with great potential include suppressing or blocking molecular mediators of the inflammatory response that lead to organ dysfunction, for example by altering the PMN-endothelial interaction, the arachidonic acid and eicosanoid response, the peptide cytokines, PAF, complement, and NO. The role of molecular mediators as inhibitors of visceral organ ischemia from cardiac arrest is purely speculative at this time. Figure 15.5 illustrates the points of action of many of the free radical scavenging agents.

In experimental models of sepsis and ischemia-reperfusion injury, isovolemic high-volume hemofiltration by using a synthetic high-cutoff membrane removes

medium molecular-weight molecules responsible for ischemia-reperfusion injury. The potential effects of high-volume hemofiltration have been evaluated by randomizing 61 patients with out-of-hospital cardiac arrest into three groups: control patients and those with high-volume hemofiltration with or without hypothermia.[141] The 6-month survival curves of the three groups were significantly different, with better survival in the hemofiltration group and in the hemofiltration-hypothermia group. The authors of this study stated that definitive conclusions should await clinical trials in a larger cohort of survivors of cardiac arrest.

Oxygen delivery and consumption

Resuscitation of the cardiac arrest victim does not end on ROSC. It is clear from many studies examining other forms of shock that patients may remain underresuscitated for days after the initial insult. This is likely to occur for the victim of cardiac arrest in whom aggressive treatment was delayed because of concerns for neurologic viability. Measures such as heart rate, blood pressure, and urine output have clearly been shown to be poor indicators of the adequacy of resuscitation.[123,124] As discussed earlier, microcirculatory failure is likely to be protracted, making it a major factor in ongoing injury, and ultimately additional oxygen deprivation of the tissues results. Since for practical purposes, flow to the visceral organs during CPR is likely to be zero, the main factors affecting oxygen debt will be time elapsed between arrest and ROSC and post-ROSC blood flows below the level of critical oxygen delivery. The requirement of exogenous vasopressors to maintain myocardial and cerebral perfusion pressure may pose a problem since ongoing visceral I/R mediated by these vasopressors is possible.

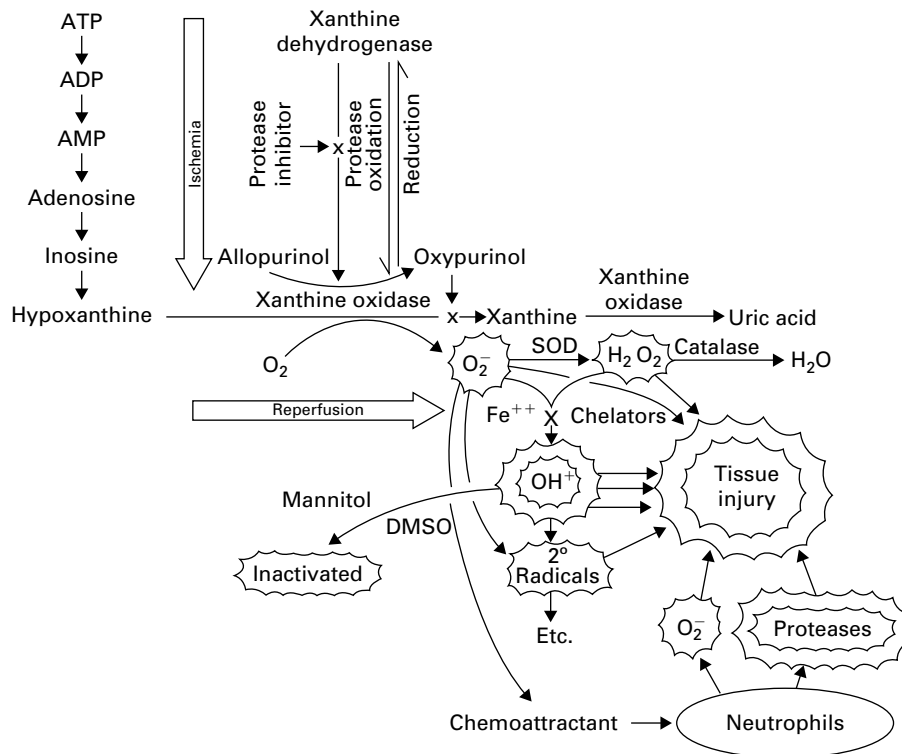
VO_2 values vary widely in critically ill patients. Certain shock states show decreases in oxygen consumption,


Fig. 15.5. Points of action (indicated by x) in free radical cascade where various scavenging agents may be effective (From Bulkley, G.B.: Mediators of splanchnic organ injury: overview and perspective. In: Marston, A., Bulkley, G.B. Fiddian-Green, R.G., Haglund, U.H., eds Splanchnic ischemia and multiple organ failure. Copyright @ 1989 by Adrian Marston, Gregory B. Bulkley, Richard, G. Fiddian-Green,Ulf H. Haglund. Reproduced by permission of Hodder & Stoughton Ltd., London.)

whereas others show higher levels. Studies reveal that survival is associated with increased levels of VO_2. It has been suggested that increasing DO_2 to levels above 600 ml/min per m^2 [140,142–144] would be helpful to overcome VO_2 defects, even though proper extraction and utilization of O_2 are not guaranteed. The exact role of this type of therapy in the postresuscitation phase of cardiac arrest is not entirely clear. In sudden cardiac death, cardiogenic shock probably predominates; however, even in this setting, postarrest cardiogenic shock is likely to be quite different from primary cardiogenic shock. Rivers *et al.* have demonstrated severe derangements in DO_2, VO_2, and oxygen extraction ratios in the postarrest state up to 6 hours after ROSC.[123] Patients receiving more than 14 mg of epinephrine showed further impairment of systemic oxygen utilization after ROSC.

Both endogenous and exogenous catecholamines, as well as the endogenous vasoactive peptides angiotensin II and vasopressin, are likely to mediate much of the VO_2 impairment that is occurring in the visceral organ

microcirculation. Studies quantifying plasma epinephrine levels during cardiac arrest have shown resting levels of 160 pmol/l, which can reach levels as high as 2 144 994 pmol/l before administration of exogenous epinephrine.[108,127] Norepinephrine levels have been found to be increased up to 90-fold after administration of epinephrine.[145] On the basis of the sensitivity of the visceral organ vasculature along with plugging of the microvasculature mediated by reperfusion, the visceral organs are at tremendous risk for VO_2 defects. VO_2 may thus be limited by constraints of diffusion, which, combined with the difficulties in increasing DO_2, put these organs at further risk.

DO_2 in the setting of postarrest cardiogenic shock is difficult to optimize. The use of catecholamines requires a delicate balance. With respect to sudden cardiac death from coronary vascular occlusion, serious consideration should be given to very early coronary angiography and angioplasty, since cardiac reserve will limit the usefulness of catecholamines in increasing cardiac index while still exerting negative effects in the visceral organs.

Intraluminal oxygenation

Part of the pathophysiology and anatomy of intestinal I/R involves injury that begins at the villous surface because of the countercurrent exchange mechanism of oxygen. This results in an early breach of the intestinal barrier to bacteria and other intestinal toxins. Since systemic perfusion to the intestine is likely to be compromised, an alternate route of O_2 via the intraluminal surface is being studied. Supplying O_2 to the intestinal lumen either by providing gaseous oxygen to the mucosa or by perfusing the lumen with oxygenated fluids has been shown in animals to prevent, in part, the development of mucosal injury.[18] Intestinal I/R-produced falls in blood pressure are significantly smaller, possibly secondary to decreased amounts of cardiotoxic substances formed and released in the intestine. In animal studies mortality has been reduced with this technique. Intraluminal oxygenation also results in increased Po_2 of the intestinal venous effluent and reduced endotoxin translocation.[18] Its ability to improve intestinal function and overall organ system function from the I/R of cardiac arrest is unclear.

Hyperbaric oxygen therapy

Theoretically the use of hyperbaric oxygen should help repay oxygen debt and reverse ongoing ischemia secondary to decreased DO_2 and VO_2. Inspiration of 100% oxygen at 3.0 atmospheres can raise PaO_2 levels to 1800 mm Hg;[146] this level dissolved in the plasma can meet the metabolic demands of the body. Areas where blood flow is intact but compromised and at risk for ischemia are supplied with O_2 because of large diffusion gradients created by nearby well-perfused areas with their high PaO_2[146]. In addition, hyperbaric oxygen has been shown to increase the deformability of red blood cells and decrease platelet aggregation, thus making their transit through debris-filled vessels easier. The end result is increased DO_2 to all areas not subject to complete vascular occlusion.

There is also evidence that hyperbaric oxygen can ameliorate reperfusion injury. In several models of I/R, hyperbaric oxygen has been shown to decrease neutrophil adherence to the endothelium, decrease lipid peroxidation, and cause increased activity of superoxide dismutase.[145,146] In addition, hyperbaric oxygen increases the ability of PMNs to kill bacteria. In theory, hyperbaric oxygen could prevent or reverse ongoing ischemia of the visceral organs, especially in the hemodynamically unstable postarrest patient who depends on vasopressors and is likely to be at risk for ongoing visceral I/R.

Intraaortic balloon pumping

Another potentially promising technique that has not been well studied is intraaortic balloon pumping. Although not proven, early use of this technique in the postresuscitation phase may reduce the requirement for vasopressors and thus decrease the incidence of vasopressor-induced visceral organ ischemia. Intraaortic balloon pumping may increase blood flow to the visceral organs as shown in one model of hemorrhagic shock.[149] Its use to decrease visceral organ I/R requires further study.

Hypothermia

Hypothermia is another potential treatment for reducing the effects of ischemia in the visceral organs. Creation of postresuscitation hypothermia has been vigorously investigated as a neuronal salvaging tactic.[150] In visceral organ ischemia, hypothermia has been studied during harvesting of organs for transplantation. Rapidly induced hypothermia in donors with recent cessation of circulation appears to extend the viability of several organs for transplantation, including the liver and kidney.[151,152] The exact mechanism by which hypothermia salvages or prevents further ischemic damage is unknown, but it may be related to slowing certain reactions that cause secondary damage at the molecular level, as well as decreasing the metabolic rate of the organ.[66,153]

Hemodilution

If disturbances in the microcirculation exist after ROSC, improving the rheologic properties of blood flow may enhance flow to ischemic organs. There appears to be little advantage in keeping hemoglobin levels above 10 g/dl.[64] Endogenous visceral organ ischemia is ongoing, taking place in the postresuscitation phase in the face of relatively normal central hemodynamics. Yano and Takori found that even after only 5 minutes of cardiac arrest without administration of vasopressors, flow to some visceral organs is decreased up to 90 minutes after arrest and that this could be prevented by hemodilution with dextran.[111] If flow to these organs can be improved by hemodilution without jeopardizing myocardial and cerebral O_2 delivery and consumption, the visceral organs may benefit. Lenov and colleagues attempted a similar hemodilution strategy to decrease postresuscitation hypoperfusion of the brain.[122] Although their attempt was successful, the hematocrit of 20 to 25% decreased oxygen content to the point that

overall DO$_2$ was not increased. Hemodilution may have its greatest benefit when coupled with other postresuscitation maneuvers such as hyperbaric oxygen therapy, whereby oxygen content can be supplemented.

Alteration of neural-humoral and hormonal response

Since the splanchnic vasculature is exquisitely sensitive to vasopressor agents, especially endogenous agents such as angiotensin II and vasopressin, temporary ablation of this response might prove beneficial.[13] In states of shock where these agents are endogenously produced at greater rates, it has been shown that the response of the splanchnic vasculature is disproportionately greater than is that of the rest of the vascular system. In models of cardiogenic shock, decreases in splanchnic blood flow occur for prolonged periods, even when the underlying cause is reversed.[154–156]

Manipulation of atrial natriuretic factor might also be beneficial. Atrial natriuretic factor is increased during cardiac arrest, possibly caused by atrial distension. Higher levels of this factor appear to blunt the pressor response to exogenously given vasopressors. Blocking the effect of the factor to increase the vasopressor response during cardiac arrest has been considered.[157] Again this must be weighed against the potentially detrimental effects on I/R damage to the visceral organs that might be incurred in the postresuscitation phase.

As previously discussed, cortisol levels may be depressed in the postresuscitation period. Supplementation of cortisol may reduce the need for potent exogenous vasopressors. One animal study demonstrated a trend toward earlier resuscitation and requirements for less epinephrine when cortisol was administered during resuscitation.[158]

Other treatments

Gut decontamination

Since ischemia may cause a breach of the intestinal barrier, selective decontamination of the gastrointestinal tract with non-absorbable antibiotics such as polymyxin, amphotericin, and tobramycin has been shown to reduce the content of gut organisms and to lower concentrations of endotoxins and cytokines.[159] It appears to lower the rate of endotoxemia and its associated complications as well as possibly reducing the incidence of nosocomial pneumonia.[160] The antibiotics work by a combination of binding lipopolysaccharide and keeping gram-negative organism concentrations in check. Other maneuvers that may aid decontamination include gut lavage with whole gut irrigation as well as early institution of enteral nutrition.[159]

Extracorporeal therapy

Several forms of extracorporeal therapy have been proposed to reduce visceral organ ischemia and its complications. Major techniques include use of activated carbon hemoperfusion and early renal dialysis. Activated carbon or charcoal hemabsorption has been proposed as an adjunct to aid in the recovery of the severely damaged ischemic liver.[161] Acute ischemic liver damage leading to hepatic failure is associated with a host of complications, including cerebral dysfunction. Charcoal can adsorb a wide range of water- and lipid-soluble molecules of size range 113 to 40 000 Da, which are both beneficial and toxic.[162] These toxic substances include, but are not limited to mercaptans, gamma-aminobutyric acid (GABA), aromatic amino acids, phenols, and other false transmitters.[161] Hemoperfusion is also capable of removing and reducing certain bacterial species such as *E. coli* and *P. aeruginosa*, as well as endotoxins.[163] The liver is responsible for removing many toxins in addition to breaking down and maintaining plasma amino acid levels within a physiologic range and clearing bacteria and endotoxin. Since many of these functions are compromised after an ischemic insult, methods to reduce the work load of the liver may be helpful.

To date, only two studies have examined the value of charcoal hemoperfusion after cardiac arrest: one showed no improvement, and the other was only minimally helpful.[162,164] Both models used cardiac arrest times between 10 and 15 minutes. In the most recent of the two studies, dogs were in arrest between 12.5 and 15 minutes.[162] Despite significant decreases in the concentrations of aromatic amino acids, the overall neurologic outcome of animals receiving charcoal hemoperfusion was no better than in controls. Aromatic amino acids increased after treatment was stopped. Blood cultures in both groups were positive. The authors suggest that a more prolonged trial of charcoal hemabsorption should be performed.

Indications for the use of renal hemodialysis in the postresuscitation phase of cardiac arrest are unclear. Early dialysis in some shock states apparently decreases the incidence of prolonged renal failure and its associated complications. The true incidence of postresuscitation renal failure is unknown, but it appears to be higher in patients than in animal models.[128,134]

Monitoring

Monitoring for visceral organ I/R would be helpful, but what should be monitored and when remain unclear. Obviously, aggressive resuscitation must continue immediately on ROSC, and monitoring of heart rate and blood pressure as guides to treatment response is insufficient. Monitoring of isolated organs will be difficult.

Pulmonary artery catheter monitoring

Since a large oxygen debt accumulates during cardiac arrest, the ability to repay this debt may be a major determinant of survival or progression to the postresuscitation syndrome and death. Rivers *et al.* indicate that derangements in oxygen utilization exist and are likely due to a combination of reperfusion-mediated events and catecholamine use during and after resuscitation.[123,124] In short, utilization defects are probably best recognized and corrected by invasive monitoring. Since the utilization defects are due to a combination of problems with DO_2 and VO_2, monitoring with an oximetric pulmonary artery catheter would provide the clinician with the most useful information allowing flow-dependent VO_2 to be better recognized.

Lactate

Normal arterial lactate level is considered to be less than 1.8 mEq/l. Levels greater than 2 mEq/l have been associated with increased mortality. Lactate accumulation may occur not only from increased production in ischemic tissue beds, but also from decreased hepatic oxidation. Liver failure only modestly increases the clearance time for lactate.[165]

Washout of lactate from ischemic tissue beds is usually short-lived and does not significantly affect lactate clearance. Following CPR, arterial lactate levels have been found to decrease by one-half over a period of 60 to 90 minutes if adequate perfusion is restored.[166] During circulatory shock, lactic acid clearance is significantly delayed and may require hours to normalize, which likely reflects the times involved for full reversal of the underlying cause of the tissue hypoperfusion. Unless arterial-venous lactate measurements are made across specific tissue beds, they cannot predictably pinpoint ischemia to a particular organ system.

Other peripheral measures of perfusion

Additional techniques that measure peripheral perfusion have been advocated as a means to recognize inadequate resuscitation and to guide treatment (see Chapter 38): these include measurement of transcutaneous oxygen and carbon dioxide, transconjunctival oxygen, subcutaneous oxygen, and temperature gradients between the great toe and ambient air.[167] None has been specifically correlated with visceral organ blood flow. An ideal situation would be to measure indicators of ischemia for each organ.

Local measures

Recently, D(-)-lactate stemming from bacterial overgrowth has been shown in animal models to be specific for intestinal ischemia. D(-)-Lactate is produced by bacteria indigenous to the gastrointestinal tract, including *Klebsiella, E. coli, Lactobacillus*, and *Bacteroides* species. Overproduction of D(-)-lactate coupled with breaches in the integrity of the mucosal barrier likely contributes to elevation of this product in the serum.[168] Although not tested in humans, this will probably become a valuable marker of intestinal ischemia.

Another endogenous marker potentially specific for ischemia to an individual visceral organ is the arterial:ketone body ratio. This is a measure of the ability of liver mitochondria to maintain a critical level of energy production via oxidation–reduction pathways, and it has been used to assess postperfusion function of liver grafts.[169] Recently, urine oxygen tension has been used to predict postoperative renal function in patients undergoing cardiac surgery.[170] More study is needed to validate these markers. A new and exciting measure of visceral organ ischemia now in use is the monitoring of gastrointestinal intramucosal pH (pHi) by gastric tonometry.[142] It is thought to reflect visceral organ blood flow as a whole because of the similar responses of all visceral organs to shock. Titration of therapy to maintain a normal pHi may be associated with improved outcomes in some forms of shock.[171] The pHi is calculated by using the Henderson-Hasselbalch equation from the PCO_2 content obtained from a nasogastrically placed tonometer and the bicarbonate concentration of an arterial blood gas.[171] The validity of this measure relies on the observation that the PCO_2 of a fluid placed in the lumen of a hollow viscus will rapidly equilibrate with the PCO_2 in the wall of the viscus and that arterial and gastric cell bicarbonate levels are the same. Although tonometrically and directly measured pHi levels generally show good correlation in states of ischemia from

septic shock, they may be somewhat less reliable in states of low flow where arterial bicarbonate is not likely to provide a true reflection of intestinal bicarbonate. The use of gastric tonometry in the postresuscitation phase of cardiac arrest has not been studied.

Magnetic resonance spectroscopy (MRS) is capable of non-invasive and repetitive measurements of the relative concentrations of different metabolites in many organs, including the brain, heart, skeletal muscle, liver, kidney, and intestine.[172,173] With different MRS techniques these metabolites include intracellular high-energy phosphates and lactate. In addition, intracellular pH, free magnesium, and intermediary metabolism can be studied. Regional blood flow measurements with MRS are also being developed. Phosphorous MRS has been used for diagnosing intestinal ischemia.[174] This technique appears promising for other visceral organs.

Summary

Damage produced to the visceral organs is complex. With regard to visceral organ I/R in the setting of cardiac arrest, the majority of the damage may take place in the postresuscitation phase because of ongoing occult ischemia. Although the postresuscitation syndrome of cardiac arrest and the MODS of other shock states are similar, it is unclear whether a state of SIRS precedes it. Better resuscitation and postresuscitation therapies guided by appropriate monitoring aimed at reducing use of vasopressors and improving postresuscitation oxygen transport may be key factors in avoiding visceral organ damage leading to the postresuscitation visceral organ syndrome. Therapies that also blunt the inflammatory mediator response need exploring. To understand these issues, animal models should be developed without regard to neurologic outcome since once effective neuronal salvaging agents are found, MODS will not overshadow their effectiveness.

Mechanisms of forward flow during external chest compression

Henry R. Halperin

Johns Hopkins University School of Medicine, Baltimore, MD, USA

There are more than 300 000 victims of cardiac arrest each year, and attempts to resuscitate them are usually unsuccessful.[1,2] Laboratory and clinical studies have shown that restoration of cardiac function after cardiac arrest is related to the level of coronary perfusion generated during resuscitation.[3–6] It has also been shown that adequate cerebral perfusion is necessary for preservation of brain function.[7,8] There is therefore a critical need for determining methods to augment blood flow generated during resuscitation. A key factor in enhancing flow is understanding the mechanisms of blood flow operative during chest compression, since it may be possible to optimize flow by exploiting those mechanisms.

Fluid movement in any hydraulic system results from the interaction of a pump, or driving force for fluid movement, and a load. In the intact cardiovascular system, the pump is obviously the heart, and the load is the vascular resistance and compliance. During resuscitation, however, the pump and load are less well defined. Continuing controversy exists over the nature of the pump operative during chest compression.[9–23] Pumps that have been proposed include direct cardiac compression,[19,22,24] intrathoracic pressure rises,[16,18,25] and a combination of both.[15,26,27] It is important to determine the nature of the pump, since the method of chest compression for optimizing flow may be different depending on which pump is operative.[4,15,28]

For optimizing flow, it may also be important to understand the effects of a number of techniques that have been investigated which may modify the pump. These techniques include: (*a*) abdominal compression,[29–32] (*b*) airway manipulation,[29,33–41] (*c*) circumferential chest compression,[4,28,42–45] and (*d*) sternal force applied during chest relaxation (active decompression).[39,46–52] A detailed understanding of how these techniques modify the pump to affect blood flow may facilitate development of methods that harness the optimal features of each technique.

In addition, the vascular load during resuscitation may have profound effects on coronary and cerebral blood flow.[4,53–56] Increases in peripheral resistance may preferentially shunt flow to the heart and brain,[4,53] whereas low peripheral resistance states may lead to vascular collapse with reduction of flow.[53,57] Changes in the distribution of arterial compliance may also affect flow.[58,59] Vasoconstrictor drugs are used routinely during resuscitation to increase peripheral resistance and improve coronary flow.[2] Other drugs used during resuscitation for other indications, however, may have profound effects on the vascular load, some of which may decrease flow. For example, calcium and some analgesics may cause vasodilation, which reduces peripheral resistance. Non-pharmacologic means, such as abdominal binding, may also change the vascular load.[60] Consequently, understanding how the vascular load affects blood flow and how the vascular load can be altered may be useful in determining means for optimizing flow.

This chapter deals with mechanisms of blood flow operative during external chest compression cardiopulmonary resuscitation (CPR), since external chest compression is not only a part of standard CPR, but also a part of the newer forms of CPR that may replace or supplement standard CPR.[4,28,49,61–63] The mechanisms discussed include the pump, techniques that can modify the pump, and the vascular load.

Basic science

The pump

With the *cardiac compression pump*, it is postulated that chest compression does not cause intrathoracic pressure to rise. Instead, the heart (and possibly some vascular structures) is compressed between the sternum and vertebral column (Fig. 16.1).[22] It is presumed that blood is squeezed from the heart into the arterial circulation during chest compression, with the cardiac valves preventing retrograde blood flow. With release of chest compression, the heart would expand and fill with blood. Coronary flow and cerebral flow are presumed to occur in a way similar to that in the intact circulation.

With the *intrathoracic pressure pump*, it is postulated that chest compression causes a rise in intrathoracic pressure, which is transmitted to the intrathoracic vasculature (Fig. 16.1).[16,18] Intrathoracic arterial pressure is transmitted fully to extrathoracic arteries. Intrathoracic venous pressure is not, however, transmitted to the extrathoracic veins because of the large extrathoracic venous compliance and because of closure of venous valves (Fig. 16.2).[18,26,64] This differential transmission of intrathoracic pressure to the extrathoracic vasculature produces extrathoracic arterial-venous pressure gradients, which cause blood to flow out of the thorax. With release of chest compression, intrathoracic pressure would fall and venous blood would return from the periphery into the thoracic venous system. Coronary flow, which is entirely inside the thorax, appears
Fig. 16.1. Schematic representation of cardiac compression pump (*left panel*) and intrathoracic pressure pump (*right panel*). With cardiac compression pump, it is postulated that chest compression causes left ventricle (*LV*) and possibly right ventricle (*RV*) of heart to be compressed between sternum and vertebral column. It is presumed that blood is squeezed from heart into arterial circulation during chest compression, with cardiac valves preventing retrograde blood flow. It is also presumed that air moves freely out of the lungs, so that intrathoracic pressure does not rise and pulmonary circulation (*pulm. circ.*) is not affected by chest compression. With chest relaxation, heart would expand and fill with blood, and air would passively return to lungs. With intrathoracic pressure pump, it is postulated that chest compression causes a rise in intrathoracic pressure (*large arrows*), which is transmitted to intrathoracic vasculature. It is presumed that intrathoracic pressure can rise because of collapse of airways (above the C) which reduces movement of air out of lungs. All intrathoracic structures are reduced in size but not necessarily equally. There is also collapse of venous structures at thoracic inlet (below the C), which helps prevent retrograde venous blood flow. With chest relaxation, intrathoracic pressure would fall, with return of venous blood from periphery into thoracic venous system.
Fig. 16.2. Pressure tracing during catheter pullback in patient undergoing chest compression. Pressure catheter was placed in internal jugular vein and advanced into thorax. Each oscillation is pressure recorded during each chest compression. As catheter tip crossed thoracic inlet during pullback, amplitude of pressure oscillations decreased substantially, indicating site of collapse. (Reproduced with permission from ref. 18. Copyright 1980 American Heart Association.)

to depend on the extrathoracic arteries (Fig. 16.3).[59] As intrathoracic pressure rises during chest compression, blood moves from intrathoracic arteries to extrathoracic arteries. As intrathoracic pressure falls during chest relaxation, it appears that some blood from the extrathoracic arteries flows retrograde into the intrathoracic arteries to perfuse the coronary arteries.[15,59,65]

History

Nearly lost in the medical literature are observations by Crile and Dolley[25] in 1906 and Eisenmenger[66] in the 1930s, who demonstrated, in experimental animals with cardiac arrest and to some extent in humans, that circulation of blood could be achieved through fluctuations of intrathoracic pressure. In 1960 the era of modern CPR was begun by Kouwenhoven, Jude, and Knickerbocker.[22] From anatomic considerations it was suggested that chest compression resulted in direct compression of the heart between the sternum and the vertebral column. Later in the 1960s, a series of investigations was performed that demonstrated, however, that no intrathoracic arterial-venous pressure gradient was present during external chest compression in the dog.[67,68] In addition, very high right atrial pressures were present during external chest compression in humans.[68] If direct cardiac compression were responsible for movement of blood, an arterial-venous pressure gradient across the heart would be expected. Arterial pressure should exceed venous pressure to provide the necessary peripheral and coronary perfusion pressures.
Fig. 16.3. Schematic of mechanism for generation of coronary blood flow by rises in intrathoracic pressure. As intrathoracic pressure rises during chest compression, blood moves from intrathoracic arteries to extrathoracic arteries. Blood does not flow into coronary arteries (*CA*) during chest compression because of high intrathoracic venous pressure. As intrathoracic pressure falls during chest relaxation, it appears that aortic valve closes and some blood from extrathoracic arteries flows retrograde into intrathoracic arteries to perfuse coronary arteries. *ABD*, abdomen; *LH*, left heart.

In 1976 Criley and associates observed that as long as a patient with cardiac arrest began to cough before unconsciousness occurred, the patient would not lose consciousness provided that coughing at a rate of 40 to 60 times per minute was continued.[9] It was suggested that blood flow resulted from direct compression of the heart by thoracic structures during the cough maneuver. Later, Niemann *et al.* performed a series of elegant cine-angiographic and hemodynamic studies in dogs which demonstrated that movement of blood during the cough

was most likely a reflection of a rise and fall in intrathoracic pressure.[10] The cough was shown to be extremely efficient at producing cyclic fluctuations in intrathoracic and vascular pressures. [9,10,69]

In 1980 Rudikoff et al. suggested that blood movement during external chest compression CPR can be accounted for by a general rise in intrathoracic pressure.[18] This suggestion was based on several observations made in patients. First, they noted that in two patients who had traumatically flail sternums and subsequently suffered cardiac arrest, no measurable arterial blood pressure fluctuations or forward carotid blood flow velocity could be generated by external chest compression. If the chest wall was bound to prevent the paradoxic expansion of the rest of the chest, however, a measurable arterial blood pressure fluctuation with each compression did occur. They reasoned that a patient with a flail sternum should be ideally suited for direct cardiac compression but that binding the chest during sternal displacement would allow intrathoracic pressure to rise. Second, they observed that the compression cycle after ventilation was the cycle that produced the greatest pressure elevation and the highest velocity of carotid blood flow. If cardiac compression were the driving force for blood movement, they reasoned that generated pressures should be lower on the cycle after ventilation, since the sternum would be further from the heart at the beginning of the cycle.

Thus by 1980 controversy existed as to whether the pump operative during external chest compression was direct cardiac compression or induced rises in intrathoracic pressure. The controversy has continued, and, more recently, investigators have suggested that both mechanisms may be operative.[26,27,65] The following discussion describes a number of approaches that have been used in attempts to determine more definitively the nature of the pump.

Determining the pump

Intrathoracic pressure

It seems the most straightforward way of gaining insight into whether blood moves because of intrathoracic pressure changes or through direct cardiac compression or both would be to measure simultaneously the generated vascular pressures and regional intrathoracic pressure. If vascular pressures were significantly higher than intrathoracic pressure, then rises in intrathoracic pressure could not account for the generated vascular pressures. There have been a number of attempts to make such simultaneous measurements.[17,19,21,29] Some investigators have reported that there is a very close correlation between the *change* in intrathoracic vascular pressures and estimates of the change in intrathoracic pressure.[17]

Those investigators presume that changes in pressure, rather than generated peak pressures, are important. They reason that pressures in the various vascular compartments may be different at the beginning of chest compression, and a rise in intrathoracic pressure would *add* to the existing pressure. Other investigators have reported, however, that changes in vascular pressures are much larger than changes in intrathoracic pressure, suggesting that intrathoracic pressure fluctuations are not primarily responsible for generating vascular pressures.[19] The following problems, however, make these studies difficult to interpret: (*a*) use of sensors for measuring intrathoracic pressure that had limited frequency response; (*b*) sensors that required entry of pleural liquid where the pleural liquid may not be present in sufficient volume; (*c*) surgical manipulation of the chest, where a pneumothorax, or alteration of anatomic relations, might be present; and (*d*) no consensus as to what method or methods give valid measurement of pleural pressures.

Venting intrathoracic pressure, while measuring vascular pressures before and after venting, has also been attempted as a method for providing insight into the driving force for blood movement. If the pressures before and after venting were essentially the same, it could be reasoned that manipulation of intrathoracic pressure had little to do with generation of vascular pressure. Based on this reasoning, some studies were done with thoracic venting attempted via bilateral chest tubes.[21] The major problem with these studies was that intrathoracic pressure was incompletely vented because of sealing of the chest tubes by the pleura,[70] so that the results are questionable.

Aortic and cardiac dimensions

Another way to gain insight into the nature of the pump operative during chest compression is to visualize changes in aortic and cardiac dimensions. Angiograms have shown that aortic size decreases during chest compression, rather than increasing as would be expected if blood flow occurred as a result of direct heart compression.[14] Direct heart compression should drive blood from the left ventricle into the aorta, leading to distension, not collapse, of the proximal aorta. Intrathoracic pressure changes, however, would tend to reduce the size of all intrathoracic vascular structures. One limitation of this study is that direct compression of the aorta could have occurred, which could decrease the anteroposterior dimension of the aorta.

Cardiac dimensional changes have been studied with chronically implanted ultrasonic crystals in dogs,[19] and with echocardiography in humans.[27,71–73] In dogs, certain left ventricular dimensions were reported to decrease during chest compression, suggesting that there is direct

left ventricular compression leading to forward blood flow.[19] Other left ventricular dimensions, however, increased, and total left ventricular volume was not measured. It is unclear therefore whether there was a change in total left ventricular volume. Similar limitations in determination of left ventricular volume were present in the echocardiographic studies of humans, also making the results of those studies inconclusive.

Mitral valve motion

A third way that has been explored for determining the driving force for blood movement during external chest compression CPR has been through investigation of mitral valve motion. It was previously shown in some preparations that the mitral and aortic valves were open during chest compression, with the heart acting as a passive conduit for flow.[72,73] It was presumed therefore that if the mitral valve closed during chest compression, then cardiac compression (without rises in intrathoracic pressure) was operative. The reasoning was that if during chest compression the left ventricular volume decreased and there were pressure gradients from the left ventricle to the left atrium,

closing of the mitral valve during chest compression established that direct compression of the heart was the cause. The conclusions of those studies are problematic, however, since (*a*) there is sufficient motion of the heart that different portions of the heart may be used for volume determinations made during chest compression and relaxation and (*b*) intrathoracic pressure was not measured. In addition, left ventricular to left atrial pressure gradients can be caused by "pure" rises in intrathoracic pressure.[23]

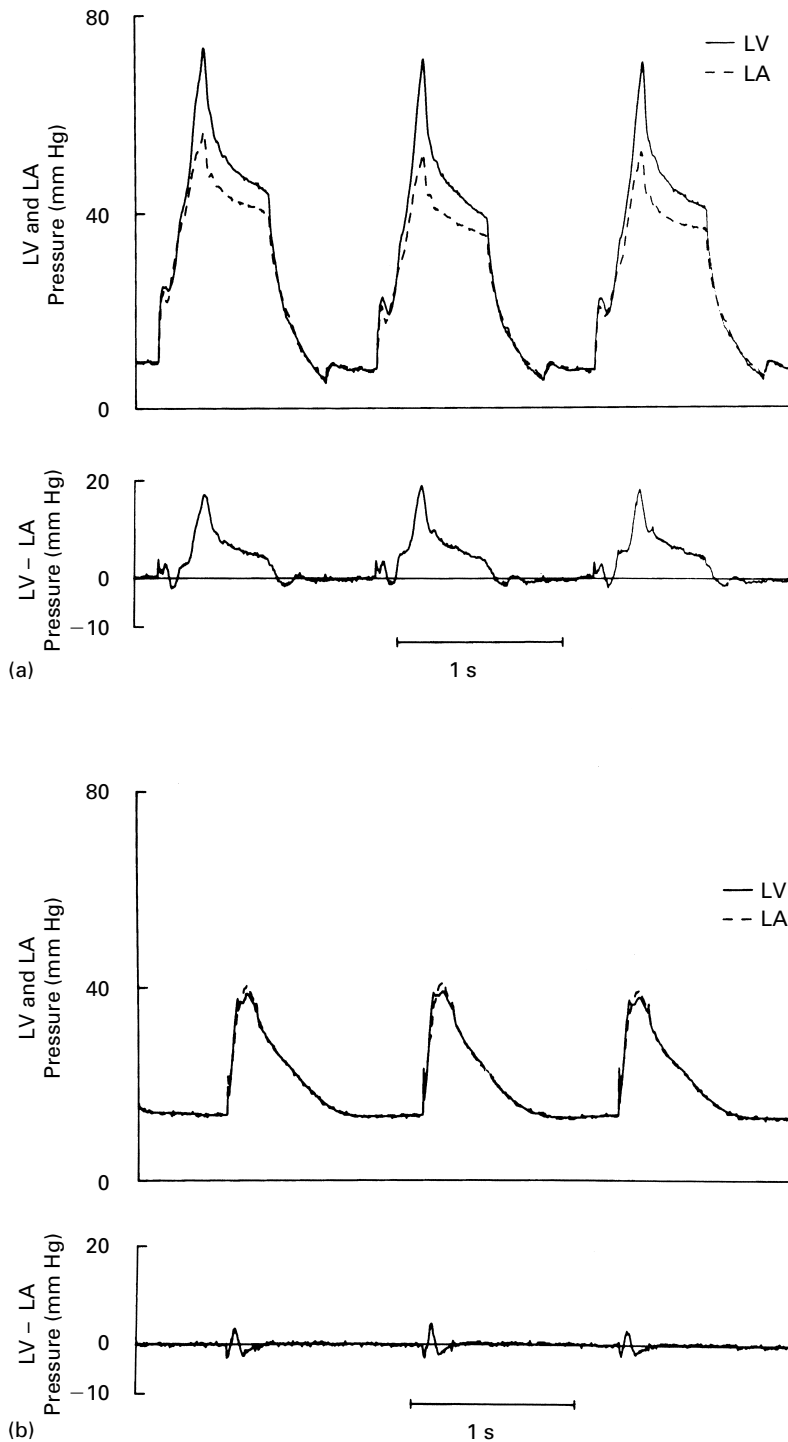
The ability of "pure" rises in intrathoracic pressure to close the mitral valve was demonstrated by using large-bore chest tubes placed into the thorax of dogs. The chest tubes were used to cyclically inflate the thorax, while left ventricular and left atrial pressures were measured and echocardiograms were recorded. With the trachea open to atmosphere during thoracic inflation, air moved out of the lungs, and the mitral valve leaflets approximated (Fig. 16.4, *upper panels*). With thoracic deflation, however, the mitral leaflets separated widely (Fig. 16.4, *lower panels*). During most of the high-pressure portion of the cycle, left ventricular pressure was higher than left atrial pressure[23] (Fig. 16.5a). With lung ventilation alone, however, the
Fig. 16.4. Parasternal long-axis echocardiographic views of hearts of three dogs (*a*), (*b*), (*c*) from right chest wall during inflation and deflation of thorax through large-bore port. Port had a baffle that directed airflow away from heart. During inflation (*upper panels*), mitral valve leaflets close (*arrow*). During deflation (*lower panels*), mitral valve leaflets open (*arrows*). *LV*, left ventricle; *LA*, left atrium. (Reproduced with permission from ref. 23. Copyright 1988 American Heart Association.)


Fig. 16.5. (a) Plot of intracardiac pressures during thoracic inflation and deflation in one dog. Left ventricular (*LV*) pressure is higher than left atrial (*LA*) pressure during most of the high-pressure phase, and the difference in those pressures (*LV – LA*) is shown separately. (b) Plot of intracardiac pressures during lung ventilation in one dog. Left ventricular (*LV*) pressure is nearly identical to left atrial (*LA*) pressure during entire cycle, and difference in those pressures (*LV – LA*) is shown separately. (Reproduced with permission from ref. 23. Copyright 1988 American Heart Association.)

mitral valve leaflets remained separated during both inspiration and expiration, and no left ventricular to left atrial pressure gradient was present[23] (Fig. 16.5b). These thoracic inflation and lung ventilation studies demonstrate therefore that mitral valve motion can depend on how intrathoracic pressure is generated.

Some echocardiographic studies of CPR in humans have shown that the mitral valve can be open during chest compression.[72,73] Since those studies tended to be late in the course of cardiac arrest, decreases in peripheral resistance may have strongly affected forward flow and resulting valve motion.[74] In addition, low compression rates and increased intravascular volume are associated with more antegrade flow through the heart during compression, whereas higher rates and decreased intravascular volume are associated with elimination of antegrade flow during compression.[74] In those echocardiographic studies of CPR in humans, therefore, it is not known (*a*) whether the level of intrathoracic pressure generated was insufficient to produce significant intracardiac pressure gradients, (*b*) whether the heart was simply a passive conduit for flow produced by intrathoracic pressure changes, (*c*) whether the degree of cardiac compression was insufficient to produce mitral valve closure, (*d*) how the duration of cardiac arrest affected the observed findings, (*e*) what the effects of the rate of compression were, or (*f*) what the effect of the intravascular volume status was. Other echocardiographic studies in humans have shown variable relationships between chest compression and mitral valve motion,[27] suggesting either that mitral valve motion gives no insight into mechanisms or that the mechanisms change during the course of chest compression.

Thus, rises in intrathoracic pressure with accompanying lung deflation can produce higher pressures in the left ventricle than in the left atrium and cause the mitral valve to close. Cardiac compression can also cause the mitral valve to close. Mitral valve closure during chest compression, therefore, does not distinguish whether blood moves because of direct cardiac compression or because of intrathoracic pressure rises.

Effects of changes in rate and duration of compression

A fourth way that has been explored for determining the driving force for blood movement during external chest compression CPR has been to examine the hemodynamic consequences of changes in applied compression rate (cycles per minute) and compression duration (percentage of cycle in compression). These indirect studies avoid the problems with pleural pressure measurements and surgical manipulation of the chest but depend on models. A mathematical model was developed that predicts that blood flow caused by intrathoracic pressure fluctuations should be insensitive to compression rate over a wide range but should depend on the applied force and compression duration.[59] With intrathoracic pressure rises, increasing the applied force should increase generated intrathoracic pressure. Blood flow should continue as the duration of compression is prolonged, as long as the venous capacitance bed is not filled with blood. If direct compression of the heart plays a major role, however, the model predicts that flow should depend on compression rate and force but, above a threshold, should be insensitive to compression duration. With cardiac compression, stroke volume should be a function of chest compression force, and an increased rate would cause more stroke volumes per unit time to be pumped into the arterial bed. Prolonging compression beyond that necessary for maximum sternal displacement would have no effect, however, because the entire stroke volume would be ejected as soon as maximum cardiac compression occurred.

The model was validated for direct cardiac compression by studying the hemodynamics of cyclic cardiac deformation following thoracotomy in dogs. As predicted by the model, no change in myocardial or cerebral perfusion pressures occurred when the duration of compression was increased from 15 to 45% of the cycle at a constant rate of 60 compressions/min. There was, however, a significant increase in perfusion pressures when the rate was increased from 60 to 150 compressions/min at a constant duration of 45%. The model was validated for intrathoracic pressure changes by studying the hemodynamics produced by a circumferential thoracic vest (vest CPR). The vest contained a bladder that was inflated and deflated. Vest CPR changed intrathoracic pressure without direct cardiac compression, since sternal displacement was less than 0.8 cm and was usually away from the heart. As predicted by the model, and opposite to direct cardiac compression, there was no change in perfusion pressures when the rate was increased from 60 to 150 compressions/min at a constant duration of 45% of the cycle.

The hemodynamic effects of changes in applied sternal force, compression rate, and compression duration were then studied during manual CPR in dogs (Fig. 16.6). In these studies there was no surgical manipulation of the chest. Myocardial and cerebral blood flows were determined with radioactive microspheres and behaved as predicted from the model of intrathoracic pressure – flow was significantly increased when the duration of compression was increased from short (13 to 19% of the cycle) to long (40 to 47%), at a rate of 60 compressions/min, but flow was unchanged for an increase in rate from 60 to 150 compressions/min at constant compression duration.[16]
Fig. 16.6. Microsphere-determined myocardial and cerebral blood flows at different rates and compression durations (percent of cycle in compression) during manual CPR in dogs ($n = 8$). Both myocardial and cerebral flows are less when manual CPR is performed at 60 compressions/min with short (15%) duration (*60S*) than when it is performed at 60 compressions/min with long (45%) duration (*60L*) or at 150 compressions/min with long duration (*150L*). There is no increase in flow when rate is increased from 60 to 150 compressions/min at same duration of compression. * = $P < 0.05$; ** = $P < 0.02$.

Similar results were found in patients. Taylor and associates demonstrated in humans that higher mean arterial pressure and Doppler-estimated carotid artery blood flow velocity were achieved by longer (50 to 60% of the cycle) rather than shorter (30% of the cycle) chest compression duration at constant maximum chest compression force and compression rate.[75] In that study a mechanical chest compression device was used to control these variables precisely. The increased compression duration itself, rather than an increase in sternal displacement with prolonged compression duration, explained the increased flow. Later studies in humans confirmed that no significant increase occurred in sternal displacement when the compression duration was increased at a constant chest compression force.[76] In contrast to the increase in pressures and flows with prolonged compression duration, very little difference in mean pressure or estimated flow occurred with changes in rate between 40 and 80 cycles/min.

In studies of chronically instrumented dogs, faster compression rates have been reported to increase blood flow,[19] suggesting that cardiac compression was the driving force for blood movement. This conclusion, however, is questionable when compression duration is also considered. In these latter studies, rate may have been important since compression duration and perhaps force were not controlled. The time of compression at each rate appears nearly constant, so that at higher rates, compression occurred for

an increased percentage of the cycle. Optimal cardiac output occurred at a rate of 120 compressions/minute, where it appears that compression was approximately 50% of the cycle.[19] Since compression force was not measured, it is possible that some of the increase in flow reflects an increase related to greater compression force at faster rates.

In summary, the above data suggest that generated changes in intrathoracic pressure can move blood during external chest compression CPR. Intrathoracic pressure rises probably are responsible for the bulk of blood movement during external chest compression. Direct cardiac compression can, however, contribute to a variable extent.

Modifiers of the pump

Abdominal pressure

Abdominal pressure influences the intrathoracic pressure pump directly, since manipulation of abdominal pressure can affect the level of generated intrathoracic pressure.[34,53,60,77] The effect of abdominal pressure on the cardiac compression pump is, however, less clear. Manipulation of abdominal pressure has been studied during both chest compression,[43,53,60] and chest relaxation.[63,78]

Increases in abdominal pressure during chest compression have generally been accomplished by applying a circumferential binder to the abdomen.[53,60] The binder restricts movement of the thoracic contents into the

abdomen during chest compression. As thoracic volume is reduced by chest compression, the thoracic contents are restricted from moving away from the compression force, and intrathoracic pressure is augmented. Right atrial pressure, however, appears to be raised excessively, which reduces the pressure gradient from the aorta to the right atrium.[53] Since the resulting decrease in coronary blood flow can reduce the likelihood of restoring the heartbeat,[4,53,79] abdominal binding is generally not considered a useful adjunct to chest compression.

Application of force to the abdomen during chest relaxation has generally been done manually and sometimes with a pressure measuring device.[63,80] This approach has been termed interposed abdominal compression (or abdominal counterpulsation) CPR.[63,80,81] In addition to an increase in intrathoracic pressure, it is presumed that abdominal compression between chest compressions can compress the aorta and produce greater retrograde aortic flow into the chest.[65] As with intraaortic balloon pumping, the resulting increase in aortic pressure would augment coronary flow. Animal studies of interposed abdominal compression have shown variable results,[32,82–84] but abdominal mechanics in humans and animals may be quite different. In humans, direct compression of the aorta by abdominal compression might be more effective than in dogs. Increasing intrathoracic pressure during chest relaxation may prolong the duration of intrathoracic pressure, which could augment coronary flow.[16,75] Alternatively, right atrial pressure may be raised relative to aortic pressure, which could decrease coronary flow. Since hemodynamic data in humans are not available, this approach requires further investigation.

Airway mechanics

For the cardiac compression pump, it would be assumed that airway mechanics are not important, since the driving force for blood movement is thought to be determined simply by the amount of cardiac deformation. For the intrathoracic pressure pump, however, airway mechanics are probably critical, since the trachea is generally not obstructed during chest compression.

It has been shown that increasing the duration of sternal compression maintains intrathoracic and vascular pressures while augmenting flow.[58,75] It has also been shown that arterial pressure is generally higher on the first compression after ventilation than on subsequent compressions.[18] In addition, high levels of intrathoracic pressure and improved survival can be produced by circumferential thoracic compressions from a pneumatic vest,[4,28] and by anterior-posterior chest compressions from a load distributing band,[85,86] despite an unobstructed trachea. If

the airways were open during chest compression, then intrathoracic pressure would rise with the initial compression of the thoracic contents. Intrathoracic pressure would subsequently fall as the lungs emptied, despite sustained chest compression. If, however, the airways closed during chest compression, then the lungs would not empty, and intrathoracic pressure would remain elevated during the period of chest compression.

It has been demonstrated that airway collapse with air trapping does occur during chest compression, which explains how intrathoracic pressure can be generated and maintained despite an unobstructed airway.[85,87] Air trapping appears to result from vigorous chest compression, which alters the properties of the airways, leading to their collapse. This air trapping probably reduces the deformation of the chest wall needed to raise intrathoracic pressure and increases the transmission of pressure to the thoracic structures. In addition, air trapping is probably greater when chest compressions begin at higher lung volumes, since chest compressions after ventilation result in larger increases in intrathoracic pressure than chest compressions without prior ventilation.[18,87]

Three phenomena have been noted in dogs that show that airway collapse and air trapping occur. First, with ventilation just before chest compression, only a portion of the inspired tidal volume moved out of the lungs during chest compression (Fig. 16.7). After chest relaxation, however, more air moved out of the lungs, indicating that a portion of the inspired tidal volume was trapped during chest compression. The trapped air was passively discharged by the elastic recoil of the respiratory system. During cycles without prior ventilation, the amount of air expired by chest compression can decrease, paradoxically, at higher levels of chest compression, indicating that air was trapped at the higher levels. Second, with a micro-manometer advanced 5 to 8 cm distal to the carina, a zone of high pressure was noted, indicating a zone of airway collapse distal to the carina. Withdrawal of the catheter only a few centimeters caused a marked decrease in the recorded phasic pressure changes, again indicating that there was a locus of constriction or collapse approximately 4 to 6 cm distal to the carina, in small or medium airways. Finally, the site of collapse was directly visualized with cineradiography during chest compression, by instillation of contrast into the airway (Fig. 16.8). The collapse site was found to be coincident with the site in the airway where the large phasic changes in airway pressure were noted.

Airway manipulation

Positive airway pressure administered simultaneously with chest compression has been used to augment intrathoracic
Fig. 16.7. Original recording during vest inflation (*left*) and during sternal displacement from a pneumatic piston (*right*). Inspiration with 500 ml occurred just before each vest inflation or piston actuation. Only expired airflow is shown. Inspired airflow is not shown since it did not go through airflow sensor. During vest inflation, note that a portion of inspired tidal volume was trapped (trapped air), since more air moved out of thorax after vest deflation. Note similar finding with piston compression. Airway bifurcates (*b*) distal to collapse site. *Center frame* was taken 17 milliseconds later and shows airway partially open (*arrow*). *Right frame* was taken another 17 milliseconds later and shows airway fully open. Bipolar electrode catheter (c) is in right ventricle and is approximately 2 mm in diameter. (Reproduced with permission from ref. 87. Copyright 1989 American Heart Association.)

pressure directly and has been termed simultaneous compression-ventilation CPR.[29,34,53,77] As with airway collapse, the mechanism for augmentation of intrathoracic pressure is the elimination of expiratory airflow during chest compression. The requirement of endotracheal intubation and a device to administer simultaneous compression and high-pressure ventilation, however, has limited use of this technique.

Obstruction of the airway with a valve has also been used to augment intrathoracic pressure.[88] The valve is generally closed during chest compression, and the mechanism of action appears to be similar to that of airway collapse. The contribution of this airway obstruction over that of intrinsic airway collapse is unknown.

Negative airway pressure has been administered during chest relaxation to produce negative intrathoracic pressure.[29,38,40,89] It was suggested that negative intrathoracic pressure, between chest compressions, would augment venous return and thereby augment forward flow.

Circumferential chest compression

Circumferential chest compression has been studied as a more effective way of generating intrathoracic pressure fluctuations[4,65] and is generally accomplished with a pneumatic vest.[28,90] The vest contains a bladder that is cyclically inflated and deflated. The increased intrathoracic pressure fluctuations appear to be mediated through increased reduction of thoracic volume and through increased air trapping.[87] In addition, chest compression force is substantially higher than that used with standard manual CPR, since the force is distributed around the thorax.[28] The increased chest compression force would raise intrathoracic pressure in relation to the reduction in thoracic volume, assuming air trapping occurred. By reducing expiratory airflow, air trapping could also increase the efficiency with which vest pressure is transmitted to the intrathoracic space. Any decrease in expiratory airflow would reduce the amount of chest deformation at any level of vest pressure. At the reduced amount of chest deformation, less of the force applied to the chest would be needed to compress the elastic structures of the thorax, resulting in greater transmission of vest pressure to the intrathoracic space.

Load distributing band

The load distributing band is an evolution of the circumferential vest compression concept.[85,91] With the load distributing band system, an electromechanical band is placed around the chest and the band is tightened and loosened by a rotating motor that is contained in a backboard assembly. The band system produces anterior-posterior chest compressions, but distributes the chest compression force over the entire anterior chest.[85,91] Similar airway collapse has been noted with the band system as with the circumferential chest compression system.[85,87]

Active chest decompression

Active, rather than passive, decompression of the chest has been reported to augment vascular pressures[48,92], and return of spontaneous circulation.[46,93] The technique has been termed active compression–decompression CPR and utilizes a suction-cup device to pull up on the chest during chest relaxation (see Chapter 31). The mechanisms operative during active decompressions have not been determined, but such active decompressions could result in greater chest expansion and filling with air between compressions. The amount of air trapped in the lungs could thereby be increased, which could augment the generated intrathoracic pressure.[87] In addition, active decompressions could induce negative intrathoracic pressure between compressions, which could augment venous return. Increased venous return could enhance the forward flow produced by cardiac compression or by intrathoracic pressure fluctuations. Few data sources are available, however, on the level of chest compression force used with this technique, so it is not known if the reported benefit for active decompression CPR results simply from an increased *total force* (peak compression to peak decompression force) applied to the chest. For example, if a 400-newton compression force and a 100-newton decompression force were applied to the chest, is it equivalent to simply applying 500-newtons of compression force, or does the decompression force have unique physiologic effects that improve blood flow? Results of studies to date have not resolved these issues.

The device used to apply the active compressions and decompressions[36] may also give the rescuer a mechanical advantage in performing chest compression, which could result in substantially higher sternal forces being applied than with standard manual CPR. These increased forces could augment the generated intrathoracic pressure or enhance cardiac compression, which could increase short-term survival. Trauma, however, could reduce long-term survival.

Impedance threshold device

This device is placed in the airway circuit and is used to impede the flow of air into the chest during chest decompression, thereby producing a particular level of negative intrathoracic pressure. This device has allowed the use of negative intrathoracic pressure between chest compressions to come into clinical use,[36,38,40,89,94] and improvements in hemodynamics and short-term survival have been reported with this device.[39,41]

The load

As with the intact circulation, the vascular load during external chest compression is probably the arterial resistance and compliance. Their values during CPR may, however, differ substantially from those of the intact circulation because of changes in neural-humoral conditions, ischemia, administered drugs, and mechanical maneuvers such as applying pressure to the abdomen.

Arterial resistance

The arterial (peripheral) resistance appears to be the most critical loading factor that influences coronary and cerebral flow. Numerous studies have shown that administering drugs that increase peripheral resistance increases coronary perfusion pressure, cerebral and coronary blood flow (Fig. 16.9), and return of spontaneous circulation.[4,53,54,56,95–100] These improvements were present regardless of the type of CPR performed. Because of the difficulty in making direct measurements in humans, both electrical and mathematic models have been developed to study the hemodynamic effects of changes in peripheral resistance.[58,59,101] These models predict increases in cerebral and myocardial flows similar to those that have been measured experimentally. One extensively validated model[59] predicts that increased peripheral resistance improves myocardial and cerebral blood flow because of an increase in the mean aortic pressure during chest compression. The increased peripheral resistance probably decreases the runoff of blood into the periphery during

chest compression, maintaining higher levels of aortic pressure, regardless of the nature of the pump.

Increasing peripheral resistance may not, however, have equivalent effects on the coronary flow produced by different CPR techniques. One study in pigs showed that active decompression CPR produced more coronary blood flow than standard CPR when vasoconstrictors were not used[48] but showed no difference in coronary flow when vasoconstrictors were used. The vasoconstrictors increased the coronary flow produced by standard CPR more than that produced by active decompression CPR, so that both flows became similar.[48] The mechanisms causing these differences are unknown, since it is assumed that peripheral resistance was increased an equivalent amount by the vasoconstrictors with each technique.

In contrast to the increase in cerebral and myocardial flow with increased peripheral resistance, there appears to be a paradoxical fall in cardiac output.[102] This fall in cardiac output is most consistent with the intrathoracic pressure pump as the driving force for blood movement. With a fixed level of intrathoracic pressure determining vascular pressure, cardiac output would be inversely related to peripheral resistance, because the mean pressure across the vascular bed would be equal to the mean flow through the bed times the resistance of the bed.[103] It would be expected therefore that with use of vasoconstrictors, cardiac output would fall as peripheral resistance rises, since the driving pressure would not change. Because myocardial blood flow during CPR is a major determinant of survival from cardiac arrest,[3,4] it is possible that with the periodic use of epinephrine, changes in
Fig. 16.9. Effect of epinephrine on cerebral and myocardial blood flow during CPR in dogs. Blood flows were measured with radioactive microspheres.

cardiac output may be uncoupled with changes in coronary blood flow, so that cardiac output would have no correlation with survival. Consequently, indicators of cardiac output, such as end-tidal CO_2 measurements, may be very limited in their utility as indicators of the efficacy of CPR.

Arterial compliance

The distribution of arterial compliance (intrathoracic versus extrathoracic) also appears to be an important determinant of myocardial blood flow.[58,59] This effect was predicted by at least two cardiovascular models[58,59] and is consistent with the intrathoracic pressure pump as the driving force for blood movement. With the intrathoracic pressure pump, intrathoracic pressure appears to be transmitted to the intrathoracic arteries collectively, so that all of the intrathoracic arteries can be represented by a single compliance. The extrathoracic arteries can also be represented by a single compliance. On the basis of using these two compliances, the models predict that coronary blood flow will be maximized when the intrathoracic arterial compliance is minimized (Fig. 16.10). The mechanisms appear to be related to bidirectional arterial flow (Fig. 16.3). During chest compression, blood will move from intrathoracic arteries to extrathoracic arteries. During

chest relaxation, however, some blood will move retrograde from the extrathoracic arteries back into the intrathoracic arteries to perfuse the coronary arteries. The less compliant are the intrathoracic arteries, the higher will be the aortic relaxation-phase pressure. If the intrathoracic arteries were very compliant, however, a greater volume of blood would be needed to fill these arteries immediately after release of chest compression, to maintain aortic relaxation-phase pressure – the intrathoracic arteries would have collapsed more during compression. Thus, if intrathoracic arterial compliance is small, blood returning to the thoracic arteries during chest relaxation quickly fills the arterial bed and improves myocardial blood flow. For the cardiac compression pump mechanism, however, the distribution of arterial compliance is probably less important.

Despite the possible importance of the distribution of arterial compliance (intrathoracic versus extrathoracic) in determining blood flow, this compliance distribution cannot be measured directly in intact animal preparations or in humans. Therefore, computer models have been used to show that the ratio of mean aortic relaxation-phase pressure to mean aortic compression-phase pressure (pressure ratio) can be used as an index of the distribution of arterial compliance between the extrathoracic and intrathoracic compartments.[59] There is an excellent correlation (r = .99) between this ratio and the ratio of extrathoracic to total arterial compliance. This pressure ratio was found to be a potent predictor of coronary blood flow in a canine model of cardiac arrest.[59]

Abdominal pressure

In addition to the effect of abdominal pressure on the level of generated vascular pressure, abdominal pressure appears also to be a factor in changing the vascular load. Abdominal binding, which reduces coronary blood flow,[53] increases abdominal pressure during chest compression.[34,53] The cardiovascular model[59] confirms that as the level of abdominal pressure increases, the generated myocardial flow decreases (r = .99) (Fig. 16.11). The mechanism of reduction of coronary blood flow with increased abdominal pressure appears to be through a reduction in the effective extrathoracic arterial compliance. The reduced extrathoracic arterial compliance would limit the amount of blood stored in extrathoracic arteries during chest compression, so that less blood could flow retrograde during chest relaxation to perfuse the coronary arteries. In addition, increased abdominal pressure could alter the distribution of intravascular volume or resistance.

Fig. 16.10. Predicted effect of compliance ratio (ratio of extrathoracic to total arterial compliance) on myocardial blood flow for two different models of blood movement in CPR. For volume pump (cardiac compression), there is little effect of compliance ratio on myocardial blood flow. For pressure pump (intrathoracic pressure), however, there is a linear increase in myocardial flow with increasing compliance ratio. These data are predictions from a mathematic model of CPR (see text).

Therapy

The goal of external chest compression CPR, after defibrillation fails or is not indicated, is to maximize the generated coronary and cerebral blood flow. Restoration of native cardiac activity and preservation of brain function are directly related to these flows. Cerebral and coronary flows should be maximized by optimizing the driving force for blood movement and the loading conditions.

Optimizing the pump

For intrathoracic pressure fluctuations, the amount of thoracic volume reduction produced by chest compression appears to be critical. By Boyle's law, the more the chest volume is reduced, the more the intrathoracic pressure will rise. In current clinical practice, chest volume is reduced by the standard anteroposterior sternal displacement technique (see Chapter 30), although other techniques are being studied that may prove to be more effective.[28,40,61,85] For maximizing cardiac compression, however, the amount of thoracic volume reduction is probably not important. The major determinant of cardiac compression is probably the amount of anteroposterior chest displacement, although the exact determinants of cardiac compression are unknown. *Whether the driving force for blood movement is intrathoracic pressure fluctuations or direct cardiac compression, the amount of chest compression is a critical determinant of flow (Fig. 16.12), and the quality of chest compression will probably be a major factor in the effectiveness of CPR.*

The ability of even properly performed chest compressions to generate adequate levels of intrathoracic pressure or cardiac compression is probably marginal, since only about 15% of cardiac arrest victims survive. Nevertheless, external chest compression is the only technique for CPR that is widely available, and many lives are saved each year by standard CPR. Proper chest compression requires that the arms are locked relatively straight (see Chapter 30) and that the whole body is used in the compressions. Often, just the arms are used for chest compression, which is extremely tiring and probably will not generate sufficient compression force.

Although the amount of chest compression force or displacement appears to be a major determinant of the level of generated vascular pressure,[16] chest compression has to be applied at the optimal rate and compression duration (Fig. 16.6). Blood flow from intrathoracic pressure fluctuations should be insensitive to rate over a wide range but dependent on the compression duration.[16,59,75] If direct compression of the heart plays a major role, however, flow
Fig. 16.11. Predicted effect of abdominal pressure on myocardial blood flow for pressure pump model of CPR. Abdominal pressure is expressed as a percentage of intrathoracic pressure. Predictions are from mathematic model.

should depend on rate but, above a threshold, should be insensitive to compression duration. The current recommendation of a rate of 80 to 100 compressions/minute probably maximizes blood flow from either pump. At that rate, the compression duration tends to be around 50%,[19] which is optimal for blood movement by intrathoracic pressure fluctuations,[59] and the rate of 80 to 100 compressions/minute is near the maximum that can be administered for any length of time by a rescuer, and would maximize the number of stroke volumes delivered to the circulation by a cardiac compression pump.[59]

The level of generated vascular pressures is likely to be affected by techniques that modify the pump, including abdominal compression,[63,80] airway manipulations,[34,40,43] circumferential chest compression,[4,28] load distributing band chest compression,[85,91] and active decompression.[50,51] The efficacy of abdominal compression, circumferential chest compression, load distributing band chest compression, and active chest decompression has not been definitively determined, so that their use in routine practice should be considered only when personnel are available who have been adequately trained in their use. Airway inflation between chest compressions should, however, be considered for routine use at this time. This airway inflation is used for ventilation, but it can also augment vascular pressures generated by the intrathoracic pressure pump. Lung inflation before chest compression can increase the amount of air trapped in the lungs during chest compression,[87] thereby augmenting the generated intrathoracic and vascular pressures and improving the efficacy of CPR.

Optimizing the vascular load

The peripheral resistance is probably the component of the vascular load that has the largest effect on blood flow. Numerous studies have shown that vascular pressures are augmented and produce increased flow to the heart muscle and brain when vasoconstrictors are used.[3,4,48,54,56,100,102] This increased flow appears to be mediated through *a*-adrenergic agonism,[96–98] which increases peripheral resistance and decreases runoff of blood to the periphery. Decreased runoff

slows decay of arterial pressure during the release phase of chest compression, thereby raising aortic pressure, myocardial perfusion pressure (aortic minus right atrial mean release phase pressure), and cerebral perfusion pressure (carotid minus intracranial mean pressure).

The vasoconstrictor most commonly used today is epinephrine, which has both α- and β-agonist effects. It is clear that the α-agonist effects are responsible for improvement in vital organ flows (Fig. 16.9). The utility of the β-agonist

effects, however, is controversial. Some investigators believe that β-agonism is detrimental because of increased myocardial work,[96,100] whereas others believe that β-agonism is beneficial by increasing inotropy.[96] The efficacy of epinephrine compared with other vasoconstrictors remains to be determined. Higher doses of epinephrine have, however, been found to be toxic[104] and are no longer recommended.

In contrast to increasing blood flow to the myocardium and brain, increased peripheral resistance can reduce total cardiac output. Cardiac output is reduced because the increases in peripheral resistance are greater than the increases in generated vascular pressures that are secondary to the increases in peripheral resistance.[102] This decreased cardiac output can explain the observation that end-tidal CO_2 can decrease with increased doses of epinephrine.[102] End-tidal CO_2 has been studied as a non-invasive method of determining the adequacy of resuscitation, since it appears to correlate with cardiac output and resuscitation success in some circumstances.[105]

In addition to the effects of vascular resistance and compliance on blood flow during CPR, it appears that the volume status contributes independently. If excessive volume is present in the vascular spaces during CPR, the venous pressures tend to be elevated during the release phase of chest compression, which can reduce the coronary perfusion pressure.[106] This finding strongly suggests that excessive volume should not be infused during resuscitation. If insufficient volume is present, however, forward flow appears to be compromised by inducing arterial collapse. Selective arterial infusion does appear to be of potential value in reversing this arterial collapse.[107]

In summary with what is currently known, the factors that appear to have the most influence on generating blood flow by external chest compression are (*a*) maximizing the amount of chest compression and (*b*) using the proper doses of vasoconstrictors. Maximization of chest compression force includes using the proper sternal force, as well as minimizing interruptions in the application of force. With standard external chest compression, the type of pump operative probably is not important, since standard external chest compression does not allow selection of a particular mechanism over that which occurs naturally.

The future

Determining the pump

Controversy continues about the nature of the pump operative during external chest compression. Future studies could potentially help resolve this controversy, but it now seems that the driving force for blood flow produced by standard external chest compression is some combination of intrathoracic pressure fluctuations and direct cardiac compression. Although standard external chest compression does not appear to allow selective utilization of intrathoracic pressure or cardiac compression, it is likely that more clever ways of applying force to the patient will be developed in the future, based on exploiting specific mechanisms.

By its more directed application of force, cardiac compression is probably more potent than intrathoracic pressure fluctuations in moving blood for a given amount of pressure rise. It remains to be determined, however, whether external CPR can compress the heart the large amount necessary to generate adequate vascular pressures.[16] It is also unclear how cardiac compression can specifically be augmented during non-invasive CPR, since the determinants of cardiac compression have not been defined. These issues could potentially be clarified with further research.

Improving standard chest compression

One simple way of potentially increasing blood flow would be to increase the amount of chest compression force and displacement. There is clearly a minimum amount of chest compression force that has to be applied to generate blood flow[16] (Fig. 16.12). It is very likely, therefore, that ineffective CPR occurs because inadequate chest compression force is applied. In routine clinical practice, there is no objective way for a rescuer to determine if adequate chest compression is applied. The American Heart Association recommends that there should be 1.5 to 2 inches of chest displacement during chest compression,[2] but it is not known whether that amount of chest compression is applied routinely or whether that amount of compression is optimal. More emphasis should be placed on ensuring that adequate chest compression is performed. This could consist of more training. Retention of trained skills is limited, however, and even well-trained rescuers have no objective way of judging whether they are performing chest compressions adequately. The widespread use of gauges or other measuring aids may increase the likelihood that chest compression is performed properly. Although it is probably true that "any CPR" (i.e., any blood flow) is better than no CPR, the available data suggest very strongly that better CPR (i.e., CPR that generates more blood flow) will improve survival.[3,4,16,53] There is little chance that ischemia will be relieved, or that drugs will be delivered adequately, if blood flow is insufficient. Increasing the level of chest compression beyond that normally used may improve blood flow

and survival. It has not been determined, however, whether increased sternal force would have a greater effect on improving blood flow and enhancing survival or on increasing trauma and limiting survival. External chest compression could also be modified by altering the point or points of force application and the rate of the force rise. Studies should be performed to investigate the influence of changes in chest compression force on blood flow and survival.

Alternative compression techniques

Understanding the mechanisms of blood flow during external chest compression is probably most important for development of improved compression techniques, since they can be aimed at exploiting specific mechanisms.

Circumferential chest compressions (vest CPR)[28] may be a more efficient way of generating vascular pressures and flow, because the amount of reduction in thoracic volume is critical for generation of intrathoracic pressure rises. There is a geometric advantage in reducing thoracic volume by a circumferential, rather than a point, compression, since the volume will decrease roughly as the square of the decrease in radius. The circumferential compression may also allow increased force to be used because the force is distributed over a much larger area than it is with standard external chest compression. Since only preliminary data are available, however, the role of vest CPR in treating cardiac arrest remains to be determined.

Chest compressions with the Load Distributing Band system[85,91] may be a more practical way of improving chest compression than the Vest CPR System. The Load Distributing Band system is much more compact than the Vest CPR system and applies forces to the entire anterior chest. Hemodynamic results with the Load Distributing Band system seem to be similar to those with the Vest CPR System.[28,85,91]

Intrathoracic pressure changes could also be enhanced through increased air trapping, which could be achieved by ventilation before each chest compression or through active chest decompressions.[46,51] The active decompressions could result in greater chest expansion and filling with air between compressions, so that the next compression results in a greater rise in intrathoracic pressure and increased flow. In addition, the impedance threshold device can be used to enhance negative intrathoracic pressure changes in between chest compressions,[41] that may augment venous return and aid either the intrathoracic pressure or cardiac compression pumps.

Last, application of force to the abdomen during chest relaxation may augment vascular pressure.[63,80] Animal studies of such abdominal compression have shown variable results, and few objective hemodynamic data are available in humans. Further studies of these techniques are therefore needed.

Improved adjuncts

The efficacy of CPR may be improved by using drugs or mechanical techniques to modify the pump or the load. Such interventions could potentially increase peripheral resistance to levels higher than currently achieved, favorably alter the distribution of arterial compliance (intrathoracic versus extrathoracic), increase air trapping, and augment venous return.

It is possible that peripheral resistance could be increased to higher levels by using increased doses of epinephrine or by using other vasoconstrictor drugs. Clearly the α-agonist effects of epinephrine increase peripheral resistance.[97,98] There is controversy, however, about the utility of the β-agonist effects. Some investigators believe that β-agonism is detrimental because of increased myocardial work,[100,108] whereas others believe that β-agonism is beneficial by increasing inotropy.[96] Increased doses of epinephrine likely have direct toxic effects on tissues, may exacerbate ischemic damage to other tissues by shunting blood away from them, and are no longer recommended for general clinical use.[104] The roles of other vasoconstrictor drugs, however, have not been resolved.

Hemodynamics of cardiac arrest

Michael. P. Frenneaux and Stig Steen

Department of Cardiovascular Medicine, University of Birmingham, UK
Department of Cardiothoracic Surgery, University Hospital of Lund, Sweden

Stroke volume and cardiac output

Each ventricle normally ejects approximately 70–75 ml with each heart beat (the stroke volume) at a rate of approximately 70 beats per minute, resulting in a cardiac output of approximately 5 litres per minute.

Stroke volume is determined by:

1. the intrinsic contractile properties of the heart (which are modified by the effects of ischemia, by circulating hormones, and by autonomic stimulation);
2. the degree of stretch of the left ventricle during diastole, i.e., its "preload" (the Frank–Starling phenomenon). This in turn is dependent on:
   (a) total blood volume,
   (b) venous tone, which determines the distribution of blood volume between the venous and central compartments
   (c) left ventricular compliance – determined by intrinsic left ventricular myocardial compliance, and in some circumstances by external constraint from the right ventricle, pericardium, and mediastinal structures (see later)
3. The "Afterload" against which the heart contracts. When the heart contracts against a high afterload, stroke volume tends to fall.

Arterial physiology and hemodynamics

Small arteries and arterioles

Mean arterial blood pressure ($\frac{2}{3}$ diastolic BP + $\frac{1}{3}$ systolic BP) is the product of cardiac output and systemic vascular resistance. Systemic vascular resistance is a static resistance, principally determined by the tone of arterioles. This tone is controlled by humoral and neural factors (particularly sympathetic tone)[1] and by paracrine factors (including nitric oxide, prostaglandins, endothelium-derived hyperpolarizing factor, and endothelin).[2] Systemic vascular resistance represents the global resistance produced by small artery and arteriolar tone. At a local level, changes in resistance vessel tone modulate tissue perfusion.

Large arteries

The large arteries are more than simply passive conduits. The fixed and dynamic properties of the large arteries profoundly affect blood pressure and left ventricular performance. In healthy young subjects the large arteries (such as the aorta, and iliac vessels) are very compliant and exert a damping effect on pulsatile left ventricular outflow, resulting in a relatively lower systolic pressure and a higher diastolic pressure. Aging of the large arteries renders them less compliant, impairing this damping function and resulting in relatively higher systolic and lower diastolic blood pressures for any given mean blood pressure. Furthermore, in the elderly, central aortic pressure is augmented by pressure wave reflection from the periphery. Following left ventricular ejection there is a forward travelling pressure wave which is then reflected back from branch sites (where there is impedance mismatch). In healthy young arteries the pressure wave travels relatively slowly and returns to the aorta in diastole, where it helps to maintain diastolic pressure and flow, whereas in stiffer elderly arteries it travels more rapidly, returning to the central aorta in systole, augmenting the systolic pressure.[3]

In summary, whereas the arterioles modulate static resistance, the properties of the large arteries determine dynamic impedance, which is analogous to resistance but relates to pulsatile rather than to steady flow.

Venous capacitance

The capacitance vessels serve a reservoir function. Over 70% of total blood volume is located in the venous compartment. Of this, the vast majority is in the small veins and venules, with the minority in the medium sized and large veins. Because of the large volume of blood within the venous compartment, relatively small changes in venous tone markedly alter the distribution of blood volume. An increase in venous tone shifts blood from the venous compartment to the heart, increasing intracardiac pressures, whereas a reduction in venous tone has the opposite effect. In patients with heart failure, for example, diuretic treatment may reduce total blood volume yet central blood volume (and jugular venous pressure) may remain high because of venoconstriction. Unlike the arteries, the venous system exerts only a modest resistance to blood flow.

Coronary blood flow

Whereas flow in most organs occurs predominantly in systole, flow in the coronary arteries occurs mainly during diastole.[4] The high pressures generated in the left ventricle during systole impede flow through the intramural microvessels (i.e., coronary vascular resistance rises markedly during systole) by generating a backward travelling compression wave, and forward flow in the coronary arteries during the latter part of isovolumic relaxation is mainly a "suction" phenomenon due to rapid relaxation of the left ventricle, with an associated rapid reduction in the pressure within the intramural coronary microvessels.[5]

Compared with other tissues, the perfusion gradient across the heart is smaller. Because flow occurs in diastole, the upstream pressure is aortic diastolic rather than mean pressure. Furthermore, although the coronary sinus drains into the right atrium, coronary microvascular pressure is markedly influenced by left ventricular diastolic pressure, which is usually substantially higher than right atrial pressure. The perfusion of the heart may be compromised by a reduction in aortic diastolic pressure, the presence of stenoses in the epicardial coronary arteries, an increase in coronary microvascular resistance, or an increase in left ventricular end diastolic pressure.

Hemodynamic changes occurring following cardiac arrest

Most of the experimental studies published have examined the hemodynamic changes occurring after the onset of ventricular fibrillation (VF). VF results in totally incoordinate ventricular activity, with effective cessation of ventricular contraction. Interestingly, as first described by William Harvey,[6] atrial contractions may continue for a considerable period after the onset of cardiac arrest. The effects of these atrial contractions may be evident in the aortic pressure tracing (Fig. 17.1).

At the instant of cardiac arrest, a large pressure gradient exists between the central aorta (mean arterial pressure) and the right side of the heart. Despite cessation of ventricular contraction, this pressure gradient drives antegrade blood flow which will continue until the pressure gradient has been completely dissipated. Direct visual inspection and cardiac MRI studies have shown a rapid increase in right ventricular volume following cardiac arrest, as blood is translocated from the systemic circulation to the right side of the heart along its pressure gradient (Fig. 17.2).[7,8] There is also a pressure gradient between pulmonary artery and left atrium, and flow therefore continues through the pulmonary circulation to dissipate this gradient. When these pressures equalise, this flow ceases and the pulmonary vasculature including the extrapericardial component of the pulmonary veins is distended with blood (Fig. 17.3). The theoretical pressure at which the pressures converge throughout the circulation was termed "Statischer Fullungsdruck" by Weber in 1851,[9] or "Static Blood Pressure" by Starr in 1940.[10] Guyton proposed that arterial and systemic venous pressure would almost reach equilibrium (at a pressure he called "Mean Circulatory Filling Pressure") 30–50 seconds after the heart stopped beating.[11] This equilibrium pressure is determined by total blood volume and by total vascular "capacitance" (of which venous capacitance provides the largest contribution). Consequently, this concept has been used by physiologists to assess the effects of interventions on venous capacitance in animal models. Mean circulatory filling pressure is estimated during brief induced ventricular fibrillation. As blood pressure falls however, baroreflex inactivation may be expected to increase sympathetic outflow, increasing venous tone and leading to an equilibrium pressure which overestimates the venous tone that existed prior to cardiac arrest. Consequently, some groups have calculated a theoretical equilibrium pressure on the basis of the pressure changes in the arteries and veins occurring during the first few seconds after onset of VF.[12] Postmortem studies have
Fig. 17.1. Example of aortic pressure and RA pressure in the pig model following the onset of VF cardiac arrest. Phasic changes in both pressures are seen due to continuing atrial contraction. (Figure provided by S. Steen.)

shown an equilibrium pressure in human corpses (well after death) of approximately 6 mmHg.[10]

Studies in animals and in man have shown that the decay in arterial pressure and the increase in venous pressure does not conform to a single mono-exponential function.[8,13] Schipke and colleagues recently studied patients with heart failure who had undergone implantation of an automatic implantable cardioverter defibrillator (AICD).[13] Ventricular fibrillation was induced in order to assess the defibrillation threshold. Haemodynamic changes were assessed during an average of 13 seconds of VF. In a subgroup, the duration of VF was over 20 seconds. The averaged data for this subgroup is shown in Fig. 17.4. As expected, LV and aortic pressure were almost identical, and both decayed rapidly. Right atrial pressure increased rapidly. Nevertheless, even at 20 seconds an arteriovenous pressure gradient of almost 10 mmHg persisted. It is clear from the data that Guyton's prediction that an equilibrium pressure would exist throughout the circulation in 30–50 seconds is not correct. This study showed that the decay in arterial pressure and the increase in right arterial pressures both conformed best to exponential curves. Exponential curves should approach an equilibrium at five times the time constant of the curve. During the first few seconds the time constant of the arterial pressure decay was

2.9 seconds – which would have predicted a plateau at approximately 14.5 seconds, yet this was not seen. The reason is that the time constant of the exponential decay progressively lengthened. Why might this be so? First, hypotension-induced baroreflex withdrawal would be expected to increase sympathetic outflow, and indeed a marked increase in sympathetic circulating catecholamines of adrenal, and to a lesser extent neural, origin has been reported after cardiac arrest.[14–16] This would be expected to increase arteriolar tone and also to increase venous tone. Secondly, it may be due to "waterfall" phenomena. As arterial pressure falls, some microvascular beds may close down, resulting in a net increase in vascular resistance. In anesthetised dogs a "waterfall" has also been demonstrated in the inferior vena cava at the level of the diaphragm.[17] However, no significant inferior vena cava waterfall was demonstrated at the level of the diaphragm before or during VF in humans.[12]

Steen and colleagues studied the hemodynamic changes occurring in anesthetised pigs during much longer periods of VF.[8] A typical example of the changes in arterial and right atrial pressures occurring after the onset of VF in non-ventilated pigs is shown in Fig. 17.5. The first 20 seconds of this recording are very similar to the human data reported by Schipke *et al.*[13] There is an early progressive reduction of
Fig. 17.2. External appearance of the heart following VF Cardiac Arrest in Pig Model. The right ventricular volume rapidly increases as blood flows from the aorta to the right heart. (Reproduced with permission from *Resuscitation.*[8])

aortic pressure, reaching a minimum of 20 mmHg after about 30 seconds. Aortic pressure then increases slightly to about 25 mmHg at 2 minutes, thereafter gradually decreasing over the next 5 minutes to approximately 10 mmHg. Right atrial pressure increases gradually after induction of VF, reaching a peak of about 18 mmHg after 2 min, decreasing thereafter to approximate aortic pressure by about 7 min. Mean circulatory filling pressure at this point is approximately 9 mmHg.

These findings cannot be explained purely by a "waterfall" effect. The increase in arterial pressure between 30 seconds and 2 minutes is probably related to transient sympathetically mediated vascular constriction. As the brainstem becomes more ischemic this sympathetic outflow is presumably reduced again, resulting in a fall in both arteriolar resistance and venous tone and a decline in both aortic and right atrial pressures.

Carotid blood flow changes following VF cardiac arrest

Figure 17.6 shows the changes in carotid blood flow following VF cardiac arrest in the anesthetised non-ventilated pig. Carotid blood flow declines exponentially after the onset of VF, but measurable carotid blood flow continues for approximately 4 minutes.

Coronary blood flow changes following VF cardiac arrest

The gradient between aorta and right atrium is often referred to as the "coronary perfusion pressure," i.e., the gradient during coronary blood flow during cardiac arrest. A "coronary perfusion pressure" of less than 15 mmHg

Ventricular fibrillation

Fig. 17.4. Pressure changes in a subgroup of patients following VF arrest in which ventricular fibrillation lasted at least 20 s ($n=14$). There is progressive decrease in arterial pressure and an increase in right atrial pressure. These changes do not conform to single monoexponential functions. Note that, at 20 seconds, a significant arterio-venous pressure gradient (9.6 mmHg) persists. (Reproduced with permission from the *American Journal of Physiology*[11].)

during the release phase of CPR has been shown to be a good predictor that recovery of spontaneous circulation (ROSC) is unlikely in both humans and in animal models.[18,19] It has been assumed in the past that this was because, below this "coronary perfusion pressure," myocardial perfusion was totally inadequate to support

recovery of myocardial function after restoration of electrical activity.

In fact, the changes in coronary blood flow and of carotid blood flow following VF cardiac arrest without CPR do not parallel each other in the anesthetised non-ventilated pig model. As shown in Fig. 17.7, coronary blood flow rapidly
Fig. 17.5. Changes in aortic pressure, right atrial pressure and calculated coronary perfusion pressure in the pig model following VF cardiac arrest. (Reproduced with permission from *Resuscitation*.[8])

declines to zero by 1 minute. For the next 2 minutes, coronary blood flow is retrograde before declining again to zero.

These observations, suggest that the term "coronary perfusion pressure" may be misleading, because "coronary perfusion pressure" is positive during this period when coronary flow is retrograde. Although the coronary sinus drains into the right atrium and therefore the aortic minus right atrial pressure gradient might be expected to determine coronary blood flow, the intramural coronary microvascular pressure is also profoundly influenced by the left ventricular intracavity pressure. The conventional "coronary perfusion pressure" therefore provides an overestimate of the actual pressure gradient driving coronary blood flow – explaining the observations above.

Hemodynamics during cardiopulmonary resuscitation

How does CPR eject blood into the aorta?

Closed chest CPR results in phasic blood flow. There has been considerable controversy regarding the mechanisms

responsible for this forward blood flow. According to the "cardiac compression theory," direct compression of the left and right ventricles between the sternum and vertebral column creates a pressure gradient between the ventricle and the aorta (or pulmonary artery in the case of the right ventricle). This pressure gradient closes the mitral (and tricuspid) valve and ejects blood forward out of the ventricle. According to this paradigm, the ventricle then refills during the decompression phase. The theory was proposed by Kouwenhoven and colleagues.[20] This view was essentially unchallenged until the 1970s. In 1976, Criley and colleagues described the phenomenon of "cough cardiopulmonary resuscitation" and ascribed the forward flow generated by coughing to the increased intrathoracic pressure generated during coughing.[21] In the 1980s, studies in dogs[22] and in man[23] led to the proposal of the "thoracic pump" theory for antegrade flow during CPR. According to the thoracic pump theory, external chest decompression increases intrathoracic pressure, forcing blood to flow from the thoracic to the systemic circulation. Retrograde flow from the right side of the heart to the systemic veins is prevented by the venous valves. According to this paradigm, the heart acts merely as a passive conduit without having a pump function.
Fig. 17.6. Changes in carotid artery flow in the pig model following VF cardiac arrest. (Modified from Steen *et al. Resuscitation* 2003; **58**: 249–258. Reproduced with permission from *Resuscitation.*[8])
Fig. 17.7. Changes in left anterior descending coronary artery and left carotid artery flow following VF cardiac arrest do not parallel each other. (With permission from Professor S. Steen, University of Lund.)

This theory requires the AV valves to be open during the compression phase of CPR. Two transthoracic echocardiographic studies reported in the early 1980s during CPR in man supported the thoracic pump theory.[24,25] Guerci and colleagues also concluded, on the basis of observations of the aortic pressure-flow relation during CPR in dogs, that aortic flow was due to fluctuations in intrathoracic pressure.[26] Other studies performed in dogs and in pigs, however, supported the cardiac pump hypothesis.[27–29]

The availability of transesophageal echocardiography has provided the opportunity to study the mechanisms involved during CPR in man in much greater detail. Transesophageal echocardiography can be performed without interrupting cardiac massage and the quality and stability of the imaging is generally superior to transthoracic echocardiography. Several studies concluded that the mechanism of antegrade flow during CPR was consistent with the cardiac pump theory.[30,31] This conclusion was based on the observations that the mitral valve closed during the compression phase and opened during the decompression phase, and that the size of both left and right ventricular cavities fell during the compression phase. In contrast, another study performed in 17 patients undergoing CPR suggests that the physiological mechanisms responsible for antegrade flow may differ from patient to patient.[32] In this study both pulmonary venous and trans-mitral flow were assessed. In 5 of the 17 patients the mitral valve closed during the compression phase of CPR, with associated mitral regurgitation and forward aortic flow, consistent with the cardiac pump theory. In the remaining 12 patients the mitral valve remained open during both the compression and decompression phases of CPR, and peak forward mitral flow also occurred during the compression phase in this group. In 8 of these 12 patients, forward mitral flow during the compression phase was accompanied by forward pulmonary vein flow, consistent with the classic "thoracic pump" mechanism. In the remaining 4 patients, forward mitral flow during the compression phase was accompanied by backwards pulmonary vein flow, which the authors suggested implied a "left atrial pump" mechanism, in which the left atrium rather than the left ventricle was the major target of chest compression. Downtime was much shorter in the 5 patients in whom the cardiac pump mechanism was thought to be operating than in the remaining 12 patients.

These three mechanisms are summarized schematically in Fig. 17.8. Whatever the mechanism, it is clear that antegrade flow occurs in both the thoracic aorta and the pulmonary artery during the compression phase of CPR and retrograde flow occurs in these vessels during the release or decompression phases.

Changes in aortic and pulmonary artery pressures during CPR

Steen and colleagues reported the hemodynamic effects of CPR using the LUCAS (Lund University Cardiac Arrest

Blood flow during chest compression
Fig. 17.8. Schematic representation of the three mechanisms by which CPR ejects blood into the aorta. LA – left atrium, LV – left ventricle, PV – pulmonary vein, Ao – aorta, MV – mitral valve. (Reproduced with permission from *Circulation*.[32])

System) device in anesthetised pigs.[33] The LUCAS device provides automatic mechanical chest compression; active "physiological" decompression.[33] CPR was instituted for 3–5 minutes after 6.5 minutes of VF (when the "coronary perfusion pressure" has reached zero). The hemodynamic effects in a typical animal are shown on the right of Fig. 17.5. Here, the compression phase is akin to "systole" and the decompression phase is akin to "diastole." During the entire 3½ minutes of CPR the compression pressure in the right atrium (top pressure trace) exceeded the pressure in the intrathoracic aorta (the second highest pressure trace). This reveals a negative "coronary perfusion pressure" during the compression phase. There was also a negative "coronary perfusion pressure" during the decompression phase for 1 minute after instituting CPR, but the "coronary perfusion pressure" during decompression then became positive, reaching a peak of 18 mmHg at 1½ minutes before declining slightly. Intrathoracic aortic pressure reached approximately 40 mmHg during CPR. Observations in man during CPR have shown peak systolic arterial pressures of between 60 and 80 mmHg.[34–36]

A study in pigs has shown that during closed chest CPR, compression phase pulmonary artery pressure was approximately 80–90 mmHg, mean pulmonary artery pressure was approximately 40 mmHg, and mean left atrial pressure approximately 3–4 mmHg lower than this.[37]

Cardiac output during CPR

Studies in dogs and in pigs have suggested that during optimal CPR, cardiac output is between 25% and 40% of pre-arrest values.[27,37–39]

Carotid and cerebral blood flow during CPR

In the pig model, Steen and colleagues showed that appreciable common carotid blood flow is apparent within seconds of initiating compression/decompression CPR using the LUCAS device. Values of approximately 300 ml/min were obtained when CPR was sustained, but even brief interruptions of CPR dramatically reduced carotid blood flow Fig. 17.9.[33] Cerebral blood flow is determined by the gradient between carotid artery and intracranial pressure. Assuming an ischemic threshold level of cerebral tissue oxygen content of 8 mmHg, a recent report suggested that, during standard CPR in
Fig. 17.9. The blood flow in the left internal carotid artery during 3.5 minutes of mechanical compressions followed by defibrillation attempts with (II) and (III) interrupting the chest compressions. Mean value ± S.E.M., $n=5$ in each group. (Reproduced with permission from *Resuscitation.*[8])

man, cerebral tissue oxygen content may be lower than this value much of the time. However, optimally performed CPR that maintained coronary perfusion pressure at least 25 mmHg was associated with cerebral tissue oxygen content greater than 8 mmHg.[40] A study in dogs demonstrated that if CPR is started immediately and "coronary perfusion pressures" are maintained above 25 mmHg, cerebral blood flow (measured by using microspheres) and cerebral ATP were both maintained at approximately 60% of pre-cardiac arrest values. In contrast, when CPR was delayed for 6 minutes after cardiac arrest, a coronary perfusion pressure of 35 mmHg was required to produce similar cerebral blood flow and cerebral ATP content. Furthermore, when CPR was delayed for 12 minutes, even this level of coronary perfusion pressure failed to restore cerebral blood flow.[41] Lindner and colleagues demonstrated that active compression–decompression CPR produced greater cerebral perfusion pressures and greater cerebral oxygen delivery than did standard CPR in a pig model.[42]

Coronary blood flow during CPR

Studies in animal models have shown that coronary flow is retrograde during the compression phase of CPR and antegrade during the release or decompression phase.[37,43,44] The retrograde flow during the compression phase continued even when the "coronary perfusion pressure" was raised throughout the CPR cycle by more effective CPR.[44] This presumably is related to the importance of left ventricular intra-cavity pressure in determining coronary blood flow. In the pig model, assessing CPR by using a mechanical device, even at 2.5-inch thumper strokes, coronary blood flow was less than 50% of pre-arrest values, and with thumper strokes of 1.5 inches, coronary flow was approximately 15% of baseline pre-arrest values.[43] Changes in coronary blood flow during CPR in dogs were related to changes in "coronary perfusion pressure."[45] Wolfe and colleagues observed that in dogs coronary blood flow fell at very high compression rates because of a reduction in "diastolic perfusion time" (i.e., the time spent in the relaxation phase during which antegrade coronary flow occurs). Optimal coronary flow occurred at a compression rate of 120/min.[46]

Effects of interruption of CPR on hemodynamics

Interrupting CPR for rescue breathing adversely affects hemodynamics. Berg and colleagues compared the effects of CPR at 100 compressions per minute with a brief rest period every minute for the rescuer to take 2 deep breaths vs. a protocol involving cycles of 15 compressions at 100 per minute each interrupted by 2 rescue breaths. The integrated coronary perfusion pressure over each cycle was substantially reduced in the rescue breathing group because of a reduction in aortic pressure during the rescue breathing phase, and because the number of chest compressions was also lower in this group.[47] Furthermore, Steen and colleagues showed in the pig model that periods of 30 seconds of CPR between defibrillation attempts were insufficient to generate an adequate "coronary perfusion pressure" (i.e., at least 15 mmHg) and, on the basis of these observations, the authors recommended at least 90 seconds of CPR between each defibrillation attempt.[8]

Coronary perfusion pressure and recovery of spontaneous circulation (ROSC)

In 1940, Wiggers noted that 3 to 5 minutes after the onset of VF (appreciably earlier than the "irretrievable failure of the central nervous system"), the heart enters an "atonic phase" in which "anoxia causes depression of contractile force and slows conduction."[48]

The impact of "coronary perfusion pressure" on the likelihood of ROSC has been described in animals and in man.[18,19,49,50] The probability of ROSC is low when coronary perfusion gradient is < 15–20 mmHg. **Fig. 17.10** shows human data relating likelihood of ROSC to coronary perfusion pressure during CPR.[19]

There are two potential reasons why this might be so.

1. At lower coronary perfusion pressures, profound myocardial ischemia may prevent ROSC. Ralston and colleagues have shown in a dog model that a mean myocardial blood flow less than 0.13 ml/min per g tissue was associated with no survival, whereas a flow of > 0.16 ml/min per g tissue was associated with survival.[51] Although this is likely to be a contributory factor, cardiac contractile function recovers after even relatively long periods of total ischemia. In the isolated perfused dog heart, postischemic contractile function was markedly depressed after 25 and 30 minutes of normothermic global ischemia, but the reduction in left ventricular contractile function after 15 to 20 minutes of global ischemia was only mild.[52] This threshold of 20 minutes is consistent with observations in other species.[53–55] In the swine model, even at 20 minutes of VF (without CPR), 89% of animals had myocardial ATP levels > 20% of control and adenylate charge ratio > 0.60 – values known to be associated with reversibility of myocyte injury.[56]

2. "Coronary perfusion pressure" is defined as the pressure difference between aorta and right atrium during the decompression phase. During VF aortic pressure is almost identical to LV pressure and right atrial pressure is almost
Fig. 17.10. Percentage of patients with return of spontaneous circulation (ROSC) as a function of the maximal coronary perfusion pressure.

identical to RV pressure. Accordingly, coronary perfusion pressure provides a measure of the pressure gradient across the interventricular septum during cardiac arrest. This is a measure of the true "preload" acting on the left ventricle. As discussed below, this may be an important determinant of ROSC, because it determines the degree of myocyte stretch and therefore, according to the Frank–Starling mechanism, the force of myocyte contraction when it is activated by electrical depolarization.

The concept of left ventricular preload and the Effect of Constraint from the Pericardium and Right Ventricle

Frank[57] first described the importance of the degree of cardiac muscle stretch during diastole (preload) in determining its subsequent force of contraction. The mechanism of this observation is related predominantly to the nature of the actin-myosin interaction in the sarcomere. The force generated by a single sarcomere is proportional to the number of actin-myosin bonds and the available energy from ATP hydrolysis. Generation of optimal force is achieved when the sarcomere length is approximately 2.2 to 2.3 microns, which corresponds to the maximum number of actin–myosin interactions. At sarcomere lengths less than approximately 1.5 microns, there are no actin–myosin interactions and force generation is more or less eliminated. In addition to the actin–myosin interaction, the giant filamentous protein Titin which

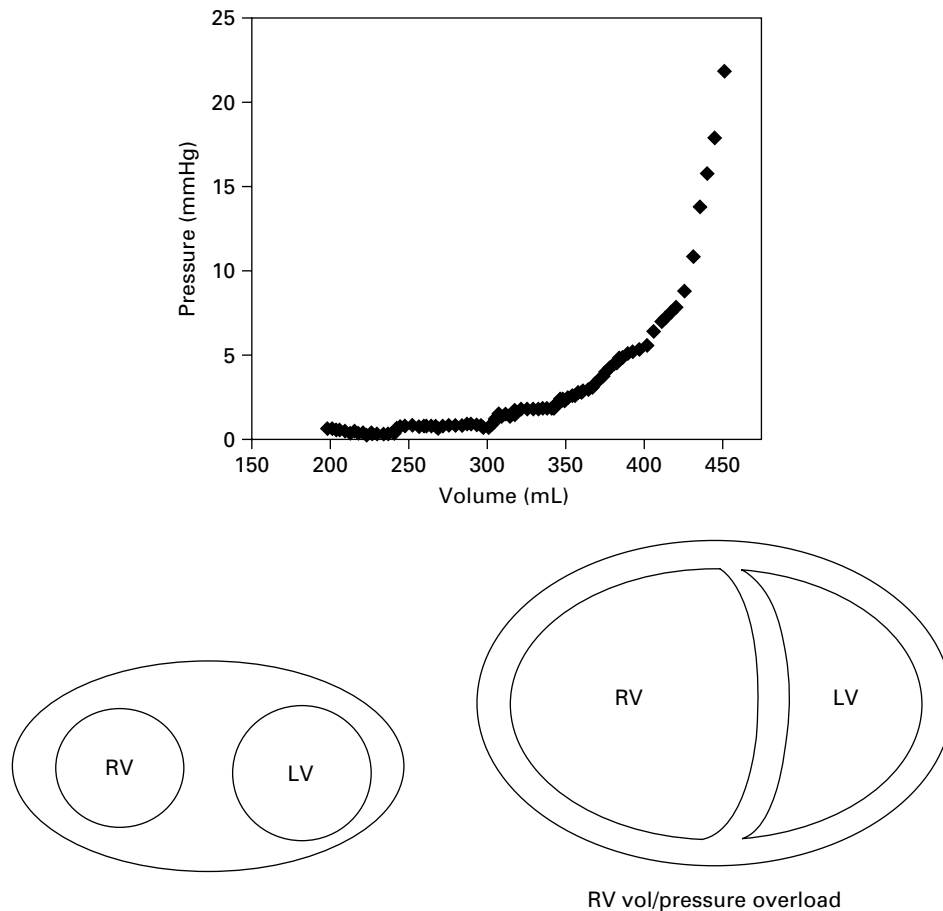
spans the sarcomere, acts like a molecular "spring," storing potential energy when it is stretched and it may also play a role in development of stretch-dependent passive tension.[58] As a result of the length dependency of the actin–myosin interaction and of titin tension development, below a certain "slack length," myocytes do not generate tension. Patterson and Starling observed that the output of the left ventricle was related to changes in the venous pressure.[59] In clinical practice it has been assumed that changes in left atrial pressure (or LV end diastole pressure or pulmonary capillary wedge pressure) parallel those of LV diastole stretch ("preload") and that changes in pressure can be used as a surrogate for changes in stretch. Indeed, the literature commonly refers to the Frank-Starling relationship, as if Frank and Starling had described the same phenomenon. Within the physiological range, the use of change in LVEDP to predict changes in preload is generally valid, but in certain pathophysiological states it is not. The effective distending pressure acting on the left ventricle at end diastole is the left ventricular end diastolic pressure minus external pressures acting on the left ventricle from the pericardium, and from the right ventricle via the interventricular septum. In health, both RV end diastolic pressure and pericardial pressure are close to zero; therefore, changes in LVEDP generally parallel those of LV end diastolic volume. As the pericardium is stretched, however, there is an exponential increase in pericardial pressure (Fig. 17.11).[60] In most situations, RVEDP and pericardial pressure are almost identical, because the RV is thin walled and therefore maintains only


Fig. 17.11. The pericardium has a J-shaped stress–strain relation. When it is stretched (e.g., by right ventricular volume overload) pericardial pressure and RV end-diastolic pressure become elevated. The filling of the LV is then impeded by external constraint from the pericardium and RV, despite a high LVEDP. The interventricular septum is shifted to the left. From Frenneaux, M. Cardiopulmonary resuscitation: some physiological considerations. *Resuscitation* 2003; **58**: 259–265. Reproduced with permission from *Resuscitation*.

a small pressure gradient across it.[61] In experimental situations in which the pericardium is stretched by acute enlargement of the right ventricle (e.g., experimental pulmonary embolism), the pericardial and right ventricular end diastolic pressures may be substantially more than zero. In this situation the filling of the left ventricle is impeded by the external constraint from the pericardium (pericardial constraint) and from the right ventricle (diastolic ventricular interaction). The measured intracavity LVEDP overestimates the true LV preload. The interventricular septum, normally convex to the right at end diastole, becomes flattened, and the position of the septum at end diastole has been shown to be very closely related to the trans-septal pressure gradient, i.e., it reflects the degree of ventricular interaction.[62]

Pericardial constraint and diastolic ventricular interaction have been well described in animal experimental models of acute right ventricular pressure and volume overload.[63] Important diastolic ventricular interaction is also seen in many patients with chronic heart failure.[64,65] Reducing central blood volume in these patients (using a lower body "suction" device) resulted in a fall in RV volume, and of right atrial and pulmonary capillary wedge pressures, but despite this, left ventricular diastolic volume increased (Fig. 17.12). The explanation was confirmed in a canine rapid pacing heart failure model. While central blood volume unloading reduced LV end diastolic pressure, it reduced pericardial pressure and RV end diastolic pressure even more; therefore, the effective distending pressure increased, resulting in an increase in LV diastolic volume and stroke volume.[66] These observations are shown in **Fig. 17.13**.

Steen's observations in the pig model suggest that important pericardially mediated ventricular interaction may occur following cardiac arrest.[8] As noted previously, Steen and colleagues observed that as blood flowed along its pressure gradient from the aorta to the right side of the heart, the right ventricle became markedly distended. Furthermore, there was a progressive increase in right atrial pressure (and, by implication right ventricular pressure) during the first 2 minutes or so after cardiac arrest, before this slowly declined again. Pericardial pressure also rose progressively during the first 2 minutes after cardiac arrest before gradually declining. As expected, right atrial pressure and pericardial pressure changes paralleled each other almost exactly, with pericardial pressure marginally lower than right atrial pressure. These changes are shown in Fig. 17.14. These observations, performed in open chest pigs, clearly show that the pericardium was stretched sufficiently to raise pericardial pressure substantially. In the closed chest situation, this effect would be expected to be greater. Right ventricular volume fell slightly when right atrial and pericardial pressures started to decline. As discussed earlier, this decline in right atrial and pericardial pressures and right ventricular volume after about 3–4 minutes presumably reflects the withdrawal of sympathetic tone, as the brainstem vasomotor centers become profoundly ischemic.

As noted previously, there is also a temporary increase in aortic pressure between approximately 1 and 3 minutes after the onset of VF (Fig. 17.5)**,** presumably due to the combined effects of increased sympathetic outflow and

"waterfall" phenomena, then aortic pressure starts to decline again, presumably because of a reduction in sympathetic outflow.

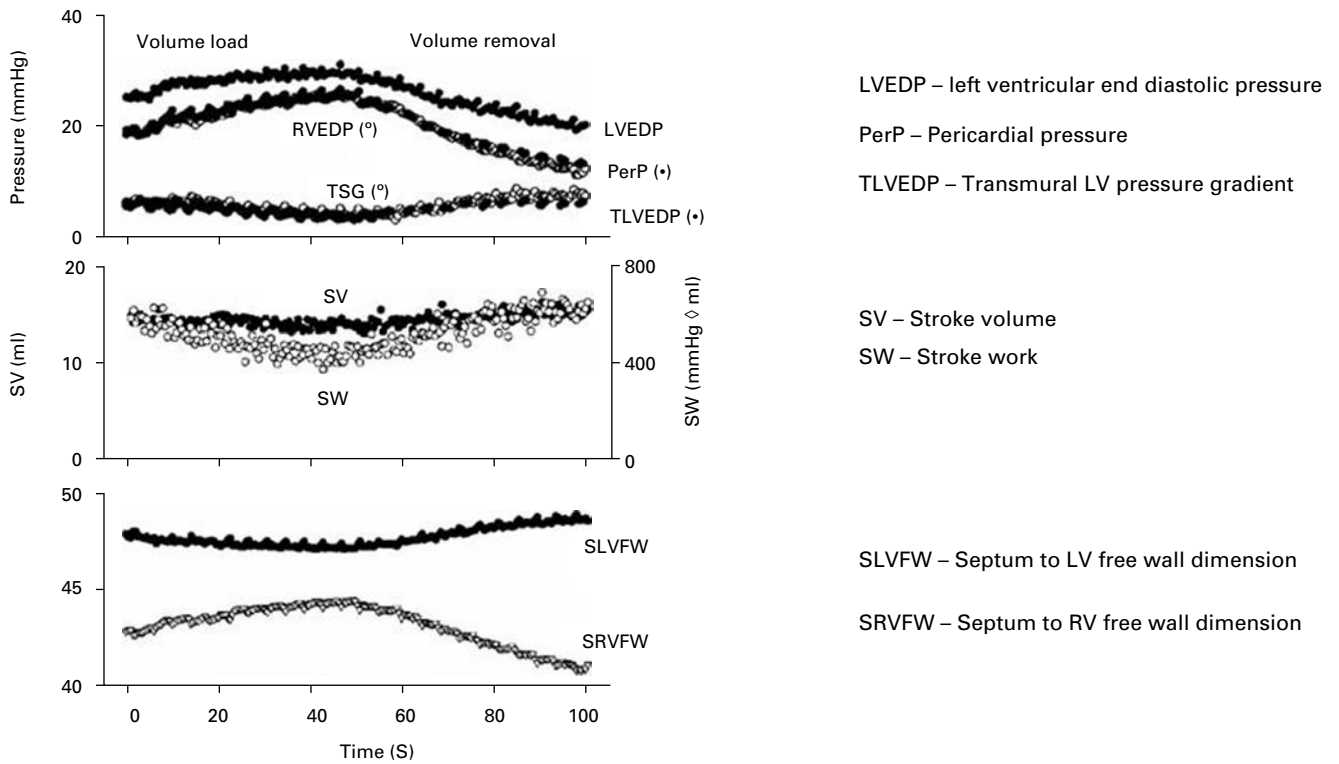
If we make the reasonable assumptions that intrathoracic aortic pressure approximates the left ventricular pressure and that right atrial pressure approximates the right ventricular pressure during cardiac arrest, then we can calculate the serial changes in left ventricular transmural pressure gradient (LV minus pericardial pressure) and trans-septal pressure gradient (left ventricular minus right ventricular pressure gradient). Changes in septal position and left ventricular volume would be expected to parallel changes in these gradients, which are in effect the distending pressures acting on the left ventricle. We have applied these calculations to a typical recording of aortic, RA, and pericardial pressures reported by Steen and colleagues.[8] A rapid initial fall in trans-septal and transmural gradients is followed by a slight increase, until approximately 4 minutes (corresponding to the period during which aortic pressures increase), followed by a subsequent decline to about zero. Berg and colleagues recently reported the changes in left and right ventricular volume after VF arrest in the pig.[7] Typical short axis MRI appearances are shown in Fig. 17.15. During the first 30 seconds after cardiac arrest there is a dramatic increase in right ventricular volume, with a shift of the interventricular septum to the left and a marked reduction in left ventricular volume. Between approximately 1 and 5 minutes, left ventricular volume increases modestly (but not back to baseline), although the interventricular septum remains


Fig. 17.13. Example of a study in the canine rapid pacing heart failure model. Volume unloading reduced pericardial pressure more than it reduced LV diastolic pressure, therefore true filling pressure increased and stroke volume increased. Fig. 17.14. Changes in aortic pressure (AP), right atrial pressure (RAP) and pericardial pressure following VF cardiac arrest in the pig Model. (Reproduced with permission from *Resuscitation.*[8])
Fig. 17.15. Short-axis views of RV and LV through same mid-ventricular slice in 1 animal during 30 minutes of untreated VF. Time 0 refers to time VF was induced, and next 8 views were at respectively labeled duration of untreated VF. (Reproduced with permission from *Circulation*.[7])

dramatically flattened. Subsequently, left ventricular volume starts to decline again. These changes imply the rapid development of very marked ventricular interaction with some amelioration of this interaction between 1 and 5 minutes, and are entirely to be anticipated on the basis of the changes in the pressure gradient calculated form the data of Steen *et al.* In Fig. 17.16, the right and left ventricular volume changes reported by Berg and colleagues are plotted above the calculated changes in transmural gradient in the data reported by Steen and colleagues. As expected, the left ventricular volume changes closely mirror the changes in the transmural and trans-septal pressure gradients. Because, during cardiac arrest, aortic pressure is approximately LV pressure and since RA pressure is approximately RV pressure, AO-RA pressure is a close approximation to the pressure gradient between LV and RV (the "trans-septal" gradient).

This may have important implications for our understanding of the mechanism of ROSC. When ventricular interaction is marked, the degree of myocyte stretch may be so small that return of electrical activity generates only a minimal force of contraction, especially if the myocytes are also profoundly ischemic.

Effects of ventilation on hemodynamics during cardiac arrest

It is common practice to ventilate patients during cardiac arrest, on the assumption that this will improve oxygen delivery to the tissues, particularly the brain. Recent observations have called into question the validity of this assumption. Jellinek *et al.* reported the hemodynamic effects of positive airways pressure in patients undergoing
Fig. 17.16. The MRI calculated LV and RV volumes reported in the swine model by Berg *et al.*[63] are plotted against the changes in aortic, RA and coronary perfusion pressures reported by Steen *et al.*[8] There are no MRI data points between 1 and 5 minutes, but the changes in LV volume are predictable on the basis of changes in "coronary perfusion pressure."

AICD threshold testing. Before VF occurred, positive airway pressure increased right atrial pressure and reduced aortic pressure and left ventricular stroke volume. During VF arrest, positive airway pressure modestly reduced the coronary perfusion pressure. There was no evidence of collapse of the inferior vena cava, but in some patients there was a marked reduction in the diameter of the superior vena cava.[12] In the dog, positive airway pressure has been shown to cause collapse of the inferior vena cava resulting in a "waterfall effect."[17]

In addition to the direct effect of positive airways pressure on coronary perfusion pressure, ventilation is associated with substantial interruptions in compressions, and, as discussed above, this may cause substantial and prolonged reductions in coronary perfusion pressure. Woollard and colleagues reported on a randomized trial comparing compression-only vs. standard telephone CPR instructions in simulated cardiac arrest. Two and a half times more compressions were delivered during a standard ambulance response time in compression-only CPR in the compression-only group.[67] Furthermore, in pigs, CPR with rescue breathing was shown by Berg and colleagues to be associated with substantially lower "integrated coronary perfusion pressure" and left ventricular blood flow than compression-only CPR.[7]

An alternative approach to ventilation is the use of the so-called "inspiratory impedance threshold Device" (ITV). During the inflow phase, this provides a respiratory resistance which increases the negative intrathoracic pressure, analogous to the Müller maneuver. The hemodynamic effects of adding the device to the respiratory circuit in pigs was assessed during VF cardiac arrest. There was a non-significant increase in the coronary perfusion pressure (from $12.5. \pm 1.5$ to 14.8 ± 1.3 mmHg averaged during 28 minutes of CPR) associated with significant increases in left ventricular and cerebral blood flows.[68] Pilot studies in humans suggest that use of the ITV during CPR is associated with improved short term survival.[69,70]

The combination of positive end expiratory pressure ventilation (PEEP) with the inspiratory threshold device was reported to have particularly beneficial hemodynamic effects during active compression-decompression CPR in the pig. The addition of PEEP did not alter diastolic coronary perfusion pressure, but may nevertheless increase myocardial perfusion because the gradient of the diastolic aorta to left ventricular pressure was augmented, probably because PEEP reduces alveolar collapse, leading to an increase in indirect myocardial compression.[71]

Hemodynamic effects of spontaneous gasping during cardiac arrest

Gasping was first described by Legallois in 1812, in a variety of animal species including man.[72] It is very common in the human newborn and is also frequently observed after cardiac arrest. In this setting it appears to be triggered by ischemia of the brainstem and persists until the respiratory center in the caudal medulla is completely disabled. In the pig model it is typically observed between the first and second minute after the onset of cardiac arrest if no CPR is given. It begins weakly, increasing to a maximum, and then disappears typically by about 5 minutes, but sometimes longer. If effective cardiac compressions are given to gasping pigs they continue to gasp as long as the chest compressions create a minimum blood flow to the brainstem. Gasping produces gas exchange, and a sharp increase in arterial oxygen saturation, and a fall in arterial carbon dioxide tension typically follows the gasp.[73,74] As shown in **Fig. 17.17**, during the expiratory phase of a gasp there is
Fig. 17.17. The effects of a gasp on aortic pressure, central venous pressure, tracheal and pleural pressures and carotid flow in the swine VF model are shown. Note the effects of persistent atrial contractions following VF arrest. During the expiratory phase of the gasp there is an increase in carotid flow. (S. Steen, unpublished observations.)

an increase in aortic pressure and in carotid blood flow. The breath occurs against a partially closed airway and generates a negative intrapleural pressure of approximately 40 mmHg. This negative intrapleural pressure markedly reduces right atrial and pericardial pressures and increases the pressure gradient between aorta and RA. Xie and colleagues showed in the pig that during the inspiratory phase of the gasp, left ventricular area substantially increased and then returned to its "pre-gasp" value during the expiratory phase. This generated a stroke volume of approximately 60% of that seen in the spontaneously beating heart. The expiratory phase of the gasp was also associated with a substantial increase in end-tidal carbon dioxide.[75]

The appearance of gasping in a patient with cardiac arrest should not therefore be considered as a sign of recovery that discourages continued resuscitative measures, but implies that the brainstem is ischemic but still viable. The frequency of gasping has been reported to be predictive of the success of resuscitation.[76,77]

Introduction

The resurgence of resuscitation research in the 1970s and 1980s initially focused on the physiological mechanisms for systemic blood flow during closed chest resuscitation for cardiac arrest.[1,2] At the same time, the importance of both myocardial and cerebral blood flow during cardiopulmonary resuscitation (CPR) became evident. Using contemporary, state-of-art techniques, investigators found that regional perfusion of vital organs occurs with closed chest compression CPR, but at substantially lower rates than that measured during normal sinus rhythm.[3–5] Such studies have shown that standard anteroposterior chest compressions can, at best, provide 30% to 40% of normal cerebral blood flow levels. Myocardial blood flow achieved with external chest compressions is often even lower, typically between 10% and 30% of normal. Peripheral perfusion is almost non-existent during CPR. Nevertheless, good CPR efforts can temporarily provide at least some perfusion to the myocardium and cerebrum until more definitive treatment (i.e., defibrillation) can be accomplished.

Myocardial perfusion during cardiac arrest can be estimated by measuring "coronary perfusion pressure" during the resuscitation effort. This perfusion pressure gradient correlates well with resultant myocardial blood flow generated with CPR and with the subsequent possibility of successful defibrillation.[3,4] The critical importance of coronary perfusion pressure during CPR has been confirmed in both laboratory and clinical studies of resuscitation. This part of the chapter focuses on coronary perfusion pressure during CPR: its generation and impact.

Determinants of coronary perfusion pressure during cardiopulmonary resuscitation

AoD pressure during CPR

The importance of an adequate perfusion pressure for resuscitation from cardiac arrest was first noted by Crile and Dolley in 1906.[6] While studying means of reversing cardiorespiratory arrest in dogs and cats asphyxiated with chloroform or ether (popular anesthetics of that time), they noted that "the basic problem, then, in resuscitations seems to us to be that of securing some means of some infusion – a coronary pressure, approximately amounting to 30 to 40 mm Hg." This concept was later reinforced by the work of Redding and Pearson.[7–10] These investigators showed that, when aortic diastolic pressure was raised above 40 mm Hg, usually with α-adrenergic drugs or other special maneuvers, experimental animals could be successfully resuscitated from cardiac arrest. When this diastolic pressure was not achieved, however, the animals could not be resuscitated. From this early work they deduced the mechanism of action for epinephrine and other α-adrenergic agonists during cardiac arrest. They postulated that such agents caused peripheral vasoconstriction, which raised the aortic diastolic pressure and increased coronary perfusion. Otto and coworkers confirmed this postulate in the late 1970s and early 1980s. By using selective blockade, they elucidated the relative importance of α- and β-adrenergic receptors during resuscitation. Animals that were α-blocked had difficulty in responding to epinephrine, i.e., diastolic aortic pressure did not increase and they were not resuscitated. In contrast, those that were β-blocked were successfully resuscitated and exhibited

peripheral vasoconstriction with elevated aortic diastolic pressures in response to adrenergic agonists.[11–13]

AoD-RAD pressure during CPR

During the early 1980s, investigators not only confirmed the importance of a perfusion pressure (i.e., the aortic diastolic pressure) but also of a defined perfusion pressure gradient, which included a "downstream" pressure from the myocardial venous system acting as an impedance to forward flow. Voorhees _et al._, measuring regional blood flow to the brain, heart, and other peripheral tissues, noted that the arteriovenous gradient was important during the compression phase of CPR for cerebral blood flow and postulated that the same arteriovenous gradient during the relaxation component of CPR was important for myocardial blood flow.[14] Both Niemann _et al._[15] and Ditchey _et al._[16] suggested that coronary perfusion pressure results from the difference in pressure between the aortic and the right atrium. Ditchey _et al._ found that coronary blood flow during CPR was a linear function of the mean pressure difference generated across the coronary circulation and that the ascending aortic and right atrial pressure difference and coronary flow were highest during the relaxation phase of each chest compression cycle (Fig. 18.1).
Fig. 18.1. Relationship as percent of control between coronary blood flow and coronary perfusion pressure defined as mean ascending aortic pressure minus mean right atrial pressure difference generated during CPR. (From ref. 16.)

Alternatives for calculating CPP

In spite of these insights on coronary perfusion pressure and its importance for generating myocardial blood flow and facilitating resuscitation, the best method for measuring coronary perfusion pressure during CPR has not been standardized. Some investigators suggested that subtracting the middiastolic right atrial pressure from simultaneously obtained middiastolic aortic pressure was sufficient,[3,17] whereas others suggested that coronary perfusion pressure be obtained by measuring the peak positive diastolic pressure gradient between the aorta and the right atrium.[18] Another approach has been to calculate the coronary perfusion pressure gradient by subtracting the mean right atrial diastolic pressure from the mean diastolic aortic pressure.[4,5] To address this uncertainty, the Utstein-style guidelines for reporting laboratory CPR research specify that the point just before compression be used as the reference point for measurement of coronary perfusion pressure. This point was selected because it is easily identified and more likely to be consistent among investigators.[19]

An alternative method for calculating coronary perfusion pressure is to measure the integrated area under the aortic diastolic pressure minus the right atrial diastolic pressure curves during each minute of cardiopulmonary resuscitation.[20] Since chest compression/relaxation cycles (i.e., the relaxation phase specifically) are responsible for generation of blood flow to the heart, a decrease in delivered chest compression cycles can markedly decrease the total amount of myocardial perfusion generated with the resuscitation effort. Calculating coronary perfusion pressure in the usual fashion (end-diastolic aortic minus right atrial pressures) does not account for periods when chest compression is interrupted. A more accurate method is to use the integrated area (iCPP) over each minute. The effect of chest compression pauses on coronary perfusion pressure becomes readily apparent, typically resulting in a 40% decrease in cumulative coronary perfusion (Fig. 18.2).

Interruption of chest compression/relaxation has direct effects on the amount of coronary perfusion pressure generated during the period of 15 compression cycles. We found that, at the beginning of each cycle of 15, the first 5–10 compressions/relaxations are "building-up" the coronary perfusion gradient and that it is not optimal until at least one-third of the series is completed.[21] Then, with cessation of chest compressions/relaxations, this diastolic gradient falls off rapidly, often returning to near zero within 5–10 seconds. Often the coronary perfusion pressure gradient falls even sooner to below the "critical closing pressure" predicting no forward flow after just a few seconds interruption of chest compression/relaxation. When chest compressions do resume, the coronary perfusion gradient must be rebuilt, usually starting from zero (Fig. 18.3).
Fig. 18.2. Caption to come

AoS-RaS: no antegrade flow to myocardium

Several investigators have explored the possibility of whether coronary flow could occur during the compression phase of CPR.[15,16,22] Data from Schleien *et al.* suggested that forward coronary flow may occur during the compression phase of CPR, when epinephrine infusions are used, because a positive aortic to right atrial pressure gradient was observed during the compression phase. They concluded that the diastolic gradient as an index of coronary blood flow during CPR may be incomplete.[22] Subsequent work has shown that many methods of CPR routinely generate some degree of aortic to right atrial pressure difference during the compression phase, either positive or negative; hence, the potential for antegrade or even retrograde coronary blood flow exists during chest compression or CPR systole.[23]
Fig. 18.3. Caption to come

Figure 18.4 shows a positive "gradient" during the compression phase of CPR. Total "net" flow during CPR may require consideration of the entire cardiac cycle (the compression phase and the relaxation phase). This hypothesis has been tested by using an intracoronary Doppler flow catheter to determine the relationship among (*a*) systolic or compression phase coronary perfusion pressure, (*b*) diastolic or relaxation-phase coronary perfusion, and (*c*) direction of coronary blood flow in the proximal left anterior coronary artery.[24] Retrograde coronary artery blood flow (from the coronary back into the ascending aorta) occurred routinely during the compression phase of manual CPR, regardless of the measured aortic to right atrial pressure gradient. Even in circumstances where the aortic pressure exceeded right atrial pressure during compressions, no antegrade coronary flow occurred. Rather, such antegrade coronary blood flow occurred exclusively during the relaxation phase of chest compression and correlated with a positive "diastolic" or relaxation-phase perfusion pressure gradient between the aorta and the right atrium. The greater the gradient, the larger the velocity of the antegrade coronary blood flow. Positive systolic coronary perfusion gradients occurring during the compression phase do not significantly improve
Fig. 18.4. Positive coronary perfusion pressure (*CPP*) gradient during compression phase of CPR where aortic systolic pressure minus right atrial systolic pressure remains positive.

antegrade blood flow and, indeed, can be associated with significant amounts of retrograde coronary flow. Hence, diastolic perfusion pressure gradients do account for the vast majority of cases of myocardial perfusion.

Under normal physiologic conditions, coronary perfusion pressure is conventionally defined as the difference in transmural myocardial pressure between the aortic and the left ventricular diastolic pressures. In subjects with normal ventricular filling pressures, the coronary driving pressure may be approximated by either the mean aortic pressure or the aortic diastolic pressure. When ventricular filling pressures are elevated, however, one of two corrections is typically used. First, the right atrial pressure could be subtracted since the coronary sinus drains into the right atrium, leaving the perfusion pressure then equal to the aortic pressure minus right atrial pressure.[25] Nevertheless, even the use of right atrial pressure tends to overestimate the perfusion pressure gradient when left ventricular diastolic pressure is increased. Second, the aortic pressure minus the left ventricular diastolic pressure could be used. CPR investigators have typically chosen the former formula and have used the right atrial pressure. Kern and coworkers (unpublished data) have assessed the relationship between transmural myocardial blood flow, measured with microspheres, and coronary perfusion pressure, which was defined as either aortic diastolic pressure minus right atrial diastolic pressure or, alternatively, aortic diastolic pressure minus left ventricular end-diastolic pressure. These investigators found that coronary perfusion pressure defined as aortic diastolic pressure minus right atrial diastolic pressure had a correlation coefficient of 0.58 with myocardial blood flow, whereas perfusion pressure defined as aortic diastolic pressure minus left ventricular end-diastolic pressure had a correlation coefficient of 0.47 during CPR.

Myocardial blood flow and coronary perfusion pressure during cardiopulmonary resuscitation

Regional perfusion or organ blood flow under nearly all physiologic conditions is determined by the pressure gradient across the vascular bed of interest divided by vascular resistance (flow equals arterial pressure minus venous pressure divided by vascular resistance or $Q = P_1 - P_2 / R$). During normal sinus rhythm in the heart in vivo, coronary vascular resistance depends on at least three physiologically distinct components termed R_1, R_2, and R_3.[26] R_1 is the resistance of the epicardial coronary conductive vessel. In the absence of vascular spasm or fixed coronary stenoses, R_1 contributes only a small percentage of the total coronary resistance. R_2, the autoregulatory resistance factor, is the major component of coronary resistance during normal

sinus physiology. R_2 results primarily from the smooth muscle tone of the arteriolar bed. The compressive resistance factor, R_3, results from intramyocardial pressure during systole compressing the intramural coronary vessels. It is the chief factor accounting for the observation that myocardial blood flow during normal sinus rhythm occurs primarily in the diastolic phase of the cardiac cycle. Other factors influencing R_3 include left ventricular diastolic pressure and transmural differences in vascular density.

During cardiac arrest, coronary vascular resistance is dramatically different. Intrinsic coronary tone (R_2) is minimal because of local, metabolically mediated coronary vasodilatation. Potential mediators of coronary vasodilatation include extracellular acidosis, endogenous adenosine release, and vasoactive compounds of endothelial origin, such as nitric oxide and endothelin. These ischemically induced vasodilatory substances are thought to induce maximal coronary vasodilatation relatively quickly during cardiac arrest, perhaps within the first 15 to 20 seconds. As a consequence, myocardial blood flow during cardiac arrest and artificial circulatory support by any method or technique will be largely determined by the driving force or "pressure head" across the coronary circulation, namely, the arterial pressure minus the venous pressure and the coronary vascular resistance. In the setting of ventricular fibrillation and CPR, coronary vascular resistance consists mainly of an R_1 component from epicardial coronary compression and R_3 from the intramyocardial pressure generated by the fibrillating myocardium and chest compression. In contrast to the resistance seen during normal sinus physiology, coronary vascular resistance during CPR is minimal during the relaxation phase of chest compression.

Careful study of the data illustrating the relationship between CPP and myocardial blood flow during CPR shows that no myocardial blood flow occurs until a minimum coronary perfusion pressure of approximately 5–10 mmHg is achieved. This corresponds to the "critical closing pressure" for coronary perfusion pressure, below which flow stops secondary to intrinsic smooth muscle tone in the arteriole wall literally causing physical closure of the arteriolar vessels.[27] Under normal physiologic conditions it is estimated that this critical closing pressure is about 30–40 mmHg, and that during intense vasodilatation it decreases to approximately 10–12 mmHg.[27] Data gathered during actual cardiac arrest suggest that during maximal vasodilatation this closing pressure may fall as low as 5–10 mmHg, but does not become zero, as some have previously postulated.[28] This "closing pressure," below which no flow seems to occur is a key concept in understanding the importance of limiting interruptions to chest compressions/relaxations during which the coronary perfusion pressure inevitably falls.

Correlation between CPP and MBF

Aortic and right atrial pressures can easily be measured in the laboratory and also, but with some effort, in the clinical setting. During the relaxation phase of chest compressions, aortic pressure largely depends upon intrinsic arterial tone. Right atrial pressure during the relaxation phase of CPR is largely determined by central venous return and venous capacitance. An excellent correlation has been established between the coronary perfusion pressure and simultaneously measured myocardial blood flow during CPR.[3–5,29] Data from three different laboratories demonstrate correlation coefficients in the range between 0.82 and 0.89. Ralston *et al.* found a correlation coefficient of 0.89 in dogs where no epinephrine was used and of 0.85 when epinephrine was used (Fig. 18.5).[3] Using epinephrine, Michael *et al.* found a

Fig. 18.6. Relationship between left ventricular blood flow and aortic diastolic pressure minus right atrial diastolic pressure during several forms of external CPR with and without use of epinephrine (From ref. 4.)

correlation coefficient of 0.84 (Fig. 18.6) and Halperin *et al.*, from the same laboratory at Johns Hopkins, found a correlation coefficient with multiple forms of CPR of 0.88 (Fig. 18.7).[4,5] Kern and coworkers reported a correlation coefficient of 0.82 between the coronary perfusion pressure achieved and the resultant myocardial blood flow to the anterior left ventricular wall.[29]

Many have noted, by general observation, that the typically low coronary perfusion pressures generated with standard CPR (10 to 20 mm Hg) produced only small

Fig. 18.7. Relationship between mean diastolic aortic pressure minus mean diastolic right atrial pressure and left ventricular free wall blood flow. Data include manual chest compressions at 60 compressions/min with prolonged duty cycle (M60L), manual compressions at 150 compressions/minute with prolonged duty cycle (M150), and vest CPR at 150 compressions/min with prolonged duration (V150). (From ref. 5.)

amounts of myocardial blood flow, usually no more than 20% of that observed during sinus rhythm. With a coronary perfusion pressure of 10 to 20 mm Hg, Ralston *et al.* found left ventricular flows of 15 to 20 ml/min/100 g.[3] Michael *et al.* found flows of 5 to 40 ml/min/100 g;[4] Halperin *et al.* found flows of 5 to 25 ml/min/100 g;[5] and Taylor *et al.* found flows of 10 to 15 ml/min/100 g.[30] These studies also demonstrated, however, that, if perfusion pressures are in the range of 40 to 60 mm Hg, excellent myocardial blood flow levels will result. Under these circumstances the following flows were found (all in milliliters per minute per 100 g): Ralston *et al.*, 60 to 90; Michael *et al.*, 40 to 100; Halperin *et al.*, 40 to 100; and Kern *et al.*, 50 to 200 (Fig. 18.8).[29]

In addition to obstructive epicardial coronary lesions that will affect the R_1 component of coronary resistance (discussed below), other interventions that increase one or more components of coronary resistance may alter the relationship between coronary perfusion pressure, and myocardial blood flow. One example of this is administration of endothelin-1. Early work with endothelin-1 as a pharmacologic adjunct for resuscitation demonstrated dramatic increases in coronary perfusion pressure, prompting initial enthusiasm for a promising new intervention.[31] Subsequent work demonstrated not only that coronary flow did not increase, but also that endothelin-1 adversely impacted affected survival 1 hour after resuscitation because sustained arterial vasoconstriction and increased cardiac work led to perfusion failure and refractory ventricular arrhythmias.[32,33]

Effect of coronary lesions on coronary flow

All of the previously described work correlating myocardial blood flow and coronary perfusion pressure was performed on experimental animals with normal coronary arteries and normal left ventricular function. The relationship between coronary perfusion pressure and myocardial blood flow during CPR has been helpful in understanding the physiology of blood flow production under these conditions. The established relationship, however, is derived from experiments in normal animals and may be limited in its applicability to humans, where the majority of sudden cardiac death victims have coronary artery disease.[34] To examine the effect of coronary artery lesions on the relationship between coronary perfusion pressure and myocardial blood flow during CPR, investigators at the University of Arizona evaluated a closed chest porcine model of fixed artificial coronary artery stenoses.[29] In this model with minimal collateral circulation, coronary artery lesions were found to have major effects on regional myocardial blood flow measured during CPR. With use of this closed chest model, chest compressions could be performed without compromising the integrity of the thoracic cage. Coronary stenoses greatly decrease the amount of distal coronary blood flow for any given coronary perfusion pressure produced. Complete coronary occlusion results in negligible distal myocardial perfusion, regardless of the coronary perfusion pressure. Myocardial blood flow measured during CPR continued to show a high correlation with coronary perfusion pressure, albeit with less myocardial blood flow for every increment in coronary perfusion pressure. With coronary perfusion pressures of 30 to 60 mm Hg, coronary stenosis resulted in an approximate 50% reduction in distal blood flow (Fig. 18.9). The data demonstrate that coronary lesions have an important effect on myocardial blood flow during CPR in that there was a substantial change in the relationship between coronary perfusion pressure and resultant myocardial blood flow. For any given coronary perfusion pressure generated with CPR, a 50% reduction in myocardial blood flow distal to the stenosis was seen (Fig. 18.10). This reduction occurred over a wide range of coronary perfusion pressures generated with external chest compressions. Previously determined levels of adequate perfusion pressure during CPR in models without coronary artery lesions may not be applicable to patients with coronary artery disease. Figure 18.11(a) and 18.11(b) shows the left anterior coronary artery before and after the creation of a 33% stenosis. Figure 18.12 shows left ventricular anterior endocardial blood flow proximal and
Fig. 18.9. Midleft anterior descending coronary artery stenosis results in significant reduction in distal myocardial blood flow over clinically realistic range of CPR-produced coronary perfusion pressures from 30 to 60 mm Hg. (From ref. 29.)
Fig. 18.10. Epicardial left ventricular blood flow above and below a patent coronary stenosis in midleft anterior descending coronary artery. Note decreased slope for myocardial blood flow as function of coronary perfusion pressure below stenosis when compared to that above stenosis. (From ref. 29.)

distal to the 33% diameter stenosis at 3 and 8 minutes of CPR. There was a significant difference between proximal and distal blood flow to the endocardium at 8 minutes of CPR. Therefore, even minimal or previously considered "insignificant" coronary lesions may have a profound effect on distal myocardial blood flow during the performance of CPR.[35]

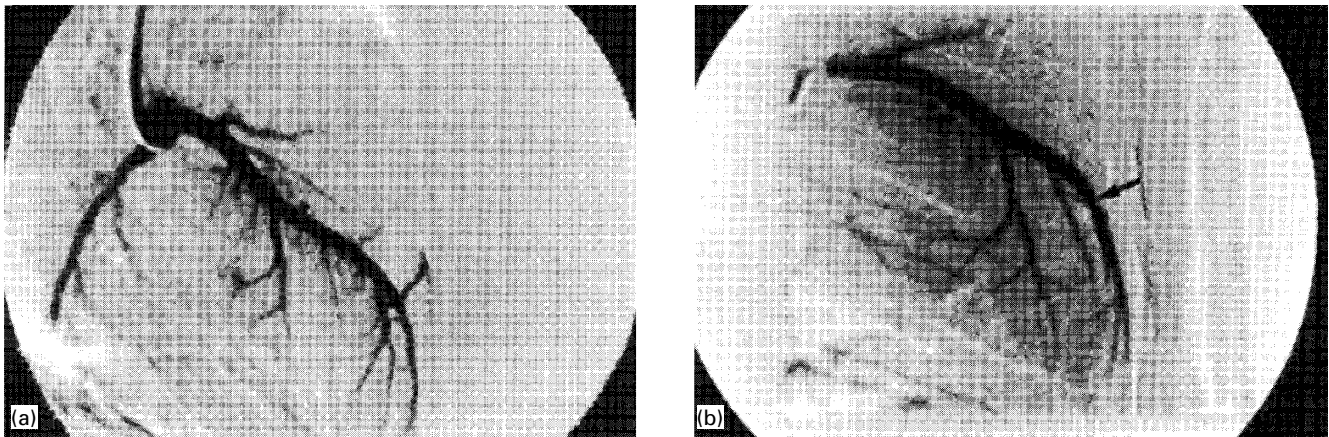
The importance of coronary artery disease in victims of cardiac arrest had not been routinely considered in previous CPR research. Intuitive thinking would indicate that


Fig. 18.11. (a) Digital cineangiography of porcine left anterior descending coronary artery before placement of Teflon cylinder creating midvessel stenosis. (b) Digital cineangiography of same porcine left anterior descending coronary artery after placement of Teflon cylinder creating 33% diameter stenosis (*arrow*). (From ref. 35.)

any coronary lesion that compromises myocardial blood flow under normal basal physiologic conditions will also be a potential problem during the extreme circumstances of CPR, but these findings of decreased blood flow below "clinically insignificant" lesions are noteworthy.

Effect of "resuscitation time" on CPP

Coronary perfusion pressure does not remain constant during the period of circulatory arrest and CPR. The highest pressure gradients and the greatest myocardial

Fig. 18.12. Left ventricular anterior endocardial blood flow proximal and distal to 33% diameter stenosis at 3 and 8 minutes of CPR. (From ref. 35.)

perfusion occur during the first minutes of resuscitation. Prolonged resuscitation is characterized by a gradual decline in regional perfusion, most notably to the heart and brain.[36] This is due to the gradual decline in arterial tone and gradual increase in right heart pressures. Maintenance of minimal perfusion pressures generally requires the use of vasoactive drugs.[4]

The effect of "downtime" on subsequent coronary perfusion pressure generated during CPR was studied by Duggal *et al*.[37] They found no compromise in coronary perfusion pressure after extending the downtime from 9 minutes to 15 minutes of untreated ventricular fibrillation. They did note, however, that the previously established threshold levels of coronary perfusion pressure for resuscitability were not valid after the longer downtimes.

Coronary perfusion pressure, resuscitation, and survival

Correlation between CPP and resuscitation outcome

Coronary perfusion pressure is a determinant of myocardial blood flow during CPR and it has also been shown to be predictive of successful resuscitation, i.e., restoration of spontaneous circulation (ROSC), short-term outcome, and long-term survival. Both Ralston *et al*.[3] and Michael *et al*.[4] showed that increased coronary perfusion pressure translated into increased myocardial blood flow and better rates of successful resuscitation (Figs. 18.13 and 18.14). Other experimental studies have confirmed the predictive value of the myocardial perfusion gradient and longer-term

survival rates, from 1- to 24-hour survival,[18,38–46] to 7-day survival rates.[47]

The ability of coronary perfusion pressure to serve as a direct monitoring adjunct during resuscitation efforts makes it attractive for use in clinical cardiac arrest. Over the last two decades, there have been reports of more than 200 patients who had coronary perfusion pressure measured during the performance of CPR.[48–57] A number of import-ant lessons have been learned. First, it is feasible to measure coronary perfusion pressure in victims of clinical cardiac arrest. The necessary instrumentation, including cannulation of the ascending aorta and right atrium, can be accomplished even during resuscitation efforts, and experience suggests that this can be done safely. It is unfortunate that, by the time the catheters are in place, the patient is often relatively late in the course of cardiac arrest, which may limit the utility of measuring coronary perfusion pressure in victims of unexpected cardiac arrest. In these cases the information is obtained so late in the course of cardiac arrest that it is not helpful. Occasionally, cardiac arrest occurs in patients who already have a pulmonary artery catheter or an arterial line. Such patients can easily be monitored for coronary perfusion pressure during CPR by the appropriate use of these pressure tracings.

The vast majority of measurements obtained in humans show poor coronary perfusion pressures. The mean coronary perfusion pressure reported in human series ranges from 0[43] to 15 mm Hg.[57] Consistent with these low values, most humans monitored for coronary perfusion pressure during CPR have not survived. Occasionally, however, survivors are reported. McDonald.[49] reported that 1 out of 12 patients survived and that patient had the highest coronary perfusion pressure from his series (16 mm Hg). Paradis *et al.*[55] reported on 100 patients, of whom 24 had return of spontaneous circulation. When coronary perfusion pressures between survivors and non-survivors were compared, there was a statistically significant difference in initial coronary perfusion pressure measured: those without return of spontaneous circulation had a mean coronary perfusion pressure of 2 mm Hg; those in whom spontaneous circulation returned had mean perfusion pressures of 13 mm Hg. Likewise, maximal coronary perfusion pressure was significantly different between the two groups: 8 mm Hg vs. 26 mm Hg. This series, in particular, substantiates the experimental data from animal models showing that coronary perfusion pressure can be a predictor of the return of spontaneous circulation. Paradis and colleagues noted that, in patients with prolonged cardiac arrest, coronary perfusion pressure was a better predictor of resuscitation outcome than was aortic pressure alone. A coronary perfusion pressure of 15 mm Hg
Fig. 18.13. Relationship between ease of resuscitation and heart blood flow produced during CPR. Class A animals were easy to resuscitate, class B were difficult, and class C could not be resuscitated. (From ref. 3.)

seemed to be necessary for the return of spontaneous circulation and may represent a reasonable goal.

CPR quality and coronary perfusion pressure

An effective myocardial perfusion gradient is dependent upon properly performed chest compressions during resuscitation efforts. Babbs and colleagues at Purdue Unversity showed that there is an effective compression threshold for generating both blood pressure and cardiac output with external chest compressions.[58] A number of studies support the contention that standard manual CPR must be properly performed to be of survival benefit. One study supporting this statement was performed in the United States and involved 2071 out-of-hospital resuscitations evaluated over a 6-month period in New York City.[59] The investigators attempted to determine whether the quality of bystander CPR affected eventual survival. CPR quality was determined to be effective or ineffective by emergency medical services (EMS) personnel in those instances in which bystander CPR was in progress at the time of their arrival on scene. CPR was judged to be effective if EMS personnel observed ventilations producing chest rise and chest compressions associated with palpable pulses in the carotid or femoral arteries in accordance with the American Heart Association guidelines. These guidelines specify 1.5 to 2 inches of sternal displacement. CPR was characterized as ineffective if effective compressions were accompanied by ineffective ventilations and vice versa, or if both compressions and ventilations were ineffective. Survival was defined as discharge from the
Fig. 18.14. Return of spontaneous circulation after 1 hour of cardiac arrest as function of coronary perfusion pressure generated during CPR. Animals with coronary perfusion pressures less than 20 in this experiment could not be resuscitated. (From ref. 4.)

hospital to home. Non-survivors were patients who died or who discharged to a facility rather than home. For the 662 patients entered in the study, the overall survival was 2.9% for those who received CPR (effective or ineffective) and 0.8% for those who received no bystander CPR. For those receiving effective CPR, 4.5% survived, compared to 0%–2% for those judged to have received ineffective CPR. After adjustments or corrections for time from collapse to initiation of bystander CPR, time from collapse to advanced cardiac life support (ACLS), and the initial rhythm, effective CPR yielded an adjusted odds ratio of 3.9 for survival. These findings were similar to the results of studies conducted in Europe and New Zealand which demonstrated that good CPR was associated with a 16%–23% survival compared to the 1%–7% survival with bad bystander CPR.[60–62] Although coronary perfusion pressure was not measured in these studies, it is logical to

assume that inadequate myocardial perfusion accompanying inadequately performed CPR was responsible for the failure to restore spontaneous circulation.

Number of chest compressions/min, coronary perfusion pressure, and ROSC

Several experimental studies indicate that interruptions in chest compressions during CPR lessen the likelihood of successful cardiac resuscitation. During pauses for artificial ventilation, aortic diastolic pressure begins to fall spontaneously toward the resting pressure which is determined by vascular tone. The initial compressions following a pause for ventilation generate a lower coronary perfusion pressure than those which precede a ventilation.[21] (Fig. 18.3) These changes in perfusion pressure result in lower myocardial perfusion than when chest compressions are performed in an uninterrupted fashion.[63] In addition, frequent interruptions for ventilation can also adversely effect neurological recovery in an animal model.[64] Additional reasons for stopping chest compressions frequently punctuate conventional resuscitation efforts. Such reasons would include rhythm interpretation, pulse checks, and defibrillator charging and discharging, all of which may alter hemodynamics and outcome.[65,66]

Recent observational clinical investigations of the quality CPR performed by paramedics, nurses, or physicians indicate that inappropriately slow chest compression rates, inappropriately high ventilation rates, inadequate depth of sternal depression, and frequent interruptions of compressions are common.[67,68] These latter studies did not evaluate the impact of poor CPR performance on outcome.

Improving outcome and coronary perfusion pressure

Since coronary perfusion pressure correlates with myocardial blood flow and myocardial blood flow correlates with resuscitation success, it follows that the greater the coronary perfusion pressure, the more likely is a successful outcome. However, achieving such benefit can rarely be accomplished by standard chest compressions alone. As seen in Fig. 18.15, the production of high levels of coronary perfusion pressure is not without problems. In an effort to maximize perfusion pressure, the use of excessive force in chest compressions may result in severe and even life-threatening injury. In an animal model (without coronary lesions) of cardiac arrest, a myocardial perfusion pressure of 30 mm Hg appears to be ideal for ensuring long-term
Fig. 18.15. Mean myocardial perfusion pressures between 10 and 15 minutes of CPR among animals that suffered CPR-induced trauma deaths, 24-hour survivors, animals that were resuscitated but died non-traumatic deaths before 24 hours, and animals that were never resuscitated. (From ref. 45.)

survival without a high degree of CPR injury. Efforts with external chest compressions to increase perfusion pressure above 30 mm Hg do not seem justified because of the resultant CPR-induced trauma and reduced rate of 24-hour survival.[45] In this series, animals that died from CPR-induced injury had a mean perfusion pressure of 39 mm Hg, whereas those that survived 24 hours had a mean perfusion pressure of 29 mm Hg. These results suggest that coronary perfusion pressure measured during CPR can also be used as a guide to avoid unnecessary injury when optimal levels have been achieved.

Although effective or good CPR is associated with a better outcome, the ability to perform effective or good CPR appears to be time-dependent, i.e., the longer CPR is performed, the less likely that compressions remain effective in terms of sternal displacement or rate per minute. This phenomenon has been demonstrated in a number of studies in which instrumented or "recording" manikins were used to record the chest compression rate and chest compression depth during uninterrupted, extended CPR (typically 5 minutes duration).[69–72] The study by Ochoa and colleagues perhaps demonstrates this time effect most dramatically.[70] In that investigation, the authors sought to evaluate the influence of rescuer fatigue on the quality of chest compressions and the influence of gender, age, weight, and height on the reduction of quality CPR. Thirty-eight healthcare professionals performed chest compressions on a recording manikin for five consecutive minutes. The manikin recorded the number of compressions per minute, the depth of sternal depression, and the location of the site of each compression (hand position). A marked decline in depth of sternal displacement was observed as early as the second minute of the trial and the mean time to fatigue, as verbalized by the participants, was 186 seconds. Although some compressions were effective, the majority were not.

A renewed interest in newer CPR methods and the development and use of automated devices for CPR[73,74] has been driven, in part, by the limitations of manual chest compressions, namely, decline in effectiveness over time and inherent interruptions. A number of alternative methods of CPR have been tested, for both CPP generation and outcome, and include, but are not limited to, the following.

Manual techniques

IAC-CPR

Interposed abdominal compression CPR (IAC-CPR) is a method of manual basic life support that has been proposed as a technique to improve coronary perfusion pressure during resuscitation. With this method, abdominal pressure is applied over the mid abdomen with two hands during the relaxation phase of chest compressions. Investigators at Purdue University rediscovered the hemodynamic advantages of intermittent abdominal compression during CPR.[75] Follow-up studies at Purdue University verified improvement in coronary perfusion pressure with the use of interposed abdominal compres-

sion CPR.[76] Two other reports examined the use of this form of CPR in experimental models, one of which found no improvement[42] and one of which did.[77] Three reports have been published concerning the use of interposed abdominal compression CPR in human subjects where coronary perfusion was measured. One patient reportedly had an increase in coronary perfusion pressure.[78] In a separate series, six patients had no significant increase,[49] and, in the largest series of 14 patients, interposed abdominal compression had inconsistent effects on the coronary perfusion pressure.[51] Despite these inconsistencies, four clinical trials comparing IAC-CPR and standard CPR demonstrated greater rates of initial successful resuscitation and a trend toward an increased survival rate to hospital discharge in the IAC-CPR group.[79]

ACD-CPR

Another new form or method of CPR is active compression-decompression CPR (ACD-CPR). Using a chest "suction cup" apparatus applied to the sternum, ACD-CPR pulls the anterior chest outward during the relaxation or release phase of chest compressions performed with the same device. In contrast, standard CPR allows passive thoracic recoil between compressions. The active "diastolic" component of ACD-CPR generates a negative intrathoracic pressure resulting in a lower diastolic right atrial pressure and a greater coronary perfusion pressure.[80] Several reports in experimental models have shown improved diastolic or relaxation-phase coronary perfusion pressure with the use of active compression-decompression CPR when compared to standard.[73] A number of clinical trials with this device have also been completed with conflicting results regarding benefit compared to standard CPR. However, a combined analysis, using chi-square trend analysis, of the nearly 3000 patients enrolled in these trials has demonstrated an increased overall survival rate.[81]

Mechanical techniques

Circumferential compression of the thorax with an inflatable vest-like garment was described in the 1980s and tested in small, selected clinical populations in the late 1980s and early 1990s.[52,56] The design of this device was based upon the concept of a "thoracic pump" as the driving force for blood flow during chest compression. Studies demonstrated that "Vest CPR" increased coronary perfusion pressure in experimental cardiac arrest models and in patients. However, the device was logistically difficult to incorporate into clinical resuscitation. Based upon the thoracic pump theory and success with a circumferential garment, redesign and experimentation led to substantial

revisions and re-introduction of a thoracic compression device (AutoPulse™, Revivant Inc., Sunnyvale, CA). This device incorporates a band applied over the anterior chest that is rhythmically tightened and released, resulting in a decrease in thoracic dimension or size of about 20%. Ongoing experimental animal and clinical studies indicate that the device produces greater coronary perfusion pressures than those measured during chest compression performed with a mechanical, pneumatic piston device.[57,82] An early clinical trial has demonstrated a greater rate of return of spontaneous circulation treated with the device when compared to a historical control group who received conventional, manual CPR.[83]

Another mechanical device, LUCAS, is also currently being evaluated. This device incorporates a gas-driven piston combined with active decompression. LUCAS CPR produces greater perfusion pressures and resuscitation rates in experimental animals than a standard, commercially available pneumatic piston device.[84]

Neither of these mechanical devices nor others in development have undergone extensive clinical testing.

Open chest CPR

Open chest cardiac massage or invasive CPR has probably been the most studied and the most impressive in its ability to improve coronary perfusion pressure.[85] Numerous studies by resuscitation research groups at the University of Pittsburgh and the University of Arizona have shown improvement in hemodynamics, specifically coronary perfusion pressure, with the institution of open chest cardiac massage.[39,40,44,47,86,87] Figure 18.16 is an excellent example of coronary perfusion pressure increasing with open chest cardiac massage.

A particularly clinically relevant investigation of open-chest resuscitation was undertaken by Sanders and colleagues. This study dramatically demonstrated the importance of the duration of inadequate coronary perfusion pressure on subsequent improvements in perfusion and ultimate resuscitation from cardiac arrest.[40] Invasive forms of resuscitation often have dramatic effects on coronary perfusion pressure but, because of morbidity associated with an invasive approach, these treatment options are often instituted late in the course of resuscitation. In an experimental model with closed chest CPR efforts for periods between 15 and 25 minutes, Sanders *et al.* found that aggressive intervention, such as open chest cardiac massage, could improve coronary perfusion pressure substantially above that achieved with continued closed chest compressions, but resuscitation would not result if such therapy was instituted beyond 15 minutes of cardiac
Fig. 18.16. Hemodynamic and electrocardiographic record from animal receiving closed chest compression CPR for 12 minutes after 3 minutes untreated cardiac arrest and then an emergent thorocotomy and 2 minutes of open chest cardiac message. (From ref. 47.)

arrest. Such data imply that improvements in coronary perfusion pressure may not translate into improved survival if they come too late in the course of resuscitation therapy.

In another series of experimental animals undergoing open chest cardiac massage after a period of ineffective closed chest compressions, tremendous improvements in mean coronary perfusion pressure were seen compared to continued closed chest efforts (65 mm Hg vs. 19 mm Hg). The animals that had improved coronary perfusion pressure during CPR not only were resuscitated more easily and survived 24 hours, but also had a better 7-day survival rate.[47] Thus it appears that even during a relatively short period of CPR, coronary perfusion pressure can be used to predict long-term 7-day survival.

CPR adjuncts

An inspiratory impedance valve has been developed and tested during several resuscitation methods or techniques. The valve is inserted into the ventilation circuit, typically between an endotracheal tube and self-inflating bag. During chest compression, the valve opens and allows passive expiration. During the relaxation phase, the valve blocks the circuit and negative intrathoracic pressure is increased. A lower intrathoracic pressure is transmitted to the right heart, resulting in a lower right atrial pressure and greater venous return.[80] Coronary perfusion pressure is

increased as a result of the lower right atrial pressure. This valve has been tested during standard, conventional CPR as well as during ACD-CPR. Coronary perfusion pressure and systemic perfusion have been shown to be significantly better with the valve than without it.[88,89]

Pharmacologic interventions

One of the main avenues to improve coronary perfusion pressure has been the use of α-adrenergic agonists. As understanding of the importance of coronary perfusion pressure has increased, so has knowledge that certain α-adrenergic agonists improved coronary perfusion pressure by raising aortic diastolic pressure above increases in the right atrial diastolic pressure.[6–13] Epinephrine was one of the first agents shown to be effective in this regard.[6] Numerous investigators have clearly pointed out the advantageous increases in coronary perfusion pressure in response to epinephrine administration during CPR.[3–5,90–96]

Although adrenergic agonists increase coronary perfusion pressure, their effect on myocardial oxygen consumption is more controversial. Ditchey and Lindenfield were the first to describe the effect of epinephrine, not only on coronary perfusion pressure, but also on myocardial oxygen supply and demand.[97] They found that, in contrast to a placebo, epinephrine increased myocardial lactate concentration and decreased myocardial adenosine triphosphate (ATP) concentration after CPR. They suggested that large

doses of epinephrine failed to improve the balance between myocardial oxygen supply and demand during CPR, even when such agents result in increased coronary blood flow. However, Brown *et al.* found that epinephrine improved the oxygen extraction ratio, which is defined as oxygen utilization divided by oxygen delivery, during CPR. They suggested that high-dose epinephrine improved not only myocardial blood flow, but also oxygen extraction ratios during CPR when compared with drugs having greater α-agonism, namely, phenylephrine in two different doses (0.1 mg/kg and 1.0 mg/kg).[92] Lindner *et al.* found that, although epinephrine effectively increased both perfusion pressure and myocardial blood flow, it also increased myocardial oxygen consumption.[96] Epinephrine led to greater increases in myocardial oxygen consumption than did norepinephrine, and any advantage in the slight increase in myocardial blood flow seen with epinephrine was negated. These authors concluded that norepinephrine improved the balance between myocardial oxygen delivery and myocardial oxygen consumption in contrast to epinephrine and thereby facilitated the restoration of spontaneous circulation.

Numerous animal studies have shown that epinephrine in doses of 0.2 mg/kg, so-called high-dose epinephrine, produces substantially higher coronary perfusion pressure and greater myocardial blood flow than does "standard"-dose epinephrine (0.02 mg/kg).[90,91,98] Figure 18.17 represents the graded response to different doses of epinephrine for both coronary perfusion pressure and myocardial blood flow. Clinical reports on the optimal dose for generation of coronary perfusion pressure during CPR are difficult to find. Gonzalez reported increases in radial artery systolic and diastolic pressures with stepwise increases in the dose of epinephrine administered to cardiac arrest patients.[99] Paradis and coworkers did study 32 patients whose cardiac arrests were refractory to advanced cardiac life support, measuring simultaneous aortic and right atrial pressures to calculate coronary perfusion pressure.[100] They found an increase in mean coronary perfusion pressure of 4 mm Hg after a standard dose of epinephrine, with a further increase of 11 mm Hg after high-dose epinephrine. They concluded that high-dose epinephrine seemed more likely to raise coronary perfusion pressure above the previously demonstrated critical value of 15 mm Hg in patients during cardiac arrest. Despite the preponderance of data supporting the benefit of high dose epinephrine in animal models, randomized trials of high-dose vs. standard-dose epinephrine in clinical cardiac arrest have failed to show an improved survival rate.[101,102] However, these studies do demonstrate some improvement in restoration of spontaneous circulation, i.e., successful cardiac resuscitation, with high dose epinephrine which would support improved myocardial perfusion during resuscitative efforts. Of note, data from
Fig. 18.17. Graded doses of epinephrine, including no epinephrine, standard-dose epinephrine (O.O2 mg/kg), and high-dose epinephrine (O.O2 mg/kg), and resultant myocardial perfusion pressures (*MPP*) and myocardial blood flows (*MBF*). High-dose epinephrine produced significantly more myocardial perfusion pressure and resultant myocardial blood flow than did either no adrenalin or standard-dose epinephrine. (From ref. 98.)

other studies suggest that epinephrine, even when administered frequently in standard doses, impairs postresuscitation circulatory dynamics and may worsen neurological outcome.[103,104]

The best adrenergic agonist for raising coronary perfusion pressures is likewise controversial. Brown *et al.* reported two studies: one compared epinephrine and phenylephrine for their effects on coronary perfusion pressure in an experimental model, and the other compared epinephrine vs. methoxamine. They found that epinephrine produced greater coronary perfusion pressures than did either of two doses of phenylephrine[92] and that epinephrine-treated animals had significantly higher coronary perfusion pressures than did methoxamine-treated animals.[105] Other authors compared the effects of epinephrine and either methoxamine or norepinephrine on aortic diastolic pressure and mean aortic pressure. Roberts *et al.* found that methoxamine produced greater diastolic aortic pressures than either high-dose or low-dose epinephrine.[106] Lindner *et al.* found epinephrine and norepinephrine to have equally potent effects on improving coronary perfusion pressure during CPR.[96] A growing body of recent literature demonstrates that vasopressin offers benefit in the resuscitation setting. Activation of vasopressin receptors in the peripheral circulation increases arterial tone and the coronary perfusion gradient. No consensus yet exists concerning the best adrenergic agonist for raising coronary perfusion pressure during resuscitation. A combination of vasopressin and epinephrine may be most beneficial.

Non-invasive alternatives to measuring coronary perfusion pressure during cardiopulmonary resuscitation

Because of its correlation with myocardial blood flow produced during CPR and with successful resuscitation outcome, coronary perfusion pressure is an ideal way to gauge effectiveness of CPR during the ongoing resuscitation effort. It is unfortunate that this measure of the effectiveness of ongoing CPR is limited in the clinical setting because these pressures are difficult to obtain and require intravascular catheters in the aorta and right atrium. Some clinical studies have accomplished such catheter placements and coronary perfusion pressure has been measured, but typically this takes 15 to 30 minutes after arrival at the hospital, and, although feasible in some patients, in many patients this is well beyond the usual time that resuscitation can be expected to be successful. There is a critical need for a simple, rapid, and preferably

non-invasive measure of the effectiveness of CPR that can be used early in the resuscitation effort. Monitoring of end-tidal CO_2 exhaled during CPR is one such possibility. A second is monitoring characteristics of the VF waveform which may reflect myocardial perfusion during CPR and predict defibrillation outcome. Carbon dioxide is byproduct of tissue metabolism and is transported to the lung and eliminated during ventilation. Carbon dioxide delivery to the lung is dependent upon venous return which is equal to cardiac output. If ventilation is held constant, expired carbon dioxide is a measure of pulmonary perfusion and cardiac output. During cardiac arrest, the fall in cardiac output is accompanied by a decrease in carbon dioxide transport from the tissues to the pulmonary circulation and a reduction in carbon dioxide elimination from the lungs. With initiation of CPR and restoration of cardiac output, pulmonary perfusion is restored, to some degree, and carbon dioxide elimination returns.

Expired carbon dioxide can be measured by interposing a capnometer between the endotracheal tube and the ventilation source during CPR. Laboratory studies have shown excellent correlations between end-tidal CO_2 and coronary perfusion pressure,[107] as well as return of spontaneous circulation.[108–110] In one study the pattern of changes in end-tidal CO_2 during resuscitation proved to be more significant than any single reading. Over a 15-minute period of resuscitation, animals that were eventually resuscitated had constant and steady levels of end-tidal CO_2; animals that failed to be resuscitated exhibited a steady decline in such levels.[109] Other studies have shown minimal levels of end-tidal CO_2 below which no animals were resuscitated.[110] End-tidal CO_2 monitoring has also been used in humans to assess ongoing resuscitation efforts.[111–114] None of these studies measured coronary perfusion pressure, but several found minimal levels of end-tidal CO_2 that appeared to be required for successful resuscitation.[113,114] Although end-tidal CO_2 monitoring has the advantage of being non-invasive and easy to use, there has been some concern recently that administration of epinephrine during CPR may adversely affect the ability of end-tidal CO_2 monitoring to predict coronary perfusion pressure, as well as resuscitation outcome.[115–117] Nevertheless, a study in humans showed that although end-tidal CO_2 may decrease temporarily after epinephrine use, the predictive value of this measurement was not eliminated.[117] The electrocardiogram is closely monitored during resuscitation efforts and cardiac rhythms detected during such efforts dictate most resuscitative interventions. Recent data suggest that computer based analysis of the VF waveform may be useful in estimating "downtime," determining the effect of interventions, including CPR, and predicting the outcome of

countershock. Such analyses typically include some component of the amplitude or frequency or both components of the recorded VF signal and include the mean frequency by Fourier transformation, both amplitude and frequency resulting in an amplitude spectrum analysis (AMSA), or fractal geometric analysis resulting in a scaling exponent.[118] Each of these methods has been shown to be predictive of countershock outcome in animal models of prolonged cardiac arrest due to VF. Two have been evaluated in the clinical population. Salutary changes in VF amplitude and frequency have been described following the initiation of CPR and are likely to reflect the adequacy of myocardial perfusion and the magnitude of the coronary perfusion gradient.

Summary

Coronary perfusion pressure obtained during CPR is a useful measurement. The aortic and right atrial pressure gradient during the relaxation phase of chest compressions defines coronary perfusion pressure during CPR. This gradient has correlated well with measured myocardial blood flow during CPR and with resuscitation outcome. Efforts to improve coronary perfusion pressure and success of resuscitation have centered around the use of adrenergic agonists and new methods of chest compression or resuscitation techniques, such as open chest cardiac massage, rapid manual CPR, interposed abdominal compression CPR, active compression–decompression CPR, and a number of new and investigational mechanical CPR methods. Measuring end-tidal CO_2 or the VF waveform may be reasonable non-invasive "surrogates" of coronary perfusion pressure in guiding resuscitation efforts.

Methods to improve cerebral blood flow and neurological outcome after cardiac arrest

Ischemic neurological injury accounts for much of the mortality and most of the morbidity among persons who are initially resuscitated from cardiac arrest.[1,2] This chapter summarizes what is known about the determinants of cerebral blood flow during cardiopulmonary resuscitation (CPR) and the relationship of cerebral blood flow to neurological outcome.

Cerebral perfusion in the intact circulation has been characterized as a classical vascular waterfall. Arterial pressure is the upstream pressure, and cerebrospinal fluid pressure is the downstream pressure. Pressure in the venous sinuses is below the downstream pressure; that is, animal studies demonstrate a significant pressure gradient between the cortical veins and the sagittal sinus.[3–5]

Determinants of cerebral blood flow

Halperin *et al.* reported a close correlation ($r = 0.89$) between cerebral blood flow and the difference between carotid arterial pressure and pressure in the lateral ventricle during CPR in dogs.[6] Accordingly, the determinants of carotid arterial pressure and intracranial cerebrospinal fluid pressure will be reviewed.

At the outset of CPR in laboratory animals, carotid artery pressure is usually equal to thoracic aortic pressure. As time goes by, however, carotid arterial pressure tends to fall, and cerebral blood flow declines in parallel.[7] This phenomenon, termed carotid collapse, appears to be mediated by loss of vascular tone and physical collapse of the carotid artery at the thoracic inlet.[7,8] α-Adrenergic agents and pressor doses of adrenalin reverse carotid collapse, in part by increasing the rigidity of the carotid artery and in

part by raising peripheral resistance, thus limiting the runoff of blood to non-essential vascular beds.[7] In animal studies, if CPR is begun immediately after the onset of cardiac arrest, carotid pressure remains as high as thoracic aortic pressure over periods of 1 hour or more as long as peripheral resistance is maximized.

Under conditions of intense α-adrenergic stimulation, carotid arterial pressure appears to be maximized by the same maneuvers that maximize thoracic aortic pressure. For the most part, this means applying the maximal amount of compression force that the sternum can withstand. Maintenance of compression for 40% to 60% of each compression-release cycle is important in dogs and probably in humans.[9] Binding the abdomen also increases thoracic aortic and carotid artery pressure, but, for the reasons cited below, abdominal binding may not maximize cerebral perfusion.

Intracranial cerebrospinal fluid pressure, the downstream pressure for cerebral blood flow, fluctuates synchronously with intrathoracic pressure during CPR. About one-third of the fluctuation in intrathoracic pressure is transmitted to the intracranial space in dogs with normal intracranial pressure. This pressure transmission takes place via non-valved veins (e.g., the paravertebral venous plexus) and cerebrospinal fluid. Evidence supporting this statement is summarized in the following paragraphs.

Intracranial pressure during CPR is unrelated to either carotid arterial or jugular venous pressure, as evidenced by the facts that balloon occlusion of the proximal aorta, which abolishes carotid flow and pressure, and interruption of the jugular venous valve at the thoracic inlet, which raises jugular pressure to the same level as intrathoracic pressure, have no effect on intracranial pressure changes

during chest compression.[10] This lack of effect of jugular pressure on intracranial pressure is explained by more cephalad valves in the jugular system.

Ligation of the cervical spinal cord reduces fluctuations in intracranial pressure by about one-third. The remaining pressure transmission occurs along vascular channels, as indicated by exsanguination of dogs during CPR, a maneuver that abolishes changes in intracranial pressure. Ligation of the paraspinal veins substantially reduces the intracranial pressure changes, indicating that the paravertebral venous plexus and perhaps other non-valved veins in the posterior cerebral circulation are responsible for the bulk of transmission of intrathoracic pressure to the intracranial space.[10]

Intracranial capacitance

The magnitude of transmission of intracranial pressure to the intracranial space is increased under conditions of elevated intrathoracic pressure and by abdominal binding.[10] These observations are explained by the abrupt limits of intracranial capacitance. The translocation of any given amount of venous blood and cerebrospinal fluid from the thorax to the intracranial space will produce larger pressure fluctuations in a closed space that is already on the lower compliance part of its volume pressure curve (elevated intracranial pressure). Alternatively, maneuvers such as abdominal binding, which simultaneously increases intrathoracic pressure during chest compression and impedes the flow of blood and cerebrospinal fluid from the thorax into the abdomen, result in the translocation of more fluid into the intracranial space.

Relationship of cerebral perfusion pressure and blood flow to cerebral metabolism and neurologic outcome

In pentobarbital-treated dogs in which CPR is initiated immediately on induction of ventricular fibrillation, cerebral blood flow of approximately 30 ml/min per 100 g is sufficient to maintain cerebral oxygen consumption and adenosine triphosphate (ATP) at prearrest levels for almost 1 hour.[11] This level of cerebral perfusion can be achieved with a cerebral perfusion pressure of about 30 mmHg.[6,11] Under conditions of normal intracranial pressure, and in the absence of abdominal binding, this level of cerebral perfusion pressure occurs when mean aortic pressure is 55 to 60 mm Hg. Animals so treated wake up and appear normal after as much as 60 minutes of CPR. Despite

maintenance of constant cerebral perfusion pressure, cerebral blood flow may deteriorate over time when the initiation of CPR is delayed.[11] This phenomenon is thought to be mediated by a multitude of factors, including increased blood viscosity, intravascular coagulation, constriction of blood vessels, vascular/perivascular edema.[12]

Clinical implications

Abundant evidence exists that the human brain cannot tolerate more than 4 or 5 minutes of complete cessation of blood flow,[2] and there is some research in humans suggesting that CPR can generate cerebral perfusion pressures greater than 25 mmHg and potential normal oxygen tension if CPR is started immediately after cardiac arrest.[13] If CPR is delayed for even a few minutes after cardiac arrest, however, it is unlikely that standard CPR can generate sufficient cerebral blood flow to preserve normal cerebral viability until cardiac function is restored.[11] This observation may explain in part why cardiac arrest has such high neurological morbidity and mortality. Therefore, new methods are needed to improve cerebral blood flow and subsequent neurological outcome from cardiac arrest. Methods to improve cerebral blood flow and neurological outcome from cardiopulmonary resuscitation have included the following:

(1) medications (vasopressin and epinephrine, HBOC)
(2) CPR techniques and devices
   open chest CPR
   minimally invasive CPR
   AutoPulse Vest CPR
   active compression–decompression CPR
   intermittent threshold valve (ITV)
   intraaortic balloon
   cardiopulmonary bypass (CPB)
(3) hypothermia
(4) combination therapy

Vasopressin is a peptide of neuronal origin produced in the hypothalamus.[14] Vasopressin was recognized to have a role in cardiac arrest as early as the 1960s, but research into its use for treatment of cardiac arrest did not begin until the 1990s. The discovery that higher levels of this peptide were present in patients resuscitated from cardiac arrest motivated investigators to develop vasopressin as a therapy for cardiac arrest.[15] Laboratory studies have shown that vasopressin given during cardiac arrest increases cerebral blood flow via cerebral vasodilatation and by increasing central aortic and carotid systolic pressure, while producing return of spontaneous circulation similar to that of adrenalin.[16] In addition, when vasopressin was added to adrenalin therapy during cardiac arrest in laboratory animals, neurological

outcome improved. The result of vasopressin in clinical trials is less clear. A preliminary human study comparing epinephrine to vasopressin for the treatment of cardiac arrest showed an improved survival rate in the vasopressin group, but there was no difference in neurological outcome in survivors of either group.[17] A larger clinical trial showed no difference between epinephrine and vasopressin on survival or neurological outcome in cardiac arrest patients unless the cardiac arrest was prolonged. A subgroup analysis of these patients suggested that those patients with asystole may have improved survival if epinephrine was followed by vasopressin for resuscitation.[18] Nonetheless, a review of all clinical trials comparing vasopressin to epinephrine does not show a clear advantage of vasopressin over epinephrine in improving survival or neurological outcome from cardiac arrest.[19] Regardless, the International Liaison Committee on Resuscitation (ILCOR) and the American Heart Association's (AHA) 2001 guidelines state that "vasopressin can be used once as an alternative to epinephrine for the treatment of shock-refractory ventricular fibrillation."[20]

Hemoglobin-based oxygen-carrying (HBOC) agents have been extensively studied for use in the treatment of hemorrhagic shock.[21] In addition to their ability to deliver oxygen to tissues, HBOCs have significant vasopressor effects.[22] These properties of HBOC agents may explain why its intravenous administration during CPR in laboratory animals improved cerebral perfusion pressure and oxygen delivery to tissues when compared with normal saline.[23] HBOC agents also improve resuscitation rates in laboratory animals, but no studies on neurological outcome were performed. There are also no studies of use of HBOC agents in humans during cardiac arrest.

Experiments in laboratory animals have shown that open chest CPR is superior to closed chest CPR in generating blood flow to the brain during cardiac arrest and increasing resuscitation rates[24]. The neurological outcome is also significantly improved with open chest CPR.[25,26] These results were so impressive that open chest CPR was recommended for use in humans after failure of standard closed chest CPR.[27] However, the simplicity of closed chest CPR and the social, fear of infection, and financial and legal concerns about open chest cardiac massage have limited its use since the arrival of closed chest CPR in the 1960s.[28] Minimally invasive direct cardiac massage (MIDCM) was developed as an alternative to thoracotomy for performing direct cardiac massage during CPR and does increase resuscitation rates and blood flow to vital organs compared with closed chest CPR.[29] No clinical trials are currently available, however, to evaluate the efficacy of this method of resuscitation.

A multitude of mechanical methods have been developed to improve upon standard closed chest CPR. The methods have been developed to increase cerebral blood flow during cardiac arrest and improve resuscitation rates in the hope that these characteristics of the modified CPR will improve neurological outcome and survival as outlined above. A review of these devices was conducted by Smith in 2002.[30] A few of some of these methods with respect to cerebral blood flow and human application are provided below.

AutoPulse (Revivant, California) CPR is performed with a band that wraps around and compresses the chest with an automated device.[31] The device increased cerebral blood flow during cardiac arrest in swine when the resuscitation was initiated 1 minute after the onset of ventricular fibrillation.[31] The device has been applied to a group of terminally ill patients and hemodynamic monitoring demonstrated that the coronary perfusion pressure was increased from 15 mmHg (standard CPR) to 20 mmHg (AutoPulse). Several before and after cohort studies have reported improved short-term outcome; however, the ASPIRE trial (a randomized, prospective trial) reported no difference in 4-hour survival and a decrease in survival to hospital discharge rate with AutoPulse.

Active compression-decompression (ACD) CPR was discovered when a layperson used a plumber's plunger to resuscitate a family member.[32] ACD CPR is unique in that a suction device, instead of passive recoil of the chest during standard CPR, is used to re-expand the chest after a chest compression. ACD CPR in pigs increases cerebral blood flow and coronary blood flow when compared to standard CPR if the resuscitation is started 30 seconds after the onset of ventricular fibrillation.[33] An impedance threshold device (ITD) is a one-way valve that creates a negative pressure in the thorax during chest decompression and increases venous return to the heart and cerebral blood flow by 20% compared to standard CPR during cardiac arrest in pigs.[34] In a 3-year study that analyzed 210 victims of out of hospital cardiac arrest, ACD CPR in combination with the intermittent threshold device (ITD) significantly improved 24-hour survival.[35] In a subgroup analysis of patients with a greater than 10-minute delay in initiation of resuscitation by EMS, the 24-hour survival of the ACD with ITD group (44%) was even greater when compared with the standard CPR group (14%). Although the rate of hospital discharge for patients with witnessed arrest was 23% for the ACD with ITD group compared with 15% in the standard CPR group (15%), it did not reach statistical significance.[35] The percentage of patients with normal neurological outcome was higher in the ACD with ITD group (15%) compared with standard CPR (5%), but also did not reach statistical

significance. To appreciate the potential benefit of ITD with ACD CPR, when 400 patients with prehospital cardiac arrest all had ACD performed and ITD was used only in the treatment group, the ITD group had a 40% 24-hour survival versus 29% in controls ($P < 0.03$).[36] Six out of ten survivors in the ACD plus ITD group had normal neurological outcome, while one of eight survivors in the ACD non-ITD group had good neurological outcome, but again the results did not reach statistical significance ($P < 0.10$).

Transfemoral balloon-catheter aortic occlusion during cardiac arrest in a canine model of open chest CPR increased coronary and cerebral perfusion pressure 100% when compared with controls.[37] In contrast, transfemoral catheter balloon occlusion of the aorta alone during CPR in a canine model of closed chest CPR did not improve coronary perfusion pressures or resuscitation rates when resuscitation efforts and balloon inflation were initiated 20 minutes after the onset of ventricular fibrillation.[38] In two separate studies, intraaortic balloon catheter occlusion did increase coronary and cerebral perfusion pressure [39] as well as return of spontaneous circulation [40] in a pig model, provided that the balloon and resuscitative efforts were initiated 8 minutes after the onset of ventricular fibrillation. When epinephrine was administered proximal to the occluded aorta via the aortic catheter during CPR, it increased coronary perfusion pressure as shown in earlier studies,[41] but provided no further increase in cerebral blood flow.[42] Administration of vasopressin through an intraaortic catheter proximal to the occluding aortic balloon increased cerebral blood flow more than the aortic occlusion alone during cardiac arrest when CPR was performed.[43] In addition, cerebral blood flow remained elevated during reperfusion even though the balloon was deflated, suggesting that vasopressin was better than the aortic balloon in maintaining elevated cerebral blood flow during reperfusion because of its vasodilatatory properties.[43] The intraaortic balloon catheter has also been used for selective perfusion of the aortic arch during CPR.[38,41] Perfusion with an oxygen-carrying solution increases resuscitation rates and the speed of resuscitation, but its combined effects on cerebral blood flow and neurological outcome are unknown.[44]

Cardiopulmonary bypass (CPB) increases resuscitation rates, cerebral blood flow, survival, and neurological recovery in laboratory experiments of cardiac arrest.[45,46] A feasibility study showed that CPB could be initiated in the emergency department and all cardiac arrest patients had a return of spontaneous circulation.[47] Nevertheless, CPB was not initiated until an average of 30 minutes after the onset of cardiac arrest and there were no long term survivors. A review of multiple human studies of CPB during cardiac arrest suggests that CPB may have a role in the future care of cardiac arrest victims.[48]

Mild hypothermia induced during cardiac arrest is the only therapy shown to improve survival and neurological outcome in victims of out of hospital cardiac arrests.[49–51] In addition to reducing brain injury caused by reperfusion disease, mild hypothermia attenuates the decrease in blood flow that occurs with delays in initiating CPR,[12] although a brief period of hypothermia after resuscitation from cardiac arrest did not alter regional blood flow when compared with normothermic controls.[52]

There currently is no single therapy that dramatically increases resuscitation rates from cardiac arrest and produces consistent normal neurological outcome. Therefore, it is likely that the combination of the above therapies in addition to development of new techniques and drug cocktails will be needed to achieve the breakthrough effect being sought to treat victims of cardiac arrest.

Clinical and Medical Affairs, Biosite Incorporated, San Diego, CA, USA

Introduction

The pharmacology of resuscitation is largely based on anecdotal evidence and descriptive research rather than on objective scientific experimentation. Our understanding of the pharmacokinetics (PK) and pharmacodynamics (PD) of drugs used to resuscitate victims of cardiac arrest is also limited by ethical and experimental constraints.

Animal models of cardiac arrest and cardiopulmonary resuscitation (CPR), jointly with clinical studies, have considerably increased our understanding of the pathophysiology of cardiac arrest and significantly improved our ability to resuscitate victims of cardiac arrest.[1–7] The great majority of such studies, however, were designed to address interventions to improve resuscitation rather than to investigate the pharmacological profile of drugs used in settings of cardiac arrest and reperfusion.[8–10] Even less evidence is available on the PK of administration of multiple drugs, a more complex but realistic scenario. During resuscitative efforts, i.e., low flow reperfusion, significant shunting of blood to vital organs occurs.[11–13] The use of vasopressors in this setting further modifies the patterns of blood flow distribution, in all likelihood affecting the PK of concomitantly administered drugs.[11,14–18]

The time from onset of cardiopulmonary arrest until restoration of an effective spontaneous circulation is the single most important determinant of long-term survival and neurological outcome. Prompt initiation of CPR and defibrillation of ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) are more likely to alter patient outcome than is pharmacologic management.[19,20] Nevertheless, treatment with pharmacologic agents is frequently required in patients with VF or VT that is refractory to electrical shocks and in patients with asystole or pulseless electrical activity (PEA).[21,22]

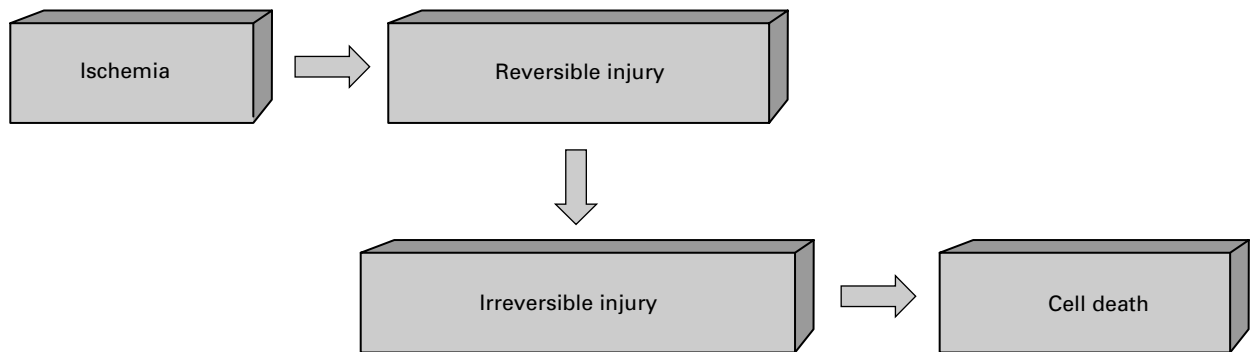
The use of pharmacological agents during CPR has been associated with a poor clinical outcome, despite initial restoration of spontaneous circulation, ultimately leading to skepticism on the effectiveness of drug therapy during CPR.[8,19,20,23] Several factors may hamper the effectiveness of pharmacological interventions during CPR. Pharmacological agents are used during resuscitation efforts with scant, if any, knowledge of the patient history, underlying medical conditions, or current medical therapy. As for other interventions in settings of cardiac arrest, time appears to be a critical factor.[23] Therapeutic agents may well be administered too late or under suboptimal conditions throughout resuscitation efforts to have a significant impact on survival, with average delays in clinical trials as long as 20–25 minutes.[21,24] In settings of VF/VT, current guidelines advocate the use of vasopressors and antiarrhythmic agents only when such rhythms are recurrent or refractory to multiple shocks, thereby resulting in a considerable delay.[25,26] Airway management and vascular access may further delay drug administration and ultimately compromise delivery to end organ targets because of the poor blood flow generated during prolonged closed chest compression.[3,27,28] Moreover, the time interval that precedes the initiation of resuscitation efforts may be extremely variable or not known with precision. With the progression of ischemia, factors such as acidosis, hypoxemia, downregulation of receptors, target end organ damage, and impaired metabolism and excretion may all interfere with the PD properties of pharmacologic agents, thereby hindering drug effectiveness.[29] Despite our progress in understanding the derangements that follow


Fig. 20.1. Reversible and irreversible injury: ischemia initiates a sequence of events that, unless interrupted by early reperfusion, leads to cell death. (Modified from ref. 36.)

global myocardial ischemia, little is known about the PK and PD profiles of drugs in this setting.[13,30–35]

The present chapter provides an overview of the pathophysiology of cardiac arrest and reperfusion, reviews basic pharmacological concepts, their (increasingly studied) underlying genetic variability, and the clinical pharmacology pertinent to the drugs used in settings of cardiac arrest and reperfusion.

Pathophysiologic considerations during cardiac arrest and reperfusion

The pathophysiology of cardiac arrest is characterized by the abrupt cessation of forward blood flow. Within seconds, global myocardial ischemia initiates a continuum of progressive intracellular derangements (Fig. 20.1). These changes, which become progressively more severe with time, are initially reversible; eventually, however, with increasing duration of ischemia, irreversible injury occurs.[36] Both the heart and the brain have high metabolic demands despite a relatively small mass, thus tolerating only a very limited period of global ischemia.

This is particularly true during VF/VT when the myocardium consumption of high energy substrate increases dramatically.[37–39] Ischemic contracture soon develops as a manifestation of severe ischemia. It becomes manifest when ATP levels are less than 10% of normal[40] and is characterized by progressive thickening of the left ventricular wall leading to a ventricular cavity size.[3,28] As a result, ventricular preload is compromised, and the amount of blood ejected by chest compression is reduced,[41] partly explaining the characteristic time-dependent decreases in the hemodynamic efficacy of closed-chest resuscitation.[42]

Under normal conditions the brain receives approximately 15% of the body's cardiac output. Consciousness is lost within 15 seconds of cardiac arrest, and brain stem function ceases within 1 minute. Although neurons have been shown to maintain some electrical activity for up to 60 minutes of complete ischemia, the maintenance of adequate cerebral perfusion during CPR is essential for survival.[43–45] Brain adenosine triphosphate (ATP) is depleted after 4–6 minutes of no-flow and it returns nearly to normal within 6 minutes of starting CPR. Animal models suggest that good neurologic outcome may be possible for 10- to 15 minute periods of normothermic cardiac arrest, pending on prompt restoration of cerebral perfusion by artificial means.[46]

Intracellular metabolic derangements

Reductions in oxygen delivery and metabolic waste removal during cardiac arrest alter cellular function and homeostasis. Myocytes have three pathways of energy production: glycolysis, glucose oxidation, and fatty acid oxidation. In contrast, neurons are unable to metabolize fatty acids. Reduced oxygen delivery requires both neurons and myocytes to switch to the only anaerobic metabolism: glycolysis. Out of 1 molecule of glucose, this inefficient anaerobic process generates 2 molecules of ATP and lactate, as compared to the 38 molecules of ATP produced via the aerobic pathway. Glycolysis, which normally accounts of 1– 5% of energy production, under anaerobic conditions becomes the most important source of energy production at the expense of glucose and of free fatty acid oxidation.[47] The result is not only an increased production of lactate – responsible for intracellular acidosis – but also of free fatty acids, which are potent cytotoxic agents.[48]

The shift of global ischemic injury from reversibility to irreversibility is related to a critical decrease in concentrations of high-energy phosphate compounds and/or in free energy change of ATP hydrolysis.[49, 50] The decrease in

high-energy phosphate levels inhibits the Na^+ pump, which results in Ca^{2+} overload. At this stage, reperfusion does not result in recovery, but instead it may actually aggravate the situation by activating positive feedback mechanisms.

Restoration of spontaneous circulation

The aim of CPR is to promote a low-flow state sufficient to maintain both brain and heart viability. Hence, CPR therapy is directed at sustaining vital organ function until natural cardiac function is restored.

Available data suggest that a myocardial blood flow of at least 16 ml min^{-1} per 100 g, and a cerebral blood flow of at least 10 ml min^{-1} per 100 g, are required to meet these metabolic demands during VF.[51–57] Myocardial and cerebral blood flow in animal models of cardiac arrest, and coronary perfusion pressure (CPP) in humans, are usually below these minimal levels during standard external CPR, especially after prolonged CPR and without the use of vasopressor agents.[53,56,58,59] During cardiac arrest, pulmonary blood flow produced by conventional closed-chest CPR is less than 20% of normal, and transalveolar drug absorption is likely to be minimal.[16–18]

Vasopressor agents administered during CPR increase aortic diastolic pressure, but not right atrium diastolic pressure, hence increasing CPP (i.e., the difference between aortic diastolic pressure and right atrial diastolic pressure).[60] The rationale for administration of vasopressor agents during CPR is to restore threshold levels of CPP and, therefore, myocardial blood flow. Restoration of threshold levels of coronary perfusion is the single overriding determinant of the success of the resuscitation effort, especially when the duration of untreated cardiac arrest exceeds 4 minutes.[11,53,57,61–67]

Reperfusion

Restoration of coronary flow increases the release of oxygen free radicals, cytokines, and other pro-inflammatory mediators that activate both neutrophils and the coronary vascular endothelium. The end result of this cascade reaction is reperfusion injury with endothelial dysfunction, microvascular collapse and blood flow defects, and additional cell necrosis and apoptosis.[68]

Upon reperfusion, cells often swell owing to increased osmotic pressure generated during ischemia.[69] The resulting increase in extravascular resistance eventually occludes the nutritive vessels. The importance of this phenomenon has been demonstrated by observing improved recovery of electrical and biochemical functions when the osmotic pressure of the reperfusing solution is increased to levels above normal to avoid cell swelling.[69]

Dangers secondary to reperfusion of ischemic tissue may also result from altered Ca^{2+} homeostasis. During ischemia the concentration of free Ca^{2+} may increase secondary to release of Ca^{2+} from the sarcoplasmic reticulum and mitochondria. Upon reperfusion the pH is rapidly restored, leading to considerable pH gradients. The sarcolemmal Na^+–H^+ exchanger restores intracellular pH after ischemia, leading to further increases in intracellular Na^+ levels. Increased sarcolemmal Na^+ influx with subsequent intracellular Na^+ overload resulting from the inability of the Na^+–K^+ pump to extrude Na^+ during myocardial ischemia has been recognized as an important pathogenic mechanism of cell injury during ischemia and reperfusion.[70–72] Na^+ becomes a "substrate" for reperfusion injury[73] and intensifies processes detrimental to cell function. The principal routes for Na^+ entry are Na^+–H^+ exchanger isoform 1 (NHE-1), the Na^+–HCO_3^- cotransporter, and Na^+ channels. Under conditions of ischemia and reperfusion, however, NHE-1 seems to be the predominant route. Na^+ overload can have detrimental effects on energy metabolism by intensifying ATP use for sodium extrusion by the Na^+–K^+ pump.[74] Sodium-induced sarcolemmal Ca^{2+} entry through the Ca^{2+}–Na^+ exchanger acting in its reverse mode appears to be the main mechanism of cell injury.[75] Experimental evidence suggests that the Ca^{2+}–Na^+ exchanger contributes to ischemia-reperfusion injury in settings of global and local myocardial ischemia. This process results in severe depletion of ATP and the development of ischemic contracture (stone heart).[3,28,40] Studies in a porcine model of cardiac arrest have demonstrated that ischemic contracture develops only after the beginning of closed-chest resuscitation, suggesting that reperfusion may be key to the development of ischemic contracture.[3] In humans, ischemic contracture has been reported during open-chest resuscitation after failure of closed-chest resuscitation as myocardial "firmness" and has been demonstrated to compromise resuscitability.[42] Sodium–hydrogen exchanger isoform 1 inhibition markedly ameliorates the aforementioned myocardial abnormalities that develop during cardiac arrest and reperfusion[76,77] and prevents increases in left ventricular wall thickness.[3]

Basic pharmacological concepts

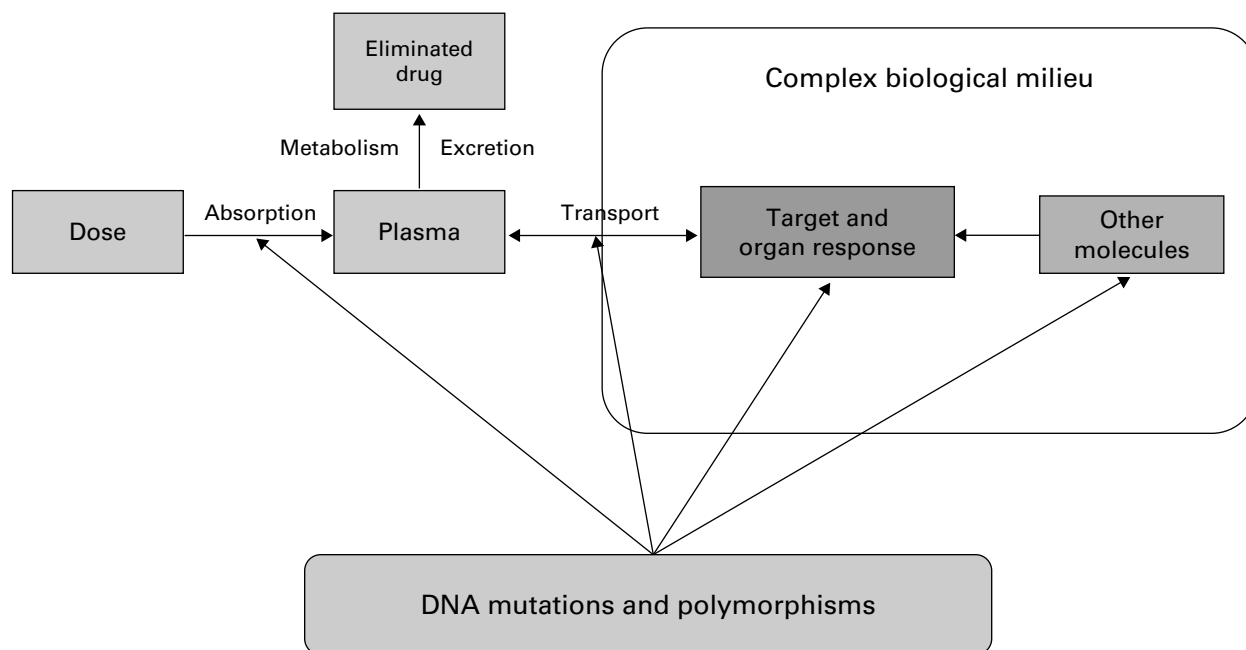
Two major processes describe the events that occur between drug administration and its effects determined by the interaction with the target organ (Fig. 20.2).


Fig. 20.2. A model for understanding variability in drug action. When a dose of a drug is administered, the processes of absorption, metabolism, excretion, and transport determine its access to specific molecular targets that mediate beneficial and toxic effects. The interaction between a drug and its molecular target then produces changes in molecular, cellular, whole organ, and ultimately whole patient physiology. This molecular interaction occurs in a complex biologic milieu modulated by multiple factors (some of which are disturbed to cause disease). DNA variants in the genes responsible for the processes of drug disposition, the molecular target, or the molecules determining the biological context in which the drug–target interaction occurs can all contribute to variability in drug action. (Modified from ref. 79.)

First, the drug must enter the systemic circulation and access its molecular site of action. The magnitude of the effect at the target is determined by the concentration of drug, and in some cases its metabolites, achieved in the plasma compartment. This process, named *pharmacokinetics*, describes drug delivery to and removal from the target molecule, and includes the processes of absorption, distribution, metabolism, and elimination (Fig. 20.3).

The second process that determines drug action has been termed *pharmacodynamics* and describes how the interaction between a drug and its specific molecular target generates effects at molecular, cellular, whole organ, and whole patient levels. Considerable intersubject variability in drug effects may arise from PD mechanisms because of the specifics of the target molecule and the complex biological milieu in which the interaction between drug and target occurs. Most frequently the biological context is altered by the same pathological processes for which that specific drug is administered.

It is only recently that the molecular basis of PK and PD has received increasing recognition, and that we have identified and characterized the genes that encode and

regulate the expression of such individual molecules. At the same time it is apparent that there is extreme interindividual genetic variability, on the order of tens of millions of DNA variants. Some, termed *mutations*, are rare and result in specific diseases such as long-QT syndrome. Other more common variants, named *polymorphisms*, may or may not interfere with the function of the encoded protein, depending on whether the polymorphism results in a variation in the original amino acid sequence, or the amount of mRNA transcribed from the gene and, as a consequence, of the amount of protein produced. The most common type of variation is confined to a single nucleotide and thus is termed *single nucleotide polymorphism*.

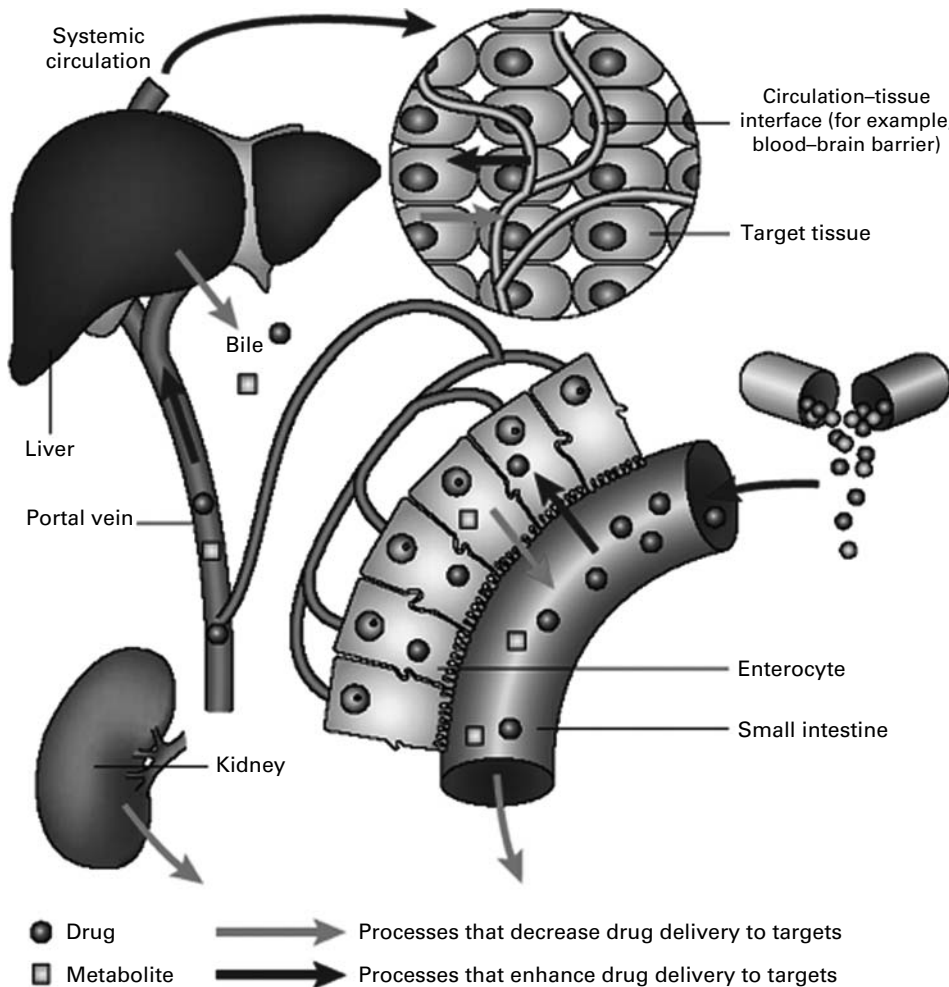
The way multiple DNA variants within the genome modulate drug responses is called *pharmacogenomics*.[80–82] An accepted hypothesis considers polymorphisms as physiologically "silent" until superimposed stressors, such as acute myocardial ischemia or drug administration, alter the biological milieu. Only then, in the context of such pathophysiological conditions, may DNA polymorphisms promote highly individual responses.[83,84]


Fig. 20.3 Determinants of drug delivery to target sites. The processes of absorption, distribution into tissues, metabolism, and elimination determine the amount of drug and metabolites that are delivered to target sites. In this figure, black arrows indicate processes that enhance drug delivery, whereas gray ones show processes that decrease it. Although some of the processes shown here might occur passively, much of this drug handling is mediated by specific drug-uptake or drug-efflux transporters, as well as by drug-metabolizing enzyme complexes. An ingested drug enters enterocytes, where it can undergo metabolism, then efflux into the portal circulation, or efflux back into the gut lumen. Similarly, a drug delivered to hepatocytes can be metabolized and excreted into the bile, or returned to the systemic circulation, from where it can also be excreted, generally through biliary or renal routes. If the molecular target is not located within the circulation, further obstacles to a drug accessing its molecular targets might be encountered at plasma-tissue barriers, which could limit drug access to certain cell populations, such as the brain or testes. Some drugs must access intracellular molecular targets, in which case uptake into, and efflux out of, the target cell might be key determinants of drug delivery and hence of drug action. (From ref. 80.)

Pharmacokinetics

Administration of an intravenous drug bolus results in maximal drug concentrations at the end of the bolus and then a decline in plasma drug concentration over time (Fig. 20.4). Most frequently, however, drugs are adminis-

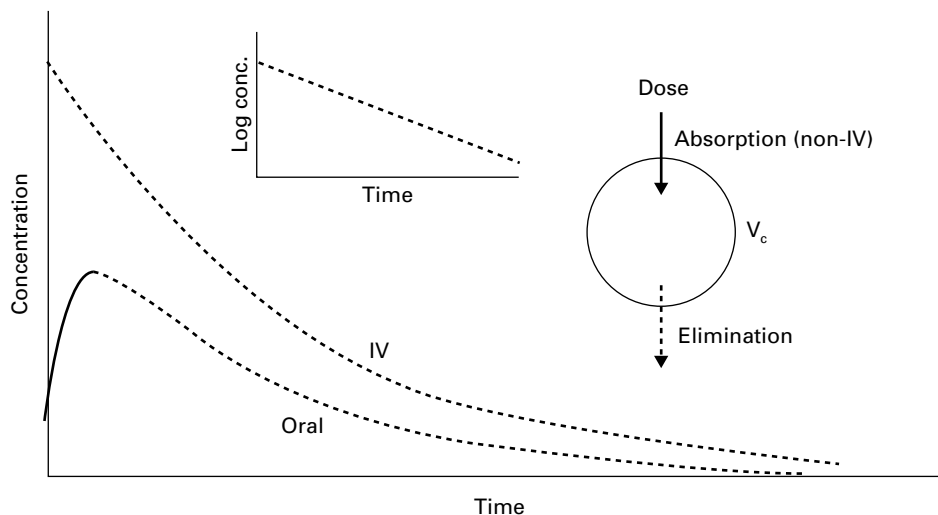
tered by non-intravenous routes such as oral, sublingual, transcutaneous, or intramuscular. During CPR, when difficulties in venous access arise, the intratracheal or intraosseous routes of administration can be used. The intrasseous route has been shown to be effective for


Fig. 20.4. Models of plasma concentrations as a function of time after a single dose of a drug. The simplest situation is one in which a drug is administered as a very rapid intravenous bolus into a volume (Vc) into which it is instantaneously and uniformly distributed. Elimination then takes place from this volume. In this case, drug elimination is monoexponential; that is, a plot of the logarithm of concentration versus time is linear, as shown in the inset. When the same dose of drug is administered orally, a distinct absorption phase is required prior to drug entry into Vc. Most absorption (shown here as a solid line) is completed prior to elimination (broken line), although the processes overlap. In this example, the amount of drug delivered by the oral route is less than that delivered by the intravenous route, assessed by the total areas under the two curves, indicating reduced bioavailability.(From ref. 79.)

administration of drugs and fluids in both children and adults, as well as laboratory analysis.[85–92] Evidence suggests that intraosseous infusion is much more reliable than tracheal administration of drugs during cardiac arrest. Two major differences distinguish the tracheal route of administration from the intravenous route. First, plasma concentrations are characterized by a rising phase as drugs slowly access the plasma compartment. Second, not all the drug administered may access the systemic circulation; thus, the plasma concentration may be less than that achieved by the intravenous route (Figs. 20.3 and 20.4). The amount of drug entering the systemic circulation by any route, compared to the same dose administered intravenously, is referred to as *bioavailability*. Bioavailability may be reduced because the drug is simply not absorbed from the site of administration or because the drug undergoes metabolism prior to entering the circulation – i.e., presystemic metabolism.

The simplest situation to describe is when a single dose of drug, administered as a rapid intravenous bolus, is eliminated in a monoexponential fashion (Fig. 20.4). The time in which 50% of the drug elimination occurs – *half-life* $(t_{1/2})$ – is a useful measure to describe its decline. After two half-lives, 75 % of the drug has been eliminated, after three half-lives 87.5 %, and after four 93.7% has been eliminated.

For practical purposes, elimination is complete after four to five elimination half-lives.

In other instances, the decline of drug concentration following administration of an intravenous bolus dose is multiexponential. The drug is not only eliminated but also undergoes more rapid distribution to peripheral tissues. Thus, the exponential term with the shorter half-life is generally associated with distribution and the longer one with elimination. Just as elimination may be usefully described by half-life, distribution half-life can also be derived from curves such as those shown in Fig. 20.5.

Rapid distribution can alter the way in which drug therapy should be initiated. When lidocaine is administered intravenously, it displays a prominent and rapid distribution phase ($t^{1/2} = 8$ min) prior to slower elimination ($t^{1/2} = 120$ min). As a consequence, an antiarrhythmic effect of lidocaine may be transiently achieved but very rapidly lost following a single bolus, due not to elimination, but to redistribution.[78] Administration of higher doses to circumvent this problem results in a greater likelihood of developing dose-related toxicity, often seizures. Hence, administration of a lidocaine loading dose of 3 to 4 mg kg^{-1} should occur over 10 to 20 minutes, a series of intravenous boluses (e.g., 50–100 mg every 5–10 minutes)
Fig. 20.5. Drug is delivered to the central volume, from which it is not only eliminated but also undergoes distribution to the peripheral sites. This distribution process is more rapid than elimination, resulting in a distinct biexponential disappearance curve. (From ref. 79.)
Fig. 20.6. Time course of drug concentrations when treatment is started or dose is changed. **Left.** The hash lines on the abscissa indicate one elimination half-life($t^{1/2}$). With a constant rate of intravenous infusion, plasma concentrations accumulate to steady state in four to five elimination half-lives. When a loading bolus is administered with the maintenance infusion, plasma concentrations are transiently higher but may dip, as shown here, prior to achieving the same steady state. When the same drug is administered by the oral route, the time course of drug accumulation is identical; in this case, the drug was administered at intervals of 50% of a $t^{1/2}$. Steady-state plasma concentrations during oral therapy fluctuate around the mean determined by intravenous therapy. **Right.** This plot shows that dosages are doubled or halved, or the drug is stopped during steady-state administration, and the time required to achieve the new steady state, four or five half-lives, is independent of the route of administration, (From ref. 79.)

or an intravenous infusion (e.g., 20 mg min^{-1} over 10–20 minutes).

With repeated doses or continuous infusions, drug levels accumulate to a *steady state*, the condition under which the rate of drug administration is equal to the rate of drug elimination in any given period of time. The elimination half-life describes not only the disappearance of a drug, but also the time course by which a drug accumulates to steady state. Whenever drug therapy is started, the drug dosage is changed, or the drug therapy is stopped, the time required to achieve a new steady-state plasma concentration is four

to five elimination half-lives (Fig. 20.6). It is important to distinguish between steady-state plasma concentrations, achieved in four to five elimination half-lives, and steady state drug effects, which may take longer to achieve. For some drugs, clinical effects develop immediately upon access to the molecular target: adrenergic agents to increase blood pressure, nitrates for angina, and nitroprusside to lower blood pressure, are all examples. In contrast, when an active metabolite must be generated first, drug effects follow plasma concentrations, but with a lag. Time may also be required for translation of the drug effect at the

molecular site to a physiologic end point. Penetration of a drug into intracellular or other tissue sites of action may be required prior to development of drug effect; this is widely cited to explain the lag time between administration of amiodarone dosages and development of its chronic effects, although the exact mechanism underlying its effect remains poorly understood.

The mechanisms underlying drug elimination from the body are metabolism and excretion. Drug metabolism often occurs in the liver, although extrahepatic metabolism is increasingly well defined, i.e., in the circulation, lungs, intestine, and kidneys. In the liver, "phase I" drug metabolism generally involves oxidation of the drug by specific drug-oxidizing enzymes, a process that renders the drug more polar, hence more likely to undergo renal excretion.[94,95] Additionally, drugs or their metabolites often undergo conjugation with specific chemical groups to increase their water solubility; these conjugation reactions are also catalyzed by specific transferases and are designated "phase II" enzymes.[95, 96]

Some drugs undergo such extensive presystemic metabolism that the amount of drug required to achieve a therapeutic effect is much greater than that required for the same drug administered intravenously. Thus, small doses of intravenous propranolol (5 mg) may achieve slowing of heart rate equivalent to that observed with much larger oral doses (80–120 mg). Propranolol is actually well absorbed, but it undergoes extensive metabolism in the intestine and the liver prior to entering the systemic circulation. Another example is amiodarone, a highly lipophilic drug consequently with very limited water solubility, which has a bioavailability of only 30% to 50% when it is administered orally. Thus, an intravenous infusion of 0.5 mg min^{-1} (720 mg day^{-1}) is equivalent to 1.5 to 2 g day^{-1} orally.

Clearance is the most useful way of quantifying drug elimination. Clearance can be viewed as a volume of plasma that is "cleared" of drug in any given period of time, or as organ-specific (e.g., renal clearance, hepatic clearance), or whole body clearance. Reduction in clearance, by disease, drug interaction, or genetic factors, will increase drug concentrations and hence drug effects. An exception are drugs whose effects are mediated by generation of active metabolites. In this case, inhibition of drug metabolism may lead to accumulation of the parent drug, but loss of therapeutic efficacy.

Pharmacodynamics

Drugs can exert variable effects, even in the absence of PK variability. As depicted in Fig. 20.2, these disturbances can be secondary to alterations in the molecular targets with which drugs interact, as well as variability in the biologic milieu that hosts the drug-target interaction. This is a frequent mechanism of variability in drug effects, e.g., the effect of lytic therapy in a patient with no clot is evidently different from that in a patient with acute coronary thrombosis; the arrhythmogenic effects of digitalis depend on K$^+$ serum concentrations; the vasodilating effects of nitrates, although beneficial in patients with limited coronary flow, can be catastrophic in patients with aortic stenosis.

When aiming at rapidly correcting disturbances in physiology, a drug should be administered intravenously in doses designed to achieve a rapid therapeutic effect. Steady state is not synonymous with stable plasma concentration. Under the same conditions, a near steady-state drug concentration can be achieved rapidly by use of a loading dose (Fig. 20.6). Nevertheless, a potential disadvant-age is that a loading dose may induce drug-related side effects, especially with large loading doses. Accordingly, this approach is best justified when benefits clearly outweigh risks. Unless therapeutic and plasma concentrations are required urgently, such as when suppressing life-threatening arrhythmias, large intravenous drug boluses carry with them a disproportionate risk of enhancing drug-related toxicity, making this approach rarely appropriate. An exception is adenosine, which must be administered as a rapid bolus because it undergoes extensive and rapid elimination from plasma by uptake into virtually all cells; as a consequence, a slow bolus or infusion rarely achieves sufficiently high concentrations at the desired site of action – the coronary arteries – to terminate arrhythmias or to prevent the "no-reflow" phenomenon.[97]

The time required to achieve steady-state plasma concentrations is determined by elimination half-life, as discussed earlier. The main determinant of loading dose is the volume of distribution i.e., the theoretical volume of plasma into which the drug distributes. Loading dose = volume distribution × desired plasma concentration. The clearance and elimination half-life will determine the need and time at which to repeat doses.

It is unusual for a patient to receive chronic drug therapy with a single agent. Rather, the rule is multiple chronic drug regimens in patients with coexisting organ dysfunctions of varying degrees. Physicians should recognize the risk of unanticipated drug effects, particularly drug toxicity, in these settings. Moreover, a number of disturbances of drug elimination and drug sensitivity may alter either the therapeutic dose or tilt the balance between risks and benefits of therapy. Some ß-blockers (e.g., propranolol and metoprolol) and cimetidine reduce hepatic blood flow and the intrinsic clearance of lidocaine, respectively.[98–100] Patients with left ventricular hypertrophy often have base-

line QT prolongation, and thus the risk of arrhythmias may increase; most guidelines suggest avoiding QT-prolonging antiarrhythmics in such patients.[78] In cases of heart failure, hepatic congestion can lead to decreased clearance and thus an increased toxicity with unadjusted doses of certain drugs, including lidocaine, ß-blockers, and some sedatives. In addition, patients with heart failure may have reduced renal perfusion and require dose adjustments on this basis. Heart failure is also characterized by a redistribution of regional blood flow that can lead to reduced volume of distribution and enhanced risk for drug toxicity. Lidocaine loading doses, for example, should be reduced in patients with heart failure because of altered distribution, whereas maintenance doses should be reduced in cases of both heart failure and liver disease because of altered clearance.

Drug interaction may also occur through PD mechanisms. Drugs may interact at the same effector site; the marked increase in isoproterenol dosage needed to increase heart rate in the presence of a ß-blocker is an example of a competitive agonist and antagonist interacting with the same target molecule, i.e., the β_1-adrenergic receptor. Drugs may also interact at the same time to produce synergistic effects, as in the case of two different antiarrhythmic Na^+ channel blockers with different dissociation characteristics, or drugs may allow additive pharmacologic effects while minimizing the risk of non-cardiac adverse effects present with high doses of a single drug.

More commonly, however, drugs interact by acting on different molecular targets, both of which modulate the end organ drug response. For example, low extracellular K^+ concentrations increase the potency of the rapidly activating component of delayed rectifier K^+ current (I_{Kr}) blockers;[101] thus, K^+-wasting diuretics act synergistically with I_{Kr} blockers to prolong the QT interval (same site). In addition, some diuretics also block the *slow* component of delayed rectifier K^+ current (I_{Ks}) to prolong the QT interval further.[102]

Pharmacogenetics

The variability of drug effects is increasingly recognized as dependent on DNA variants in genes that encode the drug targets and in key genes that control the biological milieu hosting the drug-receptor interaction.

A single nucleotide change can alter gene product function, and thus produce dramatic changes in physiology: the long QT syndromes or inherited errors in drug-biotransforming pathways are examples. Indeed, exogenous substrates, such as drugs, once aberrantly metabolized, produce unusual actions in affected patients.[79] Hence, these patients are phenotypically normal until an exogenous stressor – the drug – is added. These examples share the common mechanism of a DNA variant, a mutation, that severely disrupts protein function. Individuals and families with defects in genes encoding specific drug-metabolizing enzymes have been recognized. Individuals with defective CYP2D6, for example, exhibit markedly enhanced ß-blocking action (including bronchospasm and bradyarrhythmias) during propafenone therapy because of accumulation of the parent drug.[94,103]

In contrast to mutations, DNA polymorphisms are more common: one of the definitions of such polymorphisms is "a variant that occurs in more than 1% of a given study population." The distinction between *rare polymorphisms* and *mutations* however, can sometimes be blurred. Considerable effort is currently being devoted to identifying polymorphisms in the human genome, characterizing the way in which they alter protein function, and relating changes in polymorphism frequency to specific genotypes[80,81,104,105]

The mechanisms by which both mutations and polymorphisms can affect drug response are: (1) changes in PK; (2) changes in the target molecules; and (3) changes in the biologic context in which drug-target molecule interaction occurs (Fig. 20.7).

Specific drug-transport molecules, whose levels of expression and genetic variation are only now being explored, play a role not only in drug absorption and distribution but also excretion, generally into the urine or bile. Pharmacokinetic changes may derive from functionally important polymorphisms in the coding region of genes[107] or from variations in the mechanisms that regulate the amount of an individual messenger RNA generated by transcription of a single gene, that is, polymorphisms in the promoter,[107] including binding of multiple transcription factors to regulatory sequences of DNA. Thus, DNA variants may not only change the amino acid sequence of an encoded protein, but they may also change the amount of normally functioning protein generated by transcriptional control.[107,108]

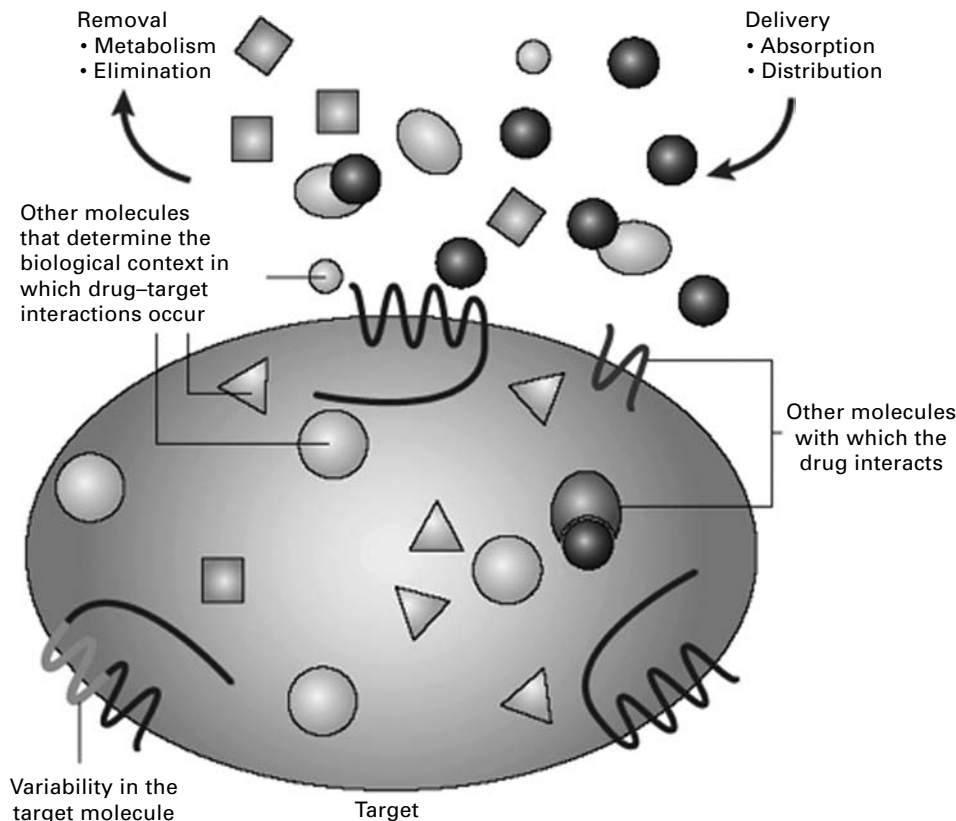
Functionally important polymorphisms may also affect target molecules. Polymorphisms in the β_1 and β_2 receptor genes have been associated with variability in heart rate and blood pressure effects with ß-blockers and ß-agonists[110-112]. Torsades de pointes during QT-prolonging antiarrhythmic therapy have been linked to polymorphisms in ion channel genes. This adverse effect sometimes arises in patients with clinically latent congenitally long QT syndrome, emphasizing the strict relation among disease, genetic background, and drug therapy.[112, 113]


Fig. 20.7. Determinants of drug action at the target site. The drug is indicated as black circles, and the metabolite as gray squares. Delivery of drug and metabolite to, and removal from, target sites on the cell surface or within the cell are controlled by processes with activities that might be genetically determined. Variability in drug action can also arise through the pharmacodynamic mechanisms illustrated here: the drug might interact with several other targets, there might be variability in the function or expression level of the drug target, or other molecules might modulate the biological context within which the drug–target interaction takes place. DNA variants in elements that control each of these processes can lead to variable drug actions. (From ref. 80.)

Correlation between polymorphisms and variability of the biologic context in which drugs act has been exemplified by studies on the mechanisms of torsades de pointes. Virtually all drugs that cause torsades de pointes are I_{Kr} blockers.[114,115] The biologic milieu in which I_{Kr} blockers act includes other mechanisms that control the action potential as well as the normal autonomic function and serum K^+. Thus, variants in any of the genes modulating these processes in theory could modulate the extent to which I_{Kr} blockers prolong the QT interval and generate torsades de pointes. For an example, administration of a drug with I_{Kr} blocking properties does not ordinarily perturb cardiac repolarization excessively, probably because of the presence of other repolarizing currents, notably the slow component termed I_{Ks}; however, individuals with subclinical loss-of-function mutations in genes encoding I_{Ks}, who

have normal cardiac repolarization at baseline, have been shown to develop marked repolarization abnormalities and arrhythmias when challenged with an I_{Kr}-blocking drug.[116–118] Consistent with this reasoning, families have been described in which patients with mutations responsible for long QT syndromes are asymptomatic until exposed to a QT-prolonging drug.[112,116]

Drug transport is an active process that is also gene-regulated, making it an appealing target of genetic therapy. Indeed, drug entry into and efflux from cellular sites often reflects normal function and expression of specific energy-dependent drug transporters.[119,120] The most studied drug transporter is P-glycoprotein, the product of expression of the *MDR1* gene. P-glycoprotein is an efflux pump extensively expressed on the apical lumen of the enterocytes, the biliary aspect of hepatocytes, and

the capillary endothelium of the brain.[121] In the latter, p-glycoprotein serves to limit access of drug to the central nervous system and thus forms an important component of the blood–brain barrier, representing at the same time a promising target for future therapeutic genetic interventions. Specific drug uptake and efflux transporters have not been identified in cardiac myocytes, and the mechanisms by which the drug accesses intracellular sites of action (relevant to virtually all antiarrhythmic drugs) is yet unknown.

Pharmacology of cardiac arrest

General considerations

Pharmacological therapies are used in cardiopulmonary resuscitation to supplement the key interventions of effective chest compression/ventilation and defibrillation. In contrast to other interventions (such as defibrillation), scientific evidence to support the use of drugs in cardiac arrest is limited. In the large Ontario Prehospital Advanced Life Support (OPALS) study, the addition of drug administration and intubation skills to the repertoire of skills of existing pre-hospital responders (trained in CPR and rapid defibrillation) had no effect on survival.[19] Despite the limited evidence to support its use, however, pharmacological therapy remains a central part of resuscitation protocols. Drugs used during cardiopulmonary resuscitation will be considered under the headings of vasopressors, antiarrhythmics, thrombolytics, and other drugs.

Specific considerations

Vasopressors

Vasopressors have been used as an adjunct to cardiopulmonary resuscitation for the last 40 years. Vasopressors are used in cardiac arrest in the belief that they will improve coronary and cerebral blood flow during CPR and thereby increase the chances of achieving a return of spontaneous circulation and neurologically intact survival. Despite their widespread inclusion in resuscitation guidelines, to date no randomized placebo-controlled clinical trials in humans have demonstrated improved survival to discharge with any of the vasopressor drugs.[25]

Several vasopressors have been studied in the context of cardiopulmonary resuscitation. Epinephrine has been the standard first-line drug for cardiac arrest for many decades. Vasopressin has been studied extensively in animal models and human clinical trials. Despite initially
Fig. 20.8 Molecular structure of epinephrine.

promising results, a recent meta-analysis of five clinical trials failed to demonstrate that it was superior to epinephrine for improving the rate of return of spontaneous circulation, or of 24-hour or discharge survival.[122] The specific pharmacological actions and efficacy of epinephrine and vasopressin are considered below. The alternative vasopressors alpha-methyl norepinephrine and endothelin-1 have been investigated in laboratory models of cardiac arrest, but to date no clinical studies have been conducted.[25] These agents are not considered further in this chapter.

Epinephrine
Epinephrine is a naturally occurring hormone synthesized from L-tyrosine in the adrenal medulla and secreted in response to activation of the sympathetic nervous system (Fig. 20.8). It is a mixed adrenergic agonist, acting on both α- and β-adrenergic receptors. The adrenergic receptors are coupled to G-protein secondary messenger systems including cyclic adenosine monophosphate (β and α_2) (Fig. 20.9) and phospholipase C (α_1 receptor) (Fig. 20.10).

The beneficial effects of epinephrine in cardiac arrest are mostly mediated by activation of the α-adrenergic receptors. Activation of α-adrenergic receptors causes vascular smooth muscle contraction, leading to systemic arteriolar vasoconstriction, which maintains peripheral vascular tone and prevents arteriolar collapse. This has the effect of increasing aortic diastolic pressure, which increases coronary perfusion and cerebral perfusion pressures.

Stimulation of β-receptors by epinephrine has both inotropic and chronotropic effects on the beating heart that increase coronary and cerebral blood flow, but at the same time increase oxygen consumption, increase ventricular ectopic activity, and reduce subendocardial perfusion. Within the lung, stimulation of β_2 receptors by epinephrine can increase arteriovenous mismatching leading to transient hypoxemia.

Epinephrine is available in a variety of formulations and is usually given intravenously during cardiac arrest. It is metabolized by catechol-o-methyltransferase and monoamine oxidase, predominantly in the liver, to inactive metabolites, which are excreted in the urine. Intravenous administration has a rapid onset of action and half-life of
Fig. 20.9 β- and α$_2$-adrenergic receptors are coupled via G-proteins to the adenylate cyclase, leading, after drug-receptor interaction, to the production of the second messenger cyclic adenosine monophosphate (CAMP).

approximately 5–10 minutes. Absorption from subcutaneous and intramuscular injection of epinephrine is slow and erratic in cardiac arrest and should be avoided. Endotracheal epinephrine is recommended in resuscitation guidelines when intravenous access cannot be established.[25] Recent animal data suggest that tracheal administration can be associated with hypotension, mediated through pulmonary β$_2$ receptors.[123] This complication was avoided with endobronchial administration.[124]

Vasopressin
Arginine vasopressin (Fig. 20.11) is a naturally occurring hormone (antidiuretic hormone) synthesized and released by the posterior pituitary in response to changes in plasma osmolality and circulating volume. Physiological concentrations of vasopressin in humans range from 2–20 pg ml.[125]

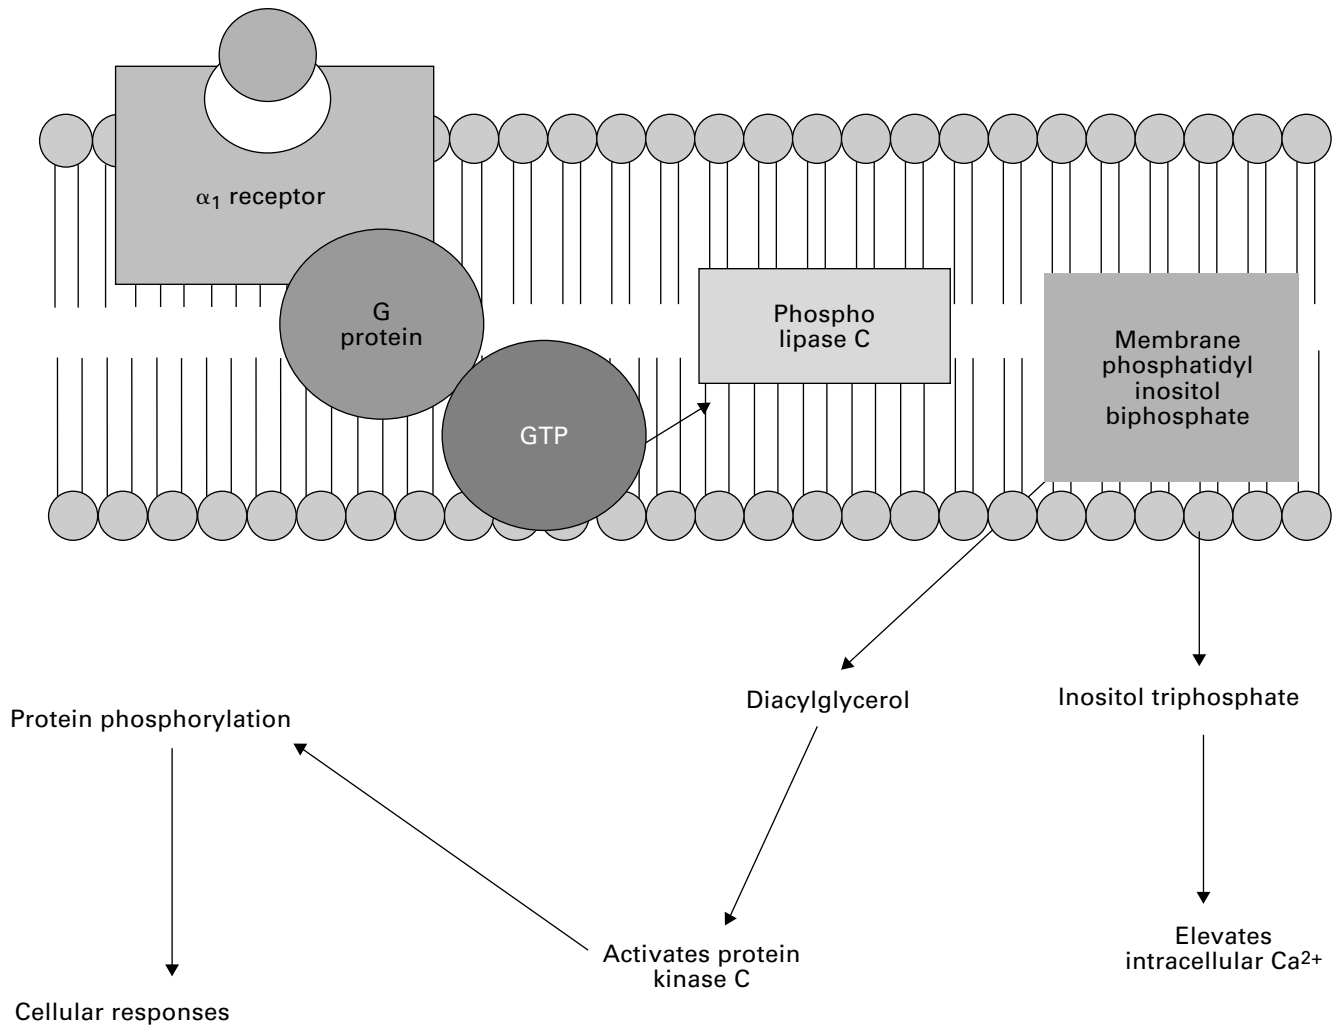
Vasopressin receptors are membrane-bound receptors coupled to G-protein-activated intracellular signaling pathways. Three different subtypes have been described: V1 receptors (previously known as V1$_a$ receptors) are the most widespread type of vasopressin receptor and are found on vascular smooth muscle cells (where they regulate vasomotor tone), the kidney, myometrium, bladder, hepatocytes, platelets, adipocytes, and spleen. V2 receptors are located in the distal tubule and collecting ducts of the kidney and control urine volume through regulating the density of aquaporin channels on the cell surface. V3 receptors (previously known as V1$_b$) are found in the pituitary gland and stimulate adrenocorticotropic hormone (ACTH) secretion and regulate memory, blood pressure, temperature, and pituitary hormone release.[125]


Fig. 20.10. The interaction of epinephrine with the α_1 adrenergic receptor determines the G-protein-mediated activation of the second messenger system via phospholipase C.

At physiological concentrations, vasopressin contributes to osmoregulation and maintenance of normovolemia. It also plays a role in hemostasis, temperature regulation, memory, and sleep. Synthetic vasopressin is available as an aqueous solution for intravenous, intramuscular or subcutaneous use. The intravenous route has been used exclusively in clinical trials in cardiac arrest patients. Animal data suggest that the intraosseous,[126] endotracheal, and intravenous routes[127,128] are equally effective. Vasopressin is not protein-bound and has a volume of distribution of 140 ml kg^{-1} and plasma half-life

Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Arg-GlyNH$_2$
Fig. 20.11. Molecular structure of vasopressin.

of 24 minutes. Its is cleared by renal elimination (65%) and metabolism (35%) by tissue peptidases.[125]

Endogenous vasopressin concentrations increase rapidly within the first few minutes of cardiac arrest. Average vasopressin concentrations are significantly higher in patients who are successfully resuscitated from cardiopulmonary arrest than in non-survivors (177 pg ml^{-1} and 58 pg ml^{-1}, $P < 0.001$).[128]

The efficacy of vasopressin in animal cardiac arrest models has been studied extensively. In porcine models of ventricular fibrillation, compared to maximal dose epinephrine (200 µg kg^{-1}), vasopressin (0.8 µg kg^{-1}) produced superior coronary and cerebral perfusion and improved cerebral oxygen delivery and ventricular fibrillation mean frequency.[129] A meta-analysis of 33 randomized controlled

animal studies (*n*=669) showed that vasopressin was associated with a higher rate of return of spontaneous circulation than was placebo (93% vs. 19%, *P*<0.001) or epinephrine (84% vs. 59%, *P*<0.001). Sub-group analysis demonstrated that vasopressin was superior to placebo in both VF and non-VF models.[130]

One of the first clinical studies to investigate vasopressin involved 8 patients in refractory cardiac arrest despite standard therapy with chest compression, epinephrine, and defibrillation; vasopressin administration (40 units) resulted in a prompt return of spontaneous circulation in all 8 cases. Of these, three subsequently survived and were discharged from hospital neurologically intact.[131] The first randomized controlled trial in humans to investigate vasopressin in cardiac arrest compared 40 U of IV vasopressin to 1 mg of epinephrine as the initial pharmacological treatment in 40 out-of-hospital subjects with shock-refractory VF. A significantly higher proportion of patients in the vasopressin group were successfully resuscitated and survived 24 hours compared to those treated with epinephrine.[132]

A prospective randomized controlled trial in 200 hospitalized cardiac arrest patients compared vasopressin (40 U) to epinephrine (1 mg) as the initial pharmacological treatment. This study failed to demonstrate any difference in the primary outcome measure of 1-hour survival (39% vasopressin vs. 35% epinephrine) or 30-day survival (vasopressin 13% vs. epinephrine 14%). The time to drug administration in these studies differed substantially (prehospital study 7.8–8.6 minutes compared to 1.1–1.3 minutes in the in-hospital study) and it was postulated at the time that vasopressin and epinephrine may be equipotent if administered early after the onset of cardiac arrest.[133]

The largest clinical trial to study the effect of vasopressin in cardiac arrest was conducted by the European Resuscitation Council Vasopressor during Cardiopulmonary Resuscitation Study Group. This study compared up to two injections of vasopressin 40 U or 1 mg of epinephrine, followed by additional treatment with epinephrine if required, during out-of-hospital cardiac arrest in Vienna, Germany, and Switzerland. The primary end point was survival to hospital admission and the secondary endpoint was survival to hospital discharge.[22]

A total of 1186 patients were randomized, of whom 589 received vasopressin and 597 epinephrine. The two treatment groups had similar characteristics at baseline. There was a trend toward improved rates of hospital admission in the vasopressin group compared to the epinephrine groups (36.3 vs. 31.2%, *P* = 0.06), but no difference in hospital discharge rates (9.9% both groups). A secondary post-hoc subgroup analysis found that patients in asystolic

cardiac arrest treated with vasopressin were more likely to survive to hospital admission (29% vs. 20.3%, *P* = 0.02) and subsequent discharge (4.7% vs. 1.5%, *P* = 0.04) than if they received epinephrine. This observation was not true for the VF or PEA groups. A second subgroup comprised 732 patients with prolonged cardiac arrest who received both the initial doses of vasopressin and then received epinephrine showed significantly better survival compared to those who received epinephrine alone (discharge survival 6.2% vs. 1.7%, *P* = 0.002). Nontheless, half (10/20) the survivors in this subset of vasopressin patients were discharged comatose or with severe cerebral disability compared with 20% (1/5) in the epinephrine group.

A systematic review and meta-analysis of five clinical trials (1519 patients) comparing epinephrine and vasopressin (which included the data from the European Resuscitation Council Vasopressin study) found no difference in return of spontaneous circulation, admission or discharge survival, or the number of neurologically intact survivors. Subgroup analysis based on initial cardiac rhythm showed no statistically significant difference between drugs.[122]

In conclusion, despite promising laboratory studies, clinical studies have failed to demonstrate a consistent survival advantage for humans in cardiac arrest. The precise indications and timing of administration for vasopressin in the management of cardiac arrest therefore remains to be defined in future clinical trials.

Antiarrhythmics

There is no evidence that administration of any antiarrhythmic drug routinely during human cardiac arrest increases survival to hospital discharge. Amiodarone improves the short-term outcome of survival to hospital admission in shock-refractory VF when compared to lidocaine or placebo. Bretylium is no longer part of international guidelines for resuscitation. Amiodarone, lidocaine, and magnesium are considered below.

Amiodarone

Amiodarone was originally developed as an antianginal agent.[134] It has complex ion channel-blocking activities.[135,136] Acute intravenous administration decreases heart rate and blood pressure with minimal changes in QRS duration or QT interval. Chronic use may lead to bradycardia and increases in action potential duration in atrioventricular (AV) nodal and ventricular tissue, with increased QRS duration and QT interval.

Amiodarone is lipophilic and is taken up by many tissues (volume distribution approximately 60 liters kg^{-1}) with large interindividual variation and complex PK.[137–139] The

short initial, context-sensitive half-life after intravenous administration represents drug redistribution. The actual elimination half-life is 40 to 60 days.

Amiodarone produces all four electrophysiological effects according to the Vaughan Williams classification. It has use-dependent class I activity, inhibition of inward Na^+ currents, and class II activity.[136] The antiadrenergic effect of amiodarone is non-competitive and additive to the effect of beta blockers. Amiodarone depresses sinoatrial node automaticity, slows the heart rate and conduction, and increases refractoriness of the AV node, properties useful in the management of supraventricular arrhythmia. Class III activity increases atrial and ventricular refractoriness and prolongs the QTc interval. Chronic amiodarone administration may increase the defibrillation threshold, although this is not observed after acute administration. Administration of amiodarone in a dog model of VF (12 dogs received acute IV amiodarone 10 mg kg^{-1} or placebo; 12 dogs were pretreated with chronic amiodarone 20 mg kg^{-1} day^{-1} for 30 days or placebo before induction of VF) increased the organization of VF by several measures without lengthening the refractory period and without changing the defibrillation threshold.[141] Amiodarone has a long list of side effects. The most important is pulmonary toxicity, which may affect up to 1% of recipients.[141]

The ARREST – Amiodarone in the Resuscitation of Refractory Sustained Ventricular Tachyarrhythmias – study was a randomized, prospective, double blind, placebo-controlled trial of 504 patients with out-of-hospital cardiac arrest in VF/VT who failed to respond to $\geq$ 3 shocks. They received either placebo or amiodarone 300 mg IV. Treatment with amiodarone was an independent predictor of admission alive to hospital (44% vs. 34%, odds ratio 1.6; 95% confidence interval 1.1 – 2.4).[24]

In the randomized, controlled, double blind ALIVE – Amiodarone versus Lidocaine in Prehospital Ventricular Fibrillation Evaluation – study, amiodarone ($n = 180$) was compared to lidocaine ($n = 167$) in out-of-hospital VF/VT resistant to three shocks: 22.8% of amiodarone-treated patients survived to hospital admission compared to 12.0% of lidocaine-treated patients. Neither the ARREST nor ALIVE studies had a sufficient sample size to show any difference in survival to hospital discharge. One possible reason for the superiority of amiodarone may be that it is effective in severe acidosis; a laboratory study shows that amiodarone remains effective despite extracellular acidosis.[142]

Amiodarone caused a significantly lower CPP compared with epinephrine alone or the combination of epinephrine and amiodarone in a dog model of VF arrest.[143] Recent human data support this,[144] suggesting that it may actually

be the combination of amiodarone and a vasopressor that is beneficial in cardiac arrest.

A new aqueous formulation of amiodarone (Amio-Aqueous) does not contain the solvents of the standard formulation (polysorbate 80 and benzyl alcohol) that are used to keep amiodarone in solution. These solvents may be responsible for the hypotensive effects of the standard amiodarone formulation. Amio-Aqueous is also more effective than lidocaine in terminating shock-resistant VT.[145] A meta-analysis of four prospective clinical trials of patients with VT shows that Amio-Aqueous is as safe as lidocaine with respect to hypotensive side effects.[146]

Finally, animal studies suggest that amiodarone may not be effective in hypothermia.[147, 148]

Lidocaine
Lidocaine, a class 1B antiarrhythmic blocks a specific site on the Na^+ channel. It decreases automaticity by decreasing the slope of phase 4 depolarization and does not affect the PR interval, QRS complex, or QT interval.

It is no longer the drug of choice in shock-refractory VF or VT (see amiodarone above). Plasma lidocaine levels above 6 μg ml^{-1} are needed for an antifibrillatory effect. Levels above 8–10 μg ml^{-1} are associated with toxicity, which includes seizures and decreased cardiac output. Patients with significant conduction system abnormalities or hemodynamic compromise can develop toxicity at very low lidocaine concentrations. Active metabolites can also contribute to toxicity even with modest concentrations of lidocaine in plasma. Lidocaine is metabolized in the liver and excreted by the kidneys. The half-life of intravenous lidocaine is about 100 minutes, but because it is metabolized in the liver (which depends on liver flow), dosage should be reduced in patients with low cardiac output. In cardiogenic shock, the half-life may exceed 10 hours.

Magnesium
Magnesium sulfate has electrophysiological properties that might make it a useful antiarrhythmic agent. Specifically, its role as a coenzyme for the Na^+–K^+ ion exchange pump (the Na^+–K^+ ATPase) and its effects on K^+ channels and intracellular Ca^{2+} accumulation all contribute to decrease automaticity. Clinically, it has been found that AV nodal conduction is prolonged in patients treated with infusions of magnesium sulfate. It also has a high therapeutic ratio and is relatively devoid of negative inotropic effects. Magnesium use during resuscitation has been of interest since normomagnesemia appeared to be related to successful resuscitation.[149, 150]

Studies have failed to show any benefit of giving magnesium in cardiac arrest.[151–152] The only real indications for

magnesium therapy seem to be hypomagnesemia and torsades de pointes. Magnesium sulfate 2 g (8 mmol) IV has also been tested as a neuroprotective agent after successful resuscitation from cardiac arrest. It did not improve neurological outcome compared to placebo when given immediately following ROSC after out-of-hospital cardiac arrest, either alone or in combination with diazepam.[156]

In summary, evidence from human studies does not favor routine use of magnesium during CPR. Recent animal data[160] point to a possible cardioprotective role of magnesium with respect to reducing oxygen free radical-induced damage and to preserving postdefibrillation left ventricular contractile function, but this requires further investigation.

Thrombolytics

Thrombolytics may be useful after initial failure of standard CPR techniques, particularly if arrest is caused by acute pulmonary embolism or other cardiac causes.[161–168] One large clinical trial[169] showed no benefit for thrombolytics in out-of-hospital patients with PEA cardiac arrest unresponsive to initial interventions. Several studies[161–164] and case series[165–168] show that there is no increase in bleeding complications with thrombolysis during CPR in non-traumatic cardiac arrest. Animal studies[170, 171] also show improved cerebral infusion with thrombolysis during CPR.

There is an argument for a more general positive effect of thrombolytic agents (even if administered prearrest or postarrest in those achieving ROSC) in preventing or diminishing no-reflow and microvascular thrombosis and organ dysfunction after cardiac arrest.[171] Several authors have suggested that this mechanism may improve neurological outcome in survivors of cardiac arrest.[164, 171, 172]

A large, prospective, randomized clinical trial – Thrombolysis In Cardiac Arrest ("TROICA") – is ongoing in Europe to study the potential value of prehospital fibrinolysis in adult, non-traumatic cardiac arrest patients who do not respond promptly to conventional therapy.

Tenecteplase can be given as a rapid intravenous bolus and hence is currently the agent of choice if thrombolysis is considered during cardiac arrest. Tenecteplase is a triple combination mutant variant of alteplase with high fibrin specificity and resistance to plasminogen activator inhibitor-1. The reduced rate of systemic clearance (fourfold slower) of the drug relative to alteplase allows tenecteplase to be given by rapid bolus injection. In patients with myocardial infarction tenecteplase has an initial plasma half-life of 20–24 minutes.

Atropine

Atropine should be considered in asystole and slow PEA. Several studies in adults[19, 23, 173–176] show that treatment with atropine is not associated with any consistent benefits after in-hospital or out-of-hospital cardiac arrests. There is, however, a physiological rationale for use of a vagolytic, as asystole can be precipitated by excessive vagal tone. Asystole is usually fatal and atropine is unlikely to have side effects in this setting.

Atropine has similar antagonist activity for all five muscarinic receptor subtypes. Thus far, the postsynaptic muscarinic receptors supposed to transduce parasympathetic impulses to the heart have been assigned to the M2 subtype, because mRNA for M1 or M3 receptors could not be found in heart muscle cells in experimental studies in adult animals. The direct effect of activation of M2 receptors in the heart is to decrease myocardial activity; that is, negative chronotropic, dromotropic, and inotropic effects occur. M2 receptors inhibit adenylate cyclase activity and enhance K^+ currents, both of which lead to decreased activation of myocardial cells. In pacemaker cells, this slows the rate of spontaneous depolarization. A negative inotropic effect decreases myocardial oxygen demand. These cardiodepressant effects are a predictable consequence of mimicking the parasympathetic nervous system and are consistent with energy conservation.

In asystolic patients 14% who received atropine survived to admission to the emergency department as opposed to 0 % who did not receive atropine.[177] In patients with severe bradycardia or asystole following administration of succinylcholine most cases resolve with atropine.[178]

Literature to refute the use of atropine is sparse and of limited quality. In a small prospective, controlled, non-randomized study of out-of-hospital cardiac arrest patients, investigators found no difference in rhythm change, ROSC, or survival when patients were given 1–2 mg of atropine as their initial resuscitation medication versus control.[179] In a prospective, controlled, blinded canine asphyxial PEA model, no differences in ROSC or survival rates were noted between standard dose atropine and placebo groups.[180] In a prospective, controlled, non-blinded canine asphyxial PEA model, methoxamine was compared to atropine and calcium chloride. Fifty percent of the animals who received atropine had ROSC vs. 20% of the control group, but this did not reach statistical significance. Additionally, a prompt response to atropine, signifying pharmacologic effect, was not noted. Subtherapeutic doses of atropine in some of the animals and lack of epinephrine use may be significant.

Bernheim *et al.*[181] investigated 25 clinically stable heart transplant patients. After endomyocardial biopsy, a temporary pacemaker was introduced and patients were monitored. Atropine was given in increasing doses (0.004 mg kg^{-1} body weight initially, total cumulative dose

0.035 mg kg^{-1} body weight). In 20% of the patients (5/25), a paradoxical response to atropine was observed. Four patients exhibited third degree AV block, one of whom also demonstrated sinus arrest; a fifth patient showed sinus arrest only. Atropine may paradoxically cause high degree AV block in patients after cardiac transplantation. It should be used with caution and appropriate monitoring in these patients.

Atropine is a naturally occurring alkaloid of "Atropa belladonna" Atropine disappears rapidly from the blood and is distributed throughout the body. It is destroyed by enzymatic hydrolysis, particularly in the liver; from 13 to 50% is excreted unchanged in the urine. Its plasma half-life is approximately 2–4 hours.

Analysis and predictive value of the ventricular fibrillation waveform

Trygve Eftestøl, Hans-Ulrich Strohmenger and Colin Robertson

Department of Emergency Medicine, The Royal Infirmary of Edinburgh, UK

Introduction: Why analyze the waveform?

Ventricular fibrillation (VF) is the cardiac arrest rhythm most amenable to successful treatment, and the vast majority of survivors from human cardiac arrest have VF as their primary rhythm. Successful treatment in these patients almost invariably requires electrical defibrillation. While advances have been made in defibrillation therapy, particularly in the introduction of automatic and semi-automatic defibrillators (AED) with rhythm recognition and the use of novel defibrillatory waveforms, the primary determinant of successful defibrillation is the duration of the VF episode.[1] With the passage of time, the chances of successful defibrillation fall dramatically. Basic life support (BLS) procedures in general and myocardial perfusion due to closed-chest compression can only retard the metabolic deterioration of the myocardium. With prolonged duration of VF, an increasing likelihood of asystole, pulseless electrical activity, or persistent VF following countershock results.[2,3] Moreover, multiple countershocks that do not result in spontaneous circulation are probably harmful by causing thermal damage to the heart and increasing cumulative defibrillation energy decreases postresuscitation myocardial function and survival.[4,5]

For these reasons, researchers attempt to interrogate the VF waveform determined from the surface electrocardiogram (ECG) trace to ascertain knowledge of the myocardial state, to assess the probability of success of a defibrillating shock, and to investigate whether, by physical or pharmacological means, the situation can be changed to improve the likelihood of restoring a spontaneous perfusing rhythm.

Data acquisition and preprocessing

Logistic difficulties

Although the primary focus of analysis is the ECG-derived VF waveform itself, additional documentation such as patient demographics, electrical, pharmacological, and physical interventions, and outcome information is required to provide meaningful conclusions. In contrast to animal experiments, human studies need substantial time and effort to gather and store field information in a form suitable for detailed analysis.

To extract meaningful information, data are imported and integrated in a software environment that facilitates signal analysis.[6] Figure 21.1 illustrates some key information including the ECG time series, events from the defibrillation log, and rhythm annotations provided by medical experts. Human VF analysis involves considerable work to establish the databases, routines for storing and transferring electronic data from the emergency medical system (EMS) and linking it with information from the signal analysis.[7–9] Separate centers typically use different equipment so the coding format of electronic information for ECG, event logs, demographic information, and annotations vary. This lack of standardization makes research on this kind of data challenging.

Filtering techniques

Mechanical activity from chest compression and ventilation during CPR introduces artefact components in the ECG signal.[10–12] At present, it is necessary to stop CPR
Fig. 21.1. ECG during resuscitation. ECG tracing illustrating VF, with artefacts from precordial chest compressions, hands-off intervals, countershocks and return of spontaneous circulation. Each line shows 30 seconds of ECG continuing from the previous line. The time stamps and defibrillator usage text above and below each line of tracing are read from the electronic defibrillator log file. The text within the tracing axes are the therapy, defibrillation outcome and rhythm annotations provided by the medical experts. (*After Eftestøl et al. Expert Rev. Cardiovasc. Ther. (2003)© Future Drugs 2003.*)

before analyzing (manually, or by AED) the artefact-free ECG rhythm. This intermittent cessation of CPR reduces the likelihood of successful defibrillation because, during these breaks, myocardial (and cerebral) perfusion does not occur.

Artefact removal has been successfully applied to animal ECGs by using high-pass digital filters with fixed coefficients.[13,14] In the human ECG, however, the frequency components of the artefacts overlap with dominant components in the human VF spectrum, and make separation by such filters unfeasible.

Adaptive filtering has been used to remove CPR artefacts in human out-of-hospital cardiac arrest ECG.[15] Reference signals that resemble different artefact types (e.g., compressions and ventilations) are recorded simultaneously with the ECG and "subtracted" from the ECG. CPR artefacts in the ECG can be reduced in this way, but not always well

enough for a shock/no-shock decision classifier. The time without blood flow from compressions can be reduced significantly by removing artefacts during CPR.[16]

Approaches to analysis

The search for one or more predictors of defibrillation outcome derived from the VF ECG waveform and for measuring the effects of therapy goes back 20 years.[2,7,10,17–21]

Time and frequency domain techniques

From a signal processing perspective, the main approaches to VF waveform analysis fall within the categories of time and frequency domain techniques. Typically, time domain approaches are applied to characterize specific events such

as detection and description of P waves, QRS complexes, or T waves in the ECG of perfusing rhythms. Perfusing rhythms are, to some degree, deterministic: a term often used to describe biomedical signals of a quasiperiodic nature. The VF waveform signals, however, do not display clearly distinctive quasiperiodic events but are governed by processes that are described and analyzed statistically. These processes, related to cardiac arrest, change with time and therapy and the parameters describing these processes change accordingly. VF analysis seeks to identify parameters that can be used to distinguish features associated with a high probability of restoration of spontaneous circulation (ROSC) following countershock from those with a low countershock success rate.

Time domain techniques applied to VF involve characterization of the signal's amplitude behavior. These techniques attempt to describe the statistical properties of the amplitude or energy distribution of the signal-generating process. As an example, the expected amplitude value can be estimated by the signal's sample mean or the signal energy can be quantified as the dispersion of the squared amplitude about its mean.[22,23] In statistical terms, these are moments of the signal amplitude's first-order distribution or probability density function (PDF). Another important family of amplitude distributions is the second-order distributions, in which more amplitudes of one signal are involved. With these it is possible to analyze the relationship between amplitude variations of the same signal at different time instants. The autocorrelation function (ACF) estimated from the signal is an expression for this relationship. The VF signal typically does not exhibit one distinct periodic component, but rather a composite spectrum of several such components more naturally expressed in frequency rather than time units. Because of this, and because signals with such properties are commonly analyzed in the frequency domain, the power spectral density (PSD) function, which is the frequency domain equivalent of the VF ACF, has been widely used in the analysis of the signal's periodic behavior.

Chaos theory and non-linear dynamics

To the naked eye, the VF waveform appears entirely random or stochastic, but "random" phenomena can, on further investigation, show predictable features. Non-linear mathematical approaches, colloquially known as "chaos theory," have been used to search for underlying structure and predictability in VF. Such approaches are not simply "blue sky" in nature. A fundamental element of mathematically chaotic systems is that miniscule changes at an early stage can lead to subsequent dramatic

perturbations – popularized as the "Butterfly effect."[24] If the VF waveform is chaotic then, instead of the 10–100s of joules required for conventional defibrillation, there is the possibility that a tiny electrical stimulus at a predetermined point could terminate the arrhythmia and restore a perfusing rhythm.

In some animal and computer models, spiral waves of electrical activity (vortices and rotors) travel through the myocardium, become fragmented and turbulent, and lead to persistence of VF.[25–27] The characterization of these initiating events, and of VF, as mathematically chaotic systems is a highly specialized area and differing analytical methods have made interpretation and extrapolation difficult. Nevertheless there is evidence that, at least in the early stages, VF does show specific phenomena of mathematical chaos with consistent exhibition of organized structure.[28–30]

Non-linear dynamic methods have been used to elucidate the fractal dimension of the VF signal and quantify its morphology and time course, independent of signal amplitude and spectral parameters. The practical difficulties of using these forms of analysis relate to the massive computer processing power needed and the necessity of using "clean," but unfiltered, signals. The ability to achieve this and provide real-time feedback will demand massive improvements before clinical therapy can be influenced.

Practically, the problem of prediction of defibrillation outcome is handled by extracting VF waveforms immediately before a defibrillation attempt with corresponding outcome information (ROSC or no-ROSC) from the available data. After this, signal analysis based on time domain, frequency domain, and/or non-linear dynamics techniques measures waveform characteristics (features) to be used in the shock outcome predictor.

Structuring the data in frequency and time-frequency representations

Characterization of the VF signal often involves a first stage in which the signal is restructured or transformed into a frequency domain representation or even combined time-frequency representations. These alternative representations are often a prelude to computing shock outcome predictors, but also offer alternative representations by which the hidden structures of VF have been revealed to the observer.

Fourier transforms

This technique involves splitting short segments of the VF waveform into small subunits and expressing each of

these as the sum of multiple simpler sine/cosine waves of varying amplitude and frequency. These component waves can then provide an amplitude or power histogram by plotting the square of the amplitude against the frequency.[31,32] The Fourier transform gives this frequency domain information when applied to the time domain signal. The power spectral density (PSD) is theoretically defined as the Fourier transform of the ACF, and has been widely used in VF analysis.

A significant problem with Fourier transforms is that the PSD is strictly defined only for signals with stable, or stationary, statistical properties. VF is a non-stationary signal, and the short time PSD has to be determined for time-limited VF segments considered quasi-stationary. In practice the discrete Fourier transform (DFT) is used. This approach has disadvantages in that it assumes that the time limited VF segment under investigation repeats periodically ad infinitum. Further, the technique is limited when analyzing sharply changing signals (Gibbs phenomenon).

Wavelet transforms

Wavelet transforms use small wave-like functions that come in different shapes and sizes to transform the VF signal. Mathematically, the wavelet transform is a convolution of the wavelet function with the signal. If the wavelet matches the shape of the signal closely at a specific scale and location, then a large value of the transform results and vice versa. Changing the type of wavelet allows the investigator to concentrate on individual small scale high frequency components or to pick up larger scale low frequency components. An energy scalogram can be produced which plots the log of the band-pass center frequency against the time where darker areas represent a higher wavelet energy coefficient and lighter areas a lower wavelet energy coefficient (Fig. 21.2).[32]

The key advantage of the continuous wavelet transform technique is that it can elucidate local spectral and temporal information simultaneously within the VF waveform. Even if short time Fourier transform (STFT) is performed on small segments of the signal at a time and moved incrementally along, this spectrogram technique uses a window of fixed width and therefore averages short duration components "smearing" the information across the window and so might lose potentially valuable information.

Time-frequency analysis as offered by both short time Fourier and especially wavelet transform analysis has allowed the extraction of previously hidden information from the VF waveform, for example observations possibly related to coordinated independent atrial activity while the ventricles remain fibrillating.[12,34] In this case, the superior temporal resolution of the wavelet transform offers the possibility of detecting the instance of the pulse complexes.[34] In addition, in animal models, chest compression artefact is seen to be clearly distinct from other VF-related features (Fig. 21.3).[11,12]

Describing the data: extracting features

After the first stages of VF analysis, whether this involves filtering and/or frequency domain transforms or not, quantification of the signal characteristics follows. This is the feature extraction stage, to capture the signal characteristics distinguishing successful from unsuccessful defibrillations.

To evaluate the ability of a feature (alone or in combination) to discriminate between outcome categories, various approaches including receiver operating characteristics (ROC) analysis have been used to determine the sensitivities and specificities of outcome predictors. These thresholds are usually linear, but some pattern recognition methods based on Bayesian decision theory have been applied to define non-linear decision borders for feature combinations.[7,9,33,35,36] Figure 21.4 illustrates a set of two-dimensional feature combinations, each coordinate representing the features computed from VF preshock waveforms. The feature space is divided into decision regions separated by non-linear decision borders. The area under the curve (AUC) may be used to determine the discriminative power of features.

Approaches to analysis

Amplitude

The magnitude of the VF waveform voltage, or VF amplitude, can be described clinically: "Coarse" VF is high amplitude ($> 0.2\,\mathrm{mV}$) usually of recent onset and has a higher probability of ROSC following defibrillation. "Fine" VF is low amplitude ($< 0.2\,\mathrm{mV}$), results from prolonged global myocardial ischemia, and is less amenable to resuscitation.[2] The "natural history" of untreated VF is progressive reduction in VF amplitude from coarse to fine, but simple clinical interpretation of the VF waveform is poor and quantitative analysis is needed to guide therapy.[37]

VF amplitude analysis by measuring either the maximum[38] or the average[13] peak-to-trough ECG voltage for a predefined time window has become much easier with improvements in digital signal analysis and computa-
Fig. 21.2. Attempted defibrillation of human ventricular fibrillation. *Top:* 7 seconds of human ECG exhibiting VF containing a defibrillation shock event. *Bottom:* Scalogram corresponding to the ECG signal. tional technique. In animal models VF amplitude during CPR reflects myocardial perfusion and energy metabolism[39] and values immediately before defibrillation are significantly higher in succesfully resuscitated animals.[38,39] Human studies confirm that maximum VF amplitude before countershock can predict outcome of defibrillation,[38,40,41] but the predictive power and discriminative value of VF amplitude are limited because of interindividual variability resulting from the main fibrillatory vector direction, electrode placement, transthoracic impedance, and shape of the thorax.

Frequency/spectral analysis

The frequency domain features used in VF analysis have mostly been calculated from a PSD estimate derived by the periodogram method[42] or variations of this. The periodogram method for PSD estimation applies a Fourier transform to the squared signal samples for each extracted preshock VF segment. Examples of some of the

main features calculated from these include the peak power frequency, median frequency, energy, spectral flatness measure, amplitude spectrum analysis (AMSA), spectral edge frequency, fibrillation power or variations of these. These features capture discriminating characteristics from the PSD.
Fig. 21.3. The energy scalogram for the first seven minutes of porcine ventricular fibrillation. CPR is initiated at 5 minutes as indicated. (After Addison *et al.* (2000) © 2000 IEEE.) (See Plate 21.3.)
Fig. 21.4. Defibrillation outcome prediction. Decision regions corresponding to the ROSC/noROSC prediction problem. The classes are identified by the following color scheme: yellow = decision region for ROSC (restoration of spontaneous circulation), blue = decision region for noROSC. The coordinate corresponding to ROSC outcomes are shown as stars (*) and noROSC as points (.). To predict the outcome of an ECG tracing, the features vPCA1 and vPCA2 are computed from the tracing. If the coordinate point corresponding to (vPCA1,vPCA2) is mapped into the yellow decision area, an ROSC outcome is predicted. If it is found to be in the blue area, a no ROSC outcome is predicted. (After Eftestøl *et al. Resuscitation* (2005) © Elsevier 2005.) (See Plate 21.4.)

The peak power or dominant frequency is the frequency corresponding to the maximum amplitude frequency component in the PSD. The median frequency (sometimes termed mean or centroid frequency) is the frequency bisecting the PSD, corresponding to the point of mass in the spectrum.[42] Both this feature and the peak power frequency emphasize the low frequency content of VF.

Energy, which is closely related to amplitude features, expresses the "coarseness" of the waveform, and corresponds to the area under the PSD curve.

The spectral flatness measure characterizes the waveform complexity and is computed as the ratio of the geometric and arithmetic mean of the PSD.[7]

In retrospective human studies, areas under ROC curves for peak power and median frequency perform worse than in animal studies, with AUC ranging from 0.53 to 0.72.[8,19,41,43,44,8] Studies of combined features have demonstrated AUC at 0.80 in an independent test[9] of an outcome predictor developed earlier.[7]

Fibrillation power was originally defined as the (amplitude)[2] of frequency components in the VF power spectrum. Power has also been defined as the integral of the power spectrum between certain frequency limits, representing energy. In this sense, the PSD method was used to investi-

gate the distribution of fibrillation power with frequency and time before defibrillation. In a porcine model of cardiac arrest, VF power is a better predictor of countershock success than are features such as mean amplitude or mean fibrillation frequency.[44] Disappointingly, human studies did not confirm this high predictive value of fibrillation power (i.e., energy)[8,44] and did not reveal significant changes of energy during manual chest-compression. Nonetheless, the low correlation between power/energy and frequency or amplitude parameters[45] provided complementary information in feature combination for outcome prediction.[7]

AMSA is the sum of the frequency-weighted PSD amplitudes, and represents the area under the amplitude frequency relationship resulting from fast Fourier transform. The method emphasizes the high frequency content of the PSD.

AMSA has yielded promising results in animal experiments.[20,46] In a pig VF model, an AMSA value of 21 mV Hz predicted defibrillation success with negative and positive predictive values (95% and 78%) superior to those for coronary perfusion pressure, mean amplitude, or median frequency.[20]

An AMSA value of 13 mV Hz retrospectively applied to recordings of 108 out-of-hospital cardiac arrest episodes in 46 patients predicted defibrillation success with ROSC with a sensitivity of 91% and specificity of 94%.[47] Eftestøl found a sensitivity of 95% and specificity of 40% for the AMSA feature for outcome prediction, but showed that the parameter increased during ongoing chest compression.[8]

Wavelet time/frequency methods

Quantification of the time frequency characteristics extracted by wavelet methods from the VF signal has been used as a marker of shock outcome prediction, and principal component analysis has been used to improve system performance. The wavelet entropy marker, in particular, offers significant improvements in terms of sensitivity and specificity as compared to similar Fourier transform-based features derived from the same data set.[7,21] In a recent study, the continuous wavelet technique showed an improved performance when compared to median frequency, spectral energy, and AMSA methods.[33,35]

Non-linear dynamics methods

N(α) histogram analysis is a non-linear dynamic method that provides analysis independent of ECG-signal ampli-

tudes or artefacts due to manual chest compression.[48] For every time interval, time-shifted ECG amplitudes are plotted in a three-dimensional coordinate system. The distribution of points found in spheres with a defined radius at specific points in space allows extraction of a local dimension α.

In a pig model the randomness of the VF ECG signal reflected by the width of $N(\alpha)$-histogram was a better predictor of countershock success than the median dimension. In addition, the more irregular the VF from the animal studied the more easily it could be defibrillated.[46] The principal disadvantage of this method, however, is the computation time requirement including sophisticated hardware and software.

The scaling exponent method has been used as a tool to quantify the self-similarity dimension of the VF waveform. The normal values of the scaling exponent D range from 1 – 2; low values indicate a high degree of organization of the VF signal and are associated with short downtime, and an increased probability of ROSC (PROSC) and hospital discharge rate.[19] Conversely, the scaling exponent increased with the duration of VF in animals and humans[19,49,50] and significantly higher values were found in patients with unfavorable outcomes.[19] Recently in a pig model of VF, scaling exponent D was used to guide the sequence of CPR interventions.[51] Although the predictive power of this single feature with respect to ROSC is low (reflected by an ROC curve area of 0.71), it may provide additional information to guide electrical therapy in human cardiac arrest.[19]

What to do with the results: Defibrillation success and PROSC

Whichever method of analysis is used, clinicians require guidance for the delivery of CPR and the timing of defibrillation. In its simplest form, this may be a YES/NO instruction based upon a predetermined probability of the technique used leading to ROSC (Fig. 21.5).[52]

Establishing these decision thresholds has its own difficulties. Using data from animal studies where all treatment groups divide clearly into ROSC/NoROSC gives a clear-cut problem that is simpler to analyze but less applicable to real-life clinical situations. Ideally, successful and unsuccessful outcomes should be mixed well in the treatment groups, although such studies have lower specificities.[53,54]

It is also important that when evaluating the performance of the parameter(s) chosen, the data set for training is separate from that used for testing. Several studies use variants of this approach, especially cross-validation tech-
Fig. 21.5. The probability of ROSC. A functional relationship between the feature representations of all the VF waveforms extracts and corresponding ROSC/NO ROSC outcome with the feature representation coordinates from Figure 4 superimposed. This can be explained as a division of the feature space defined by vPCA1 and vPCA2 into equal-sized cells. In each cell the PROSC value is estimated as the number of ROSC coordinates divided by the total number of coordinates in the cell. To compute the probability of successful outcome of an ECG tracing, the features vPCA1 and vPCA2 are computed from the tracing. The coordinate point corresponding to (vPCA1,vPCA2) is mapped onto the PROSC function surface, where the probability value can be read directly. (After Eftestøl *et al. Expert Rev. Cardiovasc. Ther.* (2003) © Future Drugs 2003.) (See Plate 21.5.)

niques, where the training and test sets are shifted among several data sets, providing several opportunities to give estimates of expected performance.[7,9,33,36] These methods attempt to provide an idea of how the predictor will perform on future data, but it is important to note that the test performances are considered in the design of the classifiers to choose the generalizing parameters. In a recent study, a final evaluation was performed on an independent data set not considered in the design process.[9]

PROSC values can also be used to monitor the efficacy of clinical interventions. In one study PROSC was used to evaluate the effect of interrupting precordial compressions and more recently to investigate the effects of giving precordial compressions. The studies demonstrated a negative change in PROSC when chest compressions were interrupted[55] and a positive change after prolonged sequences of compressions.[8]

The Future

The knowledge that, at least in its genesis and early stages, VF is not a random process and that the waveform contains elements of identifiable structure has been the first step in using the waveform for practical clinical purposes. The recognition that some of these elements can provide proxy information about the state of the underlying myocardial substrate leads to their potential to monitor and direct individual resuscitation efforts. The promise shown in animal studies has yet to be fully matched in humans and the mathematical tools used have limitations but, with continuing improvements in analytical techniques and computing power, it is inevitable that in the near future such techniques will be used clinically. The application of similar techniques to cerebrally generated waveforms holds the exciting prospect of performing and monitoring truly integrated cardiocerebral resuscitation.

Etiology, electrophysiology, and myocardial mechanics of pulseless electrical activity

Tom P. Aufderheide

Department of Emergency Medicine, Medical College of Wisconsin, Milwaukee, WI, USA

Pulseless electrical activity (PEA) is defined in this chapter based on its clinical presentation, the presence of organized electrical activity, and the absence of detectable pulses. This definition includes any pulseless organized rhythm irrespective of etiology, heart rate, or electrocardiogram (ECG) characteristics.

PEA may be viewed as a continuous mechanical and electrical phenomenon. Detectable pulses may be lacking because of the absence of synchronous myocardial fiber shortening. Detectable pulses may also be absent in the presence of weak myocardial contractions that produce measurable aortic pressures as evidenced by invasive monitoring. PEA can also be present with normotensive cardiac activity in patients with conditions such as cardiac tamponade, hypovolemic shock, or severe peripheral arteriovascular disease.

There is evidence to support the contention that the ECG characteristics in PEA reflect the degree of pathophysiologic derangement or time from onset of cardiac arrest.[1–3] Irrespective of PEA etiology, the more normal the ECG complex and the shorter the time from cardiac arrest, the higher is the likelihood of successful resuscitation or survival.[2] Conversely, the more abnormal the ECG complex, the longer time from cardiac arrest and the lower the likelihood of successful resuscitation or survival.[2] There probably has been no greater advance in understanding and managing PEA than the recent determination of a relationship between the integrity of the ECG complex and underlying mechanical activity.[1,2]

Pulseless electrical activity is classified by its clinical presentation into three groups: (a) normotensive PEA, (b) pseudo-PEA, and (c) true PEA. Normotensive PEA is defined as baseline cardiac contractions and myocardial fiber shortening in the absence of detectable pulses. Pseudo-PEA is the stage of pulseless electrical activity in which weak myocardial contractions produce detectable aortic pressure only measurable by invasive monitoring or echocardiography. True PEA is the stage of pulseless electrical activity in which myocardial contraction is absent.

PEA frequently results from a primary condition that profoundly decreases preload or afterload or causes severe inflow or outflow obstruction. The primary disorder results in hypoxia, acidosis, and increased vagal tone, which, if not rapidly reversed, affects the strength of myocardial contraction and eventually results in PEA. Causes for PEA include (a) mechanical, including tension pneumothorax, cardiac tamponade, and auto-PEEP (auto–positive end-expiratory pressure); (b) preload reduction, including hypovolemia, sepsis, and pulmonary embolism; (c) primary myocardial dysfunction, including acute myocardial infarction, congestive heart failure, drug ingestions, hyperkalemia, and hypothermia; and (d) pulmonary, including severe respiratory insufficiency or respiratory arrest (Fig. 22.1).

Another cause of pulseless electrical activity is termed *postdefibrillation PEA*; this refers to the variable electrical and mechanical cardiac activity that occurs following countershock from ventricular fibrillation. Prolonged ventricular fibrillation results in hypoxia, acidosis, and increased vagal tone, which produce a variable response to countershock, including baseline, decreased, or no cardiac contractions (Fig. 22.1).

The incidence of PEA depends on the patient population studied. The condition accounts for 16 to 22% of out-of-hospital cardiac arrests.[4,5] The frequency of PEA in-hospital cardiac arrests is higher. Raizes *et al.* found

Causes	Mechanical	Pre-load reduction	Myocardial dysfunction	Pulmonary	Post-defibrillation PEA
	Tension pneumothorax cardiac tamponade auto-PEEP	Hypovolemia Sepsis Pulmonary embolus	Acute myocardial infarction congestive heart failure Drug ingestion Hyperkalemia Hypothermia	Severe respiratory insufficiency Respiratory arrest	Prolonged ventricular fibrillation followed by electrical counter shock

Fig. 22.1. Clinical spectrum of pulseless electrical activity

that PEA accounted for 68% of monitored in-hospital sudden deaths and 10% of all in-hospital deaths.[6] Vincent *et al.* reported PEA as the initial symptom in 66% of monitored in-hospital cardiac arrests.[7] Pirolo *et al.* reviewed the results of 50 autopsies of patients dying in PEA and found that 12 of 50 (24%) had primary PEA, 22 (44%) had secondary PEA, and in six (12%) the classification of PEA could not be determined.[8]

The average age of patients presenting in PEA is 70 years.[4] The incidence of PEA as a presenting cardiac arrest rhythm is higher in the elderly (15% vs. 3%).[9] When PEA and coarse ventricular fibrillation are compared with respect to demographics, patients who present in PEA are more likely to be female (43% versus 24%); they are also more likely to have no cardiac history (54% vs. 19%),[4] but a similar percentage of patients are likely to be on cardiac medication (43% vs. 42%).[4] It is possible that cardiac medications such as β-blockers or calcium antagonists may contribute to the presentation of PEA.[4]

The successful resuscitation and save rates in PEA patients are higher in prehospital compared with hospital patients. The largest clinical prehospital study of PEA patients reported 98 (19.5%) of 503 successful resuscitations and 22 (4.4%) of 503 discharged from the hospital alive.[2] Vincent *et al.* reviewed 50 hospitalized patients experiencing sudden onset of PEA in a hospital-based critical

care setting.[7] Only 3 of 50 (6%) were discharged alive from the critical care ward, and only 1 of 50 (2%) survived to hospital discharge.[7]

Basic science

Cellular basis of cardiac contraction

The myocardium consists of a syncytium of branching and anastomosing fibers that are divided into individual cells by modified, closely opposed cell membranes termed *intercalated* disks. This apposition provides a continuous "tight junction" with free passage of ions and action potentials from cell to cell throughout the syncytium. In contrast to skeletal muscle, the myocyte has a centrally located nucleus and is richly endowed with mitochondria, necessary for the generation of large amounts of adenosine triphosphate (ATP) required for cardiac contraction. The myocyte also has an abundant sarcoplasmic reticulum and an elaborate system of large T tubules. The T tubules provide a channel for ion fluxes, especially Ca^{2+} involved in cardiac contraction. The fibers within myocytes each contain multiple cross-banded myofibrils, which run the length of the fiber and are composed of a serially repeating structure, the sarcomere.

The sarcomere is the structural and functional unit of myocardial contraction and is delimited by two adjacent transverse Z lines. Sarcomeres are characterized by cross striations caused by prominent central dark A bands of a constant width of 1.5 μm. A bands are composed of thicker filaments, principally of the protein myosin. The A band is flanked by lighter I bands composed primarily of thinner filaments of actin. The thin actin filaments are attached at their outer ends to the Z lines and, at their inner ends, interdigitate partially between the myosin filaments. Thus the A band has partially overlapping myosin and actin filaments, whereas the I band contains only actin filaments. On electron-microscopic examination, bridges can be seen to extend between the thick and thin filaments within the A band (Fig. 22.2).[10,11]

The contractile process

Both the thick and thin filaments remain at a constant overall length, both at rest and during contraction, leading to a sliding model for myocardial contraction. During myocardial contraction, repetitive interactions occur at the bridges between the actin and myosin filaments, propelling the actin filaments further into the A band. During the contractile process, the A band remains at a constant width, whereas the I band narrows, and the Z lines move toward one another.

The myosin molecule is a complex fibrous protein with a molecular weight of approximately 500 000; it has a rodlike portion that is about 1500 Å in length with a globular portion at its end. This globular portion forms the bridges between myosin and actin and contains adenosine triphosphatase activity (ATPase). These bridges project outward so that they can interact with actin to generate force and shortening.

The thin filament actin is composed of a double helix of two chains of actin molecules wound around each other, has a molecular weight of 47 000, and is associated with two regulatory proteins, tropomyosin and troponin. Troponin can be separated into three components: troponins C, I, and T. Actin has no intrinsic enzymatic activity, but it has the ability to combine reversibly with myosin in the presence of ATP and Ca^{2+}, which activates the myosin ATPase. Tropomyosin inhibits this interaction in relaxed muscle. During activation, troponin C binds Ca^{2+}, resulting in a conformational change exposing the actin cross-bridge interaction sites. Physical changes in the cross bridges result in sliding of the actin along the myosin filaments causing muscle shortening or the development of tension. Cleavage of ATP into adenosine diphosphate (ADP) and inorganic phosphate dissociates the myosin cross bridge from actin. Linkages between actin and myosin filaments are made repeatedly as long as sufficient Ca^{2+} is present; linkages are broken when Ca^{2+} concentration decreases below a critical level. At this point the troponin-tropomyosin complex again prevents binding between myosin and actin filaments. Ionic calcium is the principal mediator of the inotropic state of the heart. Most positive inotropic drugs, including digitalis and catecholamines, act by increasing delivery of Ca^{2+} to the myofilament.

The abundant sarcoplasmic reticulum is a complex network of membrane-lined intracellular channels running longitudinally within the sarcomere in close proximity to the outside membrane but which have no direct continuity with the outside of the cell. Transverse or T tubules represent tubelike invaginations of the sarcolemma that are continuous with the extracellular space and traverse adjacent to the Z lines. This complex network of membrane channels assists ion fluxes during cardiac contraction (Fig. 22.3).[10, 11]

Cardiac activation

The sarcomere at rest has an interior negative charge relative to the outside of the cell with a transmembrane potential of -80 to -100 mV. In the resting state the sarcolemma is largely impermeable to Na^+. The membrane has an Na^+ and a K^+ stimulated pump requiring ATP, which extrudes Na^+ from the cell and plays a critical role in establishing the resting potential of the membrane. The intracellular milieu is high in K^+ and low in Na^+, whereas the opposite is true extracellularly. In the resting state, at the same time, the extracellular concentration of Ca^{2+} greatly exceeds free intracellular Ca^{2+} concentration.[10,11]

During the plateau of the action potential in phase 2, there is a slow inward current reflecting primarily movement of Ca^{2+} within the cell. The absolute quantity of Ca^{2+} that crosses the surface membrane is relatively small. Nevertheless, the depolarizing current not only extends across the surface of the cell membrane but also penetrates deeply into the cell by the elaborate system of transverse tubules. Because of this transsarcolemmal movement of Ca^{2+}, much larger quantities of Ca^{2+} are released from the sarcoplasmic reticulum within the cell. This process is termed *regenerative release of* Ca^{2+}.[10,11]

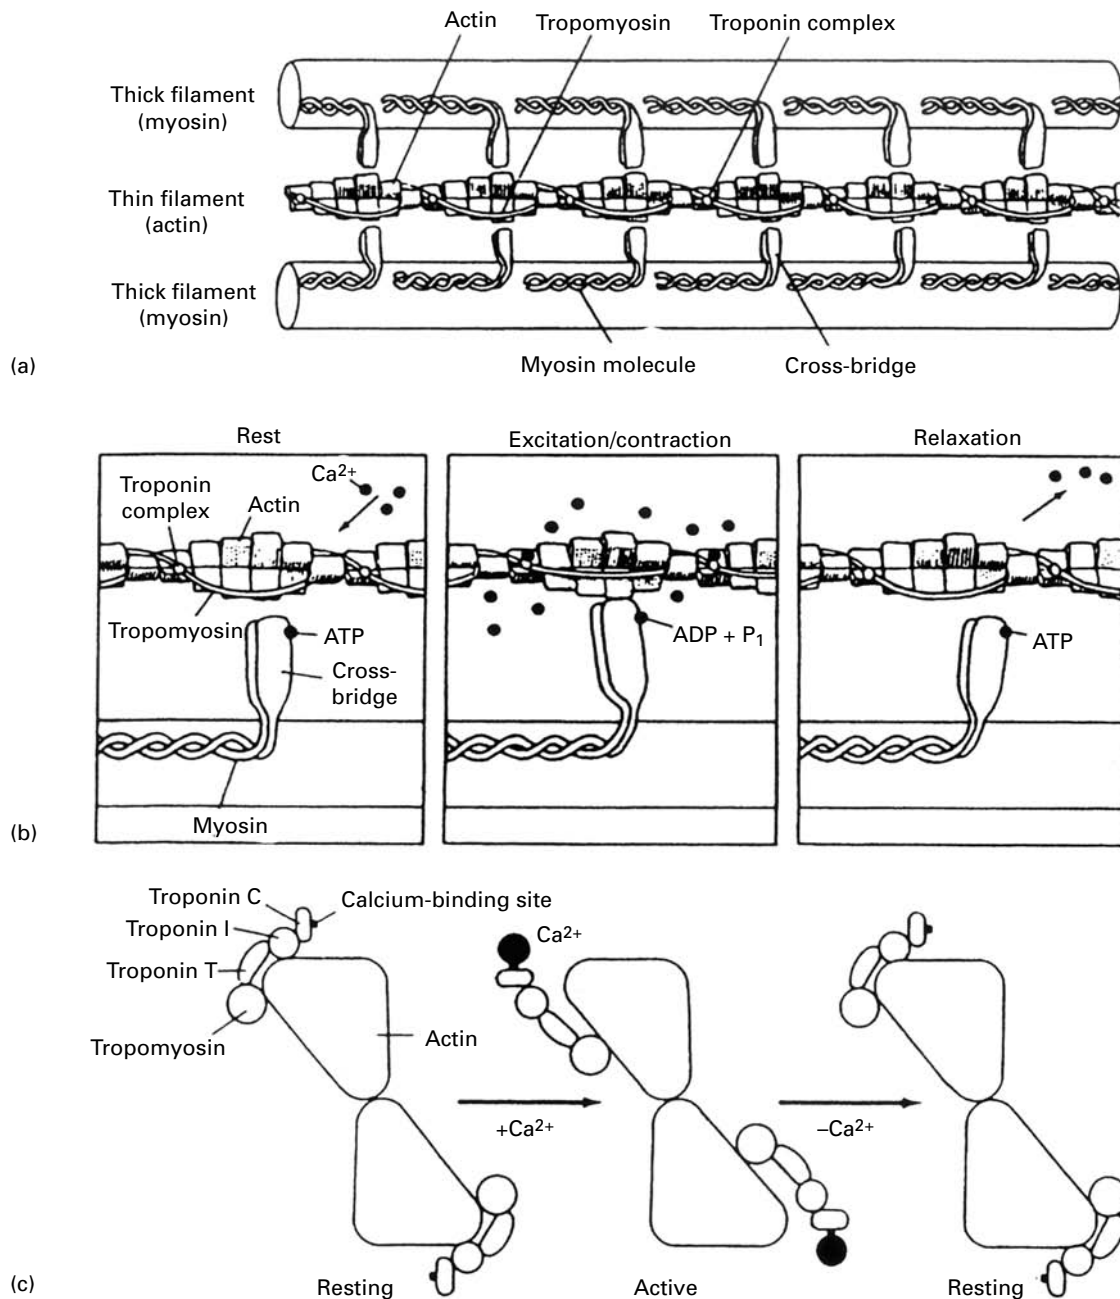
The Ca^{2+} combines with troponin, and, by repressing the inhibitor of contraction, activates the myofilaments to produce contraction. The sarcoplasmic reticulum then reaccumulates Ca^{2+} by an ATP-dependent calcium pump, lowering intracellular Ca^{2+} concentration to a level that inhibits actin-myosin interaction and leading to muscle
Fig. 22.2. Microscopic structure of heart muscle. (a) Myocardium as seen under light microscope. Branching of fibers is evident. Each fiber, or cell, contains centrally located nucleus. (b) Myocardial cell, reconstructed from electron micrographs. Each cell is composed of multiple parallel fibrils. Each fibril is composed of serially connected sarcomeres (N, nucleus). (c) Sarcomere from myofibril, with diagramatic representation of myofilaments. Thick filaments (1.5 μm long, composed of myosin) form A band, and thin filaments (1 μm long, composed primarily of actin) extend from Z line through I band into a band. Overlapping of thick and thin filaments is seen only in A band. (d) Cross-sections of sarcomere indicate specific lattice arrangements of myofilaments. In center of sarcomere only thick, or myosin, filaments arranged in a hexagonal array are seen. In distal portions of A band, both thick and thin, or actin, filaments are found, with each thick filament surrounded by six thin filaments. In I band only thin filaments are present. (Reproduced with permission from ref. 10.)


Fig. 22.3. Contractile protein interactions and role of calcium as activator messenger are shown schematically. (a) Contractile proteins (myosin and actin) and regulatory proteins (troponin complex and tropomyosin) shown in relative positions on myofilaments. (b) Contraction takes place when heads of myosin molecules, which form cross bridges of thick filament, bind to actin, followed by shift in orientation of cross bridge that pulls thin filament toward center of sarcomere. Activation requires calcium binding to troponin complex, reversing inhibition of interaction between myosin and actin. In cycle of chemical reactions underlying contraction, hydrolysis of ATP produces cross-bridge motion. Relaxation occurs when calcium becomes dissociated from troponin. (c) Molecular rearrangements at level of thin filament involve regulatory proteins (tropomyosin and troponins C, I, T) in allosteric effect. Calcium binding to troponin C loosens bond linking troponin I to actin; resulting dissociation of troponin T from actin backbone of thin filament displaces tropomyosin, exposing active sites for interaction with myosin. (From Katz AM, Smith VE. Myocardial relaxation abnormalities. Part I: mechanisms. Hosp Prac 1984; 19(1):69. Illustration by Bunji Tagawa.)

relaxation. In this way, the cell membrane, transverse tubules, and sarcoplasmic reticulum play a fundamental role in myocardial contraction and relaxation by their ability to transmit an action potential and to release and then reaccumulate Ca^{2+}.[10,11]

ATP is the principal source of energy for almost all of the mechanical work of myocardial contraction. The high-energy phosphate stores in ATP are in equilibrium with those present in creatine phosphate. The activity of the myosin ATPase determines the rate of forming and breaking the actin-myosin cross bridges and ultimately the velocity of muscle contraction (Fig. 22.4).[10,11]

Myocardial contraction

The mechanical activity of myocardial muscle can ultimately be explained by a combination of force and velocity of muscle contraction. The Frank–Starling relation (Starling's law of the heart) describes the relationship between the initial length of myocardial muscle fibers and the development of force. Within limits, the initial length of myocardial muscle (which is a function of left ventricular end-diastolic volume) is related to the force of ventricular contraction. It has been postulated that increasing the initial length of myocardial muscle to an optimum of 2.2 μm results in the most advantageous overlap of interdigitating contractile filaments within the sarcomere and also optimizes their sensitivity to Ca^{2+}.

Changes in the velocity of shortening the myocardial muscle may also occur, even at a constant muscle length. This type of shift in the force-velocity curve may be seen with administration of a positive inotropic agent such as digitalis or norepinephrine. It has also been postulated that increased velocity of myocardial contraction is ultimately related to either the concentration of Ca^{2+} in the vicinity of the myofilaments or their sensitivity to Ca^{2+} or both of these factors. Whatever the mechanism, velocity of myocardial contraction appears primarily related to increased availability of Ca^{2+} within the cell.

Ultimately, stroke volume is determined by three influences: (*a*) the length of the muscle at the onset of contraction (the preload), (*b*) the inotropic state of the heart, and (*c*) the tension that the myocardium must develop during contraction (the afterload).

Preload

Ventricular end-diastolic volume determines the length of the muscle fiber at the onset of contraction, affecting stroke volume. Depletion in total blood volume results in decreased ventricular end-diastolic volume, reflected in a reduction in ventricular performance. Ventricular enddiastolic volume can also be influenced by the distribution of blood between the intrathoracic and extrathoracic compartments. Gravitational forces tend to pool blood in dependent positions. Elevation of intrathoracic pressure, as occurs in tension pneumothorax or with positive end-expiratory pressure, impedes venous return to the heart, diminishes intrathoracic blood volume, and reduces ventricular end-diastolic volume. Elevated intrapericardial pressure, as with pericardial tamponade, interferes with ventricular filling, lowering stroke volume and ventricular work. Venoconstriction and the pumping action of skeletal muscle are active systems responsible for venous return to the heart. Their loss preceding and during cardiac arrest results in decreased intrathoracic blood volume.

Inotropic state

Many factors determine and influence the velocity of myocardial fiber shortening. Variations in sympathetic nerve activity modify the quantity of norepinephrine released to act on the β-adrenergic receptors of the myocardium. Sympathetic nerve activity is one of the most important mechanisms determining the position of the myocardium on the force-velocity and ventricular function curves under physiologic conditions. When stimulated by sympathetic nerve activity the adrenal medulla releases catecholamines, thus augmenting the inotropic state of the heart. Exogenously administered inotropic agents such as epinephrine, norepinephrine, isoproterenol, calcium, caffeine, and theophylline improve the myocardial force-velocity relation, increasing ventricular performance. Conversely, physiologic depressants, acting either singly or in combination, can exert a depressant effect on the myocardial force-velocity curve, lowering ventricular performance. Physiologic depressants include severe myocardial hypoxia, hypercapnia, ischemia, and acidosis. Pharmacologic depressants, including β-blockers, calcium channel blockers, barbiturates, local and general anesthetics, and many other drugs, likewise reduce ventricular work. Myocardial stunning or necrosis caused by ischemia may profoundly affect total ventricular performance.

Afterload

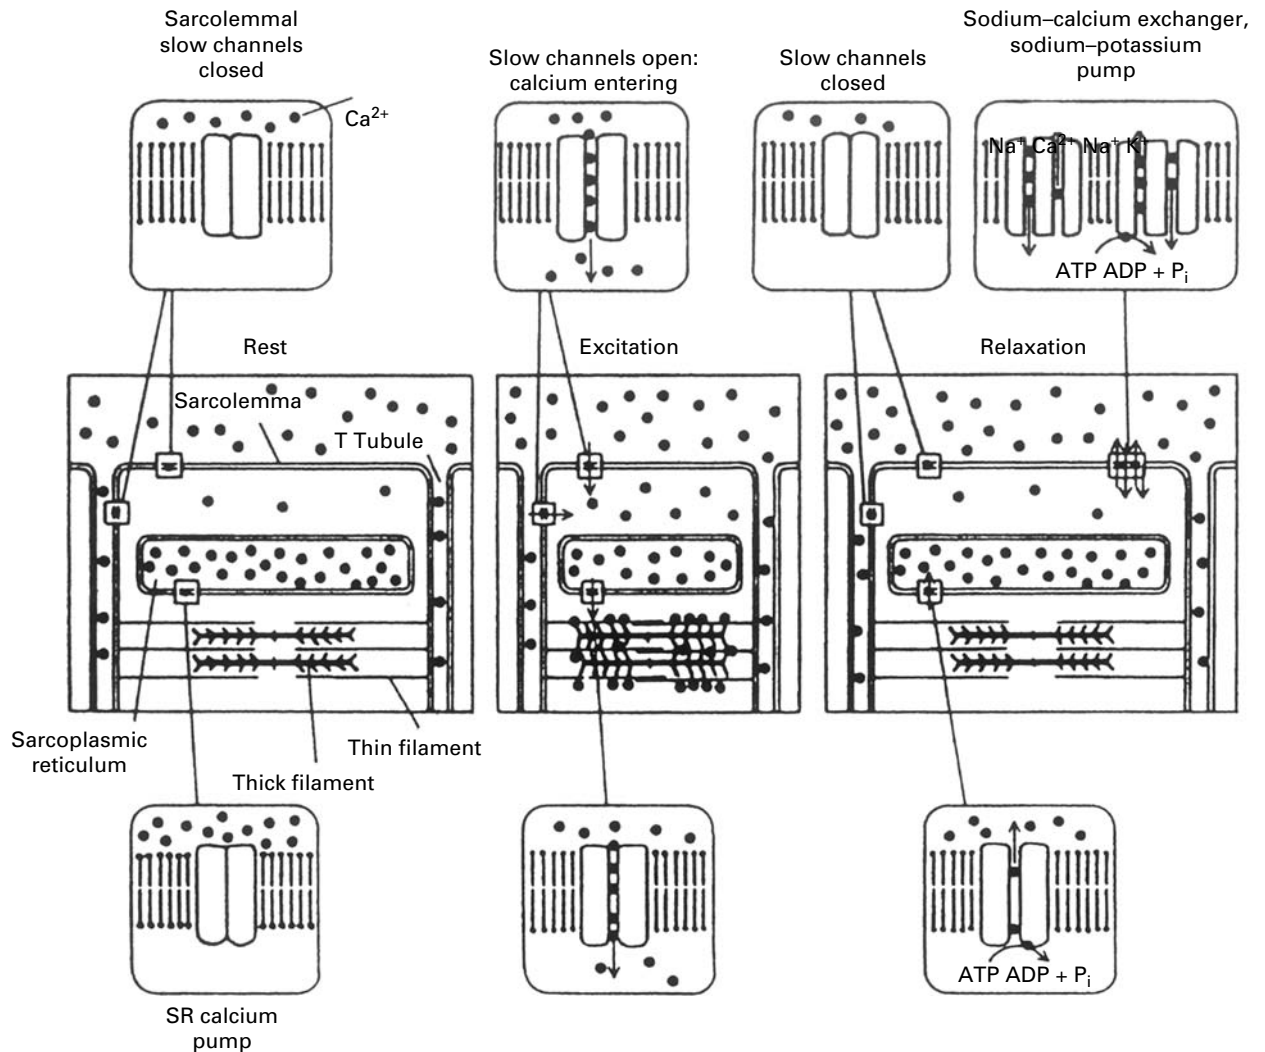
The force and velocity of myocardial muscle fiber shortening at any given diastolic fiber length and myocardial inotropic state are inversely related to the afterload imposed on the myocardium. Stroke volume is determined by myocardial fiber length and velocity of fiber shortening. In turn, stroke volume and heart rate produce cardiac output, which, with peripheral arterial resistance produce arterial pressure or afterload. As ventricular function becomes more impaired, left ventricular afterload becomes


Fig. 22.4. Calcium fluxes that activate contraction are downhill, and those that cause relaxation are uphill. As depicted in heart muscle at rest, calcium channels in sarcolemmal membrane are closed, and intracellular calcium is stored in sarcoplasmic reticulum. With excitation and membrane depolarization, voltage-sensitive sodium channels (not shown) and calcium channels in sarcolemma open to allow rapid entry of extracellular sodium and calcium. Entry of calcium is now believed to cause release of calcium from sarcoplasmic reticulum that initiates contraction. Reuptake of calcium by sarcoplasmic reticulum by an ATP-dependent calcium pump is essential for heart to relax. Of importance, contraction is activated mainly by passive calcium fluxes from sarcoplasmic reticulum. By contrast, during diastole calcium must be pumped actively out of cytosol to accomplish relaxation. Energy also must be expended during diastole to restore sodium and calcium gradients across sarcolemma, which provide for depolarizing ionic currents that generate action potential. Sodium transport is accomplished by sarcolemmal sodium pump (Na^+-K^+ ATPase), which utilizes ATP to pump sodium out of the cell in exchange for potassium. Resultant sodium gradient is largely responsible for active transport of calcium out of cell during relaxation, via sodium-calcium exchange. (From Katz AM, Smith VE. Myocardial relaxation abnormalities. Part I: mechanisms. *Hosp. Prac.* 1984; 19(1):69. Illustration by Bunji Tagawa.)

increasingly important in determining cardiac performance. Influences on the arterial bed of neural, humoral, or structural changes that increase afterload may further reduce cardiac output while myocardial oxygen requirements are increased.

Pulseless electrical activity feedback loop

Preceding the onset of PEA, as the force and velocity of myocardial contraction decrease, stroke volume is reduced. Although a transient compensatory increase in heart rate

can be seen, eventually cardiac output and aortic pressure are decreased. Lowered aortic pressure decreases coronary artery perfusion, resulting in increased myocardial ischemia, hypoxemia, and reduced myocardial function. The force and velocity of myocardial fiber shortening are further reduced, exacerbating lowered stroke volume and further decreasing aortic pressure. This negative feedback loop characterizes the pathophysiology of PEA and represents the challenge for therapeutic intervention (Fig. 22.5).

Animal models of pulseless electrical activity

The various animal models for PEA provide insight into its pathophysiology and reflect its heterogeneous nature. PEA may be generated in the isolated perfused rat heart or intact dog by producing severe acidosis with a perfusion fluid of acetoacetate and glucose.[12] High concentrations of acetoacetate and lactic acid produced by cellular utilization of glucose via anaerobic glycolysis result in severe extracellular and intracellular acidosis that reliably inhibits ventricular contraction.[12] Perfusion of the heart in a calcium-free medium also produces PEA.[13] These animal models have been developed primarily to study techniques of open heart surgery and cardiopulmonary bypass.

The two animal models most commonly used to study resuscitation techniques in PEA are the asphyxia model and postdefibrillation model in dogs. In the asphyxia model, after anesthesia, intubation, and instrumentation, the endotracheal tube is occluded at the end of exhalation. This is followed by initial hypertension and tachycardia and then progressive hypotension and bradycardia until aortic pressure fluctuations cease approximately 10 minutes after airway obstruction. To simulate downtime in cardiac arrest, most experimental protocols continue airway obstruction without intervention for 5 to 10 minutes after the last systolic aortic pressure fluctuation. During this time period, the ECG of the dog shows normal or nearly normal sequences of P, QRS, and T waves, usually at a bradycardic rate unaccompanied by any fluctuation in aortic pressure. Following this predetermined downtime, the obstruction of the endotracheal tube is reversed, cardiopulmonary resuscitation (CPR) is started, and the experimental protocol is initiated.[14] Because ECG activity continues for prolonged periods after complete cessation of myocardial contraction, the asphyxia model can study the effects of interventions at either short or long downtimes.

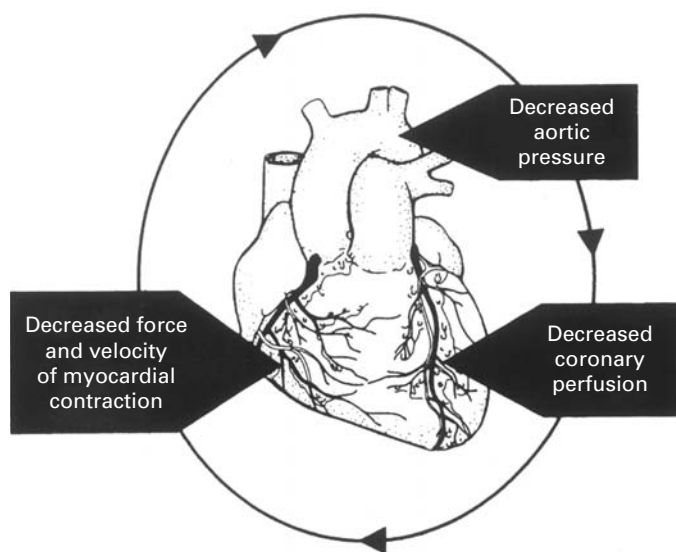
Some investigators think that the asphyxia dog model for PEA more closely approximates the clinical presentation of patients with PEA who frequently have a respiratory cause for cardiac arrest and variable downtimes. This


Fig. 22.5. PEA feedback loop.

model provides some evidence that following the onset and persistence of severe hypoxia in human patients, the presence of initial hypertension and tachycardia may indicate a grave sign of impending cardiac arrest.

In the postdefibrillation animal model, after anesthesia, intubation, and instrumentation, PEA is induced by passing an AC current through a bipolar electrode positioned at the right ventricle, initiating ventricular fibrillation. After a predetermined time (approximately 5 minutes) of ventricular fibrillation without artificial circulatory or ventilatory support, one or more transthoracic countershocks are administered until ventricular fibrillation is terminated. After this treatment responses can vary: there may be electrical activity with detectable pulses, electrical activity with absent pulses but measurable aortic pressures of 20 to 40 mm Hg, or electrical activity without detectable pulses and no measurable aortic pressures. With ventricular fibrillation times of 5 to 7 minutes, the most frequent response is spontaneous cardiac electrical activity accompanied by absent aortic pressure fluctuations. In such circumstances, CPR is begun and the experimental protocol initiated. The situation in the postdefibrillation animal model closely resembles the pulseless, spontaneous cardiac rhythm seen in up to 60% of resuscitation attempts following prehospital ventricular fibrillation.[15,16] The postdefibrillation animal model, however, has the disadvantage of a potentially variable response following defibrillation, which appears related to the time of ventricular fibrillation before the defibrillation attempt. This may be consistent with the clinical observation that postdefibrillation PEA may be more common after countershock of fine ventricular fibrillation

in patients with longer downtimes.[17] Some investigators postulate that the development of PEA immediately following defibrillation represents a transitory recovery rhythm that in some cases improves spontaneously leading to the appearance of pulses, supraventricular activity, and stabilization of hemodynamic status.[18]

Another model, the acute cardiac tamponade model, is produced by making a small incision in the dog pericardium, inserting a polyethylene catheter into the pericardial sac, and fastening the cut pericardium around the catheter with a string suture. Tamponade is induced by injecting fixed volumes (60 ml/increment) of warmed saline (37 °C) into the pericardial cavity through the intrapericardial catheter until peak left ventricular pressure is depressed to 25 mm Hg. The intrapericardial volume is maintained until PEA occurs, as verified by the absence of left ventricular pressures corresponding with the QRS complex of the ECG. This acute cardiac tamponade model allows study of the role of the sympathetic and parasympathetic nervous systems in the initiation of PEA during acute cardiac tamponade and the response to therapeutic intervention.

Notably, the use of different models with different pathophysiologic processes and variable downtimes makes comparison between studies and application to the clinical setting difficult.

Normotensive, pseudo-, and true pulseless electrical activity

Pathophysiologic associations

Ischemia
Although the precise cause and pathogenesis of PEA remain poorly understood, much evidence points toward ischemia as the underlying cause of myocardial excitation contraction uncoupling.[19,20] Ischemia may occur locally or globally. Under experimental conditions, occlusion of a coronary vessel rapidly leads to disappearance of myocardial contraction in the area at risk, although electrical activity may be initially unchanged.[6,21,22] The clinical syndrome of PEA may arise when a large enough area of myocardium is rendered ischemic. Subsequent local ischemia may result in systolic or diastolic left ventricular dysfunction severe enough to produce hypotension that eventually leads to global ischemia (Fig. 22.5).

In studies of localized coronary artery occlusions of various durations in the anesthetized dog, the rate of improvement of myocardial function was shown to be inversely proportional to the duration of occlusion.[23–28] A period of coronary occlusion of less than 20 minutes may not be associated with the development of myocardial necrosis but may result in depressed myocardial contraction for several days.[29] Braunwald and Kloner postulated that ischemia may interfere with normal myocardial function, biochemical processes, and ultrastructure for prolonged periods, resulting in myocardial stunning.[29]

The development of PEA, however, is not thought to depend solely on local occlusion of a coronary artery. Global ischemia resulting in hypoxia, acidosis, and increased vagal tone from any source appears to make the myocardium vulnerable to global depolarization and the uncoupling of excitation and contraction.[8,22]

Calcium
With global ischemia there is neither washout of metabolites nor delivery of substrate; thus, after an initial rapid loss of myocardial function, further cellular damage is slowly progressive.[30] Some investigators have shown that it is reperfusion of ischemic tissues that actually causes the most significant damage.[31–33] The role of calcium in producing ultrastructural myocardial damage associated with ischemia and reperfusion was first examined by Shen and Jennings.[34,35] Forty minutes of ischemia followed by 10 minutes of arterial reperfusion in an animal model resulted in an 18-fold increase in calcium uptake in injured myocardial tissue.[30,34,35] Calcium uptake was accompanied by massive cellular swelling, mitochondrial and myofibrillar damage, and the appearance of contraction bands and intramitochondrial calcium phosphate deposits.

Calcium may be involved in the development of PEA by several mechanisms. Defects in excitatory Ca^{2+} release could occur because of the loss of the triggering Ca^{2+} current or because of a change in the sarcoplasmic reticular Ca^{2+} store.[19] The sensitivity of the contraction process to calcium may be reduced.[19] For example, the affinity of Ca^{2+} for troponin C necessary for excitation contraction coupling can be reduced by some metabolic factors, such as acidosis.[19]

Intracellular pH
Persistent ischemia or anoxia results in continued anaerobic glycolysis, lactic acid production, and acidosis. It has been proposed that intracellular acidosis changes the affinity of troponin C for Ca^{2+}, thus contributing to excitation contraction uncoupling. Whether acidosis initiates this process fast enough to entirely explain complete contractile failure in PEA remains unanswered. Measurements of intracellular pH changes by magnetic resonance provide values integrated over 3 to 4 minutes, and, as a result, the intracellular changes in the first few minutes of PEA are

difficult to measure.[19,36] Further, magnetic resonance methodology uses the phase shift for inorganic phosphate to determine intracellular pH, which may be encountered by the contractile proteins.[19] Conversely, extracellular acidosis is known to occur quickly after the onset of ischemia. The decrease in affinity of troponin C for Ca^{2+} resulting from intracellular acidosis is probably partially responsible for excitation contraction coupling; however, there is insufficient evidence at this time to attribute contractile failure entirely to acidosis.

Adenosine triphosphate

Depletion of ATP may be a key factor in the development of PEA and in determining the potential reversibility of the process.[7,30,37,38] Some investigators have shown that intracellular ATP concentrations in ischemic myocardium fall to approximately 50% of normal after 15 minutes of ischemia.[29,39] Myocardial ATP levels in these studies also remained reduced for days following reperfusion.[29,39] Since recovery of myocardial function parallels the recovery of intracellular ATP concentrations, it is tempting to speculate that they are causally related.[29] It is possible that myocardial function remains depressed until ATP stores or at least the pool of ATP directly related to the contractile process has returned to normal. However, other factors including calcium flux also may be responsible.[29]
